Preface ix

Part I Fundamentals of Compilation

1 Introduction 3
   1.1 Modules and interfaces 4
   1.2 Tools and software 5
   1.3 Data structures for tree languages 7

2 Lexical Analysis 16
   2.1 Lexical tokens 17
   2.2 Regular expressions 18
   2.3 Finite automata 21
   2.4 Nondeterministic finite automata 24
   2.5 Lex: a lexical analyzer generator 30

3 Parsing 39
   3.1 Context-free grammars 41
   3.2 Predictive parsing 46
   3.3 LR parsing 56
   3.4 Using parser generators 69
   3.5 Error recovery 76

4 Abstract Syntax 88
   4.1 Semantic actions 88
   4.2 Abstract parse trees 92

5 Semantic Analysis 103
   5.1 Symbol tables 103
   5.2 Bindings for the Tiger compiler 112
CONTENTS

5.3 Type-checking expressions 115
5.4 Type-checking declarations 118

6 Activation Records 125
6.1 Stack frames 127
6.2 Frames in the Tiger compiler 135

7 Translation to Intermediate Code 150
7.1 Intermediate representation trees 151
7.2 Translation into trees 154
7.3 Declarations 170

8 Basic Blocks and Traces 176
8.1 Canonical trees 177
8.2 Taming conditional branches 185

9 Instruction Selection 191
9.1 Algorithms for instruction selection 194
9.2 CISC machines 202
9.3 Instruction selection for the Tiger compiler 205

10 Liveness Analysis 218
10.1 Solution of dataflow equations 220
10.2 Liveness in the Tiger compiler 229

11 Register Allocation 235
11.1 Coloring by simplification 236
11.2 Coalescing 239
11.3 Precolored nodes 243
11.4 Graph coloring implementation 248
11.5 Register allocation for trees 257

12 Putting It All Together 265

Part II Advanced Topics

13 Garbage Collection 273
13.1 Mark-and-sweep collection 273
13.2 Reference counts 278
13.3 Copying collection 280
13.4 Generational collection 285
13.5 Incremental collection 287
13.6 Baker’s algorithm 290
13.7 Interface to the compiler 291

14 Object-Oriented Languages 299
14.1 Classes 299
14.2 Single inheritance of data fields 302
14.3 Multiple inheritance 304
14.4 Testing class membership 306
14.5 Private fields and methods 310
14.6 Classless languages 310
14.7 Optimizing object-oriented programs 311

15 Functional Programming Languages 315
15.1 A simple functional language 316
15.2 Closures 318
15.3 Immutable variables 319
15.4 Inline expansion 326
15.5 Closure conversion 332
15.6 Efficient tail recursion 335
15.7 Lazy evaluation 337

16 Polymorphic Types 350
16.1 Parametric polymorphism 351
16.2 Type inference 359
16.3 Representation of polymorphic variables 369
16.4 Resolution of static overloading 378

17 Dataflow Analysis 383
17.1 Intermediate representation for flow analysis 384
17.2 Various dataflow analyses 387
17.3 Transformations using dataflow analysis 392
17.4 Speeding up dataflow analysis 393
17.5 Alias analysis 402

18 Loop Optimizations 410
18.1 Dominators 413
CONTENTS

18.2 Loop-invariant computations 418
18.3 Induction variables 419
18.4 Array-bounds checks 425
18.5 Loop unrolling 429

19 Static Single-Assignment Form 433
19.1 Converting to SSA form 436
19.2 Efficient computation of the dominator tree 444
19.3 Optimization algorithms using SSA 451
19.4 Arrays, pointers, and memory 457
19.5 The control-dependence graph 459
19.6 Converting back from SSA form 462
19.7 A functional intermediate form 464

20 Pipelining and Scheduling 474
20.1 Loop scheduling without resource bounds 478
20.2 Resource-bounded loop pipelining 482
20.3 Branch prediction 490

21 The Memory Hierarchy 498
21.1 Cache organization 499
21.2 Cache-block alignment 502
21.3 Prefetching 504
21.4 Loop interchange 510
21.5 Blocking 511
21.6 Garbage collection and the memory hierarchy 514

Appendix: Tiger Language Reference Manual 518
A.1 Lexical issues 518
A.2 Declarations 518
A.3 Variables and expressions 521
A.4 Standard library 525
A.5 Sample Tiger programs 526

Bibliography 528

Index 537
Over the past decade, there have been several shifts in the way compilers are built. New kinds of programming languages are being used: object-oriented languages with dynamic methods, functional languages with nested scope and first-class function closures; and many of these languages require garbage collection. New machines have large register sets and a high penalty for memory access, and can often run much faster with compiler assistance in scheduling instructions and managing instructions and data for cache locality.

This book is intended as a textbook for a one- or two-semester course in compilers. Students will see the theory behind different components of a compiler, the programming techniques used to put the theory into practice, and the interfaces used to modularize the compiler. To make the interfaces and programming examples clear and concrete, I have written them in the C programming language. Other editions of this book are available that use the Java and ML languages.

Implementation project. The “student project compiler” that I have outlined is reasonably simple, but is organized to demonstrate some important techniques that are now in common use: abstract syntax trees to avoid tangling syntax and semantics, separation of instruction selection from register allocation, copy propagation to give flexibility to earlier phases of the compiler, and containment of target-machine dependencies. Unlike many “student compilers” found in textbooks, this one has a simple but sophisticated back end, allowing good register allocation to be done after instruction selection.

Each chapter in Part I has a programming exercise corresponding to one module of a compiler. Software useful for the exercises can be found at

http://www.cs.princeton.edu/~appel/modern/c
Exercises. Each chapter has pencil-and-paper exercises; those marked with a star are more challenging, two-star problems are difficult but solvable, and the occasional three-star exercises are not known to have a solution.

Course sequence. The figure shows how the chapters depend on each other.

- A one-semester course could cover all of Part I (Chapters 1–12), with students implementing the project compiler (perhaps working in groups); in addition, lectures could cover selected topics from Part II.
- An advanced or graduate course could cover Part II, as well as additional topics from the current literature. Many of the Part II chapters can stand independently from Part I, so that an advanced course could be taught to students who have used a different book for their first course.
- In a two-quarter sequence, the first quarter could cover Chapters 1–8, and the second quarter could cover Chapters 9–12 and some chapters from Part II.

Acknowledgments. Many people have provided constructive criticism or helped me in other ways on this book. I would like to thank Leonor Abraido-Fandino, Scott Ananian, Stephen Bailey, Max Hailperin, David Hanson, Jeffrey Hsu, David MacQueen, Torben Mogensen, Doug Morgan, Robert Netzer, Elma Lee Noah, Mikael Petterson, Todd Proebsting, Anne Rogers, Barbara Ryder, Amr Sabry, Mooly Sagiv, Zhong Shao, Mary Lou Soffa, Andrew Tormach, Kwangkeun Yi, and Kenneth Zadeck.
PART ONE
Fundamentals of Compilation
A compiler was originally a program that “compiled” subroutines [a link-loader]. When in 1954 the combination “algebraic compiler” came into use, or rather into misuse, the meaning of the term had already shifted into the present one.

Bauer and Eickel [1975]

This book describes techniques, data structures, and algorithms for translating programming languages into executable code. A modern compiler is often organized into many phases, each operating on a different abstract “language.” The chapters of this book follow the organization of a compiler, each covering a successive phase.

To illustrate the issues in compiling real programming languages, I show how to compile Tiger, a simple but nontrivial language of the Algol family, with nested scope and heap-allocated records. Programming exercises in each chapter call for the implementation of the corresponding phase; a student who implements all the phases described in Part I of the book will have a working compiler. Tiger is easily modified to be functional or object-oriented (or both), and exercises in Part II show how to do this. Other chapters in Part II cover advanced techniques in program optimization. Appendix A describes the Tiger language.

The interfaces between modules of the compiler are almost as important as the algorithms inside the modules. To describe the interfaces concretely, it is useful to write them down in a real programming language. This book uses the C programming language.
1.1  

MODULES AND INTERFACES

Any large software system is much easier to understand and implement if the designer takes care with the fundamental abstractions and interfaces. Figure 1.1 shows the phases in a typical compiler. Each phase is implemented as one or more software modules.

Breaking the compiler into this many pieces allows for reuse of the components. For example, to change the target-machine for which the compiler produces machine language, it suffices to replace just the Frame Layout and Instruction Selection modules. To change the source language being compiled, only the modules up through Translate need to be changed. The compiler can be attached to a language-oriented syntax editor at the Abstract Syntax interface.

The learning experience of coming to the right abstraction by several iterations of think–implement–redesign is one that should not be missed. However, the student trying to finish a compiler project in one semester does not have
1.2. TOOLS AND SOFTWARE

this luxury. Therefore, I present in this book the outline of a project where the abstractions and interfaces are carefully thought out, and are as elegant and general as I am able to make them.

Some of the interfaces, such as Abstract Syntax, IR Trees, and Assem, take the form of data structures: for example, the Parsing Actions phase builds an Abstract Syntax data structure and passes it to the Semantic Analysis phase. Other interfaces are abstract data types; the Translate interface is a set of functions that the Semantic Analysis phase can call, and the Tokens interface takes the form of a function that the Parser calls to get the next token of the input program.

DESCRIPTION OF THE PHASES

Each chapter of Part I of this book describes one compiler phase, as shown in Table 1.2

This modularization is typical of many real compilers. But some compilers combine Parse, Semantic Analysis, Translate, and Canonicalize into one phase; others put Instruction Selection much later than I have done, and combine it with Code Emission. Simple compilers omit the Control Flow Analysis, Data Flow Analysis, and Register Allocation phases.

I have designed the compiler in this book to be as simple as possible, but no simpler. In particular, in those places where corners are cut to simplify the implementation, the structure of the compiler allows for the addition of more optimization or fancier semantics without violence to the existing interfaces.

1.2. TOOLS AND SOFTWARE

Two of the most useful abstractions used in modern compilers are context-free grammars, for parsing, and regular expressions, for lexical analysis. To make best use of these abstractions it is helpful to have special tools, such as Yacc (which converts a grammar into a parsing program) and Lex (which converts a declarative specification into a lexical analysis program).

The programming projects in this book can be compiled using any ANSI-standard C compiler, along with Lex (or the more modern Flex) and Yacc (or the more modern Bison). Some of these tools are freely available on the Internet; for information see the World Wide Web page:

http://www.cs.princeton.edu/~appel/modern/c

**TABLE 1.2.** Description of compiler phases.

Source code for some modules of the Tiger compiler, skeleton source code and support code for some of the programming exercises, example Tiger programs, and other useful files are also available from the same Web address. The programming exercises in this book refer to this directory as `$TIGER/` when referring to specific subdirectories and files contained therein.
1.3. DATA STRUCTURES FOR TREE LANGUAGES

Many of the important data structures used in a compiler are *intermediate representations* of the program being compiled. Often these representations take the form of trees, with several node types, each of which has different attributes. Such trees can occur at many of the phase-interfaces shown in Figure 1.1.

Tree representations can be described with grammars, just like programming languages. To introduce the concepts, I will show a simple programming language with statements and expressions, but no loops or if-statements (this is called a language of *straight-line programs*).

The syntax for this language is given in Grammar 1.3.

The informal semantics of the language is as follows. Each \( \text{Stm} \) is a statement, each \( \text{Exp} \) is an expression. \( s_1; s_2 \) executes statement \( s_1 \), then statement \( s_2 \). \( i := e \) evaluates the expression \( e \), then “stores” the result in variable \( i \). \( \text{print}(e_1, e_2, \ldots, e_n) \) displays the values of all the expressions, evaluated left to right, separated by spaces, terminated by a newline.

An *identifier expression*, such as \( i \), yields the current contents of the variable \( i \). A *number* evaluates to the named integer. An *operator expression* \( e_1 \ \text{op} \ e_2 \) evaluates \( e_1 \), then \( e_2 \), then applies the given binary operator. And an *expression sequence* \((s, e)\) behaves like the C-language “comma” operator, evaluating the statement \( s \) for side effects before evaluating (and returning the result of) the expression \( e \).

**Grammar 1.3.** A straight-line programming language.
For example, executing this program
\[ a := 5 + 3; \ b := (\text{print} (a, a-1), 10 * a); \text{print} (b) \]

prints
\[ 8 \ 7 \ 80 \]

How should this program be represented inside a compiler? One representation is source code, the characters that the programmer writes. But that is not so easy to manipulate. More convenient is a tree data structure, with one node for each statement (Stm) and expression (Exp). Figure 1.4 shows a tree representation of the program; the nodes are labeled by the production labels of Grammar 1.3, and each node has as many children as the corresponding grammar production has right-hand-side symbols.

We can translate the grammar directly into data structure definitions, as shown in Program 1.5. Each grammar symbol corresponds to a typedef in the data structures:
1.3. DATA STRUCTURES FOR TREE LANGUAGES

<table>
<thead>
<tr>
<th>Grammar</th>
<th>typedef</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stm</td>
<td>A_stm</td>
</tr>
<tr>
<td>Exp</td>
<td>A_exp</td>
</tr>
<tr>
<td>ExpList</td>
<td>A_expList</td>
</tr>
<tr>
<td>id</td>
<td>string</td>
</tr>
<tr>
<td>num</td>
<td>int</td>
</tr>
</tbody>
</table>

For each grammar rule, there is one constructor that belongs to the union for its left-hand-side symbol. The constructor names are indicated on the right-hand side of Grammar 1.3.

Each grammar rule has right-hand-side components that must be represented in the data structures. The CompoundStm has two Stm’s on the right-hand side; the AssignStm has an identifier and an expression; and so on. Each grammar symbol’s struct contains a union to carry these values, and a kind field to indicate which variant of the union is valid.

For each variant (CompoundStm, AssignStm, etc.) we make a constructor function to malloc and initialize the data structure. In Program 1.5 only the prototypes of these functions are given; the definition of A_CompoundStm would look like this:

```c
A_stm A_CompoundStm(A_stm stm1, A_stm stm2) {
    A_stm s = checked_malloc(sizeof(*s));
    s->kind = A_compoundStm;
    s->u.compound.stm1=stm1; s->u.compound.stm2=stm2;
    return s;
}
```

For Binop we do something simpler. Although we could make a Binop struct – with union variants for Plus, Minus, Times, Div – this is overkill because none of the variants would carry any data. Instead we make an enum type A_binop.

**Programming style.** We will follow several conventions for representing tree data structures in C:

1. Trees are described by a grammar.
2. A tree is described by one or more typedefs, corresponding to a symbol in the grammar.
3. Each typedef defines a pointer to a corresponding struct. The struct name, which ends in an underscore, is never used anywhere except in the declaration of the typedef and the definition of the struct itself.
4. Each struct contains a kind field, which is an enum showing different variants, one for each grammar rule; and a u field, which is a union.
CHAPTER ONE. INTRODUCTION

typedef char *string;
typedef struct A_stm_ *A_stm;
typedef struct A_exp_ *A_exp;
typedef struct A_expList_ *A_expList;
typedef enum {A_plus, A_minus, A_times, A_div} A_binop;

struct A_stm_ {enum {A_compoundStm, A_assignStm, A_printStm} kind;
   union {struct {A_stm stm1, stm2;} compound;
      struct {string id; A_exp exp;} assign;
      struct {A_expList exps;} print;
   } u;
};
A_stm A_CompoundStm(A_stm stm1, A_stm stm2);
A_stm A_AssignStm(string id, A_exp exp);
A_stm A_PrintStm(A_expList exps);

struct A_exp_ {enum {A_idExp, A_numExp, A_opExp, A_eseqExp} kind;
   union {string id;
      int num;
      struct {A_exp left; A_binop oper; A_exp right;} op;
      struct {A_stm stm; A_exp exp;} eseq;
   } u;
};
A_exp A_IdExp(string id);
A_exp A_NumExp(int num);
A_exp A_OpExp(A_exp left, A_binop oper, A_exp right);
A_exp A_EseqExp(A_stm stm, A_exp exp);

struct A_expList_ {enum {A_pairExpList, A_lastExpList} kind;
   union {struct {A_exp head; A_expList tail;} pair;
         A_exp last;
   } u;
};

PROGRAM 1.5. Representation of straight-line programs.

5. If there is more than one nontrivial (value-carrying) symbol in the right-hand side of a rule (example: the rule CompoundStm), the union will have a component that is itself a struct comprising these values (example: the compound element of the A_stm union).

6. If there is only one nontrivial symbol in the right-hand side of a rule, the union will have a component that is the value (example: the num field of the A_exp union).

7. Every class will have a constructor function that initializes all the fields. The malloc function shall never be called directly, except in these constructor functions.
8. Each module (header file) shall have a prefix unique to that module (example, A_ in Program 1.5).

9. Typedef names (after the prefix) shall start with lowercase letters; constructor functions (after the prefix) with uppercase; enumeration atoms (after the prefix) with lowercase; and union variants (which have no prefix) with lowercase.

**Modularity principles for C programs.** A compiler can be a big program; careful attention to modules and interfaces prevents chaos. We will use these principles in writing a compiler in C:

1. Each phase or module of the compiler belongs in its own “.c” file, which will have a corresponding “.h” file.
2. Each module shall have a prefix unique to that module. All global names (structure and union fields are not global names) exported by the module shall start with the prefix. Then the human reader of a file will not have to look outside that file to determine where a name comes from.
3. All functions shall have prototypes, and the C compiler shall be told to warn about uses of functions without prototypes.
4. We will `#include "util.h"` in each file:

```c
/* util.h */
#include <assert.h>

typedef char *string;
string String(char *);

typedef char bool;
#define TRUE 1
#define FALSE 0

void *checked_malloc(int);
```

The inclusion of `assert.h` encourages the liberal use of assertions by the C programmer.

5. The `string` type means a heap-allocated string that will not be modified after its initial creation. The `String` function builds a heap-allocated string from a C-style character pointer (just like the standard C library function `strdup`). Functions that take `string`s as arguments assume that the contents will never change.

6. C’s `malloc` function returns NULL if there is no memory left. The Tiger compiler will not have sophisticated memory management to deal with this problem. Instead, it will never call `malloc` directly, but call only our own function, `checked_malloc`, which guarantees never to return NULL:
void *checked_malloc(int len) {
    void *p = malloc(len);
    assert(p);
    return p;
}

7. We will never call free. Of course, a production-quality compiler must free its unused data in order to avoid wasting memory. The best way to do this is to use an automatic garbage collector, as described in Chapter 13 (see particularly conservative collection on page 296). Without a garbage collector, the programmer must carefully free(p) when the structure p is about to become inaccessible – not too late, or the pointer p will be lost, but not too soon, or else still-useful data may be freed (and then overwritten). In order to be able to concentrate more on compiling techniques than on memory deallocation techniques, we can simply neglect to do any freeing.

PROGRAM

STRAIGHT-LINE PROGRAM INTERPRETER

Implement a simple program analyzer and interpreter for the straight-line programming language. This exercise serves as an introduction to environments (symbol tables mapping variable-names to information about the variables); to abstract syntax (data structures representing the phrase structure of programs); to recursion over tree data structures, useful in many parts of a compiler; and to a functional style of programming without assignment statements.

It also serves as a “warm-up” exercise in C programming. Programmers experienced in other languages but new to C should be able to do this exercise, but will need supplementary material (such as textbooks) on C.

Programs to be interpreted are already parsed into abstract syntax, as described by the data types in Program 1.5.

However, we do not wish to worry about parsing the language, so we write this program by applying data constructors:

\[
\begin{align*}
A_{\text{stm}} \text{ prog } &= \\
&= A_{\text{CompoundStm}}(A_{\text{AssignStm}}("a", \\
&\quad A_{\text{OpExp}}(A_{\text{NumExp}}(5), A_{\text{plus}}, A_{\text{NumExp}}(3))), \\
&\quad A_{\text{CompoundStm}}(A_{\text{AssignStm}}("b", \\
&\quad A_{\text{EseqExp}}(A_{\text{PrintStm}}(A_{\text{PairExpList}}(A_{\text{IdExp}}("a"), \\
&\quad A_{\text{LastExpList}}(A_{\text{OpExp}}(A_{\text{IdExp}}("a"), A_{\text{minus}}, \\
&\quad A_{\text{NumExp}}(1))))), \\
&\quad A_{\text{OpExp}}(A_{\text{NumExp}}(10), A_{\text{times}}, A_{\text{IdExp}}("a"))), \\
&\quad A_{\text{PrintStm}}(A_{\text{LastExpList}}(A_{\text{IdExp}}("b"))));
\end{align*}
\]
Files with the data type declarations for the trees, and this sample program, are available in the directory $TIGER/chap1.

Writing interpreters without side effects (that is, assignment statements that update variables and data structures) is a good introduction to denotational semantics and attribute grammars, which are methods for describing what programming languages do. It’s often a useful technique in writing compilers, too; compilers are also in the business of saying what programming languages do.

Therefore, in implementing these programs, never assign a new value to any variable or structure-field except when it is initialized. For local variables, use the initializing form of declaration (for example, int i=j+3;) and for each kind of struct, make a “constructor” function that allocates it and initializes all the fields, similar to the A_CompoundStm example on page 9.

1. Write a function int maxargs(A_stm) that tells the maximum number of arguments of any print statement within any subexpression of a given statement. For example, maxargs(prog) is 2.

2. Write a function void interp(A_stm) that “interprets” a program in this language. To write in a “functional programming” style – in which you never use an assignment statement – initialize each local variable as you declare it.

For part 1, remember that print statements can contain expressions that contain other print statements.

For part 2, make two mutually recursive functions interpStm and interpExp. Represent a “table,” mapping identifiers to the integer values assigned to them, as a list of id int pairs.

```c
typedef struct table *Table_;
struct table {string id; int value; Table_ tail};
Table_ Table(string id, int value, struct table *tail) {
    Table_ t = malloc(sizeof(*t));
    t->id=id; t->value=value; t->tail=tail;
    return t;
}
```

The empty table is represented as NULL. Then interpStm is declared as

```c
Table_ interpStm(A_stm s, Table_ t)
```

taking a table $t_1$ as argument and producing the new table $t_2$ that’s just like $t_1$ except that some identifiers map to different integers as a result of the statement.
For example, the table \( t_1 \) that maps \( a \) to 3 and maps \( c \) to 4, which we write \( \{ a \mapsto 3, \ c \mapsto 4 \} \) in mathematical notation, could be represented as the linked list \[ a \leftarrow 3 \rightarrow c \leftarrow 4 \].

Now, let the table \( t_2 \) be just like \( t_1 \), except that it maps \( c \) to 7 instead of 4. Mathematically, we could write,

\[ t_2 = \text{update}(t_1, c, 7) \]

where the update function returns a new table \( \{ a \mapsto 3, \ c \mapsto 7 \} \).

On the computer, we could implement \( t_2 \) by putting a new cell at the head of the linked list: \[ c \leftarrow 7 \rightarrow a \leftarrow 3 \rightarrow c \leftarrow 4 \] as long as we assume that the first occurrence of \( c \) in the list takes precedence over any later occurrence.

Therefore, the update function is easy to implement; and the corresponding lookup function

\[ \text{int lookup(Table}_ \ t, \ \text{string key}) \]

just searches down the linked list.

Interpreting expressions is more complicated than interpreting statements, because expressions return integer values and have side effects. We wish to simulate the straight-line programming language’s assignment statements without doing any side effects in the interpreter itself. (The print statements will be accomplished by interpreter side effects, however.) The solution is to declare interpExp as

\[
\text{struct IntAndTable} \left\{ \text{int i; Table}_ \ t; \right\};
\text{struct IntAndTable interpExp(A}_ \ exp \ e, \ \text{Table}_ \ t) \; \ldots
\]

The result of interpreting an expression \( e_1 \) with table \( t_1 \) is an integer value \( i \) and a new table \( t_2 \). When interpreting an expression with two subexpressions (such as an OpExp), the table \( t_2 \) resulting from the first subexpression can be used in processing the second subexpression.

Hanson [1997] describes principles for writing modular software in C.
EXERCISES

1.1 This simple program implements *persistent* functional binary search trees, so that if tree2 = insert(x, tree1), then tree1 is still available for lookups even while tree2 can be used.

define struct tree *T_tree;
struct tree {T_tree left; String key; T_tree right;};
T_tree Tree(T_tree l, String k, T_tree r) {
    T_tree t = checked_malloc(sizeof(*t));
    t->left = l; t->key = k; t->right = r;
    return t;
}

T_tree insert(String key, T_tree t) {
    if (t == NULL) return Tree(NULL, key, NULL)
    if (strcmp(key, t->key) < 0)
        return Tree(insert(key, t->left), t->key, t->right);
    if (strcmp(key, t->key) > 0)
        return Tree(t->left, t->key, insert(key, t->right));
    else return Tree(t->left, key, t->right);
}

a. Implement a member function that returns TRUE if the item is found, else FALSE.

b. Extend the program to include not just membership, but the mapping of keys to bindings:

    T_tree insert(string key, void *binding, T_tree t);
    void * lookup(string key, T_tree t);

c. These trees are not balanced; demonstrate the behavior on the following two sequences of insertions:

(a) tspipfbst
(b) abcdefghi

d. Research balanced search trees in Sedgewick [1997] and recommend a balanced-tree data structure for functional symbol tables. **Hint:** To preserve a functional style, the algorithm should be one that rebalances on insertion but not on lookup, so a data structure such as splay trees is not appropriate.
To translate a program from one language into another, a compiler must first pull it apart and understand its structure and meaning, then put it together in a different way. The front end of the compiler performs analysis; the back end does synthesis.

The analysis is usually broken up into

**Lexical analysis**: breaking the input into individual words or “tokens”;
**Syntax analysis**: parsing the phrase structure of the program; and
**Semantic analysis**: calculating the program’s meaning.

The lexical analyzer takes a stream of characters and produces a stream of names, keywords, and punctuation marks; it discards white space and comments between the tokens. It would unduly complicate the parser to have to account for possible white space and comments at every possible point; this is the main reason for separating lexical analysis from parsing.

Lexical analysis is not very complicated, but we will attack it with high-powered formalisms and tools, because similar formalisms will be useful in the study of parsing and similar tools have many applications in areas other than compilation.
2.1. LEXICAL TOKENS

A lexical token is a sequence of characters that can be treated as a unit in the grammar of a programming language. A programming language classifies lexical tokens into a finite set of token types. For example, some of the token types of a typical programming language are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>ID</td>
<td>foo  n14  last</td>
</tr>
<tr>
<td>NUM</td>
<td>73  0 00 515 082</td>
</tr>
<tr>
<td>REAL</td>
<td>66.1 .5 10. 1e67 5.5e-10</td>
</tr>
<tr>
<td>IF</td>
<td>if</td>
</tr>
<tr>
<td>COMMA</td>
<td>,</td>
</tr>
<tr>
<td>NOTEQ</td>
<td>!=</td>
</tr>
<tr>
<td>LPAREN</td>
<td>(</td>
</tr>
<tr>
<td>RPAREN</td>
<td>)</td>
</tr>
</tbody>
</table>

Punctuation tokens such as IF, VOID, RETURN constructed from alphabetic characters are called *reserved words* and, in most languages, cannot be used as identifiers.

Examples of nontokens are

- comment /* try again */
- preprocessor directive #include<stdio.h>
- preprocessor directive #define NUMS 5, 6
- macro NUMS
- blanks, tabs, and newlines

In languages weak enough to require a macro preprocessor, the preprocessor operates on the source character stream, producing another character stream that is then fed to the lexical analyzer. It is also possible to integrate macro processing with lexical analysis.

Given a program such as

```c
float match0(char *s) /* find a zero */
{
    if (!strncmp(s, "0.0", 3))
        return 0.;
}
```

the lexical analyzer will return the stream

```
FLOAT ID(match0) LPAREN CHAR STAR ID(s) RPAREN LBRACE IF LPAREN BANG ID(strncmp) LPAREN ID(s)...
```
CHAPTERTWO. LEXICAL ANALYSIS

COMMA STRING(0.0) COMMA NUM(3) RPAREN RPAREN
RETURN REAL(0.0) SEMI RBRACE EOF

where the token-type of each token is reported; some of the tokens, such as identifiers and literals, have semantic values attached to them, giving auxiliary information in addition to the token type.

How should the lexical rules of a programming language be described? In what language should a lexical analyzer be written?

We can describe the lexical tokens of a language in English; here is a description of identifiers in C or Java:

An identifier is a sequence of letters and digits; the first character must be a letter. The underscore _ counts as a letter. Upper- and lowercase letters are different. If the input stream has been parsed into tokens up to a given character, the next token is taken to include the longest string of characters that could possibly constitute a token. Blanks, tabs, newlines, and comments are ignored except as they serve to separate tokens. Some white space is required to separate otherwise adjacent identifiers, keywords, and constants.

And any reasonable programming language serves to implement an ad hoc lexer. But we will specify lexical tokens using the formal language of regular expressions, implement lexers using deterministic finite automata, and use mathematics to connect the two. This will lead to simpler and more readable lexical analyzers.

2.2 REGULAR EXPRESSIONS

Let us say that a language is a set of strings; a string is a finite sequence of symbols. The symbols themselves are taken from a finite alphabet.

The Pascal language is the set of all strings that constitute legal Pascal programs; the language of primes is the set of all decimal-digit strings that represent prime numbers; and the language of C reserved words is the set of all alphabetic strings that cannot be used as identifiers in the C programming language. The first two of these languages are infinite sets; the last is a finite set. In all of these cases, the alphabet is the ASCII character set.

When we speak of languages in this way, we will not assign any meaning to the strings; we will just be attempting to classify each string as in the language or not.

To specify some of these (possibly infinite) languages with finite descrip-
tions, we will use the notation of regular expressions. Each regular expression stands for a set of strings.

**Symbol:** For each symbol $a$ in the alphabet of the language, the regular expression $a$ denotes the language containing just the string $a$.

**Alternation:** Given two regular expressions $M$ and $N$, the alternation operator written as a vertical bar $|$ makes a new regular expression $M | N$. A string is in the language of $M | N$ if it is in the language of $M$ or in the language of $N$. Thus, the language of $a | b$ contains the two strings $a$ and $b$.

**Concatenation:** Given two regular expressions $M$ and $N$, the concatenation operator makes a new regular expression $M \cdot N$. A string is in the language of $M \cdot N$ if it is the concatenation of any two strings $\alpha$ and $\beta$ such that $\alpha$ is in the language of $M$ and $\beta$ is in the language of $N$. Thus, the regular expression $(a | b) \cdot a$ defines the language containing the two strings $aa$ and $ba$.

**Epsilon:** The regular expression $\epsilon$ represents a language whose only string is the empty string. Thus, $(a \cdot b) | \epsilon$ represents the language {$"", "ab$"$}$.

**Repetition:** Given a regular expression $M$, its Kleene closure is $M^*$. A string is in $M^*$ if it is the concatenation of zero or more strings, all of which are in $M$. Thus, $((a | b) \cdot a)^*$ represents the infinite set {$"", "aa", "ba", "aaaa", "baaa", "aaba", "baba", "aaaaaa", \ldots$}.

Using symbols, alternation, concatenation, epsilon, and Kleene closure we can specify the set of ASCII characters corresponding to the lexical tokens of a programming language. First, consider some examples:

- $(0 | 1)^* \cdot 0$ Binary numbers that are multiples of two.
- $b^*(abb^*)^*(a|\epsilon)$ Strings of $a$’s and $b$’s with no consecutive $a$’s.
- $(a|b)^*aa(a|b)^*$ Strings of $a$’s and $b$’s containing consecutive $a$’s.

In writing regular expressions, we will sometimes omit the concatenation symbol or the epsilon, and we will assume that Kleene closure “binds tighter” than concatenation, and concatenation binds tighter than alternation; so that $ab | c$ means $(a \cdot b) | c$, and $(a | c)$ means $(a \cdot \epsilon)$.

Let us introduce some more abbreviations: $[abcd]$ means $(a | b | c | d)$, $[b-g]$ means $[bcdedg]$, $[b-gM-Qkr]$ means $[bcdedgMNOPQkr]$, $M?$ means $(M \mid \epsilon)$, and $M^+$ means $(M \cdot M^*)$. These extensions are convenient, but none extend the descriptive power of regular expressions: Any set of strings that can be described with these abbreviations could also be described by just the basic set of operators. All the operators are summarized in Figure 2.1.

Using this language, we can specify the lexical tokens of a programming language (Figure 2.2). For each token, we supply a fragment of C code that reports which token type has been recognized.
CHAPTER TWO. LEXICAL ANALYSIS

a
An ordinary character stands for itself.

ε
The empty string.

Another way to write the empty string.

M | N
Alternation, choosing from M or N.

M · N
Concatenation, an M followed by an N.

MN
Another way to write concatenation.

M*
Repetition (zero or more times).

M+
Repetition, one or more times.

M?
Optional, zero or one occurrence of M.

[a - zA - Z]
Character set alternation.

.  
A period stands for any single character except newline.

"a.+*"
Quotation, a string in quotes stands for itself literally.

FIGURE 2.1.  Regular expression notation.

if [a-z][a-z0-9]* {return IF;}
[a-z] {return ID;}
[0-9]+ {return NUM;}
("--"[a-z]"\n")|(" "|"\n"|"\t") { /* do nothing */}
. {error();}

FIGURE 2.2.  Regular expressions for some tokens.

The fifth line of the description recognizes comments or white space, but does not report back to the parser. Instead, the white space is discarded and the lexer resumed. The comments for this lexer begin with two dashes, contain only alphabetic characters, and end with newline.

Finally, a lexical specification should be complete, always matching some initial substring of the input; we can always achieve this by having a rule that matches any single character (and in this case, prints an “illegal character” error message and continues).

These rules are a bit ambiguous. For example, does if8 match as a single identifier or as the two tokens if and 8? Does the string if 89 begin with an identifier or a reserved word? There are two important disambiguation rules used by Lex and other similar lexical-analyzer generators:

Longest match: The longest initial substring of the input that can match any regular expression is taken as the next token.

Rule priority: For a particular longest initial substring, the first regular expres-
2.3. FINITE AUTOMATA

Regular expressions are convenient for specifying lexical tokens, but we need a formalism that can be implemented as a computer program. For this we can use finite automata (N.B. the singular of automata is automaton). A finite automaton has a finite set of states; edges lead from one state to another, and each edge is labeled with a symbol. One state is the start state, and certain of the states are distinguished as final states.

Figure 2.3 shows some finite automata. We number the states just for convenience in discussion. The start state is numbered 1 in each case. An edge labeled with several characters is shorthand for many parallel edges; so in the ID machine there are really 26 edges each leading from state 1 to 2, each labeled by a different letter.

Thus, \( \text{if}8 \) matches as an identifier by the longest-match rule, and \( \text{if} \) matches as a reserved word by rule-priority.
FIGURE 2.4. Combined finite automaton.

In a *deterministic* finite automaton (DFA), no two edges leaving from the same state are labeled with the same symbol. A DFA *accepts* or *rejects* a string as follows. Starting in the start state, for each character in the input string the automaton follows exactly one edge to get to the next state. The edge must be labeled with the input character. After making \( n \) transitions for an \( n \)-character string, if the automaton is in a final state, then it accepts the string. If it is not in a final state, or if at some point there was no appropriately labeled edge to follow, it rejects. The *language* recognized by an automaton is the set of strings that it accepts.

For example, it is clear that any string in the language recognized by automaton ID must begin with a letter. Any single letter leads to state 2, which is final; so a single-letter string is accepted. From state 2, any letter or digit leads back to state 2, so a letter followed by any number of letters and digits is also accepted.

In fact, the machines shown in Figure 2.3 accept the same languages as the regular expressions of Figure 2.2.

These are six separate automata; how can they be combined into a single machine that can serve as a lexical analyzer? We will study formal ways of doing this in the next section, but here we will just do it ad hoc: Figure 2.4 shows such a machine. Each final state must be labeled with the token-type
2.3. FINITE AUTOMATA

that it accepts. State 2 in this machine has aspects of state 2 of the IF machine
and state 2 of the ID machine; since the latter is final, then the combined state
must be final. State 3 is like state 3 of the IF machine and state 2 of the ID
machine; because these are both final we use rule priority to disambiguate
– we label state 3 with IF because we want this token to be recognized as a
reserved word, not an identifier.

We can encode this machine as a transition matrix: a two-dimensional ar-
ray (a vector of vectors), subscripted by state number and input character. There will be a “dead” state (state 0) that loops to itself on all characters; we
use this to encode the absence of an edge.

```c
int edges[][256] = {
    /* state 0 */ {0, 0, ...0, 0, 0, ...0, 0, 0, 0, 0, 0, ...},
    /* state 1 */ {0, 0, ...7, 7, 7, ...9, 4, 4, 4, 4, 2, 4, ...},
    /* state 2 */ {0, 0, ...4, 4, 4, ...0, 4, 4, 4, 4, 4, 4, ...},
    /* state 3 */ {0, 0, ...4, 4, 4, ...0, 4, 4, 4, 4, 4, 4, ...},
    /* state 4 */ {0, 0, ...4, 4, 4, ...0, 4, 4, 4, 4, 4, 4, ...},
    /* state 5 */ {0, 0, ...6, 6, 6, ...0, 0, 0, 0, 0, 0, ...},
    /* state 6 */ {0, 0, ...6, 6, 6, ...0, 0, 0, 0, 0, 0, ...},
    /* state 7 */ {0, 0, ...7, 7, 7, ...0, 0, 0, 0, 0, 0, ...},
    /* state 8 */ {0, 0, ...8, 8, 8, ...0, 0, 0, 0, 0, 0, ...},
    et cetera
};
```

There must also be a “finality” array, mapping state numbers to actions – final
state 2 maps to action ID, and so on.

RECOGNIZING THE LONGEST MATCH

It is easy to see how to use this table to recognize whether to accept or reject
a string, but the job of a lexical analyzer is to find the longest match, the
longest initial substring of the input that is a valid token. While interpreting
transitions, the lexer must keep track of the longest match seen so far, and the
position of that match.

Keeping track of the longest match just means remembering the last time
the automaton was in a final state with two variables, Last-Final (the state
number of the most recent final state encountered) and Input-Position-
at-Last-Final. Every time a final state is entered, the lexer updates these
variables; when a dead state (a nonfinal state with no output transitions) is
reached, the variables tell what token was matched, and where it ended.

Figure 2.5 shows the operation of a lexical analyzer that recognizes longest
matches; note that the current input position may be far beyond the most
recent position at which the recognizer was in a final state.
2.4 NONDETERMINISTIC FINITE AUTOMATA

A nondeterministic finite automaton (NFA) is one that has a choice of edges – labeled with the same symbol – to follow out of a state. Or it may have special edges labeled with $\epsilon$ (the Greek letter epsilon), that can be followed without eating any symbol from the input.

Here is an example of an NFA:
In the start state, on input character $a$, the automaton can move either right or left. If left is chosen, then strings of $a$’s whose length is a multiple of three will be accepted. If right is chosen, then even-length strings will be accepted. Thus, the language recognized by this NFA is the set of all strings of $a$’s whose length is a multiple of two or three.

On the first transition, this machine must choose which way to go. It is required to accept the string if there is any choice of paths that will lead to acceptance. Thus, it must “guess,” and must always guess correctly.

Edges labeled with $\epsilon$ may be taken without using up a symbol from the input. Here is another NFA that accepts the same language:

![NFA Diagram]

Again, the machine must choose which $\epsilon$-edge to take. If there is a state with some $\epsilon$-edges and some edges labeled by symbols, the machine can choose to eat an input symbol (and follow the corresponding symbol-labeled edge), or to follow an $\epsilon$-edge instead.

**CONVERTING A REGULAR EXPRESSION TO AN NFA**

Nondeterministic automata are a useful notion because it is easy to convert a (static, declarative) regular expression to a (simulatable, quasi-executable) NFA.

The conversion algorithm turns each regular expression into an NFA with a tail (start edge) and a head (ending state). For example, the single-symbol regular expression $a$ converts to the NFA

![NFA Diagram for a]

The regular expression $ab$, made by combining $a$ with $b$ using concatenation is made by combining the two NFAs, hooking the head of $a$ to the tail of $b$. The resulting machine has a tail labeled by $a$ and a head into which the $b$ edge flows.
In general, any regular expression $M$ will have some NFA with a tail and head:

We can define the translation of regular expressions to NFAs by induction. Either an expression is primitive (a single symbol or $\epsilon$) or it is made from smaller expressions. Similarly, the NFA will be primitive or made from smaller NFAs.

Figure 2.6 shows the rules for translating regular expressions to nondeterministic automata. We illustrate the algorithm on some of the expressions in Figure 2.2 – for the tokens IF, ID, NUM, and error. Each expression is translated to an NFA, the “head” state of each NFA is marked final with a different token type, and the tails of all the expressions are joined to a new start node. The result – after some merging of equivalent NFA states – is shown in Figure 2.7.
CONVERTING AN NFA TO A DFA

As we saw in Section 2.3, implementing deterministic finite automata (DFAs) as computer programs is easy. But implementing NFAs is a bit harder, since most computers don’t have good “guessing” hardware.

We can avoid the need to guess by trying every possibility at once. Let us simulate the NFA of Figure 2.7 on the string `in`. We start in state 1. Now, instead of guessing which $\epsilon$-transition to take, we just say that at this point the NFA might take any of them, so it is in one of the states \{1, 4, 9, 14\}; that is, we compute the $\epsilon$-closure of \{1\}. Clearly, there are no other states reachable without eating the first character of the input.

Now, we make the transition on the character `i`. From state 1 we can reach 2, from 4 we reach 5, from 9 we go nowhere, and from 14 we reach 15. So we have the set \{2, 5, 15\}. But again we must compute $\epsilon$-closure: from 5 there is an $\epsilon$-transition to 8, and from 8 to 6. So the NFA must be in one of the states \{2, 5, 6, 8, 15\}.

On the character `n`, we get from state 6 to 7, from 2 to nowhere, from 5 to nowhere, from 8 to nowhere, and from 15 to nowhere. So we have the set \{7\}; its $\epsilon$-closure is \{6, 7, 8\}.

Now we are at the end of the string `in`; is the NFA in a final state? One of the states in our possible-states set is 8, which is final. Thus, `in` is an ID token.

We formally define $\epsilon$-closure as follows. Let $\text{edge}(s, c)$ be the set of all NFA states reachable by following a single edge with label $c$ from state $s$. 

---

2.4. NONDETERMINISTIC FINITE AUTOMATA

**FIGURE 2.7.** Four regular expressions translated to an NFA.
For a set of states $S$, $\text{closure}(S)$ is the set of states that can be reached from a state in $S$ without consuming any of the input, that is, by going only through $\epsilon$ edges. Mathematically, we can express the idea of going through $\epsilon$ edges by saying that $\text{closure}(S)$ is smallest set $T$ such that

$$T = S \cup \left( \bigcup_{s \in T} \text{edge}(s, \epsilon) \right).$$

We can calculate $T$ by iteration:

$$
T \leftarrow S \\
\text{repeat} \quad T' \leftarrow T \\
\quad T \leftarrow T' \cup \left( \bigcup_{s \in T'} \text{edge}(s, \epsilon) \right) \\
\text{until} \quad T = T'
$$

Why does this algorithm work? $T$ can only grow in each iteration, so the final $T$ must include $S$. If $T = T'$ after an iteration step, then $T$ must also include $\bigcup_{s \in T'} \text{edge}(s, \epsilon)$. Finally, the algorithm must terminate, because there are only a finite number of distinct states in the NFA.

Now, when simulating an NFA as described above, suppose we are in a set $d = \{s_i, s_k, s_l\}$ of NFA states $s_i, s_k, s_l$. By starting in $d$ and eating the input symbol $c$, we reach a new set of NFA states; we’ll call this set $\text{DFAedge}(d, c)$:

$$\text{DFAedge}(d, c) = \text{closure}(\bigcup_{s \in d} \text{edge}(s, c))$$

Using $\text{DFAedge}$, we can write the NFA simulation algorithm more formally. If the start state of the NFA is $s_1$, and the input string is $c_1, \ldots, c_k$, then the algorithm is:

$$
d \leftarrow \text{closure}([s_1]) \\
\text{for } i \leftarrow 1 \text{ to } k \\
\quad d \leftarrow \text{DFAedge}(d, c_i)
$$

Manipulating sets of states is expensive – too costly to want to do on every character in the source program that is being lexically analyzed. But it is possible to do all the sets-of-states calculations in advance. We make a DFA from the NFA, such that each set of NFA states corresponds to one DFA state. Since the NFA has a finite number $n$ of states, the DFA will also have a finite number (at most $2^n$) of states.

DFA construction is easy once we have $\text{closure}$ and $\text{DFAedge}$ algorithms. The DFA start state $d_1$ is just $\text{closure}(s_1)$, as in the NFA simulation algo-
2.4. NONDETERMINISTIC FINITE AUTOMATA

A state \( d \) is final in the DFA if any NFA-state in \( \text{states}[d] \) is final in the NFA. Labeling a state final is not enough; we must also say what token is recognized; and perhaps several members of \( \text{states}[d] \) are final in the NFA. In this case we label \( d \) with the token-type that occurred first in the list of

\[
\text{FIGURE 2.8. NFA converted to DFA.}
\]

The algorithm does not visit unreachable states of the DFA. This is extremely important, because in principle the DFA has \( 2^n \) states, but in practice we usually find that only about \( n \) of them are reachable from the start state. It is important to avoid an exponential blowup in the size of the DFA interpreter’s transition tables, which will form part of the working compiler.

A state \( d \) is final in the DFA if any NFA-state in \( \text{states}[d] \) is final in the NFA. Labeling a state final is not enough; we must also say what token is recognized; and perhaps several members of \( \text{states}[d] \) are final in the NFA. In this case we label \( d \) with the token-type that occurred first in the list of
regular expressions that constitute the lexical specification. This is how rule priority is implemented.

After the DFA is constructed, the “states” array may be discarded, and the “trans” array is used for lexical analysis.

Applying the DFA construction algorithm to the NFA of Figure 2.7 gives the automaton in Figure 2.8.

This automaton is suboptimal. That is, it is not the smallest one that recognizes the same language. In general, we say that two states \( s_1 \) and \( s_2 \) are equivalent when the machine starting in \( s_1 \) accepts a string \( \sigma \) if and only if starting in \( s_2 \) it accepts \( \sigma \). This is certainly true of the states labeled \([5,6,8,15]\) and \([6,7,8]\) in Figure 2.8; and of the states labeled \([10,11,13,15]\) and \([11,12,13]\).

In an automaton with two equivalent states \( s_1 \) and \( s_2 \), we can make all of \( s_2 \)'s incoming edges point to \( s_1 \) instead and delete \( s_2 \).

How can we find equivalent states? Certainly, \( s_1 \) and \( s_2 \) are equivalent if they are both final or both non-final and for any symbol \( c \), \( \text{trans}[s_1, c] = \text{trans}[s_2, c] \). \([10,11,13,15]\) and \([11,12,13]\) satisfy this criterion. But this condition is not sufficiently general; consider the automaton

Here, states 2 and 4 are equivalent, but \( \text{trans}[2, a] \neq \text{trans}[4, a] \).

After constructing a DFA it is useful to apply an algorithm to minimize it by finding equivalent states; see Exercise 2.6.

### 2.5 Lex: A LEXICAL ANALYZER GENERATOR

DFA construction is a mechanical task easily performed by computer, so it makes sense to have an automatic lexical analyzer generator to translate regular expressions into a DFA.

Lex is a lexical analyzer generator that produces a C program from a lexical specification. For each token type in the programming language to be lexically analyzed, the specification contains a regular expression and an action.
The action communicates the token type (perhaps along with other information) to the next phase of the compiler.

The output of Lex is a program in C – a lexical analyzer that interprets a DFA using the algorithm described in Section 2.3 and executes the action fragments on each match. The action fragments are just C statements that return token values.

The tokens described in Figure 2.2 are specified in Lex as shown in Program 2.9.

The first part of the specification, between the %{···}% braces, contains includes and declarations that may be used by the C code in the remainder of the file.

The second part of the specification contains regular-expression abbreviations and state declarations. For example, the declaration digits [0-9]+ in this section allows the name {digits} to stand for a nonempty sequence of digits within regular expressions.

The third part contains regular expressions and actions. The actions are fragments of ordinary C code. Each action must return a value of type int, denoting which kind of token has been found.
In the action fragments, several special variables are available. The string matched by the regular expression is \texttt{yytext}. The length of the matched string is \texttt{yyleng}.

In this particular example, we keep track of the position of each token, measured in characters since the beginning of the file, in the variable \texttt{charPos}. The \texttt{EM_tokPos} variable of the error message module \texttt{errormsg.h} is continually told this position by calls to the macro \texttt{ADJ}. The parser will be able to use this information in printing informative syntax error messages.

The include file \texttt{tokens.h} in this example defines integer constants \texttt{IF}, \texttt{ID}, \texttt{NUM}, and so on; these values are returned by the action fragments to tell what token-type is matched.

Some tokens have \textit{semantic values} associated with them. For example, \texttt{ID}'s semantic value is the character string constituting the identifier; \texttt{NUM}'s semantic value is an integer; and \texttt{IF} has no semantic value (any \texttt{IF} is indistinguishable from any other). The values are communicated to the parser through the global variable \texttt{yylval}, which is a union of the different types of semantic values. The token-type returned by the lexer tells the parser which variant of the union is valid.

\section*{START STATES}

Regular expressions are \textit{static} and \textit{declarative}; automata are \textit{dynamic} and \textit{imperative}. That is, you can see the components and structure of a regular expression without having to simulate an algorithm, but to understand an automaton it is often necessary to “execute” it in your mind. Thus, regular expressions are usually more convenient to specify the lexical structure of programming-language tokens.

But sometimes the step-by-step, state-transition model of automata is appropriate. Lex has a mechanism to mix states with regular expressions. One can declare a set of \textit{start states}; each regular expression can be prefixed by the set of start states in which it is valid. The action fragments can explicitly change the start state. In effect, we have a finite automaton whose edges are labeled, not by single symbols, but by regular expressions. This example shows a language with simple identifiers, \texttt{if} tokens, and comments delimited by (\* and *) brackets:

\begin{verbatim}
if ([a-z]+)

INITIAL

COMMENT

if

(*)

.
\end{verbatim}
Though it is possible to write a single regular expression that matches an entire comment, as comments get more complicated it becomes more difficult, or even impossible if nested comments are allowed.

The Lex specification corresponding to this machine is

```
: the usual preamble ...
%Start INITIAL COMMENT
%
<INITIAL>if    {ADJ; return IF;}
<INITIAL>[a-z]+ {ADJ; yylval.sval=String(yytext); return ID;}
<INITIAL>"(*)  {ADJ; BEGIN COMMENT;}
<INITIAL>.    {ADJ; EM_error("illegal character");}
<COMMENT>"*)" {ADJ; BEGIN INITIAL;}
<COMMENT>.*   {ADJ;}
    {BEGIN INITIAL; yyless(1);}
```

where INITIAL is the “outside of any comment” state. The last rule is a hack to get Lex into this state. Any regular expression not prefixed by a <STATE> operates in all states; this feature is rarely useful.

This example can be easily augmented to handle nested comments, via a global variable that is incremented and decremented in the semantic actions.

**PROGRAM**

**LEXICAL ANALYSIS**

Use Lex to implement a lexical analyzer for the Tiger language. Appendix A describes, among other things, the lexical tokens of Tiger.

This chapter has left out some of the specifics of how the lexical analyzer should be initialized and how it should communicate with the rest of the compiler. You can learn this from the Lex manual, but the “skeleton” files in the $TIGER/chap2 directory will also help get you started.

Along with the tiger.lex file you should turn in documentation for the following points:

- how you handle comments;
- how you handle strings;
- error handling;
- end-of-file handling;
- other interesting features of your lexer.
Supporting files are available in $TIGER/chap2 as follows:

tokens.h Definition of lexical-token constants, and yylval.
errmsg.h, errmsg.c The error message module, useful for producing error messages with file names and line numbers.
driver.c A test scaffold to run your lexer on an input file.
tiger.lex The beginnings of a real tiger.lex file.
makfile A “makefile” to compile everything.

When reading the Tiger Language Reference Manual (Appendix A), pay particular attention to the paragraphs with the headings Identifiers, Comments, Integer literal, and String literal.

The reserved words of the language are: while, for, to, break, let, in, end, function, var, type, array, if, then, else, do, of, nil.

The punctuation symbols used in the language are: , : ; ( ) [ ] { } . + - * / = <> < <= > >= & | :=

The string value that you return for a string literal should have all the escape sequences translated into their meanings.

There are no negative integer literals; return two separate tokens for -32.
Detect unclosed comments (at end of file) and unclosed strings.

The directory $TIGER/testcases contains a few sample Tiger programs.
To get started: Make a directory and copy the contents of $TIGER/chap2 into it. Make a file test.tig containing a short program in the Tiger language. Then type make; Lex will run on tiger.lex, producing lex.yy.c, and then the appropriate C files will be compiled.

Finally, lextest test.tig will lexically analyze the file using a test scaffold.

Lex was the first lexical-analyzer generator based on regular expressions [Lesk 1975]; it is still widely used.

Computing \( \epsilon \)-closure can be done more efficiently by keeping a queue or stack of states whose edges have not yet been checked for \( \epsilon \)-transitions [Aho et al. 1986]. Regular expressions can be converted directly to DFAs without going through NFAs [McNaughton and Yamada 1960; Aho et al. 1986].

DFA transition tables can be very large and sparse. If represented as a simple two-dimensional matrix \((\text{states} \times \text{symbols})\) they take far too much mem-
ory. In practice, tables are compressed; this reduces the amount of memory required, but increases the time required to look up the next state [Aho et al. 1986].

Lexical analyzers, whether automatically generated or handwritten, must manage their input efficiently. Of course, input is buffered, so that a large batch of characters is obtained at once; then the lexer can process one character at a time in the buffer. The lexer must check, for each character, whether the end of the buffer is reached. By putting a sentinel – a character that cannot be part of any token – at the end of the buffer, it is possible for the lexer to check for end-of-buffer only once per token, instead of once per character [Aho et al. 1986]. Gray [1988] uses a scheme that requires only one check per line, rather than one per token, but cannot cope with tokens that contain end-of-line characters. Bumbulis and Cowan [1993] check only once around each cycle in the DFA; this reduces the number of checks (from once per character) when there are long paths in the DFA.

Automatically generated lexical analyzers are often criticized for being slow. In principle, the operation of a finite automaton is very simple and should be efficient, but interpreting from transition tables adds overhead. Gray [1988] shows that DFAs translated directly into executable code (implementing states as case statements) can run as fast as hand-coded lexers. The Flex “fast lexical analyzer generator” [Paxson 1995] is significantly faster than Lex.

**EXERCISES**

2.1 Write regular expressions for each of the following.

a. Strings over the alphabet \{a, b, c\} where the first a precedes the first b.

b. Strings over the alphabet \{a, b, c\} with an even number of a’s.

c. Binary numbers that are multiples of four.

d. Binary numbers that are greater than 101001.

e. Strings over the alphabet \{a, b, c\} that don’t contain the contiguous substring baa.

f. The language of nonnegative integer constants in C, where numbers
beginning with 0 are octal constants and other numbers are decimal constants.

g. Binary numbers \( n \) such that there exists an integer solution of \( a^n + b^n = c^n \).

2.2 For each of the following, explain why you’re not surprised that there is no regular expression defining it.

a. Strings of \( a \)'s and \( b \)'s where there are more \( a \)'s than \( b \)'s.

b. Strings of \( a \)'s and \( b \)'s that are palindromes (the same forward as backward).

c. Syntactically correct C programs.

2.3 Explain in informal English what each of these finite state automata recognizes.

a. [Diagram of finite state automaton]

b. [Diagram of finite state automaton]

c. [Diagram of finite state automaton]

2.4 Convert these regular expressions to nondeterministic finite automata.

a. (if|then|else)

b. \( a((b|a^c)x)^*|x^a \)

2.5 Convert these NFAs to deterministic finite automata.

a. [Diagram of deterministic finite automaton]

b. [Diagram of deterministic finite automaton]
2.6 Find two equivalent states in the following automaton, and merge them to produce a smaller automaton that recognizes the same language. Repeat until there are no longer equivalent states.

Actually, the general algorithm for minimizing finite automata works in reverse. First, find all pairs of inequivalent states. States $X$, $Y$ are inequivalent if $X$ is final and $Y$ is not or (by iteration) if $X \xrightarrow{a} X'$ and $Y \xrightarrow{a} Y'$ and $X'$, $Y'$ are inequivalent. After this iteration ceases to find new pairs of inequivalent states, then $X$, $Y$ are equivalent if they are not inequivalent. See Hopcroft and Ullman [1979], Theorem 3.10.

*2.7 Any DFA that accepts at least one string can be converted to a regular expression. Convert the DFA of Exercise 2.3c to a regular expression. Hint: First, pretend state 1 is the start state. Then write a regular expression for excursions to state 2 and back, and a similar one for excursions to state 0 and back. Or look in Hopcroft and Ullman [1979], Theorem 2.4, for the algorithm.
2.8 Suppose this DFA were used by Lex to find tokens in an input file.

a. How many characters past the end of a token might Lex have to examine before matching the token?

b. Given your answer \( k \) to part (a), show an input file containing at least two tokens such that the first call to Lex will examine \( k \) characters past the end of the first token before returning the first token. If the answer to part (a) is zero, then show an input file containing at least two tokens, and indicate the endpoint of each token.

2.9 An interpreted DFA-based lexical analyzer uses two tables, 

- `edges` indexed by state and input symbol, yielding a state number, and
- `final` indexed by state, returning 0 or an action-number.

Starting with this lexical specification,

```
(aba)+ (action 1);
(a(b*)a) (action 2);
(a|b) (action 3);
```

generate the `edges` and `final` tables for a lexical analyzer. Then show each step of the lexer on the string `abaabbaba`. Be sure to show the values of the important internal variables of the recognizer. There will be repeated calls to the lexer to get successive tokens.

2.10 Lex has a lookahead operator `/` so that the regular expression `abc/def` matches `abc` only when followed by `def` (but `def` is not part of the matched string, and will be part of the next token(s)). Aho et al. [1986] describe, and Lex [Lesk 1975] uses, an incorrect algorithm for implementing lookahead (it fails on `(a|ab) /ba` with input `aba`, matching `ab` where it should match `a`). Flex [Paxson 1995] uses a better mechanism that works correctly for `(a|ab) /ba` but fails (with a warning message) on `zx*/xy*`.

Design a better lookahead mechanism.
3

Parsing

**syn-tax:** the way in which words are put together to form phrases, clauses, or sentences.

*Webster's Dictionary*

The abbreviation mechanism in Lex, whereby a symbol stands for some regular expression, is convenient enough that it is tempting to use it in interesting ways:

\[
digits = [0 - 9]^* \\
sum = (digits "+")* digits
\]

These regular expressions define sums of the form 28+301+9.

But now consider

\[
digits = [0 - 9]^* \\
sum = expr "+" expr \\
expr = "(" sum "")" | digits
\]

This is meant to define expressions of the form:

\[
(109+23) \\
61 \\
(1+(250+3))
\]

in which all the parentheses are balanced. But it is impossible for a finite automaton to recognize balanced parentheses (because a machine with \( N \) states cannot remember a parenthesis-nesting depth greater than \( N \)), so clearly \( sum \) and \( expr \) cannot be regular expressions.

So how does Lex manage to implement regular-expression abbreviations such as \( digits \)? The answer is that the right-hand-side \([[0-9] +\)] is simply
CHAPTER THREE. PARSING

substituted for \texttt{digits} wherever it appears in regular expressions, \textit{before} translation to a finite automaton.

This is not possible for the \texttt{sum-and-expr} language; we can first substitute \texttt{sum} into \texttt{expr}, yielding

\[
expr = "(" expr "+" expr ")" | digits
\]

but now an attempt to substitute \texttt{expr} into itself leads to

\[
expr = "(" (" (" expr "+" expr ")" | digits ")" | digits ")" | digits
\]

and the right-hand side now has just as many occurrences of \texttt{expr} as it did before – in fact, it has more!

Thus, the notion of abbreviation does not add expressive power to the language of regular expressions – there are no additional languages that can be defined – unless the abbreviations are recursive (or mutually recursive, as are \texttt{sum} and \texttt{expr}).

The additional expressive power gained by recursion is just what we need for parsing. Also, once we have abbreviations with recursion, we do not need alternation except at the top level of expressions, because the definition

\[
expr = ab(c | d)e
\]

can always be rewritten using an auxiliary definition as

\[
\begin{align*}
\text{aux} &= c | d \\
expr &= a b \text{ aux} e
\end{align*}
\]

In fact, instead of using the alternation mark at all, we can just write several allowable expansions for the same symbol:

\[
\begin{align*}
\text{aux} &= c \\
\text{aux} &= d \\
expr &= a b \text{ aux} e
\end{align*}
\]

The Kleene closure is not necessary, since we can rewrite it so that

\[
expr = (a b c)^*
\]

becomes

\[
\begin{align*}
expr &= (a b c) expr \\
expr &= \epsilon
\end{align*}
\]
What we have left is a very simple notation, called *context-free grammars*. Just as regular expressions can be used to define lexical structure in a static, declarative way, grammars define syntactic structure declaratively. But we will need something more powerful than finite automata to parse languages described by grammars.

In fact, grammars can also be used to describe the structure of lexical tokens, although regular expressions are adequate — and more concise — for that purpose.

**3.1. CONTEXT-FREE GRAMMARS**

As before, we say that a *language* is a set of *strings*; each string is a finite sequence of *symbols* taken from a finite *alphabet*. For parsing, the strings are source programs, the symbols are lexical tokens, and the alphabet is the set of token types returned by the lexical analyzer.

A context-free grammar describes a language. A grammar has a set of *productions* of the form

\[ \text{symbol} \rightarrow \text{symbol symbol} \cdots \text{symbol} \]

where there are zero or more symbols on the right-hand side. Each symbol is either *terminal*, meaning that it is a token from the alphabet of strings in the language, or *nonterminal*, meaning that it appears on the left-hand side of some production. No token can ever appear on the left-hand side of a production. Finally, one of the nonterminals is distinguished as the *start symbol* of the grammar.

**Grammar 3.1** is an example of a grammar for straight-line programs. The start symbol is $S$ (when the start symbol is not written explicitly it is conventional to assume that the left-hand nonterminal in the first production is the start symbol). The terminal symbols are

\[ \text{id \ print \ num \ , \ + \ ( \ ) : = ; } \]
and the nonterminals are $S$, $E$, and $L$. One sentence in the language of this grammar is

$$id := \text{num}; id := id + (id := \text{num} + \text{num}, \ id)$$

where the source text (before lexical analysis) might have been

$$a := 7;$$
$$b := c + (d := 5 + 6, \ d)$$

The token-types (terminal symbols) are $id$, $\text{num}$, $:=$, and so on; the names ($a, b, c, d$) and numbers ($7, 5, 6$) are *semantic values* associated with some of the tokens.

**DERIVATIONS**

To show that this sentence is in the language of the grammar, we can perform a *derivation*: start with the start symbol, then repeatedly replace any nonterminal by one of its right-hand sides, as shown in Derivation 3.2.

There are many different derivations of the same sentence. A *leftmost* derivation is one in which the leftmost nonterminal symbol is always the one expanded; in a *rightmost* derivation, the rightmost nonterminal is always next to be expanded.
3.1. CONTEXT-FREE GRAMMARS

Derivation 3.2 is neither leftmost nor rightmost; a leftmost derivation for this sentence would begin,

\[
\begin{align*}
S & \\
S & \Rightarrow S \\
id & := E \\
id & := \text{num} \\
id & := \text{num} \\
id & := E + E \\
\vdots
\end{align*}
\]

PARSE TREES
A parse tree is made by connecting each symbol in a derivation to the one from which it was derived, as shown in Figure 3.3. Two different derivations can have the same parse tree.

AMBIGUOUS GRAMMARS
A grammar is ambiguous if it can derive a sentence with two different parse trees. Grammar 3.1 is ambiguous, since the sentence \( \text{id} := \text{id} + \text{id} + \text{id} \) has two parse trees (Figure 3.4).

Grammar 3.5 is also ambiguous; Figure 3.6 shows two parse trees for the sentence \( 1 - 2 - 3 \), and Figure 3.7 shows two trees for \( 1 + 2 * 3 \). Clearly, if we use
**FIGURE 3.4.** Two parse trees for the same sentence using Grammar 3.1.

\[
E \rightarrow \text{id}
\]
\[
E \rightarrow \text{num}
\]
\[
E \rightarrow E \ast E
\]
\[
E \rightarrow E / E
\]
\[
E \rightarrow E + E
\]
\[
E \rightarrow E - E
\]
\[
E \rightarrow (E)
\]

**GRAMMAR 3.5.**

**FIGURE 3.6.** Two parse trees for the sentence 1 - 2 - 3 in Grammar 3.5.

**FIGURE 3.7.** Two parse trees for the sentence 1 + 2 * 3 in Grammar 3.5.
parse trees to interpret the meaning of the expressions, the two parse trees for 1-2-3 mean different things: \((1 - 2) - 3 = -4\) versus \(1 - (2 - 3) = 2\). Similarly, \((1 + 2) \times 3\) is not the same as \(1 + (2 \times 3)\). And indeed, compilers do use parse trees to derive meaning.

Therefore, ambiguous grammars are problematic for compiling: in general we would prefer to have unambiguous grammars. Fortunately, we can often transform ambiguous grammars to unambiguous grammars.

Let us find an unambiguous grammar that accepts the same language as Grammar 3.5. First, we would like to say that \(\ast\) binds tighter than \(+\), or has higher precedence. Second, we want to say that each operator associates to the left, so that we get \((1 - 2) - 3\) instead of \(1 - (2 - 3)\). We do this by introducing new nonterminal symbols to get Grammar 3.8.

The symbols \(E\), \(T\), and \(F\) stand for expression, term, and factor; conventionally, factors are things you multiply and terms are things you add.

This grammar accepts the same set of sentences as the ambiguous grammar, but now each sentence has exactly one parse tree. Grammar 3.8 can never produce parse trees of the form shown in Figure 3.9 (see Exercise 3.17).

Had we wanted to make \(\ast\) associate to the right, we could have written its production as \(T \rightarrow F \ast T\).

We can usually eliminate ambiguity by transforming the grammar. Though there are some languages (sets of strings) that have ambiguous grammars but no unambiguous grammar, such languages may be problematic as programming languages because the syntactic ambiguity may lead to problems in writing and understanding programs.
CHAPTER THREE. PARSING

\[ S \rightarrow E \, $ \]
\[ E \rightarrow E \, + \, T \]
\[ E \rightarrow E \, - \, T \]
\[ E \rightarrow T \]
\[ T \rightarrow T \, \ast \, F \]
\[ T \rightarrow T \, / \, F \]
\[ T \rightarrow F \]
\[ F \rightarrow \text{id} \]
\[ F \rightarrow \text{num} \]
\[ F \rightarrow ( \, E \, ) \]

**GRAMMAR 3.10.**

\[ S \rightarrow \text{if} \, E \, \text{then} \, S \, \text{else} \, S \]
\[ S \rightarrow \text{begin} \, S \, L \]
\[ S \rightarrow \text{print} \, E \]
\[ L \rightarrow \text{end} \]
\[ L \rightarrow ; \, S \, L \]
\[ E \rightarrow \text{num} \, = \, \text{num} \]

**GRAMMAR 3.11.**

**END-OF-FILE MARKER**

Parsers must read not only terminal symbols such as +, -, num, and so on, but also the end-of-file marker. We will use $ to represent end of file.

Suppose $S$ is the start symbol of a grammar. To indicate that $\$ must come after a complete $S$-phrase, we augment the grammar with a new start symbol $S'$ and a new production $S' \rightarrow S \$$. In Grammar 3.8, $E$ is the start symbol, so an augmented grammar is Grammar 3.10.

**3.2 PREDICTIVE PARSING**

Some grammars are easy to parse using a simple algorithm known as recursive descent. In essence, each grammar production turns into one clause of a recursive function. We illustrate this by writing a recursive-descent parser for Grammar 3.11.

A recursive-descent parser for this language has one function for each non-terminal and one clause for each production.
3.2. PREDICTIVE PARSING

enum token {IF, THEN, ELSE, BEGIN, END, PRINT, SEMI, NUM, EQ};
extern enum token getToken(void);

enum token tok;
void advance() {tok=getToken();}
void eat(enum token t) {if (tok==t) advance(); else error();}

void S(void) {switch(tok) {
    case IF:   eat(IF); E(); eat(THEN); S();
              eat(ELSE); S(); break;
    case BEGIN: eat(BEGIN); S(); L(); break;
    case PRINT: eat(PRINT); E(); break;
    default:   error();
    }}
void L(void) {switch(tok) {
    case END:  eat(END); break;
    case SEMI: eat(SEMI); S(); L(); break;
    default:   error();
    }}
void E(void) { eat(NUM); eat(EQ); eat(NUM); }

With suitable definitions of error and getToken, this program will parse very nicely.

Emboldened by success with this simple method, let us try it with Grammar 3.10:

void S(void) { E(); eat(EOF); }
void E(void) {switch (tok) {
    case ?: E(); eat(PLUS); T(); break;
    case ?: E(); eat(MINUS); T(); break;
    case ?: T(); break;
    default: error();
    }}
void T(void) {switch (tok) {
    case ?: T(); eat(TIMES); F(); break;
    case ?: T(); eat(DIV); F(); break;
    case ?: F(); break;
    default: error();
    }}

There is a conflict here: the $E$ function has no way to know which clause to use. Consider the strings $(1*2-3)+4$ and $(1*2-3)$. In the former case, the initial call to $E$ should use the $E \rightarrow E + T$ production, but the latter case should use $E \rightarrow T$.

Recursive-descent, or predictive, parsing works only on grammars where the first terminal symbol of each subexpression provides enough information.
to choose which production to use. To understand this better, we will formalize the notion of FIRST sets, and then derive conflict-free recursive-descent parsers using a simple algorithm.

Just as lexical analyzers can be constructed from regular expressions, there are parser-generator tools that build predictive parsers. But if we are going to use a tool, then we might as well use one based on the more powerful LR(1) parsing algorithm, which will be described in Section 3.3.

Sometimes it’s inconvenient or impossible to use a parser-generator tool. The advantage of predictive parsing is that the algorithm is simple enough that we can use it to construct parsers by hand – we don’t need automatic tools.

**FIRST AND FOLLOW SETS**

Given a string $\gamma$ of terminal and nonterminal symbols, $\text{FIRST}(\gamma)$ is the set of all terminal symbols that can begin any string derived from $\gamma$. For example, let $\gamma = T \ast F$. Any string of terminal symbols derived from $\gamma$ must start with id, num, or (. Thus,

$$\text{FIRST}(T \ast F) = \{\text{id}, \text{num}, (\}.$$  

If two different productions $X \to \gamma_1$ and $X \to \gamma_2$ have the same left-hand-side symbol ($X$) and their right-hand sides have overlapping FIRST sets, then the grammar cannot be parsed using predictive parsing. If some terminal symbol $I$ is in $\text{FIRST}(\gamma_1)$ and also in $\text{FIRST}(\gamma_2)$, then the $X$ function in a recursive-descent parser will not know what to do if the input token is $I$.

The computation of FIRST sets looks very simple: if $\gamma = X Y Z$, it seems as if $Y$ and $Z$ can be ignored, and $\text{FIRST}(X)$ is the only thing that matters. But consider Grammar 3.12. Because $Y$ can produce the empty string – and therefore $X$ can produce the empty string – we find that $\text{FIRST}(X Y Z)$ must include $\text{FIRST}(Z)$. Therefore, in computing FIRST sets, we must keep track of which symbols can produce the empty string; we say such symbols are nullable. And we must keep track of what might follow a nullable symbol.

With respect to a particular grammar, given a string $\gamma$ of terminals and nonterminals,
3.2. PREDICTIVE PARSING

- nullable\( (X) \) is true if \( X \) can derive the empty string.
- FIRST\( (\gamma) \) is the set of terminals that can begin strings derived from \( \gamma \).
- FOLLOW\( (X) \) is the set of terminals that can immediately follow \( X \). That is, \( t \in \text{FOLLOW}(X) \) if there is any derivation containing \( Xt \). This can occur if the derivation contains \( XYZt \) where \( Y \) and \( Z \) both derive \( \epsilon \).

A precise definition of FIRST, FOLLOW, and nullable is that they are the smallest sets for which these properties hold:

For each terminal symbol \( Z \), \( \text{FIRST}[Z] = \{Z\} \).

\[\text{for each production } X \rightarrow Y_1 Y_2 \cdots Y_k \]
\[\text{for each } i \text{ from 1 to } k, \text{ each } j \text{ from } i + 1 \text{ to } k, \]
\[\text{if all the } Y_i \text{ are nullable} \]
\[\text{then } \text{nullable}[X] = \text{true} \]
\[\text{if } Y_1 \cdots Y_{i-1} \text{ are all nullable} \]
\[\text{then } \text{FIRST}[X] = \text{FIRST}[X] \cup \text{FIRST}[Y_i] \]
\[\text{if } Y_{i+1} \cdots Y_k \text{ are all nullable} \]
\[\text{then } \text{FOLLOW}[Y_i] = \text{FOLLOW}[Y_i] \cup \text{FOLLOW}[X] \]
\[\text{if } Y_{i+1} \cdots Y_{j-1} \text{ are all nullable} \]
\[\text{then } \text{FOLLOW}[Y_i] = \text{FOLLOW}[Y_i] \cup \text{FIRST}[Y_j] \]

Algorithm 3.13 for computing FIRST, FOLLOW, and nullable just follows from these facts; we simply replace each equation with an assignment statement, and iterate.

Of course, to make this algorithm efficient it helps to examine the productions in the right order; see Section 17.4. Also, the three relations need not be computed simultaneously; nullable can be computed by itself, then FIRST, then FOLLOW.

This is not the first time that a group of equations on sets has become the algorithm for calculating those sets; recall the algorithm on page 28 for computing \( \epsilon \)-closure. Nor will it be the last time; the technique of iteration to a fixed point is applicable in dataflow analysis for optimization, in the back end of a compiler.

We can apply this algorithm to Grammar 3.12. Initially, we have:

<table>
<thead>
<tr>
<th></th>
<th>nullable</th>
<th>FIRST</th>
<th>FOLLOW</th>
</tr>
</thead>
<tbody>
<tr>
<td>( X )</td>
<td>no</td>
<td></td>
<td></td>
</tr>
<tr>
<td>( Y )</td>
<td>no</td>
<td></td>
<td></td>
</tr>
<tr>
<td>( Z )</td>
<td>no</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In the first iteration, we find that \( a \in \text{FIRST}[X] \), \( Y \) is nullable, \( c \in \text{FIRST}[Y] \), \( d \in \text{FIRST}[Z] \), \( d \in \text{FOLLOW}[X] \), \( c \in \text{FOLLOW}[X] \),...
Algorithm to compute FIRST, FOLLOW, and nullable.
Initialize FIRST and FOLLOW to all empty sets, and nullable to all false.
for each terminal symbol $Z$
    $\text{FIRST}[Z] \leftarrow \{Z\}$
repeat
    for each production $X \rightarrow Y_1 Y_2 \cdots Y_k$
        for each $i$ from 1 to $k$, each $j$ from $i + 1$ to $k$,
            if all the $Y_i$ are nullable
                then $\text{nullable}[X] \leftarrow \text{true}$
            if $Y_1 \cdots Y_{i-1}$ are all nullable
                then $\text{FIRST}[X] \leftarrow \text{FIRST}[X] \cup \text{FIRST}[Y_i]$
            if $Y_{i+1} \cdots Y_k$ are all nullable
                then $\text{FOLLOW}[Y_i] \leftarrow \text{FOLLOW}[Y_i] \cup \text{FOLLOW}[X]$
            if $Y_{i+1} \cdots Y_{j-1}$ are all nullable
                then $\text{FOLLOW}[Y_i] \leftarrow \text{FOLLOW}[Y_i] \cup \text{FIRST}[Y_j]$
until FIRST, FOLLOW, and nullable did not change in this iteration.

**Algorithm 3.13.** Iterative computation of FIRST, FOLLOW, and nullable.

$d \in \text{FOLLOW}[Y]$. Thus:

<table>
<thead>
<tr>
<th></th>
<th>nullable</th>
<th>FIRST</th>
<th>FOLLOW</th>
</tr>
</thead>
<tbody>
<tr>
<td>$X$</td>
<td>no</td>
<td>$a$</td>
<td>$c \ d$</td>
</tr>
<tr>
<td>$Y$</td>
<td>yes</td>
<td>$c$</td>
<td>$d$</td>
</tr>
<tr>
<td>$Z$</td>
<td>no</td>
<td>$d$</td>
<td></td>
</tr>
</tbody>
</table>

In the second iteration, we find that $X$ is nullable, $c \in \text{FIRST}[X]$, $\{a, c\} \subseteq \text{FIRST}[Z]$, $\{a, c, d\} \subseteq \text{FOLLOW}[X]$, $\{a, c, d\} \subseteq \text{FOLLOW}[Y]$. Thus:

<table>
<thead>
<tr>
<th></th>
<th>nullable</th>
<th>FIRST</th>
<th>FOLLOW</th>
</tr>
</thead>
<tbody>
<tr>
<td>$X$</td>
<td>yes</td>
<td>$a \ c$</td>
<td>$a \ c \ d$</td>
</tr>
<tr>
<td>$Y$</td>
<td>yes</td>
<td>$c$</td>
<td>$a \ c \ d$</td>
</tr>
<tr>
<td>$Z$</td>
<td>no</td>
<td>$a \ c \ d$</td>
<td></td>
</tr>
</tbody>
</table>

The third iteration finds no new information, and the algorithm terminates. It is useful to generalize the FIRST relation to strings of symbols:

$\text{FIRST}(X \gamma) = \text{FIRST}[X]$ if not nullable$[X]$
$\text{FIRST}(X \gamma) = \text{FIRST}[X] \cup \text{FIRST}(\gamma)$ if nullable$[X]$
and similarly, we say that a string $\gamma$ is nullable if each symbol in $\gamma$ is nullable.

**CONSTRUCTING A PREDICTIVE PARSER**

Consider a recursive-descent parser. The parsing function for some nonterminal $X$ has a clause for each $X$-production; it must choose one of these clauses based on the next token $T$ of the input. If we can choose the right production for each $(X, T)$, then we can write the recursive-descent parser. All the information we need can be encoded as a two-dimensional table of productions, indexed by nonterminals $X$ and terminals $T$. This is called a *predictive parsing* table.

To construct this table, enter production $X \rightarrow \gamma$ in row $X$, column $T$ of the table for each $T \in \text{FIRST}(\gamma)$. Also, if $\gamma$ is nullable, enter the production in row $X$, column $T$ for each $T \in \text{FOLLOW}[X]$.

Figure 3.14 shows the predictive parser for Grammar 3.12. But some of the entries contain more than one production! The presence of duplicate entries means that predictive parsing will not work on Grammar 3.12.

If we examine the grammar more closely, we find that it is ambiguous. The sentence $d$ has many parse trees, including:

```
Z
  | d
|  ^
Z
  |Z
  | |  ^
  |X  Y  Z
  |  |  |  ^
  |  Y  |  |  ^
  |  |  Y  |  ^
  |  |  |  d
```

An ambiguous grammar will always lead to duplicate entries in a predictive parsing table. If we need to use the language of Grammar 3.12 as a programming language, we will need to find an unambiguous grammar.

Grammars whose predictive parsing tables contain no duplicate entries
are called LL(1). This stands for Left-to-right parse, Leftmost-derivation, 1-symbol lookahead. Clearly a recursive-descent (predictive) parser examines the input left-to-right in one pass (some parsing algorithms do not, but these are generally not useful for compilers). The order in which a predictive parser expands nonterminals into right-hand sides (that is, the recursive-descent parser calls functions corresponding to nonterminals) is just the order in which a leftmost derivation expands nonterminals. And a recursive-descent parser does its job just by looking at the next token of the input, never looking more than one token ahead.

We can generalize the notion of FIRST sets to describe the first \( k \) tokens of a string, and to make an LL(\( k \)) parsing table whose rows are the nonterminals and columns are every sequence of \( k \) terminals. This is rarely done (because the tables are so large), but sometimes when you write a recursive-descent parser by hand you a need to look more than one token ahead.

Grammars parsable with LL(2) parsing tables are called LL(2) grammars, and similarly for LL(3), etc. Every LL(1) grammar is an LL(2) grammar, and so on. No ambiguous grammar is LL(\( k \)) for any \( k \).

**ELIMINATING LEFT RECURSION**

Suppose we want to build a predictive parser for Grammar 3.10. The two productions

\[
E \rightarrow E + T \\
E \rightarrow T
\]

are certain to cause duplicate entries in the LL(1) parsing table, since any token in FIRST(\( T \)) will also be in FIRST(\( E + T \)). The problem is that \( E \) appears as the first right-hand-side symbol in an \( E \)-production; this is called left recursion. Grammars with left recursion cannot be LL(1).

To eliminate left recursion, we will rewrite using right recursion. We introduce a new nonterminal \( E' \), and write

\[
E \rightarrow T \ E' \\
E' \rightarrow + \ T \ E' \\
E' \rightarrow 
\]

This derives the same set of strings (on \( T \) and \( + \)) as the original two productions, but now there is no left recursion.
3.2. PREDICTIVE PARSING

\[
\begin{align*}
S & \rightarrow E \, $ \\
E & \rightarrow T \, E' \\
E' & \rightarrow + \, T \, E' \\
E' & \rightarrow - \, T \, E' \\
E' & \rightarrow \, \\
T & \rightarrow F \, T' \\
T' & \rightarrow * \, F \, T' \\
T' & \rightarrow / \, F \, T' \\
F & \rightarrow \text{id} \\
F & \rightarrow \text{num} \\
F & \rightarrow ( \, E \, ) \\
F & \rightarrow \, \\
\end{align*}
\]

**GRAMMAR 3.15.**

<table>
<thead>
<tr>
<th>nullable</th>
<th>FIRST</th>
<th>FOLLOW</th>
</tr>
</thead>
<tbody>
<tr>
<td>$S$</td>
<td>no</td>
<td>( id num $</td>
</tr>
<tr>
<td>$E$</td>
<td>no</td>
<td>( id num ) $</td>
</tr>
<tr>
<td>$E'$</td>
<td>yes</td>
<td>+ - ) $</td>
</tr>
<tr>
<td>$T$</td>
<td>no</td>
<td>( id num ) + - $</td>
</tr>
<tr>
<td>$T'$</td>
<td>yes</td>
<td>* / ) + - $</td>
</tr>
<tr>
<td>$F$</td>
<td>no</td>
<td>( id num ) * / + - $</td>
</tr>
</tbody>
</table>

**TABLE 3.16.** Nullable, FIRST, and FOLLOW for Grammar 3.8.

In general, whenever we have productions $X \rightarrow X \gamma$ and $X \rightarrow \alpha$, where $\alpha$ does not start with $X$, we know that this derives strings of the form $\alpha \gamma^*$, an $\alpha$ followed by zero or more $\gamma$. So we can rewrite the regular expression using right recursion:

\[
\begin{align*}
\left( X \rightarrow X \, \gamma_1 \right) & \quad \left( X \rightarrow X \, \gamma_2 \right) \\
\left( X \rightarrow \alpha_1 \right) & \quad \left( X \rightarrow \alpha_2 \right) \\
\end{align*}
\]

\[
\Rightarrow \begin{align*}
\left( X \rightarrow \alpha_1 \, X' \right) & \quad \left( X \rightarrow \alpha_2 \, X' \right) \\
X' & \rightarrow \gamma_1 \, X' \\
X' & \rightarrow \gamma_2 \, X' \\
X' & \rightarrow \ \\
\end{align*}
\]

Applying this transformation to Grammar 3.10, we obtain Grammar 3.15.

To build a predictive parser, first we compute nullable, FIRST, and FOLLOW (Table 3.16). The predictive parser for Grammar 3.15 is shown in Table 3.17.

**LEFT FACTORING**

We have seen that left recursion interferes with predictive parsing, and that it can be eliminated. A similar problem occurs when two productions for the
same nonterminal start with the same symbols. For example:

\[
S \rightarrow \text{ if } E \text{ then } S \text{ else } S \\
S \rightarrow \text{ if } E \text{ then } S
\]

In such a case, we can left factor the grammar – that is, take the allowable endings (“else S” and \( \epsilon \)) and make a new nonterminal \( X \) to stand for them:

\[
S \rightarrow \text{ if } E \text{ then } SX \\
X \rightarrow \text{ else } S
\]

The resulting productions will not pose a problem for a predictive parser.

**ERROR RECOVERY**

Armed with a predictive parsing table, it is easy to write a recursive-descent parser. Here is a representative fragment of a parser for Grammar 3.15:

```c
void T(void) {switch (tok) {
    case ID: 
    case NUM: 
    case LPAREN: F(); Tprime(); break;  
    default: error!
    }}
void Tprime(void) {switch (tok) {
    case PLUS: break;  
    case TIMES: eat(TIMES); F(); Tprime(); break; 
    case EOF: break; 
    case RPAREN: break; 
    default: error!
    }}
```
A blank entry in row $T$, column $x$ of the LL(1) parsing table indicates that the parsing function $T()$ does not expect to see token $x$—this will be a syntax error. How should error be handled? It is safe just to raise an exception and quit parsing, but this is not very friendly to the user. It is better to print an error message and recover from the error, so that other syntax errors can be found in the same compilation.

A syntax error occurs when the string of input tokens is not a sentence in the language. Error recovery is a way of finding some sentence similar to that string of tokens. This can proceed by deleting, replacing, or inserting tokens.

For example, error recovery for $T$ could proceed by inserting a num token. It’s not necessary to adjust the actual input; it suffices to pretend that the num was there, print a message, and return normally.

```c
void T(void) {switch (tok) {
    case ID:
    case NUM:
    case LPAREN: F(); Tprime(); break;
    default: printf("expected id, num, or left-paren");
}}
```

It’s a bit dangerous to do error recovery by insertion, because if the error cascades to produce another error, the process might loop infinitely. Error recovery by deletion is safer, because the loop must eventually terminate when end-of-file is reached.

Simple recovery by deletion works by skipping tokens until a token in the FOLLOW set is reached. For example, error recovery for $T'$ could work like this:

```c
int Tprime_follow [] = {PLUS, TIMES, RPAREN, EOF, -1};

void Tprime(void) { switch (tok) {
    case PLUS: break;
    case TIMES: eat(TIMES); F(); Tprime(); break;
    case RPAREN: break;
    case EOF: break;
    default: printf("expected +, *, right-paren, or end-of-file");
        skipto(Tprime_follow);
}}
```

A recursive-descent parser’s error-recovery mechanisms must be adjusted (sometimes by trial and error) to avoid a long cascade of error-repair messages resulting from a single token out of place.
3.3 LR PARSING

The weakness of LL(\(k\)) parsing techniques is that they must predict which production to use, having seen only the first \(k\) tokens of the right-hand side. A more powerful technique, LR(\(k\)) parsing, is able to postpone the decision until it has seen input tokens corresponding to the entire right-hand side of the production in question (and \(k\) more input tokens beyond).

LR(\(k\)) stands for Left-to-right parse, Rightmost-derivation, \(k\)-token lookahead. The use of a rightmost derivation seems odd; how is that compatible with a left-to-right parse? Figure 3.18 illustrates an LR parse of the program

\[
a := 7; \\
b := c + (d := 5 + 6, d)
\]

using Grammar 3.1, augmented with a new start production \(S' \rightarrow S\).

The parser has a stack and an input. The first \(k\) tokens of the input are the lookahead. Based on the contents of the stack and the lookahead, the parser performs two kinds of actions:

- **Shift**: move the first input token to the top of the stack.
- **Reduce**: Choose a grammar rule \(X \rightarrow ABC\); pop \(C, B, A\) from the top of the stack; push \(X\) onto the stack.

Initially, the stack is empty and the parser is at the beginning of the input. The action of shifting the end-of-file marker \$ is called accepting and causes the parser to stop successfully.

In Figure 3.18, the stack and input are shown after every step, along with an indication of which action has just been performed. The concatenation of stack and input is always one line of a rightmost derivation; in fact, Figure 3.18 shows the rightmost derivation of the input string, upside-down.

**LR PARSING ENGINE**

How does the LR parser know when to shift and when to reduce? By using a deterministic finite automaton! The DFA is not applied to the input – finite automata are too weak to parse context-free grammars – but to the stack. The edges of the DFA are labeled by the symbols (terminals and non-terminals) that can appear on the stack. Table 3.19 is the transition table for Grammar 3.1.

The elements in the transition table are labeled with four kinds of actions:
3.3. LR PARSING

Shift-reduce parse of a sentence. Numeric subscripts in the Stack are DFA state numbers; see Table 3.19.

To use this table in parsing, treat the shift and goto actions as edges of a DFA, and scan the stack. For example, if the stack is $id := E$, then the DFA goes from state 1 to 4 to 6 to 11. If the next input token is a semicolon, then the “;” column in state 11 says to reduce by rule 2. The second rule of the
grammar is $S \rightarrow \text{id} := E$, so the top three tokens are popped from the stack and $S$ is pushed.

The action for “+” in state 11 is to shift; so if the next token had been + instead, it would have been eaten from the input and pushed on the stack.

Rather than rescan the stack for each token, the parser can remember instead the state reached for each stack element. Then the parsing algorithm is:
Look up top stack state, and input symbol, to get action;
If action is
Shift(n): Advance input one token; push n on stack.
Reduce(k): Pop stack as many times as the number of symbols on the right-hand side of rule k;
Let X be the left-hand-side symbol of rule k;
In the state now on top of stack, look up X to get “goto n”;
Push n on top of stack.
Accept: Stop parsing, report success.
Error: Stop parsing, report failure.

**LR(0) PARSER GENERATION**

An LR(k) parser uses the contents of its stack and the next k tokens of the input to decide which action to take. Table 3.19 shows the use of one symbol of lookahead. For k = 2, the table has columns for every two-token sequence and so on; in practice, k > 1 is not used for compilation. This is partly because the tables would be huge, but more because most reasonable programming languages can be described by LR(1) grammars.

LR(0) grammars are those that can be parsed looking only at the stack, making shift/reduce decisions without any lookahead. Though this class of grammars is too weak to be very useful, the algorithm for constructing LR(0) parsing tables is a good introduction to the LR(1) parser construction algorithm.

We will use Grammar 3.20 to illustrate LR(0) parser generation. Consider what the parser for this grammar will be doing. Initially, it will have an empty stack, and the input will be a complete S-sentence followed by $; that is, the right-hand side of the S’ rule will be on the input. We indicate this as $S' \rightarrow .S$ where the dot indicates the current position of the parser.

In this state, where the input begins with S, that means that it begins with any possible right-hand side of an S-production; we indicate that by

\[
\begin{align*}
S' & \rightarrow .S \\
S & \rightarrow .x \\
S & \rightarrow .(L)
\end{align*}
\]

Call this state 1. A grammar rule, combined with the dot that indicates a position in its right-hand side, is called an *item* (specifically, an LR(0) item). A state is just a set of items.
Shift actions. In state 1, consider what happens if we shift an x. We then know that the end of the stack has an x; we indicate that by shifting the dot past the x in the \( S \to x \) production. The rules \( S' \to .S$ \) and \( S \to .(L) \) are irrelevant to this action, so we ignore them; we end up in state 2:

\[
S \to x. \tag{2}
\]

Or in state 1 consider shifting a left parenthesis. Moving the dot past the parenthesis in the third item yields \( S \to (.L) \), where we know that there must be a left parenthesis on top of the stack, and the input begins with some string derived by \( L \), followed by a right parenthesis. What tokens can begin the input now? We find out by including all \( L \)-productions in the set of items. But now, in one of those \( L \)-items, the dot is just before an \( S \), so we need to include all the \( S \)-productions:

\[
\begin{align*}
S & \to (.L) \\
L & \to .L, S \\
L & \to .S \\
S & \to .(L) \\
S & \to .x
\end{align*} \tag{3}
\]

Goto actions. In state 1, consider the effect of parsing past some string of tokens derived by the \( S \) nonterminal. This will happen when an x or left parenthesis is shifted, followed (eventually) by a reduction of an \( S \)-production. All the right-hand-side symbols of that production will be popped, and the parser will execute the goto action for \( S \) in state 1. The effect of this can be simulated by moving the dot past the \( S \) in the first item of state 1, yielding state 4:

\[
S' \to S.$ \tag{4}
\]

Reduce actions. In state 2 we find the dot at the end of an item. This means that on top of the stack there must be a complete right-hand side of the corresponding production \((S \to x)\), ready to reduce. In such a state the parser could perform a reduce action.

The basic operations we have been performing on states are closure\((I)\), and goto\((I, X)\), where \( I \) is a set of items and \( X \) is a grammar symbol (terminal or nonterminal). Closure adds more items to a set of items when there is a dot to the left of a nonterminal; goto moves the dot past the symbol \( X \) in all items.
3.3. LR PARSING

**Closure**<br>
\[ \text{Closure}(I) = \]

\[ \text{repeat} \]

\[ \text{for any item } A \rightarrow \alpha.X\beta \text{ in } I \]

\[ \text{for any production } X \rightarrow \gamma \]

\[ I \leftarrow I \cup \{X \rightarrow .\gamma\} \]

\[ \text{until } I \text{ does not change.} \]

\[ \text{return } I \]

**Goto**<br>
\[ \text{Goto}(I, X) = \]

\[ \text{set } J \text{ to the empty set} \]

\[ \text{for any item } A \rightarrow \alpha.X\beta \text{ in } I \]

\[ \text{add } A \rightarrow \alpha.X.\beta \text{ to } J \]

\[ \text{return } \text{Closure}(J) \]

Now here is the algorithm for LR(0) parser construction. First, augment the grammar with an auxiliary start production \( S' \rightarrow S.\$ \). Let \( T \) be the set of states seen so far, and \( E \) the set of (shift or goto) edges found so far.

Initialize \( T \) to \{Closure\{\( S' \rightarrow .S.\$ \)\}\}\)

Initialize \( E \) to empty.

**repeat**

\[ \text{for each state } I \text{ in } T \]

\[ \text{for each item } A \rightarrow \alpha.X\beta \text{ in } I \]

\[ \text{let } J \text{ be } \text{Goto}(I, X) \]

\[ T \leftarrow T \cup \{J\} \]

\[ E \leftarrow E \cup \{I \rightarrow X \rightarrow J\} \]

**until** \( E \) and \( T \) did not change in this iteration

However, for the symbol \( \$ \) we do not compute \( \text{Goto}(I, \$) \); instead we will make an accept action.

For Grammar 3.20 this is illustrated in Figure 3.21.

Now we can compute set \( R \) of LR(0) reduce actions:

\[ R \leftarrow \{\} \]

\[ \text{for each state } I \text{ in } T \]

\[ \text{for each item } A \rightarrow \alpha. \text{ in } I \]

\[ R \leftarrow R \cup \{(I, A \rightarrow \alpha)\} \]

We can now construct a parsing table for this grammar (Table 3.22). For each edge \( I \rightarrow \alpha \rightarrow J \) where \( X \) is a terminal, we put the action shift \( J \) at position \((I, X)\) of the table; if \( X \) is a nonterminal we put goto \( J \) at position \((I, X)\). For each state \( I \) containing an item \( S' \rightarrow S.\$ \) we put an accept action at \((I, \$)\). Finally, for a state containing an item \( A \rightarrow \gamma. \) (production \( n \) with the dot at the end), we put a reduce \( n \) action at \((I, Y)\) for every token \( Y \).

In principle, since LR(0) needs no lookahead, we just need a single action for each state: a state will shift or reduce, but not both. In practice, since we
need to know what state to shift into, we have rows headed by state numbers and columns headed by grammar symbols.

**SLR PARSER GENERATION**

Let us attempt to build an LR(0) parsing table for Grammar 3.23. The LR(0) states and parsing table are shown in Figure 3.24.

In state 3, on symbol $+$, there is a duplicate entry: the parser must shift into state 4 and also reduce by production 2. This is a conflict and indicates that
the grammar is not LR(0) – it cannot be parsed by an LR(0) parser. We will need a more powerful parsing algorithm.

A simple way of constructing better-than-LR(0) parsers is called SLR, which stands for Simple LR. Parser construction for SLR is almost identical to that for LR(0), except that we put reduce actions into the table only where indicated by the FOLLOW set.

Here is the algorithm for putting reduce actions into an SLR table:

\[
R \leftarrow \{ \} \\
\text{for each state } I \text{ in } T \\
\quad \text{for each item } A \rightarrow \alpha \text{ in } I \\
\quad \quad \text{for each token } X \text{ in FOLLOW}(A) \\
\quad \quad \quad R \leftarrow R \cup \{(I, X, A \rightarrow \alpha)\}
\]

The action \((I, X, A \rightarrow \alpha)\) indicates that in state \(I\), on lookahead symbol \(X\), the parser will reduce by rule \(A \rightarrow \alpha\).

Thus, for Grammar 3.23 we use the same LR(0) state diagram (Figure 3.24), but we put fewer reduce actions into the SLR table, as shown in Figure 3.25.

The SLR class of grammars is precisely those grammars whose SLR parsing table contains no conflicts (duplicate entries). Grammar 3.23 belongs to this class, as do many useful programming-language grammars.
LR(1) ITEMS; LR(1) PARSING TABLE

Even more powerful than SLR is the LR(1) parsing algorithm. Most programming languages whose syntax is describable by a context-free grammar have an LR(1) grammar.

The algorithm for constructing an LR(1) parsing table is similar to that for LR(0), but the notion of an item is more sophisticated. An LR(1) item consists of a grammar production, a right-hand-side position (represented by the dot), and a lookahead symbol. The idea is that an item \((A \rightarrow \alpha.\beta, x)\) indicates that the sequence \(\alpha\) is on top of the stack, and at the head of the input is a string derivable from \(\beta x\).

An LR(1) state is a set of LR(1) items, and there are Closure and Goto operations for LR(1) that incorporate the lookahead:

\[
\text{Closure}(I) = \text{repeat} \quad \text{for any item } (A \rightarrow \alpha.\beta, z) \text{ in } I \quad \text{for any production } X \rightarrow \gamma \quad \text{add } (A \rightarrow \alpha X.\beta, z) \text{ to } J \quad \text{return } \text{Closure}(J).
\]

\[
\text{Goto}(I, X) = \quad J \leftarrow \{\} \quad \text{for any item } (A \rightarrow \alpha.\beta, z) \text{ in } I \quad \text{for any } w \in \text{FIRST}(\beta z) \quad I \leftarrow I \cup \{(X \rightarrow .\gamma, w)\} \quad \text{return } \text{Closure}(J).
\]

The start state is the closure of the item \((S' \rightarrow .S \$, ?)\), where the lookahead symbol ? will not matter, because the end-of-file marker will never be shifted.

The reduce actions are chosen by this algorithm:

\[
R \leftarrow \{\} \quad \text{for each state } I \text{ in } T \quad \text{for each item } (A \rightarrow \alpha., z) \text{ in } I \quad R \leftarrow R \cup \{(I, z, A \rightarrow \alpha)\}
\]
The action \((I, z, A \to \alpha)\) indicates that in state \(I\), on lookahead symbol \(z\), the parser will reduce by rule \(A \to \alpha\).

Grammar 3.26 is not SLR (see Exercise 3.9), but it is in the class of LR(1) grammars. Figure 3.27 shows the LR(1) states for this grammar; in the figure, where there are several items with the same production but different lookahead, as at left below, I have abbreviated as at right:

\[
\begin{align*}
S' & \to . S & ? \\
S & \to . V = E & $ \\
S & \to . E & $ \\
E & \to . V & $ \\
V & \to . x & $ \\
V & \to . * E & $ \\
V & \to . x & = \\
\end{align*}
\]

The LR(1) parsing table derived from this state graph is Table 3.28a. Whenever the dot is at the end of a production (as in state 3 of Figure 3.27, where it is at the end of production \(E \to V\)), then there is a reduce action for that production in the LR(1) table, in the row corresponding to the state number and the column corresponding to the lookahead of the item (in this case, the lookahead is $). Whenever the dot is to the left of a terminal symbol or non-terminal, there is a corresponding shift or goto action in the LR(1) parsing table, just as there would be in an LR(0) table.

**LALR(1) ParsinG Tables**

LR(1) parsing tables can be very large, with many states. A smaller table can be made by merging any two states whose items are identical except for lookahead sets. The result parser is called an LALR(1) parser, for Look-Ahead LR(1).

For example, the items in states 6 and 13 of the LR(1) parser for Grammar 3.26 (Figure 3.27) are identical if the lookahead sets are ignored. Also, states 7 and 12 are identical except for lookahead, as are states 8 and 11 and states 10 and 14. Merging these pairs of states gives the LALR(1) parsing table shown in Figure 3.28b.

For some grammars, the LALR(1) table contains reduce-reduce conflicts where the LR(1) table has none, but in practice the difference matters little.
**CHAPTER THREE. PARSING**

**GRAMMAR 3.26.** A grammar capturing the essence of expressions, variables, and pointer-dereference (by the *) operator in the C language.

\[ 0 \quad S' \rightarrow S \, \$ \\
1 \quad S \rightarrow V = E \\
2 \quad S \rightarrow E \\
3 \quad E \rightarrow V \\
4 \quad V \rightarrow x \\
5 \quad V \rightarrow * \, E \]

**FIGURE 3.27.** LR(1) states for Grammar 3.26.

**TABLE 3.28.** LR(1) and LALR(1) parsing tables for Grammar 3.26.
3.3. LR PARSING

What does matter is that the LALR(1) parsing table requires less memory to represent than the LR(1) table, since there can be many fewer states.

HIERARCHY OF GRAMMAR CLASSES
A grammar is said to be LALR(1) if its LALR(1) parsing table contains no conflicts. All SLR grammars are LALR(1), but not vice versa. Figure 3.29 shows the relationship between several classes of grammars.

Any reasonable programming language has a LALR(1) grammar, and there are many parser-generator tools available for LALR(1) grammars. For this reason, LALR(1) has become a standard for programming languages and for automatic parser generators.
LR PARSING OF AMBIGUOUS GRAMMARS

Many programming languages have grammar rules such as

\[
S \rightarrow \text{if } E \text{ then } S \text{ else } S \\
S \rightarrow \text{if } E \text{ then } S \\
S \rightarrow \text{other}
\]

which allow programs such as

\[
\text{if } a \text{ then } \text{if } b \text{ then } s_1 \text{ else } s_2
\]

Such a program could be understood in two ways:

\[
(1) \quad \text{if } a \text{ then } \{ \text{if } b \text{ then } s_1 \text{ else } s_2 \} \\
(2) \quad \text{if } a \text{ then } \{ \text{if } b \text{ then } s_1 \} \text{ else } s_2
\]

In most programming languages, an `else` must match the most recent possible `then`, so interpretation (1) is correct. In the LR parsing table there will be a shift-reduce conflict:

<table>
<thead>
<tr>
<th>Rule</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>S \rightarrow if E then S . else</code></td>
<td>Shift if <code>else</code> is possible</td>
</tr>
<tr>
<td><code>S \rightarrow if E then S . else S (any)</code></td>
<td>Reduce if <code>else</code> is not possible</td>
</tr>
</tbody>
</table>

Shifting corresponds to interpretation (1) and reducing to interpretation (2).

The ambiguity can be eliminated by introducing auxiliary nonterminals `M` (for `matched statement`) and `U` (for `unmatched statement`):

\[
S \rightarrow M \\
S \rightarrow U \\
M \rightarrow \text{if } E \text{ then } M \text{ else } M \\
M \rightarrow \text{other} \\
U \rightarrow \text{if } E \text{ then } S \\
U \rightarrow \text{if } E \text{ then } M \text{ else } U
\]

But instead of rewriting the grammar, we can leave the grammar unchanged and tolerate the shift-reduce conflict. In constructing the parsing table this conflict should be resolved by shifting, since we prefer interpretation (1).

It is often possible to use ambiguous grammars by resolving shift-reduce conflicts in favor of shifting or reducing, as appropriate. But it is best to use this technique sparingly, and only in cases (such as the dangling-else described here, and operator-precedence to be described on page 73) that are
well understood. Most shift-reduce conflicts, and probably all reduce-reduce
conflicts, should not be resolved by fiddling with the parsing table. They are
symptoms of an ill-specified grammar, and they should be resolved by elimi-
nating ambiguities.

3.4 USING PARSER GENERATORS

The task of constructing LR(1) or LALR(1) parsing tables is simple enough
to be automated. And it is so tedious to do by hand that LR parsing for real-
istic grammars is rarely done except using parser-generator tools. Yacc (“Yet
another compiler-compiler”) is a classic and widely used parser generator;
Bison and occs are more recent implementations.

A Yacc specification is divided into three sections, separated by %% marks:

```
pars declarations
%%
grammar rules
%%
programs
```

The parser declarations include a list of the terminal symbols, nonterminals,
and so on. The programs are ordinary C code usable from the semantic ac-
tions embedded in the earlier sections.

The grammar rules are productions of the form

```
exp : exp PLUS exp { semantic action }
```

where exp is a nonterminal producing a right-hand side of exp+exp, and
PLUS is a terminal symbol (token). The semantic action is written in ordinary
C and will be executed whenever the parser reduces using this rule.
Consider Grammar 3.30. It can be encoded in Yacc as shown in Grammar 3.31. The Yacc manual gives a complete explanation of the directives in a grammar specification; in this grammar, the terminal symbols are ID, WHILE, etc.; the nonterminals are prog, stm, stmlist; and the grammar’s start symbol is prog.

CONFLICTS
Yacc reports shift-reduce and reduce-reduce conflicts. A shift-reduce conflict is a choice between shifting and reducing; a reduce-reduce conflict is a choice of reducing by two different rules. By default, Yacc resolves shift-reduce conflicts by shifting, and reduce-reduce conflicts by using the rule that appears earlier in the grammar.

Yacc will report that this Grammar 3.30 has a shift-reduce conflict. Any conflict is cause for concern, because it may indicate that the parse will not be as the grammar-designer expected. The conflict can be examined by reading the verbose description file that Yacc produces. Figure 3.32 shows this file.

A brief examination of state 17 reveals that the conflict is caused by the familiar dangling else. Since Yacc’s default resolution of shift-reduce conflicts is to shift, and shifting gives the desired result of binding an else to the nearest then, this conflict is not harmful.
3.4. USING PARSER GENERATORS

FIGURE 3.32. LR states for Grammar 3.30.
Shift-reduce conflicts are acceptable in a grammar if they correspond to well understood cases, as in this example. But most shift-reduce conflicts, and all reduce-reduce conflicts, are serious problems and should be eliminated by rewriting the grammar.

### PRECEDENCE DIRECTIVES

No ambiguous grammar is LR($k$) for any $k$; the LR($k$) parsing table of an ambiguous grammar will always have conflicts. However, ambiguous grammars can still be useful if we can find ways to resolve the conflicts.

For example, Grammar 3.5 is highly ambiguous. In using this grammar to describe a programming language, we intend it to be parsed so that * and / bind more tightly than + and −, and that each operator associates to the left. We can express this by rewriting the unambiguous Grammar 3.8.

But we can avoid introducing the $T$ and $F$ symbols and their associated “trivial” reductions $E \rightarrow T$ and $T \rightarrow F$. Instead, let us start by building the LR(1) parsing table for Grammar 3.5, as shown in Table 3.33. We find many conflicts. For example, in state 13 with lookahead + we find a conflict between shift into state 8 and reduce by rule 3. Two of the items in state 13 are:

---

</table>

---
In this state the top of the stack is \( \cdots E * E \). Shifting will lead to a stack \( \cdots E * E + \) and eventually \( \cdots E * E + E \) with a reduction of \( E + E \) to \( E \). Reducing now will lead to the stack \( \cdots E + E \) and then the \( + \) will be shifted. The parse trees obtained by shifting and reducing are:

\[
\begin{align*}
\text{Shift} & : \quad E \quad * \quad E \quad + \\
\text{Reduce} & : \quad E \quad * \quad E
\end{align*}
\]

If we wish \( * \) to bind tighter than \( + \), we should reduce instead of shift. So we fill the \((13, +)\) entry in the table with \( r3 \) and discard the \( s8 \) action.

Conversely, in state 9 on lookahead \( * \), we should shift instead of reduce, so we resolve the conflict by filling the \((9, *)\) entry with \( s12 \).

The case for state 9, lookahead \( + \) is

\[
\begin{align*}
E & \rightarrow E \quad + \quad E \\
E & \rightarrow E \quad . \quad + \quad E \quad \quad \text{(any)}
\end{align*}
\]

Shifting will make the operator right-associative; reducing will make it left-associative. Since we want left associativity, we fill \((9, +)\) with \( r5 \).

Consider the expression \( a - b - c \). In most programming languages, this associates to the left, as if written \( (a - b) - c \). But suppose we believe that this expression is inherently confusing, and we want to force the programmer to put in explicit parentheses, either \( (a - b) - c \) or \( a - (b - c) \). Then we say that the minus operator is nonassociative, and we would fill the \((11, -)\) entry with an error entry.

The result of all these decisions is a parsing table with all conflicts resolved (Table 3.34).

Yacc has precedence directives to indicate the resolution of this class of shift-reduce conflicts. A series of declarations such as

\[
\begin{align*}
\%\text{nonassoc} & \quad EQ \quad NEQ \\
\%\text{left} & \quad PLUS \quad MINUS \\
\%\text{left} & \quad TIMES \quad DIV \\
\%\right & \quad EXP
\end{align*}
\]
CHAPTER THREE. PARSING

\[
\begin{array}{cccccc}
+ & - & * & / & \vdots \\
9 & r5 & r5 & s12 & s14 \\
11 & \cdot & \cdot & s12 & s14 & \cdot \\
13 & r3 & r3 & r3 & r3 \\
15 & r4 & r4 & \vdots \\
\end{array}
\]

TABLE 3.34. Conflicts of Table 3.33 resolved.

indicates that + and - are left-associative and bind equally tightly; that * and / are left-associative and bind more tightly than +; that ^ is right-associative and binds most tightly; and that = and \neq are nonassociative, and bind more weakly than +.

In examining a shift-reduce conflict such as

\[
E \rightarrow E * E . \quad + \\
E \rightarrow E . + E \quad \text{(any)}
\]

there is the choice of shifting a token and reducing by a rule. Should the rule or the token be given higher priority? The precedence declarations (%left, etc.) give priorities to the tokens; the priority of a rule is given by the last token occurring on the right-hand side of that rule. Thus the choice here is between a rule with priority * and a token with priority +; the rule has higher priority, so the conflict is resolved in favor of reducing.

When the rule and token have equal priority, then a %left precedence favors reducing, %right favors shifting, and %nonassoc yields an error action.

Instead of using the default “rule has precedence of its last token,” we can assign a specific precedence to a rule using the %prec directive. This is commonly used to solve the “unary minus” problem. In most programming languages a unary minus binds tighter than any binary operator, so \(-6 * 8\) is parsed as \((-6) * 8\), not \(-6 * 8\). Grammar 3.35 shows an example.

The token UMINUS is never returned by the lexer; it is merely a placeholder in the chain of precedence (%left) declarations. The directive %prec UMINUS gives the rule \(\text{exp: MINUS exp}\) the highest precedence, so reducing by this rule takes precedence over shifting any operator, even a minus sign.
3.4. USING PARSER GENERATORS

```%{ declarations of yylex and yyerror %}
%token INT PLUS MINUS TIMES UMINUS
%start exp

%left PLUS MINUS
%left TIMES
%left UMINUS
%%

exp : INT
    | exp PLUS exp
    | exp MINUS exp
    | exp TIMES exp
    | MINUS exp %prec UMINUS
```

### GRAMMAR 3.35.

Precedence rules are helpful in resolving conflicts, but they should not be abused. If you have trouble explaining the effect of a clever use of precedence rules, perhaps instead you should rewrite the grammar to be unambiguous.

### SYNTAX VERSUS SEMANTICS

Consider a programming language with arithmetic expressions such as \( x + y \) and boolean expressions such as \( x + y = z \) or \( a \& (b = c) \). Arithmetic operators bind tighter than the boolean operators; there are arithmetic variables and boolean variables; and a boolean expression cannot be added to an arithmetic expression. **Grammar 3.36** gives a syntax for this language.

The grammar has a reduce-reduce conflict, as shown in *Figure 3.37*. How should we rewrite the grammar to eliminate this conflict?

Here the problem is that when the parser sees an identifier such as \( a \), it has no way of knowing whether this is an arithmetic variable or a boolean variable – syntactically they look identical. The solution is to defer this analysis until the “semantic” phase of the compiler; it’s not a problem that can be handled naturally with context-free grammars. A more appropriate grammar is:

\[
S \rightarrow \text{id} := E \\
E \rightarrow \text{id} \\
E \rightarrow E \& E \\
E \rightarrow E = E \\
E \rightarrow E + E
\]

Now the expression \( a + 5 \& b \) is syntactically legal, and a later phase of the compiler will have to reject it and print a semantic error message.
LR(k) parsing tables contain shift, reduce, accept, and error actions. On page 59 I claimed that when an LR parser encounters an error action it stops parsing and reports failure. This behavior would be unkind to the programmer, who would like to have all the errors in her program reported, not just the first error.

**ERROR RECOVERY**

Local error recovery mechanisms work by adjusting the parse stack and the input at the point where the error was detected in a way that will allow parsing to resume. One local recovery mechanism – found in many versions of the Yacc parser generator – uses a special error symbol to control the recovery process. Wherever the special error symbol appears in a grammar rule, a sequence of erroneous input tokens can be matched.

For example, in a Yacc grammar for Tiger, we might have productions such as

**RECOVERY USING THE ERROR SYMBOL**

3.5

ERROR RECOVERY

LR(k) parsing tables contain shift, reduce, accept, and error actions. On page 59 I claimed that when an LR parser encounters an error action it stops parsing and reports failure. This behavior would be unkind to the programmer, who would like to have all the errors in her program reported, not just the first error.

**RECOVERY USING THE ERROR SYMBOL**

Local error recovery mechanisms work by adjusting the parse stack and the input at the point where the error was detected in a way that will allow parsing to resume. One local recovery mechanism – found in many versions of the Yacc parser generator – uses a special error symbol to control the recovery process. Wherever the special error symbol appears in a grammar rule, a sequence of erroneous input tokens can be matched.

For example, in a Yacc grammar for Tiger, we might have productions such as
3.5. ERROR RECOVERY

FIGURE 3.37. LR states for Grammar 3.36.

\[
\begin{align*}
\exp & \rightarrow \text{ID} \\
\exp & \rightarrow \exp + \exp \\
\exp & \rightarrow ( \expseq ) \\
\expseq & \rightarrow \exp \\
\expseq & \rightarrow \expseq ; \exp
\end{align*}
\]

Informally, we can specify that if a syntax error is encountered in the middle of an expression, the parser should skip to the next semicolon or right parenthesis (these are called synchronizing tokens) and resume parsing. We do
this by adding error-recovery productions such as

\[ exp \rightarrow ( \text{error} ) \]
\[ exps \rightarrow \text{error} ; \ exp \]

What does the parser-generator do with the `error` symbol? In parser generation, `error` is considered a terminal symbol, and shift actions are entered in the parsing table for it as if it were an ordinary token.

When the LR parser reaches an error state, it takes the following actions:

1. Pop the stack (if necessary) until a state is reached in which the action for the `error` token is `shift`.
2. Shift the `error` token.
3. Discard input symbols (if necessary) until a state is reached that has a non-error action on the current lookahead token.
4. Resume normal parsing.

In the two `error` productions illustrated above, we have taken care to follow the `error` symbol with an appropriate synchronizing token – in this case, right parenthesis or semicolon. Thus, the “non-error action” taken in step 3 will always `shift`. If instead we used the production `exp \rightarrow \text{error}`, the “non-error action” would be `reduce`, and (in an SLR or LALR parser) it is possible that the original (erroneous) lookahead symbol would cause another error after the reduce action, without having advanced the input. Therefore, grammar rules that contain `error` not followed by a token should be used only when there is no good alternative.

**Caution.** One can attach *semantic actions* to Yacc grammar rules; whenever a rule is reduced, its semantic action is executed. Chapter 4 explains the use of semantic actions. Popping states from the stack can lead to seemingly “impossible” semantic actions, especially if the actions contain side effects. Consider this grammar fragment:

```
statements:   statements exp SEMICOLON
              | statements error SEMICOLON
              | /* empty */

exp : increment exp decrement
     | ID

increment:   LPAREN {nest=nest+1;}
decrement:   RPAREN   {nest=nest-1;}
```

78
“Obviously” it is true that whenever a semicolon is reached, the value of \texttt{nest} is zero, because it is incremented and decremented in a balanced way according to the grammar of expressions. But if a syntax error is found after some left parentheses have been parsed, then states will be popped from the stack without “completing” them, leading to a nonzero value of \texttt{nest}. The best solution to this problem is to have side-effect-free semantic actions that build abstract syntax trees, as described in Chapter 4.

\section*{GLOBAL ERROR REPAIR}

What if the best way to recover from the error is to insert or delete tokens from the input stream at a point \textit{before} where the error was detected? Consider the following Tiger program:

\begin{verbatim}
let type a := intArray [ 10 ] of 0 in ...
\end{verbatim}

A local technique will discover a syntax error with := as lookahead symbol. Error recovery based on \textit{error} productions would likely delete the phrase from \texttt{type} to 0, resynchronizing on the \texttt{in} token. Some local repair techniques can insert tokens as well as delete them; but even a local repair that replaces the := by = is not very good, and will encounter another syntax error at the [ token. Really, the programmer’s mistake here is in using \texttt{type} instead of \texttt{var}, but the error is detected two tokens too late.

\textit{Global error repair} finds the smallest set of insertions and deletions that would turn the source string into a syntactically correct string, \textit{even if the insertions and deletions are not at a point where an LL or LR parser would first report an error}. In this case, global error repair would do a single-token substitution, replacing \texttt{type} by \texttt{var}.

\textbf{Burke-Fisher error repair.} I will describe a limited but useful form of global error repair, which tries every possible single-token insertion, deletion, or replacement at every point that occurs no earlier than \(K\) tokens before the point where the parser reported the error. Thus, with \(K = 15\), if the parsing engine gets stuck at the 100th token of the input, then it will try every possible repair between the 85th and 100th token.

The correction that allows the parser to parse furthest past the original reported error is taken as the best error repair. Thus, if a single-token substitution of \texttt{var} for \texttt{type} at the 98th token allows the parsing engine to proceed past the 104th token without getting stuck, this repair is a successful one.
Generally, if a repair carries the parser \( R = 4 \) tokens beyond where it originally got stuck, this is “good enough.”

The advantage of this technique is that the LL(\( k \)) or LR(\( k \)) (or LALR, etc.) grammar is not modified at all (no error productions), nor are the parsing tables modified. Only the parsing engine, which interprets the parsing tables, is modified.

The parsing engine must be able to back up \( K \) tokens and reparse. To do this, it needs to remember what the parse stack looked like \( K \) tokens ago. Therefore, the algorithm maintains two parse stacks: the current stack and the old stack. A queue of \( K \) tokens is kept; as each new token is shifted, it is pushed on the current stack and also put onto the tail of the queue; simultaneously, the head of the queue is removed and shifted onto the old stack. With each shift onto the old or current stack, the appropriate reduce actions are also performed. Figure 3.38 illustrates the two stacks and queue.

Now suppose a syntax error is detected at the current token. For each possible insertion, deletion, or substitution of a token at any position of the queue, the Burke-Fisher error repairer makes that change to within (a copy of) the queue, then attempts to reparse from the old stack. The success of a modification is in how many tokens past the current token can be parsed; generally, if three or four new tokens can be parsed, this is considered a completely successful repair.

In a language with \( N \) kinds of tokens, there are \( K + K \cdot N + K \cdot N \) possible deletions, insertions, and substitutions within the \( K \)-token window. Trying
3.5. ERROR RECOVERY

this many repairs is not very costly, especially considering that it happens only when a syntax error is discovered, not during ordinary parsing.

**Semantic actions.** Shift and reduce actions are tried repeatedly and discarded during the search for the best error repair. Parser generators usually perform programmer-specified semantic actions along with each reduce action, but the programmer does not expect that these actions will be performed repeatedly and discarded – they may have side effects. Therefore, a Burke-Fisher parser does not execute any of the semantic actions as reductions are performed on the *current* stack, but waits until the same reductions are performed (permanently) on the *old* stack.

This means that the lexical analyzer may be up to $K + R$ tokens ahead of the point to which semantic actions have been performed. If semantic actions affect lexical analysis – as they do in C, compiling the `typedef` feature – this can be a problem with the Burke-Fisher approach. For languages with a pure context-free grammar approach to syntax, the delay of semantic actions poses no problem.

**Semantic values for insertions.** In repairing an error by insertion, the parser needs to provide a semantic value for each token it inserts, so that semantic actions can be performed as if the token had come from the lexical analyzer. For punctuation tokens no value is necessary, but when tokens such as numbers or identifiers must be inserted, where can the value come from? The ML-Yacc parser generator, which uses Burke-Fischer error correction, has a `%value` directive, allowing the programmer to specify what value should be used when inserting each kind of token:

```
%value ID ("bogus")
%value INT (1)
%value STRING ("")
```

**Programmer-specified substitutions.** Some common kinds of errors cannot be repaired by the insertion or deletion of a single token, and sometimes a particular single-token insertion or substitution is very commonly required and should be tried first. Therefore, in an ML-Yacc grammar specification the programmer can use the `%change` directive to suggest error corrections to be tried first, before the default “delete or insert each possible token” repairs.

```
%change EQ -> ASSIGN | ASSIGN -> EQ
| SEMICOLON ELSE -> ELSE | -> IN INT END
```
CHAPTER THREE. PARSING

Here the programmer is suggesting that users often write “; else” where they mean “else” and so on.

The insertion of in 0 end is a particularly important kind of correction, known as a scope closer. Programs commonly have extra left parentheses or right parentheses, or extra left or right brackets, and so on. In Tiger, another kind of nesting construct is let ... in ... end. If the programmer forgets to close a scope that was opened by left parenthesis, then the automatic single-token insertion heuristic can close this scope where necessary. But to close a let scope requires the insertion of three tokens, which will not be done automatically unless the compiler-writer has suggested “change nothing to in 0 end” as illustrated in the %change command above.

PROGRAM

PARSING

Use Yacc to implement a parser for the Tiger language. Appendix A describes, among other things, the syntax of Tiger.

You should turn in the file tiger.grm and a README.

Supporting files available in $TIGER/chap3 include:

makefile  The “makefile.”
errormsg.[ch]  The Error Message structure, useful for producing error messages with file names and line numbers.
lex.yy.c  The lexical analyzer. I haven’t provided the source file tiger.lex, but I’ve provided the output of Lex that you can use if your lexer isn’t working.
parsetest.c  A driver to run your parser on an input file.
tiger.grm  The skeleton of a file you must fill in.

You won’t need tokens.h anymore; instead, the header file for tokens is y.tab.h, which is produced automatically by Yacc from the token specification of your grammar.

Your grammar should have as few shift-reduce conflicts as possible, and no reduce-reduce conflicts. Furthermore, your accompanying documentation should list each shift-reduce conflict (if any) and explain why it is not harmful.

My grammar has a shift-reduce conflict that’s related to the confusion between

```
variable [ expression ]
type-id [ expression ] of expression
```

In fact, I had to add a seemingly redundant grammar rule to handle this confusion. Is there a way to do this without a shift-reduce conflict?
Use the precedence directives (%left, %nonassoc, %right) when it is straightforward to do so.

Do not attach any semantic actions to your grammar rules for this exercise.

Optional: Add error productions to your grammar and demonstrate that your parser can sometimes recover from syntax errors.

Conway [1963] describes a predictive (recursive-descent) parser, with a notion of FIRST sets and left-factoring. LL(1) parsing theory was formalized by Lewis and Stearns [1968].

LR(k) parsing was developed by Knuth [1965]; the SLR and LALR techniques by DeRemer [1971]; LALR(1) parsing was popularized by the development and distribution of Yacc [Johnson 1975] (which was not the first parser-generator, or “compiler-compiler,” as can be seen from the title of the cited paper).

Figure 3.29 summarizes many theorems on subset relations between grammar classes. Heilbrunner [1981] shows proofs of several of these theorems, including LL(k) ⊂ LR(k) and LL(1) ⊄ LALR(1) (see Exercise 3.14). Backhouse [1979] is a good introduction to theoretical aspects of LL and LR parsing.

Aho et al. [1975] showed how deterministic LL or LR parsing engines can handle ambiguous grammars, with ambiguities resolved by precedence directives (as described in Section 3.4).

Burke and Fisher [1987] invented the error-repair tactic that keeps a K-token queue and two parse stacks.

3.1 Translate each of these regular expressions into a context-free grammar.
   a. ((xy*x)(yx*y))?
   b. ((0|1)+ . n(0|1)+)((0|1)* . n(0|1)+)

*3.2 Write a grammar for English sentences using the words

   time, arrow, banana, flies, like, a, an, the, fruit
and the semicolon. Be sure to include all the senses (noun, verb, etc.) of each word. Then show that this grammar is ambiguous by exhibiting more than one parse tree for “time flies like an arrow; fruit flies like a banana.”

3.3 Write an unambiguous grammar for each of the following languages. **Hint:** One way of verifying that a grammar is unambiguous is to run it through Yacc and get no conflicts.

a. Palindromes over the alphabet \{a, b\} (strings that are the same backward and forward).

b. Strings that match the regular expression \(a^*b^*\) and have more a’s than b’s.

c. Balanced parentheses and square brackets. Example: `(([](()[])))`

d. Balanced parentheses and brackets, where a closing bracket also closes any outstanding open parentheses (up to the previous open bracket). Example: `[([()])][()]]. **Hint:** First, make the language of balanced parentheses and brackets, where extra open parentheses are allowed; then make sure this nonterminal must appear within brackets.

e. All subsets and permutations (without repetition) of the keywords `public final static synchronized transient`. (Then comment on how best to handle this situation in a real compiler.)

f. Statement blocks in Pascal or ML where the semicolons separate the statements:

```
( statement ; ( statement ; statement ) ; statement )
```

g. Statement blocks in C where the semicolons terminate the statements:

```
{ expression; { expression; expression; } expression; }
```

3.4 Write a grammar that accepts the same language as Grammar 3.1, but that is suitable for LL(1) parsing. That is, eliminate the ambiguity, eliminate the left recursion, and (if necessary) left-factor.

3.5 Find nullable, FIRST, and FOLLOW sets for this grammar; then construct the LL(1) parsing table.

```
0  S' \rightarrow S \$ 
1  S \rightarrow 
2  S \rightarrow X S 
3  B \rightarrow \begin{\text{begin}\{\text{WORD}\}\end{\text{end}\}} 
4  E \rightarrow \begin{\text{end}\{\text{WORD}\}\end{\text{end}\}} 
5  X \rightarrow B S E 
6  X \rightarrow \{ S \} 
7  X \rightarrow \text{WORD} 
8  X \rightarrow \text{begin} 
9  X \rightarrow \text{end} 
10 X \rightarrow \text{\WORD} 
```
3.6  a. Calculate nullable, FIRST, and FOLLOW for this grammar:

\[
\begin{align*}
S & \rightarrow u \ B \ D \ z \\
B & \rightarrow \ B \ v \\
B & \rightarrow \ d \\
D & \rightarrow \ E \ F \\
E & \rightarrow \ y \\
E & \rightarrow \\
F & \rightarrow x \\
F & \rightarrow \\
\end{align*}
\]

b. Construct the LL(1) parsing table.

c. Give evidence that this grammar is not LL(1).

d. Modify the grammar as little as possible to make an LL(1) grammar that accepts the same language.

*3.7  a. Left-factor this grammar.

\[
\begin{align*}
0 & \ S \rightarrow \ G \ \$ \\
1 & \ G \rightarrow \ P \\
2 & \ G \rightarrow \ P \ G \\
3 & \ P \rightarrow \ \text{id} : \ R \\
4 & \ R \rightarrow \\
5 & \ R \rightarrow \ \text{id} \ R \\
\end{align*}
\]

b. Show that the resulting grammar is LL(2). You can do this by constructing FIRST sets (etc.) containing two-symbol strings; but it is simpler to construct an LL(1) parsing table and then argue convincingly that any conflicts can be resolved by looking ahead one more symbol.

c. Show how the \texttt{tok} variable and \texttt{advance} function should be altered for recursive-descent parsing with two-symbol lookahead.

d. Use the grammar class hierarchy (Figure 3.29) to show that the (left-factored) grammar is LR(2).

e. Prove that no string has two parse trees according to this (left-factored) grammar.

3.8 Make up a tiny grammar containing left recursion, and use it to demonstrate that left recursion is not a problem for LR parsing. Then show a small example comparing growth of the LR parse stack with left recursion versus right recursion.

3.9 Diagram the LR(0) states for Grammar 3.26, build the SLR parsing table, and identify the conflicts.

3.10 Diagram the LR(1) states for the grammar of Exercise 3.7 (without left-factoring), and construct the LR(1) parsing table. Indicate clearly any conflicts.

3.11 Construct the LR(0) states for this grammar, and then determine whether it is an
CHAPTER THREE. PARSING

SLR grammar.

\[
\begin{align*}
0 & \quad S \rightarrow B \, $ \\
1 & \quad B \rightarrow \text{id} \, P \\
2 & \quad B \rightarrow \text{id} \, ( \, E \, ) \\
3 & \quad P \rightarrow \, \quad ( \, E \, ) \\
4 & \quad P \rightarrow \, \quad ( \, E \, ) \\
5 & \quad E \rightarrow B \\
6 & \quad E \rightarrow B \, , \, E
\end{align*}
\]

3.12 a. Build the LR(0) DFA for this grammar:

\[
\begin{align*}
0 & \quad S \rightarrow E \, $ \\
1 & \quad E \rightarrow \text{id} \\
2 & \quad E \rightarrow \text{id} \, ( \, E \, ) \\
3 & \quad E \rightarrow E \, + \, \text{id}
\end{align*}
\]

b. Is this an LR(0) grammar? Give evidence.

c. Is this an SLR grammar? Give evidence.

d. Is this an LR(1) grammar? Give evidence.

3.13 Show that this grammar is LALR(1) but not SLR:

\[
\begin{align*}
0 & \quad S \rightarrow X \, $ \\
1 & \quad X \rightarrow \text{Ma} \\
2 & \quad X \rightarrow \text{bMc} \\
3 & \quad X \rightarrow \text{dc} \\
4 & \quad X \rightarrow \text{bda} \\
5 & \quad M \rightarrow \text{d}
\end{align*}
\]

3.14 Show that this grammar is LL(1) but not LALR(1):

\[
\begin{align*}
1 & \quad S \rightarrow \, ( \, X \, ) \\
2 & \quad S \rightarrow \, E \, ] \\
3 & \quad S \rightarrow \, F \, ) \\
4 & \quad X \rightarrow \, E \, ) \\
5 & \quad X \rightarrow \, F \, ] \\
6 & \quad E \rightarrow \, A \\
7 & \quad F \rightarrow \, A \\
8 & \quad A \rightarrow
\end{align*}
\]

*3.15* Feed this grammar to Yacc; from the output description file, construct the LALR(1) parsing table for this grammar, with duplicate entries where there are conflicts. For each conflict, show whether shifting or reducing should be chosen so that the different kinds of expressions have “conventional” precedence. Then show the Yacc-style precedence directives that resolve the conflicts this way.

\[
\begin{align*}
0 & \quad S \rightarrow E \, $ \\
1 & \quad E \rightarrow \text{while} \, E \, \text{do} \, E \\
2 & \quad E \rightarrow \text{id} \, := \, E \\
3 & \quad E \rightarrow E \, + \, E \\
4 & \quad E \rightarrow \text{id}
\end{align*}
\]
*3.16 Explain how to resolve the conflicts in this grammar, using precedence directives, or grammar transformations, or both. Use Yacc as a tool in your investigations, if you like.

1. $E \rightarrow \text{id}$
2. $E \rightarrow E B E$
3. $B \rightarrow +$
4. $B \rightarrow -$  
5. $B \rightarrow \times$
6. $B \rightarrow /$

*3.17 Prove that Grammar 3.8 cannot generate parse trees of the form shown in Figure 3.9. Hint: What nonterminals could possibly be where the $?X$ is shown? What does that tell us about what could be where the $?Y$ is shown?
Abstract Syntax

A compiler must do more than recognize whether a sentence belongs to the language of a grammar – it must do something useful with that sentence. The **semantic actions** of a parser can do useful things with the phrases that are parsed.

In a recursive-descent parser, semantic action code is interspersed with the control flow of the parsing actions. In a parser specified in Yacc, semantic actions are fragments of C program code attached to grammar productions.

**4.1 SEMANTIC ACTIONS**

Each terminal and nonterminal may be associated with its own type of semantic value. For example, in a simple calculator using Grammar 3.35, the type associated with `exp` and `INT` might be `int`; the other tokens would not need to carry a value. The type associated with a token must, of course, match the type that the lexer returns with that token.

For a rule `A → B C D`, the semantic action must return a value whose type is the one associated with the nonterminal `A`. But it can build this value from the values associated with the matched terminals and nonterminals `B`, `C`, `D`.

**RECURSIVE DESCENT**

In a recursive-descent parser, the semantic actions are the values returned by parsing functions, or the side effects of those functions, or both. For each terminal and nonterminal symbol, we associate a *type* (from the implementation
4.1. SEMANTIC ACTIONS

enum token {EOF, ID, NUM, PLUS, MINUS, ... };  
union tokenval {string id; int num; ... };  

enum token tok;  
union tokenval tokval;  

int lookup(String id) { ... }  

int F_follow[] = { PLUS, TIMES, RPAREN, EOF, -1 };  
int F(void) {switch (tok) {
    case ID: {int i=lookup(tokval.id); advance(); return i;}  
    case NUM: {int i=tokval.num; advance(); return i;}  
    case LPAREN: eat(LPAREN); { int i = E();  
        eatOrSkipTo(RPAREN, F_follow);  
        return i; }  
    case EOF:  
    default: printf("expected ID, NUM, or left-paren");  
        skipto(F_follow);  
        return 0;  
}}  

int T_follow[] = { PLUS, RPAREN, EOF, -1 };  
int T(void) {switch (tok) {
    case ID: case NUM: case LPAREN: return Tprime(F());  
    default: printf("expected ID, NUM, or left-paren");  
        skipto(T_follow);  
        return 0;  
}}  

int Tprime(int a) {switch (tok) {
    case TIMES: eat(TIMES); return Tprime(a*F());  
    case PLUS: case RPAREN: case EOF: return a;  
    default: ...  
}}  

void eatOrSkipTo(int expected, int *stop) {
    if (tok==expected) eat(expected);  
    else {printf(...); skipto(stop);}  
}  

PROGRAM 4.1. Recursive-descent interpreter for part of Grammar 3.15.
language of the compiler) of \textit{semantic values} representing phrases derived from that symbol.

Program 4.1 is a recursive-descent interpreter for Grammar 3.15. The tokens \texttt{ID} and \texttt{NUM} must now carry values of type \texttt{string} and \texttt{int}, respectively. We will assume there is a lookup table mapping identifiers to integers. The type associated with \texttt{E}, \texttt{T}, \texttt{F}, etc. is \texttt{int}, and the semantic actions are easy to implement.

The semantic action for an artificial symbol such as \texttt{T'} (introduced in the elimination of left recursion) is a bit tricky. Had the production been \texttt{T \rightarrow T \ast F} then the semantic action would have been

\begin{verbatim}
{int a,b; a = T(); eat(TIMES); int b=F(); return a*b;}
\end{verbatim}

With the rearrangement of the grammar, the production \texttt{T' \rightarrow \ast F T'} is missing the left operand of the \texttt{*}. One solution is for \texttt{T} to pass the left operand as an argument to \texttt{T'}, as shown in Program 4.1.

\section*{Yacc-generated parsers}

A parser specification for Yacc consists of a set of grammar rules, each annotated with a semantic action that is a C statement. Whenever the generated parser reduces by a rule, it will execute the corresponding semantic action fragment.
4.1. SEMANTIC ACTIONS

Program 4.2 shows how this works for Grammar 3.35. The semantic action can refer to the semantic values of the \(i\)th right-hand-side symbol as \(\$i\). It can produce a value for the left-hand-side nonterminal symbol by assigning to \(\$$\). The %union declaration declares different possible types for semantic values to carry; each terminal or nonterminal symbol declares which variant of the union it uses by means of the \(<\text{variant}>\) notation.

In a more realistic example, there might be several nonterminals each carrying a different type.

A Yacc-generated parser implements semantic values by keeping a stack of them parallel to the state stack. Where each symbol would be on a simple parsing stack, now there is a semantic value. When the parser performs a reduction, it must execute a C-language semantic action; it satisfies each reference to a right-hand-side semantic value by a reference to one of the top \(k\) elements of the stack (for a rule with \(k\) right-hand-side symbols). When the
CHAPTER FOUR. ABSTRACT SYNTAX

parser pops the top $k$ elements from the symbol stack and pushes a nonterminal symbol, it also pops $k$ from the semantic value stack and pushes the value obtained by executing the C semantic action code.

Figure 4.3 shows an LR parse of a string using Program 4.2. The stack holds states and semantic values (in this case, the semantic values are all integers). When a rule such as $E \rightarrow E + E$ is reduced (with a semantic action such as $\text{exp1+exp2}$), the top three elements of the semantic stack are $\text{exp1}$, empty (a place-holder for the trivial semantic value carried by $+$), and $\text{exp2}$, respectively.

AN INTERPRETER IN SEMANTIC ACTIONS

Program 4.2 shows how semantic values for nonterminals can be calculated from the semantic values of the right-hand side of the productions. The semantic actions in this example do not have side effects that change any global state, so the order of evaluation of the right-hand-side symbols does not matter.

However, an LR parser does perform reductions, and associated semantic actions, in a deterministic and predictable order: a bottom-up, left-to-right traversal of the parse tree. In other words, the (virtual) parse tree is traversed in postorder. Thus, one can write semantic actions with global side effects, and be able to predict the order of their occurrence.

Program 4.4 shows an interpreter for the straight-line program language. It uses a global variable for the symbol table (a production-quality interpreter would use a better data structure than a linked list; see Section 5.1).

4.2 ABSTRACT PARSE TREES

It is possible to write an entire compiler that fits within the semantic action phrases of a Yacc parser. However, such a compiler is difficult to read and maintain. And this approach constrains the compiler to analyze the program in exactly the order it is parsed.

To improve modularity, it is better to separate issues of syntax (parsing) from issues of semantics (type-checking and translation to machine code). One way to do this is for the parser to produce a parse tree – a data structure that later phases of the compiler can traverse. Technically, a parse tree has exactly one leaf for each token of the input and one internal node for each grammar rule reduced during the parse.
4.2. ABSTRACT PARSE TREES

{%
typedef struct table *Table_;
Table_ {string id; int value; Table_ tail};
Table_ Table(string id, int value, struct table *tail); (see page 13)
Table_table=NULL;
int lookup(Table_ table, string id) {
    assert(table!=NULL);
    if (id==table.id) return table.value;
    else return lookup(table.tail, id);
}
void update(Table_ *tabptr, string id, int value) {
    *tabptr = Table(id, value, *tabptr);
}
%
union {int num; string id;}

%token <num> INT

exp : stm COMMA exp {$$=$3;}  
exp : LPAREN exp RPAREN {$$=$2;}

PROGRAM 4.4.  An interpreter in imperative style.
### Grammar 4.5. Abstract syntax of straight-line programs.

\[
\begin{align*}
S & \rightarrow S; S \\
S & \rightarrow \text{id} := E \\
S & \rightarrow \text{print } L \\
E & \rightarrow \text{id} \\
E & \rightarrow \text{num} \\
E & \rightarrow E B E \\
E & \rightarrow S, E \\
L & \rightarrow \\
L & \rightarrow L E \\
B & \rightarrow + \\
B & \rightarrow - \\
B & \rightarrow \times \\
B & \rightarrow / \\
\end{align*}
\]

Such a parse tree, which we will call a *concrete parse tree* representing the *concrete syntax* of the source language, is inconvenient to use directly. Many of the punctuation tokens are redundant and convey no information – they are useful in the input string, but once the parse tree is built, the structure of the tree conveys the structuring information more conveniently.

Furthermore, the structure of the parse tree depends too much on the grammar! The grammar transformations shown in Chapter 3 – factoring, elimination of left recursion, elimination of ambiguity – involve the introduction of extra nonterminal symbols and extra grammar productions for technical purposes. These details should be confined to the parsing phase and should not clutter the semantic analysis.

An *abstract syntax* makes a clean interface between the parser and the later phases of a compiler (or, in fact, for the later phases of other kinds of program-analysis tools such as dependency analyzers). The abstract syntax tree conveys the phrase structure of the source program, with all parsing issues resolved but without any semantic interpretation.

Many early compilers did not use an abstract syntax data structure because early computers did not have enough memory to represent an entire compilation unit’s syntax tree. Modern computers rarely have this problem. And many modern programming languages (ML, Modula-3, Java) allow forward reference to identifiers defined later in the same module; using an abstract syntax tree makes compilation easier for these languages. It may be that Pascal and C require clumsy *forward* declarations because their designers wanted to avoid an extra compiler pass on the machines of the 1970s.

Grammar 4.5 shows the abstract syntax of a straight-line-program language. This grammar is completely impractical for parsing: the grammar is
4.2. ABSTRACT PARSE TREES

quite ambiguous, since precedence of the operators is not specified, and many of the punctuation keywords are missing.

However, Grammar 4.5 is not meant for parsing. The parser uses the concrete syntax (Program 4.6) to build a parse tree for the abstract syntax. The semantic analysis phase takes this abstract syntax tree; it is not bothered by the ambiguity of the grammar, since it already has the parse tree!

The compiler will need to represent and manipulate abstract syntax trees as data structures. In C, these data structures are organized according to the principles outlined in Section 1.3: a typedef for each nonterminal, a union-variant for each production, and so on. Program 1.5 shows the data structure declarations for Grammar 4.5.

The Yacc (or recursive-descent) parser, parsing the concrete syntax, constructs the abstract syntax tree. This is shown in Program 4.6.

POSITIONS

In a one-pass compiler, lexical analysis, parsing, and semantic analysis (type-checking) are all done simultaneously. If there is a type error that must be reported to the user, the current position of the lexical analyzer is a reasonable approximation of the source position of the error. In such a compiler, the lexical analyzer keeps a “current position” global variable, and the error-message routine just prints the value of that variable with each message.

A compiler that uses abstract-syntax-tree data structures need not do all the parsing and semantic analysis in one pass. This makes life easier in many ways, but slightly complicates the production of semantic error messages. The lexer reaches the end of file before semantic analysis even begins; so if a semantic error is detected in traversing the abstract syntax tree, the current position of the lexer (at end of file) will not be useful in generating a line-number for the error message. Thus, the source-file position of each node of the abstract syntax tree must be remembered, in case that node turns out to contain a semantic error.

To remember positions accurately, the abstract-syntax data structures must be sprinkled with pos fields. These indicate the position, within the original source file, of the characters from which these abstract syntax structures were derived. Then the type-checker can produce useful error messages.

The lexer must pass the source-file positions of the beginning and end of each token to the parser. Ideally, the automatically generated parser should maintain a position stack along with the semantic value stack, so that the beginning and end positions of each token and phrase are available for the
semantic actions to use in reporting error messages. The *Bison* parser generator can do this; *Yacc* does not. When using *Yacc*, one solution is to define a nonterminal symbol `pos` whose semantic value is a source location (line number, or line number and position within line). Then, if one wants to access the position of the `PLUS` from the semantic action after `exp PLUS exp`, the following works:
4.2. ABSTRACT PARSE TREES

```c
%{ extern A_OpExp(A_exp, A_binop, A_exp, position); %}
%union{int num; string id; position pos; ... ;}
%type <pos> pos

pos : { $$ = EM_tokPos; }
ex : exp PLUS pos exp { $$ = A_OpExp($1,A_plus,$4,$3); }
```

But this trick can be dangerous. With \texttt{pos} after \texttt{PLUS}, it works; but with \texttt{pos} too early in the production, it does not:

```c
ex : pos exp PLUS exp { $$ = A_OpExp($2,A_plus,$4,$1); }
```

This is because the LR(1) parser must reduce \texttt{pos} → \( \epsilon \) before seeing the \texttt{PLUS}. A shift-reduce or reduce-reduce conflict will result.

### ABSTRACT SYNTAX FOR Tiger

Figure 4.7 shows for the abstract syntax of Tiger. The meaning of each constructor in the abstract syntax should be clear after a careful study of Appendix A, but there are a few points that merit explanation.

Figure 4.7 shows only the constructor functions, not the typedefs and structs. The definition of \texttt{A\_var} would actually be written as

```c
/* absyn.h */
typedef struct A_var_ *A_var;
struct A_var_
    {enum {A_simpleVar, A_fieldVar, A_subscriptVar} kind;
     A_pos pos;
     union {S_symbol simple;
             struct {A_var var;
                      S_symbol sym;} field;
             struct {A_var var;
                      A_exp exp;} subscript;
          } u;
    };
```

This follows the principles outlined on page 9.

The Tiger program

```
(a := 5; a+1)
```

translates into abstract syntax as
FIGURE 4.7. Abstract syntax for the Tiger language. Only the constructor functions are shown; the structure fields correspond exactly to the names of the constructor arguments.
4.2. ABSTRACTPARSE TREES

A\_SeqExp(2,
  A\_ExpList(A\_AssignExp(4,A\_SimpleVar(2,S\_Symbol("a\")),A\_IntExp(7,5)),
  A\_ExpList((A\_OpExp(11,A\_plusOp,A\_VarExp(A\_SimpleVar(10,
                     S\_Symbol("a\")), A\_IntExp(12,1))),
         NULL))))

This is a sequence expression containing two expressions separated by
a semicolon: an assignment expression and an operator expression. Within
these are a variable expression and two integer constant expressions.
The positions sprinkled throughout are source-code character count. The
position I have chosen to associate with an AssignExp is that of the :=
operator, for an OpExp that of the + operator, and so on. These decisions are
a matter of taste; they represent my guesses about how they will look when
included in semantic error messages.

Now consider

```
let var a := 5
  function f() : int = g(a)
  function g(i: int) = f()
  in f()
end
```

The Tiger language treats adjacent function declarations as (possibly) mutu-
ally recursive. The FunctionDec constructor of the abstract syntax takes
a list of function declarations, not just a single function. The intent is that
this list is a maximal consecutive sequence of function declarations. Thus,
functions declared by the same FunctionDec can be mutually recursive.
Therefore, this program translates into the abstract syntax,

```
A\_LetExp(
  A\_DecList(A\_VarDec(S\_Symbol("a")),NULL,A\_IntExp(5)),
  A\_DecList(A\_FunctionDec(
    A\_FundecList(A\_Fundec(  
      S\_Symbol("f"),NULL,S\_Symbol("int"),
      A\_CallExp(S\_Symbol("g"),···)),
    A\_FundecList(A\_Fundec(  
      S\_Symbol("g"),
      A\_FieldList(S\_Symbol("i"),S\_Symbol("int"),NULL),
      NULL,
      A\_CallExp(S\_Symbol("f"),···)),
    NULL)),
  NULL)),
A\_CallExp(S\_Symbol("f"), NULL))
```
where the positions are omitted for clarity.

The \texttt{TypeDec} constructor also takes a list of type declarations, for the same reason; consider the declarations

\begin{verbatim}
type tree = {key: int, children: treelist}
type treelist = {head: tree, tail: treelist}
\end{verbatim}

which translate to \textit{one} type declaration, not two:

\begin{verbatim}
A_TypeDec(
    A_NametyList(A_Namety(S_Symbol("tree")),
    A_RecordTy(
        A_FieldList(A_Field(S_Symbol("key"),S_Symbol("int")),
        A_FieldList(A_Field(S_Symbol("children"),
            S_Symbol("treelist")),
        NULL))),
    A_NametyList(A_NameTy(S_Symbol("treelist")),
    A_RecordTy(
        A_FieldList(A_Field(S_Symbol("head"),S_Symbol("tree")),
        A_FieldList(A_Field(S_Symbol("tail"),S_Symbol("treelist")),
        NULL))),
    NULL)))
\end{verbatim}

There is no abstract syntax for "\&" and "\mid" expressions; instead, \(e_1 \& e_2\) is translated as \(\text{if } e_1 \text{ then } e_2 \text{ else } 0\), and \(e_1 \mid e_2\) is translated as though it had been written \(\text{if } e_1 \text{ then } 1 \text{ else } e_2\).

Similarly, unary negation \((-i)\) should be represented as subtraction \((0 - i)\) in the abstract syntax.\(^1\) Also, where the body of a \texttt{LetExp} has multiple statements, we must use a \texttt{seqExp}. An empty statement is represented by \(\text{A_seqExp}(\text{NULL})\).

By using these representations for \&, \mid, and unary negation, we keep the abstract syntax data type smaller and make fewer cases for the semantic analysis phase to process. On the other hand, it becomes harder for the type-checker to give meaningful error messages that relate to the source code.

The lexer returns ID tokens with \texttt{string} values. The abstract syntax requires identifiers to have \texttt{symbol} values. The function \texttt{S_symbol} (from \texttt{symbol.h}) converts strings to symbols, and the function \texttt{S_name} converts back. The representation of symbols is discussed in Chapter 5.

\(^1\)This might not be adequate in an industrial-strength compiler. The most negative two’s complement integer of a given size cannot be represented as \(0 - i\) for any \(i\) of the same size. In floating point numbers, \(0 - x\) is not the same as \(-x\) if \(x = 0\). We will neglect these issues in the Tiger compiler.
The semantic analysis phase of the compiler will need to keep track of which local variables are used from within nested functions. The \texttt{escape} component of a \texttt{varDec} or \texttt{field} is used to keep track of this. This \texttt{escape} field is not mentioned in the parameters of the constructor function, but is always initialized to \texttt{TRUE}, which is a conservative approximation. The \texttt{field} type is used for both formal parameters and record fields; \texttt{escape} has meaning for formal parameters, but for record fields it can be ignored.

Having the \texttt{escape} fields in the abstract syntax is a “hack,” since escaping is a global, nonsyntactic property. But leaving \texttt{escape} out of the \texttt{Absyn} would require another data structure for describing escapes.

\section*{Program Abstract Syntax}

Add semantic actions to your parser to produce abstract syntax for the Tiger language.

You should turn in the file \texttt{tiger.grm}.

Supporting files available in $TIGER/chap4 include:

\begin{itemize}
  \item \texttt{absyn.h} The abstract syntax declarations for Tiger.
  \item \texttt{absyn.c} Implementation of the constructor functions.
  \item \texttt{prabsyn.[ch]} A pretty-printer for abstract syntax trees, so you can see your results.
  \item \texttt{errormsg.[ch]} As before.
  \item \texttt{lex.yy.c} Use this only if your own lexical analyzer still isn’t working.
  \item \texttt{symbol.[ch]} A module to turn strings into symbols.
  \item \texttt{makefile} As usual.
  \item \texttt{parse.[ch]} A driver to run your parser on an input file.
  \item \texttt{tiger.grm} The skeleton of a grammar specification.
\end{itemize}

\section*{Further Reading}

Many compilers mix recursive-descent parsing code with semantic-action code, as shown in Program 4.1; Gries [1971] and Fraser and Hanson [1995] are ancient and modern examples. Machine-generated parsers with semantic actions (in special-purpose “semantic-action mini-languages”) attached to the grammar productions were tried out in 1960s [Feldman and Gries 1968]; Yacc [Johnson 1975] was one of the first to permit semantic action fragments to be written in a conventional, general-purpose programming language.
The notion of *abstract syntax* is due to McCarthy [1963], who designed the abstract syntax for Lisp [McCarthy et al. 1962]. The abstract syntax was intended to be used writing programs until designers could get around to creating a concrete syntax with human-readable punctuation (instead of Lots of Irritating Silly Parentheses), but programmers soon got used to programming directly in abstract syntax.

The search for a theory of programming-language semantics, and a notation for expressing semantics in a compiler-compiler, led to ideas such as *denotational semantics* [Stoy 1977]. The denotational semanticists also advocated the separation of concrete syntax from semantics – using abstract syntax as a clean interface – because in a full-sized programming language the syntactic clutter gets in the way of understanding the semantic analysis.

**EXERCISES**

4.1 Write type declarations and constructor functions to express the abstract syntax of regular expressions.

4.2 Implement Program 4.4 as a recursive-descent parser, with the semantic actions embedded in the parsing functions.
5

Semantic Analysis

**Semantic Analysis**

The *semantic analysis* phase of a compiler connects variable definitions to their uses, checks that each expression has a correct type, and translates the abstract syntax into a simpler representation suitable for generating machine code.

### 5.1 SYMBOL TABLES

This phase is characterized by the maintenance of *symbol tables* (also called *environments*) mapping identifiers to their types and locations. As the declarations of types, variables, and functions are processed, these identifiers are bound to “meanings” in the symbol tables. When *uses* (nondefining occurrences) of identifiers are found, they are looked up in the symbol tables.

Each local variable in a program has a *scope* in which it is visible. For example, in a Tiger expression `let D in E end` all the variables, types, and functions declared in `D` are visible only until the end of `E`. As the semantic analysis reaches the end of each scope, the identifier bindings local to that scope are discarded.

An environment is a set of *bindings* denoted by the `↦` arrow. For example, we could say that the environment `σ₀` contains the bindings `{g ↦ string, a ↦ int};` meaning that the identifier `a` is an integer variable and `g` is a string variable.

Consider a simple example in the Tiger language:
Suppose we compile this program in the environment $\sigma_0$. The formal parameter declarations on line 1 give us the table $\sigma_1$ equal to $\sigma_0 + \{a \mapsto \text{int}, b \mapsto \text{int}, c \mapsto \text{int}\}$, that is, $\sigma_0$ extended with new bindings for $a$, $b$, and $c$. The identifiers in line 2 can be looked up in $\sigma_1$. At line 3, the table $\sigma_2 = \sigma_1 + \{j \mapsto \text{int}\}$ is created; and at line 4, $\sigma_3 = \sigma_2 + \{a \mapsto \text{string}\}$ is created.

How does the $+$ operator for tables work when the two environments being “added” contain different bindings for the same symbol? When $\sigma_2$ and $\{a \mapsto \text{string}\}$ map $a$ to int and string, respectively? To make the scoping rules work the way we expect them to in real programming languages, we want $\{a \mapsto \text{string}\}$ to take precedence. So we say that $X + Y$ for tables is not the same as $Y + X$; bindings in the right-hand table override those in the left.

Finally, in line 6 we discard $\sigma_3$ and go back to $\sigma_1$ for looking up the identifier $b$ in line 7. And at line 8, we discard $\sigma_1$ and go back to $\sigma_0$.

How should this be implemented? There are really two choices. In a functional style, we make sure to keep $\sigma_1$ in pristine condition while we create $\sigma_2$ and $\sigma_3$. Then when we need $\sigma_1$ again, it’s rested and ready.

In an imperative style, we modify $\sigma_1$ until it becomes $\sigma_2$. This destructive update “destroys” $\sigma_1$; while $\sigma_2$ exists, we cannot look things up in $\sigma_1$. But when we are done with $\sigma_2$, we can undo the modification to get $\sigma_1$ back again. Thus, there is a single global environment $\sigma$ which becomes $\sigma_0, \sigma_1, \sigma_2, \sigma_3, \sigma_1, \sigma_0$ at different times and an “undo stack” with enough information to remove the destructive updates. When a symbol is added to the environment, it is also added to the undo stack; at the end of scope (e.g., at line 6 or 8), symbols popped from the undo stack have their latest binding removed from $\sigma$ (and their previous binding restored).

Either the functional or imperative style of environment management can be used regardless of whether the language being compiled, or the implementation language of the compiler, is a “functional” or “imperative” or “object-oriented” language.
5.1. SYMBOL TABLES

(a) An example in ML

(b) An example in Java

**FIGURE 5.1.** Several active environments at once.

**MULTIPLE SYMBOL TABLES**

In some languages there can be several active environments at once: each module, or class, or record, in the program has a symbol table $\sigma$ of its own.

In analyzing Figure 5.1, let $\sigma_0$ be the base environment containing pre-defined functions, and let

\[
\begin{align*}
\sigma_1 &= \{a \mapsto \text{int}\} \\
\sigma_2 &= \{E \mapsto \sigma_1\} \\
\sigma_3 &= \{b \mapsto \text{int}, a \mapsto \text{int}\} \\
\sigma_4 &= \{N \mapsto \sigma_3\} \\
\sigma_5 &= \{d \mapsto \text{int}\} \\
\sigma_6 &= \{D \mapsto \sigma_5\} \\
\sigma_7 &= \sigma_2 + \sigma_4 + \sigma_6
\end{align*}
\]

In ML, the $N$ is compiled using environment $\sigma_0 + \sigma_2$ to look up identifiers; $D$ is compiled using $\sigma_0 + \sigma_2 + \sigma_4$, and the result of the analysis is $\{M \mapsto \sigma_7\}$.

In Java, forward reference is allowed (so inside $N$ the expression $D.d$ would be legal), so $E$, $N$, and $D$ are all compiled in the environment $\sigma_7$; for this program the result is still $\{M \mapsto \sigma_7\}$.

**EFFICIENT IMPERATIVE SYMBOL TABLES**

Because a large program may contain thousands of distinct identifiers, symbol tables must permit efficient lookup.
struct bucket {string key; void *binding; struct bucket *next;};

#define SIZE 109

struct bucket *table[SIZE];

unsigned int hash(char *s0)
{
    unsigned int h=0; char *s;
    for(s=s0; *s; s++)
        h = h*65599 + *s;
    return h;
}

struct bucket *Bucket(string key, void *binding, struct bucket *next) {
    struct bucket *b = checked_malloc(sizeof(*b));
    b->key=key; b->binding=binding; b->next=next;
    return b;
}

void insert(string key, void *binding) {
    int index = hash(key) % SIZE;
    table[index] = Bucket(key, binding, table[index]);
}

void *lookup(string key) {
    int index = hash(key) % SIZE;
    struct bucket *b;
    for(b=table[index]; b; b=b->next)
        if (0==strcmp(b->key,key)) return b->binding;
    return NULL;
}

void pop(string key) {
    int index = hash(key) % SIZE;
    table[index] = table[index]->next;
}

PROGRAM 5.2. Hash table with external chaining.

Imperative-style environments are usually implemented using hash tables, which are very efficient. The operation $\sigma' = \sigma + \{ a \mapsto \tau \}$ is implemented by inserting $\tau$ in the hash table with key $a$. A simple hash table with external chaining works well and supports deletion easily (we will need to delete $\{ a \mapsto \tau \}$ to recover $\sigma$ at the end of the scope of $a$).

Program 5.2 implements a simple hash table. The $i$th bucket is a linked list of all the elements whose keys hash to $i$ mod $\text{SIZE}$. 
5.1. SYMBOL TABLES

Consider \( \sigma + \{a \mapsto \tau_2\} \) when \( \sigma \) contains \( a \mapsto \tau_1 \) already. The insert function leaves \( a \mapsto \tau_1 \) in the bucket and puts \( a \mapsto \tau_2 \) earlier in the list. Then, when \( \text{pop}(a) \) is done at the end of \( a \)'s scope, \( \sigma \) is restored. Of course, \( \text{pop} \) works only if bindings are inserted and popped in a stacklike fashion.

An industrial-strength implementation would improve on this in several ways; see Exercise 5.1.

EFFICIENT FUNCTIONAL SYMBOL TABLES

In the functional style, we wish to compute \( \sigma' = \sigma + \{a \mapsto \tau\} \) in such a way that we still have \( \sigma \) available to look up identifiers. Thus, instead of “altering” a table by adding a binding to it we create a new table by computing the “sum” of an existing table and a new binding. Similarly, when we add \( 7 + 8 \) we don’t alter the 7 by adding 8 to it; we create a new value 15 – and the 7 is still available for other computations.

However, nondestructive update is not efficient for hash tables. Figure 5.3a shows a hash table implementing mapping \( m_1 \). It is fast and efficient to add \( \text{mouse} \) to the fifth slot; just make the \( \text{mouse} \) record point at the (old) head of the fifth linked list, and make the fifth slot point to the \( \text{mouse} \) record. But then we no longer have the mapping \( m_1 \): we have destroyed it to make \( m_2 \). The other alternative is to copy the array, but still share all the old buckets, as shown in Figure 5.3b. But this is not efficient: the array in a hash table should be quite large, proportional in size to the number of elements, and we cannot afford to copy it for each new entry in the table.

By using binary search trees we can perform such “functional” additions to search trees efficiently. Consider, for example, the search tree in Figure 5.4.
which represents the mapping

\[ m_1 = \{ bat \mapsto 1, \hspace{1em} camel \mapsto 2, \hspace{1em} dog \mapsto 3 \}. \]

We can add the binding mouse \mapsto 4, creating the mapping \( m_2 \) without destroying the mapping \( m_1 \), as shown in Figure 5.4b. If we add a new node at depth \( d \) of the tree, we must create \( d \) new nodes – but we don’t need to copy the whole tree. So creating a new tree (that shares some structure with the old one) can be done as efficiently as looking up an element: in \( \log(n) \) time for a balanced tree of \( n \) nodes. This is an example of a persistent data structure; a persistent red-black tree can be kept balanced to guarantee \( \log(n) \) access time (see Exercise 1.1c, and also page 292).

**SYMBOLS IN THE Tiger COMPILER**

The hash table of Program 5.2 must examine every character of the string \( s \) for the hash operation, and then again each time it compares \( s \) against a string in the \( ith \) bucket. To avoid unnecessary string comparisons, we can convert each string to a symbol, so that all the different occurrences of any given string convert to the same symbol object.

The Symbol module implements symbols and has these important properties:

- Comparing two symbols for equality is very fast (just pointer or integer comparison).
5.1. SYMBOL TABLES

/* symbol.h */
typedef struct S_symbol_ *S_symbol;
S_symbol S_Symbol(string);
string S_name(S_symbol);

typedef struct TAB_table_ *S_table;
S_table S_empty(void);
void S_enter(S_table t, S_symbol sym, void *value);
void *S_look(S_table t, S_symbol sym);
void S_beginScope(S_table t);
void S_endScope(S_table t);

PROGRAM 5.5. symbol.h, the interface for symbols and symbol tables.

- Extracting an integer hash-key is very fast (in case we want to make hash table mapping symbols to something else). We will use the Symbol-pointer itself as the integer hash-key.
- Comparing two symbols for “greater-than” (in some arbitrary ordering) is very fast (in case we want to make binary search trees).

Even if we intend to make functional-style environments mapping symbols to bindings, we can use a destructive-update hash table to map strings to symbols: we need this to make sure the second occurrence of “abc” maps to the same symbol as the first occurrence. Program 5.5 shows the interface of the Symbol module.

Environments are implemented in symbol.c as S_Tables mapping S_Symbols to bindings. We want different notions of binding for different purposes in the compiler – type bindings for types, value bindings for variables and functions – so we let the bindings be void*, though in any given table every binding should be a type binding, or every binding should be a value binding, and so on.

To implement S_Symbol (Program 5.6), we use hashing much as in Program 5.2.

For the Tiger compiler in C we choose to use destructive-update environments. The S_empty() function of the symbol module makes a new S_Table.

To handle the “undo” requirements of destructive update, the interface function S_beginScope remembers the current state of the table, and S_endScope restores the table to where it was at the most recent beginScope that has not already been ended.

An imperative table is implemented using a hash table. When the binding
#include <stdio.h>
#include <string.h>
#include "util.h"
#include "symbol.h"

struct S_symbol_ {string name; S_symbol next;};

static S_symbol mksymbol(string name, S_symbol next) {
    S_symbol s = checked_malloc(sizeof(*s));
    s->name = name; s->next = next;
    return s;
}

#define SIZE 109
static S_symbol hashtable[SIZE];

static unsigned int hash(char *s0) {... as in Program 5.2}

S_symbol S_Symbol(string name) {
    int index = hash(name) % SIZE;
    S_symbol sym = hashtable[index], sym;
    for(sym=syms; sym; sym=sym->next)
        if (0==strcmp(sym->name,name)) return sym;
    sym = mksymbol(name,syms);
    hashtable[index] = sym;
    return sym;
}

string S_name(S_symbol sym) {
    return sym->name;
}

S_table S_empty(void) { return TAB_empty(); }
void S_enter(S_table t, S_symbol sym, void *value){TAB_enter(t,sym,value);}
void *S_look(S_table t, S_symbol sym) {return TAB_look(t,sym);}

static struct S_symbol_ marksym = {"<mark>",0};
void S_beginScope(S_table t) { S_enter(t,&marksym,NULL); }
void S_endScope(S_table t) {
    S_symbol s;
    do s=TAB_pop(t); while (s != &marksym);
}

:  

PROGRAM 5.6. Symbol table (symbol.c) implementation.
5.1. SYMBOL TABLES

/* table.h - generic hash table */

typedef struct TAB_table_ *TAB_table;

TAB_table TAB_empty(void);  /* Make a new table */

void TAB_enter(TAB_table t, void *key, void *value); /* Enter key→value into table t, shadowing any previous binding for key. */

void *TAB_look(TAB_table t, void *key);    /* Look up key in t */

void *TAB_pop(TAB_table t);    /* Pop the most recent binding and return its key. This may expose another binding for the same key. */

---

**PROGRAM 5.7.** The table.h interface.

\[ x \mapsto b \] is entered \((S_{\text{enter}}(\text{table}, x, b))\), \(x\) is hashed into an index \(i\), and a Binder object \(x \mapsto b\) is placed at the head of the linked list for the \(i\)th bucket. If the table had already contained a binding \(x \mapsto b'\), that would still be in the bucket, hidden by \(x \mapsto b\). This is important because it will support the implementation of undo (beginScope and endScope).

The key \(x\) is not a character string, but is the \(S_{\text{symbol}}\) pointer itself. Module table implements generic pointer hash tables (TAB_table), mapping a key type (void*) to a binding type (also void*). Program 5.7 shows the table.h interface. Since using so many void*’s can easily lead to programming mistakes, the symbol module will encapsulate these operations with functions \(S_{\text{empty}}, S_{\text{enter}}, \) and so on, where the key type is \(S_{\text{symbol}}\) instead of void*.

There must also be an auxiliary stack, showing in what order the symbols were “pushed” into the symbol table. When \(x \mapsto b\) is entered, then \(x\) is pushed onto this stack. A beginScope operation pushes a special marker onto the stack. Then, to implement endScope, symbols are popped off the stack down to and including the topmost marker. As each symbol is popped, the head binding in its bucket is removed.

The auxiliary stack can be integrated into the Binder by having a global variable top showing the most recent Symbol bound in the table. Then “pushing” is accomplished by copying top into the prevtop field of the Binder. Thus, the “stack” is threaded through the binders.
FUNCTIONAL-STYLE SYMBOL TABLES

If we wanted to use functional-style symbol tables in the Tiger compiler, the \texttt{S\_table} interface might look like this:

\begin{verbatim}
typedef struct TAB_table_ *S_table;
S_table S_empty(void);
S_table S_enter(S_table t, S_symbol sym, void *value);
void *S_look(S_table t, S_symbol sym);
\end{verbatim}

The \texttt{S\_enter} function would return a new table without modifying the old one. We wouldn’t need \texttt{beginScope} and \texttt{endScope}, because we could keep an old version of the table even as we use the new version.

5.2 BINDINGS FOR THE Tiger COMPILER

With what should a symbol table be filled – that is, what is a binding? Tiger has two separate name spaces, one for types and the other for functions and variables. A type identifier will be associated with a \texttt{Ty\_ty}. The \texttt{Types} module describes the structure of types, as shown in Program 5.8.

The primitive types in Tiger are \texttt{int} and \texttt{string}; all types are either primitive types or constructed using records and arrays from other (primitive, record, or array) types.

Record types carry additional information: the names and types of the fields. Arrays work just like records: the \texttt{Ty\_array} constructor carries the type of the array elements.

For array and record types, there is another implicit piece of information carried by the \texttt{Ty\_array} or \texttt{Ty\_record} object: the address of the object itself. That is, every Tiger-language “record type expression” creates a new (and different) record type, even if the fields are similar. We can encode this in our compiler by using \texttt{==} to compare record types to see if they are the same.

If we were compiling some other language, we might have the following as a legal program:

\begin{verbatim}
let type a = {x: int, y: int}
  type b = {x: int, y: int}
  var i : a := ...
  var j : b := ...
in i := j
end
\end{verbatim}
5.2. BINDINGS FOR THE TIGER COMPILER

/* types.h */
typedef struct Ty_ty_ *Ty_ty;
typedef struct Ty_tyList_ *Ty_tyList;
typedef struct Ty_field_ *Ty_field;
typedef struct Ty_fieldList_ *Ty_fieldList;

struct Ty_ty_ {enum {Ty_record, Ty_nil, Ty_int, Ty_string,
    Ty_array, Ty_name, Ty_void} kind;
    union {Ty_fieldList record;
        Ty_ty array;
        struct {S_symbol sym; Ty_ty ty;} name;
    } u;
};

Ty_ty Ty_Nil(void);
Ty_ty Ty_Int(void);
Ty_ty Ty_String(void);
Ty_ty Ty_Void(void);

Ty_ty Ty_Record(Ty_fieldList fields);
Ty_ty Ty_Array(Ty_ty ty);
Ty_ty Ty_Name(S_symbol sym, Ty_ty ty);

struct Ty_tyList_ {Ty_ty head; Ty_tyList tail};
Ty_tyList Ty_TyList(Ty_ty head, Ty_tyList tail);

struct Ty_field_ {S_symbol name; Ty_ty ty};
Ty_field Ty_Field(S_symbol name, Ty_ty ty);

struct Ty_fieldList_ {Ty_field head; Ty_fieldList tail};
Ty_fieldList Ty_FieldList(Ty_field head, Ty_fieldList tail);

PROGRAM 5.8. Module Types.

This is illegal in Tiger, but would be legal in a language where structurally equivalent types are interchangeable. To test type equality in a compiler for such a language, we would need to examine record types field by field, recursively.

However, the following Tiger program is legal, since type c is the same as type a:
CHAPTER FIVE. SEMANTIC ANALYSIS

let type a = {x: int, y: int}
  type c = a
  var i : a := ...
  var j : c := ...
  in i := j
end

It is not the type declaration that causes a new and distinct type to be made, but the type expression \{x:int,y:int\}.

In Tiger, the expression \texttt{nil} belongs to any record type. We handle this exceptional case by inventing a special “nil” type. There are also expressions that return “no value,” so we invent a type \texttt{Ty_Void}.

When processing mutually recursive types, we will need a place-holder for types whose name we know but whose definition we have not yet seen. We can create a \texttt{Ty_Name(sym,NULL)} as a place-holder for the type-name \texttt{sym} and later on fill in the \texttt{ty} field of the \texttt{Ty_Name} object with the type that \texttt{sym} is supposed to stand for.

ENVIRONMENTS
The table type of the \texttt{Symbol} module provides mappings from symbols to bindings. Thus, we will have a type \texttt{environment} and a value \texttt{environment}. The following Tiger program demonstrates that one environment will not suffice:

let type a = int
  var a : a := 5
  var b : a := a
  in b+a
end

The symbol \texttt{a} denotes the type “a” in syntactic contexts where type identifiers are expected, and the variable “a” in syntactic contexts where variables are expected.

For a type identifier, we need to remember only the type that it stands for. Thus a type environment is a mapping from symbol to \texttt{Ty_ty} – that is, a \texttt{S_table} whose \texttt{S_lookup} function always returns \texttt{Ty_ty} pointers. As shown in Figure 5.9, the \texttt{Env} module will contain a \texttt{base_tenv} value – the “base” or “predefined” type environment. This maps the symbol \texttt{int} to \texttt{Ty_Int} and \texttt{string} to \texttt{Ty_String}.

We need to know, for each value identifier, whether it is a variable or a function; if a variable, what is its type; if a function, what are its parameter and result types, and so on. The type \texttt{enventry} holds all this information, as
5.3 TYPE-CHECKING EXPRESSIONS

typedef struct E_enventry_ *E_enventry;

struct E_enventry_ {enum {E_varEntry, E_funEntry} kind;
    union {struct {Ty_ty ty;} var;
        struct {Ty_tyList formals; Ty_ty result;} fun;
    } u;
};

E_enventry E_VarEntry(Ty_ty ty);
E_enventry E_FunEntry(Ty_tyList formals, Ty_ty result);

S_table E_base_tenv(void); /* Ty_ty environment */
S_table E_base_venv(void); /* E_enventry environment */

FIGURE 5.9. env.h: Environments for type-checking.

shown in Figure 5.9; and a value environment is a mapping from symbol to environment-entry.

A variable will map to a VarEntry telling its type. When we look up a function we will obtain a FunEntry containing:

- **formals** The types of the formal parameters.
- **result** The type of result returned by the function (or UNIT).

For type-checking, only formals and result are needed; we will add other fields later for translation into intermediate representation.

The base_venv environment contains bindings for predefined functions flush, ord, chr, size, and so on, described in Appendix A.

Environments are used during the type-checking phase.

As types, variables, and functions are declared, the type-checker augments the environments; they are consulted for each identifier that is found during processing of expressions (type-checking, intermediate code generation).

5.3 TYPE-CHECKING EXPRESSIONS

The Semant module (semant.h, semant.c) performs semantic analysis – including type-checking – of abstract syntax. It contains four functions that recur over syntax trees:

- struct expty transVar(S_table venv, S_table tenv, A_var v);
- struct expty transExp(S_table venv, S_table tenv, A_exp a);
- void transDec(S_table venv, S_table tenv, A_dec d);
- struct Ty_ty transTy (S_table tenv, A_ty a);
CHAPTER FIVE. SEMANTIC ANALYSIS

The type-checker is a recursive function of the abstract syntax tree. I will call it transExp because we will later augment this function not only to type-check but also to translate the expressions into intermediate code. The arguments of transExp are a value environment venv, a type environment tenv, and an expression. The result will be an expty, containing a translated expression and its Tiger-language type:

```c
struct expty {Tr_exp exp; Ty_ty ty;};
struct expty expTy(Tr_exp exp, Ty_ty ty) {
  struct expty e; e.exp=exp; e.ty=ty; return e;
}
```

where Tr_exp is the translation of the expression into intermediate code, and ty is the type of the expression.

To avoid a discussion of intermediate code at this point, let us define a dummy Translate module:

```c
typedef void *Tr_exp;
```

and use NULL for every value. We will flesh out the Tr_exp type in Chapter 7.

Let’s take a very simple case: an addition expression $e_1 + e_2$. In Tiger, both operands must be integers (the type-checker must check this) and the result will be an integer (the type-checker will return this type).

In most languages, addition is overloaded: the + operator stands for either integer addition or real addition. If the operands are both integers, the result is integer; if the operands are both real, the result is real. And in many languages if one operand is an integer and the other is real, the integer is implicitly converted into a real, and the result is real. Of course, the compiler will have to make this conversion explicit in the machine code it generates.

Tiger’s nonoverloaded type-checking is easy to implement:
5.3. TYPE-CHECKING EXPRESSIONS

```c
struct expty transExp(S_table venv, S_table tenv, A_exp a) {
    switch(a->kind) {
        :
    case A_opExp: {
        A_oper oper = a->u.op.oper;
        struct expty left = transExp(venv, tenv, a->u.op.left);
        struct expty right = transExp(venv, tenv, a->u.op.right);
        if (oper==A_plusOp) {
            if (left.ty->kind!=Ty_int)
                EM_error(a->u.op.left->pos, "integer required");
            if (right.ty->kind!=Ty_int)
                EM_error(a->u.op.right->pos, "integer required");
            return expTy(NULL, Ty_Int());
        }
        :
    }
    assert(0); /* should have returned from some clause of the switch */
}
```

This works well enough, although we have not yet written the cases for other kinds of expressions (and operators other than +), so when the recursive calls on `left` and `right` are executed, an assertion will fail. You can fill in the other cases yourself (see page 122).

**TYPE-CHECKING VARIABLES, SUBSCRIPTS, AND FIELDS**

The function `transVar` recurs over `A_var` expressions just as `transExp` recurs over `A_exp`.

```c
struct expty transVar(S_table venv, S_table tenv, A_var v) {
    switch(v->kind) {
        case A_simpleVar: {
            E_enventry x = S_look(venv, v->u.simple);
            if (x && x->kind==E_varEntry)
                return expTy(NULL, actual_ty(x->u.var.ty));
            else {EM_error(v->pos,"undefined variable %s", S_name(v->u.simple));
                return expTy(NULL, Ty_Int());}
        }
        case A_fieldVar:
            :
    }
```

The clause of `transVar` that type-checks a `SimpleVar` illustrates the use of environments to look up a variable binding. If the identifier is present in the
environment and is bound to a VarEntry (not a FunEntry), then its type is
the one given in the VarEntry (Figure 5.9).

The type in the VarEntry will sometimes be a “Name type” (Program 5.8),
and all the types returned from transExp should be “actual” types (with the
names traced through to their underlying definitions). It is therefore useful to
have a function, perhaps called actual_ty, to skip past all the Names. The
result will be a Ty_ty that is not a Name, though if it is a record or array type
it might contain Name types to describe its components.

For function calls, it is necessary to look up the function identifier in the en-
vironment, yielding a FunEntry containing a list of parameter types. These
types must then be matched against the arguments in the function-call expres-
sion. The FunEntry also gives the result type of the function, which becomes
the type of the function call as a whole.

Every kind of expression has its own type-checking rules, but in all the
cases I have not already described the rules can be derived by reference to the

### 5.4 TYPE-CHECKING DECLARATIONS

Environments are constructed and augmented by declarations. In Tiger, decla-
rations appear only in a let expression. Type-checking a let is easy enough,
using transDec to translate declarations:

```c
struct expty transExp(S_table venv, S_table tenv, A_exp a) {
    switch(a->kind) {
        :
        case A_letExp: {
            struct expty exp;
            A_decList d;
            S_beginScope(venv);
            S_beginScope(tenv);
            for (d = a->u.let.decs; d; d=d->tail)
                transDec(venv,tenv,d->head);
            exp = transExp(venv,tenv,a->u.let.body);
            S_endScope(tenv);
            S_endScope(venv);
            return exp;
        }
        :
    }
}
```
5.4. TYPE-CHECKING DECLARATIONS

Here \texttt{transExp} marks the current “state” of the environments by calling \texttt{beginScope();} calls \texttt{transDec} to augment the environments (\texttt{venv, tenv}) with new declarations; translates the body expression; then reverts to the original state of the environments using \texttt{endScope();}.

**VARIABLE DECLARATIONS**

In principle, processing a declaration is quite simple: a declaration augments an environment by a new binding, and the augmented environment is used in the processing of subsequent declarations and expressions.

The only problem is with (mutually) recursive type and function declarations. So we will begin with the special case of nonrecursive declarations.

For example, it is quite simple to process a variable declaration without a type constraint, such as \texttt{var \textit{x} := \textit{exp}.}

```c
void transDec(S_table venv, S_table tenv, A_dec d) {
    switch(d->kind) {
    case A_varDec: {
        struct expty e = transExp(venv,tenv,d->u.var.init);
        S_enter(venv, d->u.var.var, E_VarEntry(e.ty));
    }
    
    ...
    }
}
```

What could be simpler? In practice, if \texttt{d->typ} is present, as in

```c
var \textit{x} : \textit{type-id} := \textit{exp}
```

it will be necessary to check that the constraint and the initializing expression are compatible. Also, initializing expressions of type \texttt{Ty Nil} must be constrained by a \texttt{Ty_Record} type.

**TYPE DECLARATIONS**

Nonrecursive type declarations are not too hard:

```c
void transDec(S_table venv, S_table tenv, A_dec d) {
    ...
    case A_typeDec: {
        S_enter(tenv, d->u.type->head->name, transTy(d->u.type->head->ty));
    }
    ...
}
```
The \texttt{transTy} function translates type expressions as found in the abstract syntax (\texttt{A\_ty}) to the digested type descriptions that we will put into environments (\texttt{Ty\_ty}). This translation is done by recurring over the structure of an \texttt{A\_ty}, turning \texttt{A\_recordTy} into \texttt{Ty\_Record}, etc. While translating, \texttt{transTy} just looks up any symbols it finds in the type environment \texttt{tenv}.

The program fragment shown is not very general, since it handles only a type-declaration list of length 1, that is, a singleton list of mutually recursive type declarations. The reader is invited to generalize this to lists of arbitrary length.

\section*{FUNCTION DECLARATIONS}

Function declarations are a bit more tedious:

\begin{verbatim}
void transDec(S_table venv, S_table tenv, A_dec d) {
    switch(d->kind) {
    case A_functionDec: {
        A_fundec f = d->u.function->head;
        Ty_ty resultTy = S_look(tenv,f->result);
        Ty_tyList formalTys = makeFormalTyList(tenv,f->params);
        S_enter(venv,f->name,E_FunEntry(formalTys,resultTy));
        S_beginScope(venv);
        {A_fieldList l; Ty_tyList t;
         for(l=f->params, t=formalTys; l; l=l->tail, t=t->tail)
             S_enter(venv,l->head->name,E_VarEntry(t->head));
        }
        transExp(venv, tenv, d->u.function->body);
        S_endScope(venv);
        break;
    }
    ...
}
\end{verbatim}

This is a very stripped-down implementation: it handles only the case of a single function; it does not handle recursive functions; it handles only a function with a result (a function, not a procedure); it doesn’t handle program errors such as undeclared type identifiers, etc; and it doesn’t check that the type of the body expression matches the declared result type.

So what does it do? Consider the Tiger declaration

\begin{verbatim}
function f(a: ta, b: tb) : rt = body.
\end{verbatim}

First, \texttt{transDec} looks up the result-type identifier \texttt{rt} in the type environment. Then it calls the local function \texttt{makeFormalTyList}, which traverses
the list of formal parameters and returns a list of their types (by looking each parameter type-id in the \textit{tenv}). Now \texttt{transDec} has enough information to construct the \texttt{FunEntry} for this function and enter it in the value environment.

Next, the formal parameters are entered (as \texttt{VarEntries}) into the value environment; this environment is used to process the \textit{body} (with the \texttt{transExp} function). Finally, \texttt{endScope()} discards the formal-parameters (but not the \texttt{FunEntry}) from the environment; the resulting environment is used for processing expressions that are allowed to call the function \texttt{f}.

**RECURSIVE DECLARATIONS**

The implementations above will not work on recursive type or function declarations, because they will encounter undefined type or function identifiers (in \texttt{transTy} for recursive record types or \texttt{transExp(body)} for recursive functions).

The solution for a set of mutually recursive things (types or functions) \(t_1, ..., t_n\) is to put all the “headers” in the environment first, resulting in an environment \(e_1\). Then process all the “bodies” in the environment \(e_1\). During processing of the bodies it will be necessary to look up some of the newly defined names, but they will in fact be there – though some of them may be empty headers without bodies.

What is a header? For a type declaration such as

\begin{verbatim}
  type list = {first: int, rest: list}
\end{verbatim}

the header is approximately \texttt{type list =}.

To enter this header into an environment \texttt{tenv} we can use a \texttt{Ty_Name} type with an empty binding:

\begin{verbatim}
  S_enter(tenv, name, Ty_Name(name,NULL));
\end{verbatim}

Now, we can call \texttt{transTy} on the “body” of the type declaration, that is, on the record expression \{\texttt{first: int, rest: list}\}.

It’s important that \texttt{transTy} stop as soon as it gets to any \texttt{Ty_Name} type. If, for example, \texttt{transTy} behaved like \texttt{actual_ty} and tried to look “through” the \texttt{Ty_Name} type bound to the identifier \texttt{list}, all it would find (in this case) would be \texttt{NULL} – which it is certainly not prepared for. This \texttt{NULL} can be replaced only by a valid type after the entire \{\texttt{first:int, rest:list}\} is translated.
The type that transTy returns can then be assigned into the ty field within the Ty_Name struct. Now we have a fully complete type environment, on which actual_ty will not have a problem.

Every cycle in a set of mutually recursive type declarations must pass through a record or array declaration; the declaration

```plaintext
type a = b
type b = d
type c = a
type d = a
```

contains an illegal cycle \( a \rightarrow b \rightarrow d \rightarrow a \). Illegal cycles should be detected by the type-checker.

Mutually recursive functions are handled similarly. The first pass gathers information about the _header_ of each function (function name, formal parameter list, return type) but leaves the bodies of the functions untouched. In this pass, the _types_ of the formal parameters are needed, but not their names (which cannot be seen from outside the function).

The second pass processes the bodies of all functions in the mutually recursive declaration, taking advantage of the environment augmented with all the function headers. For each body, the formal parameter list is processed again, this time entering the parameters as VarEntries in the value environment.

**PROGRAM**

**TYPE-CHECKING**

Write a type-checking phase for your compiler, a module `semant.c` matching the following header file:

```c
/* semant.h */
void SEM_transProg(A_exp exp);
```

that type-checks an abstract syntax tree and produces any appropriate error messages about mismatching types or undeclared identifiers.

Also provide the implementation of the `Env` module described in this chapter. Make a module `Main` that calls the parser, yielding an `A_exp`, and then calls `SEM_transProg` on this expression.

You must use precisely the `Absyn` interface described in Figure 4.7, but you are free to follow or ignore any advice given in this chapter about the internal organization of the `Semant` module.

You’ll need your parser that produces abstract syntax trees. In addition, supporting files available in `$TIGER/chap5` include:
types.h, types.c  Describes data types of the Tiger language.

and other files as before. Modify the makefile from the previous exercise as necessary.

**Part a.** Implement a simple type-checker and declaration processor that does not handle recursive functions or recursive data types (forward references to functions or types need not be handled). Also don’t bother to check that each break statement is within a for or while statement.

**Part b.** Augment your simple type-checker to handle recursive (and mutually recursive) functions; (mutually) recursive type declarations; and correct nesting of break statements.

---

**EXERCISES**

5.1 Improve the hash table implementation of Program 5.2:

a. Double the size of the array when the average bucket length grows larger than 2 (so table is now a pointer to a dynamically allocated array). To double an array, allocate a bigger one and rehash the contents of the old array; then discard the old array.

b. Allow for more than one table to be in use by making the table a parameter to insert and lookup.

c. Hide the representation of the table type inside an abstraction module, so that clients are not tempted to manipulate the data structure directly (only through the insert, lookup, and pop operations).

***5.2*** In many applications, we want a + operator for environments that does more than add one new binding: instead of $\sigma' = \sigma + \{a \mapsto \tau\}$, we want $\sigma' = \sigma_1 + \sigma_2$, where $\sigma_1$ and $\sigma_2$ are arbitrary environments (perhaps overlapping, in which case bindings in $\sigma_2$ take precedence).

We want an efficient algorithm and data structure for environment “adding.” Balanced trees can implement $\sigma + \{a \mapsto \tau\}$ efficiently (in $\log(N)$ time, where $N$ is the size of $\sigma$), but take $O(N)$ to compute $\sigma_1 + \sigma_2$, if $\sigma_1$ and $\sigma_2$ are both about size $N$.

To abstract the problem, solve the general nondisjoint integer-set union prob-
lem. The input is a set of commands of the form,

\[
\begin{align*}
s_1 &= \{4\} & \text{(define singleton set)} \\
s_2 &= \{7\} \\
s_3 &= s_1 \cup s_2 & \text{(nondestructive union)} \\
s_4 &= s_1 \cup s_3 \\
s_5 &= \{9\} \\
s_6 &= s_4 \cup s_5 \\
s_7 &\in s_2
\end{align*}
\]

An efficient algorithm is one that can process an input of \( N \) commands, answering all membership queries, in less than \( o(N^2) \) time.

*a.* Implement an algorithm that is efficient when a typical set union \( a \leftarrow b \cup c \) has \( b \) much smaller than \( c \) [Brown and Tarjan 1979].

***b.* Design an algorithm that is efficient even in the worst case, or prove that this can’t be done (see Lipton et al. [1997] for a lower bound in a restricted model).

*5.3* The Tiger language definition states that every cycle of type definitions must go through a record or array. But if the compiler forgets to check for this error, nothing terrible will happen. Explain why.
6 Activation Records

**stack**: an orderly pile or heap

*Webster’s Dictionary*

In almost any modern programming language, a function may have *local* variables that are created upon entry to the function. Several invocations of the function may exist at the same time, and each invocation has its own *instantiations* of local variables.

In the Tiger function,

```tiger
function f(x: int) : int =
  let var y := x+x
  in if y < 10
      then f(y)
      else y-1
  end
```

a new instantiation of \( x \) is created (and initialized by \( f \)'s caller) each time that \( f \) is called. Because there are recursive calls, many of these \( x \)'s exist simultaneously. Similarly, a new instantiation of \( y \) is created each time the body of \( f \) is entered.

In many languages (including C, Pascal, and Tiger), local variables are destroyed when a function returns. Since a function returns only after all the functions it has called have returned, we say that function calls behave in last-in-first-out (LIFO) fashion. If local variables are created on function entry and destroyed on function exit, then we can use a LIFO data structure – a stack – to hold them.
CHAPTER SIX. ACTIVATION RECORDS

fun f(x) =
  let fun g(y) = x+y
  in g
  end

val h = f(3)
val j = f(4)
val z = h(5)
val w = j(7)

(a) Written in ML

int (*)() f(int x) {
  int g(int y) {return x+y;}
  return g;
}

int (*h)() = f(3);
int (*j)() = f(4);
int z = h(5);
int w = j(7);

(b) Written in pseudo-C

PROGRAM 6.1. An example of higher-order functions.

HIGHER-ORDER FUNCTIONS

But in languages supporting both nested functions and function-valued variables, it may be necessary to keep local variables after a function has returned! Consider Program 6.1: This is legal in ML, but of course in C one cannot really nest the function g inside the function f.

When f(3) is executed, a new local variable x is created for the activation of function f. Then g is returned as the result of f(x); but g has not yet been called, so y is not yet created.

At this point f has returned, but it is too early to destroy x, because when h(5) is eventually executed it will need the value x = 3. Meanwhile, f(4) is entered, creating a different instance of x, and it returns a different instance of g in which x = 4.

It is the combination of nested functions (where inner functions may use variables defined in the outer functions) and functions returned as results (or stored into variables) that causes local variables to need lifetimes longer than their enclosing function invocations.

Pascal (and Tiger) have nested functions, but they do not have functions as returnable values. C has functions as returnable values, but not nested functions. So these languages can use stacks to hold local variables.

ML, Scheme, and several other languages have both nested functions and functions as returnable values (this combination is called higher-order functions). So they cannot use stacks to hold all local variables. This complicates the implementation of ML and Scheme – but the added expressive power of higher-order functions justifies the extra implementation effort.

For the remainder of this chapter we will consider languages with stackable
6.1. STACK FRAMES

local variables and postpone discussion of higher-order functions to Chapter 15.

6.1 STACK FRAMES

The simplest notion of a stack is a data structure that supports two operations, \emph{push} and \emph{pop}. However, it turns out that local variables are pushed in large batches (on entry to functions) and popped in large batches (on exit). Furthermore, when local variables are created they are not always initialized right away. Finally, after many variables have been pushed, we want to continue accessing variables deep within the stack. So the abstract \emph{push} and \emph{pop} model is just not suitable.

Instead, we treat the stack as a big array, with a special register – the stack pointer – that points at some location. All locations beyond the stack pointer are considered to be garbage, and all locations before the stack pointer are considered to be allocated. The stack usually grows only at the entry to a function, by an increment large enough to hold all the local variables for that function, and, just before the exit from the function, shrinks by the same amount. The area on the stack devoted to the local variables, parameters, return address, and other temporaries for a function is called the function’s \emph{activation record} or \emph{stack frame}. For historical reasons, run-time stacks usually start at a high memory address and grow toward smaller addresses. This can be rather confusing: stacks grow downward and shrink upward, like icicles.

The design of a frame layout takes into account the particular features of an instruction set architecture and the programming language being compiled. However, the manufacturer of a computer often prescribes a “standard” frame layout to be used on that architecture, where possible, by all compilers for all programming languages. Sometimes this layout is not the most convenient one for a particular programming language or compiler. But by using the “standard” layout, we gain the considerable benefit that functions written in one language can call functions written in another language.

Figure 6.2 shows a typical stack frame layout. The frame has a set of \emph{incoming arguments} (technically these are part of the previous frame but they are at a known offset from the frame pointer) passed by the caller. The return address is created by the CALL instruction and tells where (within the calling function) control should return upon completion of the current function. Some local variables are in this frame; other local variables are kept in

</tbody>
</table>
machine registers. Sometimes a local variable kept in a register needs to be saved into the frame to make room for other uses of the register; there is an area in the frame for this purpose. Finally, when the current function calls other functions, it can use the outgoing argument space to pass parameters.

THE FRAME POINTER
Suppose a function \( g(\ldots) \) calls the function \( f(a_1, \ldots, a_n) \). We say \( g \) is the caller and \( f \) is the callee. On entry to \( f \), the stack pointer points to the first argument that \( g \) passes to \( f \). On entry, \( f \) allocates a frame by simply subtracting the frame size from the stack pointer \( SP \).

The old \( SP \) becomes the current frame pointer \( FP \). In some frame layouts, \( FP \) is a separate register; the old value of \( FP \) is saved in memory (in the frame) and the new \( FP \) becomes the old \( SP \). When \( f \) exits, it just copies \( FP \) back to \( SP \) and fetches back the saved \( FP \). This arrangement is useful if \( f \)'s frame size can vary, or if frames are not always contiguous on the stack. But if the frame size is fixed, then for each function \( f \) the \( FP \) will always differ from \( SP \) by a known constant, and it is not necessary to use a register for \( FP \) at all – \( FP \) is a “fictional” register whose value is always \( SP + \text{framesize} \).

Why talk about a frame pointer at all? Why not just refer to all variables, parameters, etc. by their offset from \( SP \), if the frame size is constant? The frame size is not known until quite late in the compilation process, when the number of memory-resident temporaries and saved registers is determined. But it is useful to know the offsets of formal parameters and local variables much earlier. So, for convenience, we still talk about a frame pointer. And we put the formals and locals right near the frame pointer at offsets that are known early; the temporaries and saved registers go farther away, at offsets that are known later.

REGISTERS
A modern machine has a large set of registers (typically 32 of them). To make compiled programs run fast, it’s useful to keep local variables, intermediate results of expressions, and other values in registers instead of in the stack frame. Registers can be directly accessed by arithmetic instructions; on most machines, accessing memory requires separate load and store instructions. Even on machines whose arithmetic instructions can access memory, it is faster to access registers.

A machine (usually) has only one set of registers, but many different procedures and functions need to use registers. Suppose a function \( f \) is using
register \( r \) to hold a local variable and calls procedure \( g \), which also uses \( r \) for its own calculations. Then \( r \) must be saved (stored into a stack frame) before \( g \) uses it and restored (fetched back from the frame) after \( g \) is finished using it. But is it \( f \)’s responsibility to save and restore the register, or \( g \)’s? We say that \( r \) is a caller-save register if the caller (in this case, \( f \)) must save and restore the register, and \( r \) is callee-save if it is the responsibility of the callee (in this case, \( g \)).

On most machine architectures, the notion of caller-save or callee-save register is not something built into the hardware, but is a convention described in the machine’s reference manual. On the MIPS computer, for example, registers 16–23 are preserved across procedure calls (callee-save), and all other registers are not preserved across procedure calls (caller-save).

Sometimes the saves and restores are unnecessary. If \( f \) knows that the value of some variable \( x \) will not be needed after the call, it may put \( x \) in a caller-save register and not save it when calling \( g \). Conversely, if \( f \) has a local variable \( i \) that is needed before and after several function calls, it may put \( i \) in some callee-save register \( r_i \) and, save \( r_i \) just once (upon entry to \( f \)) and fetch it back just once (before returning from \( f \)). Thus, the wise selection of a caller-save or callee-save register for each local variable and temporary can reduce the number of stores and fetches a program executes. We will rely on our register allocator to choose the appropriate kind of register for each local variable and temporary value.

**PARAMETER PASSING**

On most machines whose calling conventions were designed in the 1970s, function arguments were passed on the stack.\(^1\) But this causes needless memory traffic. Studies of actual programs have shown that very few functions have more than four arguments, and almost none have more than six. Therefore, parameter-passing conventions for modern machines specify that the first \( k \) arguments (for \( k = 4 \) or \( k = 6 \), typically) of a function are passed in registers \( r_p, \ldots, r_{p+k-1} \), and the rest of the arguments are passed in memory.

Now, suppose \( f (a_1, \ldots, a_n) \) (which received its parameters in \( r_1, \ldots, r_n \), for example) calls \( h(z) \). It must pass the argument \( z \) in \( r_1 \); so \( f \) saves the old contents of \( r_1 \) (the value \( a_1 \)) in its stack frame before calling \( h \). But there is the memory traffic that was supposedly avoided by passing arguments in registers! How has the use of registers saved any time?

\(^1\)Before about 1960, they were passed not on the stack but in statically allocated blocks of memory, which precluded the use of recursive functions.
6.1. STACK FRAMES

There are four answers, any or all of which can be used at the same time:

1. Some procedures don’t call other procedures – these are called leaf procedures. What proportion of procedures are leaves? Well, if we make the (optimistic) assumption that the average procedure calls either no other procedures or calls at least two others, then we can describe a “tree” of procedure calls in which there are more leaves than internal nodes. This means that most procedures called are leaf procedures.

Leaf procedures need not write their incoming arguments to memory. In fact, often they don’t need to allocate a stack frame at all. This is an important savings.

2. Some optimizing compilers use interprocedural register allocation, analyzing all the functions in an entire program at once. Then they assign different procedures different registers in which to receive parameters and hold local variables. Thus \( f(x) \) might receive \( x \) in \( r_1 \), but call \( h(z) \) with \( z \) in \( r_7 \).

3. Even if \( f \) is not a leaf procedure, it might be finished with all its use of the argument \( x \) by the time it calls \( h \) (technically, \( x \) is a dead variable at the point where \( h \) is called). Then \( f \) can overwrite \( r_1 \) without saving it.

4. Some architectures have register windows, so that each function invocation can allocate a fresh set of registers without memory traffic.

If \( f \) needs to write an incoming parameter into the frame, where in the frame should it go? Ideally, \( f \)’s frame layout should matter only in the implementation of \( f \). A straightforward approach would be for the caller to pass arguments \( a_1, \ldots, a_k \) in registers and \( a_{k+1}, \ldots, a_n \) at the end of its own frame – the place marked outgoing arguments in Figure 6.2 – which become the incoming arguments of the callee. If the callee needed to write any of these arguments to memory, it would write them to the area marked local variables.

The C programming language actually allows you to take the address of a formal parameter and guarantees that all the formal parameters of a function are at consecutive addresses! This is the varargs feature that printf uses. Allowing programmers to take the address of a parameter can lead to a dangling reference if the address outlives the frame – as the address of \( x \) will in \( \text{int } *f(int x) \{ \text{return } &x; \} \) – and even when it does not lead to bugs, the consecutive-address rule for parameters constrains the compiler and makes stack-frame layout more complicated. To resolve the contradiction that parameters are passed in registers, but have addresses too, the first \( k \) parameters are passed in registers; but any parameter whose address is taken must be written to a memory location on entry to the function. To satisfy printf, the memory locations into which register arguments are written must all be
consecutive with the memory locations in which arguments \(k+1, k+2, \text{ etc.} \) are written. Therefore, C programs can’t have some of the arguments saved in one place and some saved in another – they must all be saved contiguously.

So in the standard calling convention of many modern machines the \textit{calling} function reserves space for the register arguments in its own frame, next to the place where it writes argument \( k+1 \). But the calling function does not actually write anything there; that space is written into \textit{by the called function}, and only if the called function needs to write arguments into memory for any reason.

A more dignified way to take the address of a local variable is to use \textit{call-by-reference}. With call-by-reference, the programmer does not explicitly manipulate the address of a variable \( x \). Instead, if \( x \) is passed as the argument to \( f(y) \) where \( y \) is a “by-reference” parameter, the compiler generates code to pass the address of \( x \) instead of the contents of \( x \). At any use of \( y \) within the function, the compiler generates an extra pointer dereference. With call-by-reference, there can be no “dangling reference,” since \( y \) must disappear when \( f \) returns, and \( f \) returns before \( x \)’s scope ends.

\textbf{RETURN ADDRESSES}

When function \( g \) calls function \( f \), eventually \( f \) must return. It needs to know where to go back to. If the \textit{call} instruction within \( g \) is at address \( a \), then (usually) the right place to return to is \( a+1 \), the next instruction in \( g \). This is called the \textit{return address}.

On 1970s machines, the return address was pushed on the stack by the \textit{call} instruction. Modern science has shown that it is faster and more flexible to pass the return address in a register, avoiding memory traffic and also avoiding the need to build any particular stack discipline into the hardware.

On modern machines, the \textit{call} instruction merely puts the return address (the address of the instruction after the call) in a designated register. A non-leaf procedure will then have to write it to the stack (unless interprocedural register allocation is used), but a leaf procedure will not.

\textbf{FRAME-RESIDENT VARIABLES}

So a modern procedure-call convention will pass function parameters in registers, pass the return address in a register, and return the function result in a register. Many of the local variables will be allocated to registers, as will the intermediate results of expression evaluation. Values are written to memory (in the stack frame) only when necessary for one of these reasons:
6.1. STACK FRAMES

- the variable will be passed by reference, so it must have a memory address (or, in the C language the & operator is anywhere applied to the variable);
- the variable is accessed by a procedure nested inside the current one;
- the value is too big to fit into a single register;
- the variable is an array, for which address arithmetic is necessary to extract components;
- the register holding the variable is needed for a specific purpose, such as parameter passing (as described above), though a compiler may move such values to other registers instead of storing them in memory;
- or there are so many local variables and temporary values that they won’t all fit in registers, in which case some of them are “spilled” into the frame.

We will say that a variable escapes if it is passed by reference, its address is taken (using C’s & operator), or it is accessed from a nested function.

When a formal parameter or local variable is declared, it’s convenient to assign it a location – either in registers or in the stack frame – right at that point in processing the program. Then, when occurrences of that variable are found in expressions, they can be translated into machine code that refers to the right location. Unfortunately, the conditions in our list don’t manifest themselves early enough. When the compiler first encounters the declaration of a variable, it doesn’t yet know whether the variable will ever be passed by reference, accessed in a nested procedure, or have its address taken; and doesn’t know how many registers the calculation of expressions will require (it might be desirable to put some local variables in the frame instead of in registers). An industrial-strength compiler must assign provisional locations to all formals and locals, and decide later which of them should really go in registers.

STATIC LINKS

In languages that allow nested function declarations (such as Pascal, ML, and Tiger), the inner functions may use variables declared in outer functions. This language feature is called block structure.

For example, in Program 6.3, write refers to the outer variable output, and indent refers to outer variables n and output. To make this work, the function indent must have access not only to its own frame (for variables i and s) but also to the frames of show (for variable n) and prettyprint (for variable output).

2However, with register allocation across function boundaries, local variables accessed by inner functions can sometimes go in registers, as long as the inner function knows where to look.
3However, some compilers spread out a large value into several registers for efficiency.
There are several methods to accomplish this:

- Whenever a function $f$ is called, it can be passed a pointer to the frame of the function statically enclosing $f$; this pointer is the static link.
- A global array can be maintained, containing – in position $i$ – a pointer to the frame of the most recently entered procedure whose static nesting depth is $i$. This array is called a display.
- When $g$ calls $f$, each variable of $g$ that is actually accessed by $f$ (or by any function nested inside $f$) is passed to $f$ as an extra argument. This is called lambda lifting.

I will describe in detail only the method of static links. Which method should be used in practice? See Exercise 6.7.

Whenever a function $f$ is called, it is passed a pointer to the stack frame of the “current” (most recently entered) activation of the function $g$ that immediately encloses $f$ in the text of the program.

For example, in Program 6.3:

**Line #**
21 prettyprint calls show, passing prettyprint’s own frame pointer as show’s static link.
6.2. FRAMES IN THE TIGER COMPILER

show stores its static link (the address of prettyprint’s frame) into its own frame.

show calls indent, passing its own frame pointer as indent’s static link.

show calls show, passing its own static link (not its own frame pointer) as the static link.

indent uses the value n from show’s frame. To do so, it fetches at an appropriate offset from indent’s static link (which points at the frame of show).

indent calls write. It must pass the frame pointer of prettyprint as the static link. To obtain this, it first fetches at an offset from its own static link (from show’s frame), the static link that had been passed to show.

indent uses the variable output from prettyprint’s frame. To do so it starts with its own static link, then fetches show’s, then fetches output. This program would be cleaner if show called write here instead of manipulating output directly, but it would not be as instructive.

So on each procedure call or variable access, a chain of zero or more fetches is required; the length of the chain is just the difference in static nesting depth between the two functions involved.

---

6.2 FRAMES IN THE Tiger COMPILER

What sort of stack frames should the Tiger compiler use? Here we face the fact that every target machine architecture will have a different standard stack frame layout. If we want Tiger functions to be able to call C functions, we should use the standard layout. But we don’t want the specifics of any particular machine intruding on the implementation of the semantic analysis module of the Tiger compiler.

Thus we must use abstraction. Just as the Symbol module provides a clean interface, and hides the internal representation of $s_table$ from its clients, we must use an abstract representation for frames.

The frame interface will look something like this:

---

This program would be cleaner if show called write here instead of manipulating output directly, but it would not be as instructive.
/* frame.h */

typedef struct F_frame_ *F_frame;
typedef struct F_access_ *F_access;

typedef struct F_accessList_ *F_accessList;
struct F_accessList_ {F_access head; F_accessList tail;};

F_frame F_newFrame(Temp_label name, U_boolList formals);
Temp_label F_name(F_frame f);
F_accessList F_formals(F_frame f);
F_access F_allocLocal(F_frame f, bool escape);
...

The abstract interface frame.h is implemented by a module specific to
the target machine. For example, if compiling to the MIPS architecture, there
would be a file mipsframe.c containing

#include "frame.h"

In general, we may assume that the machine-independent parts of the com-
piler have access to this implementation of frame.h; for example,

/* in translate.c */
#include "frame.h"
...;
F_frame frame = F_newFrame(...);

In this way the rest of the compiler may access the Frame module without
knowing the identity of the target machine.

The type F_frame holds information about formal parameters and local
variables allocated in this frame. To make a new frame for a function f with
k formal parameters, call F_newFrame(f, l), where l is a list of k booleans:
true for each parameter that escapes and false for each parameter that
does not. The result will be a F_frame object. For example, consider a three-
argument function named g whose first argument escapes (needs to be kept
in memory). Then

F_newFrame(g, U_BoolList(TRUE,
              U_BoolList(FALSE,
              U_BoolList(FALSE, NULL))))
returns a new frame object.

The F_access type describes formals and locals that may be in the frame or in registers. This is an abstract data type, so the contents of struct F_access are visible only inside the Frame module:

```c
/* mipsframe.c */
#include "frame.h"

struct F_access_
    {enum {inFrame, inReg} kind;
     union {
         int offset;     /* InFrame */
         Temp_temp reg;  /* InReg */
     } u;
    };
static F_access InFrame(int offset);
static F_access InReg(Temp_temp reg);
```

InFrame (X) indicates a memory location at offset X from the frame pointer; InReg(t84) indicates that it will be held in “register” t84. F_access is an abstract data type, so outside of the module the InFrame and InReg constructors are not visible. Other modules manipulate accesses using interface functions to be described in the next chapter.

The F_formals interface function extracts a list of k “accesses” denoting the locations where the formal parameters will be kept at run time, as seen from inside the callee. Parameters may be seen differently by the caller and the callee. For example, if parameters are passed on the stack, the caller may put a parameter at offset 4 from the stack pointer, but the callee sees it at offset 4 from the frame pointer. Or the caller may put a parameter into register 6, but the callee may want to move it out of the way and always access it from register 13. On the Sparc architecture, with register windows, the caller puts a parameter into register o1, but the save instruction shifts register windows so the callee sees this parameter in register i1.

Because this “shift of view” depends on the calling conventions of the target machine, it must be handled by the Frame module, starting with newFrame. For each formal parameter, newFrame must calculate two things:

- How the parameter will be seen from inside the function (in a register, or in a frame location);
- What instructions must be produced to implement the “view shift.”

For example, a frame-resident parameter will be seen as “memory at offset

**TABLE 6.4.** Formal parameters for \(g(x_1, x_2, x_3)\) where \(x_1\) escapes.

\(X\) from the frame pointer,” and the view shift will be implemented by copying the stack pointer to the frame pointer on entry to the procedure.

**REPRESENTATION OF FRAME DESCRIPTIONS**

The implementation module Frame is supposed to keep the representation of the \(F\_frame\) type secret from any clients of the Frame module. But really it’s a data structure holding:

- the locations of all the formals,
- instructions required to implement the “view shift,”
- the number of locals allocated so far,
- and the label at which the function’s machine code is to begin (see page 141).

Table 6.4 shows the formals of the three-argument function \(g\) (see page 136) as newFrame would allocate them on three different architectures: the Pentium, MIPS, and Sparc. The first parameter escapes, so it needs to be InFrame on all three machines. The remaining parameters are InFrame on the Pentium, but InReg on the other machines.

The freshly created temporaries \(t_{157}\) and \(t_{158}\), and the move instructions that copy \(r4\) and \(r5\) into them (or on the Sparc, \(i1\) and \(i2\)) may seem superfluous. Why shouldn’t the body of \(g\) just access these formals directly from the registers in which they arrive? To see why not, consider

\[
function m(x:int, y:int) = (h(y,y); h(x,x))
\]

If \(x\) stays in “parameter register 1” throughout \(m\), and \(y\) is passed to \(h\) in parameter register 1, then there is a problem.

The register allocator will eventually choose which machine register should hold \(t_{157}\). If there is no interference of the type shown in function \(m\), then (on
the MIPS) the allocator will take care to choose register $r4$ to hold $t_{157}$ and $r5$ to hold $t_{158}$. Then the *move* instructions will be unnecessary and will be deleted at that time.

See also pages 172 and 267 for more discussion of the view shift.

**LOCAL VARIABLES**

Some local variables are kept in the frame; others are kept in registers. To allocate a new local variable in a frame $f$, the semantic analysis phase calls

$$F\_allocLocal(f, \text{TRUE})$$

This returns an *InFrame* access with an offset from the frame pointer. For example, to allocate two local variables on the Sparc, *allocLocal* would be called twice, returning successively *InFrame*(−4) and *InFrame*(−8), which are standard Sparc frame-pointer offsets for local variables.

The boolean argument to *allocLocal* specifies whether the new variable escapes and needs to go in the frame; if it is false, then the variable can be allocated in a register. Thus, $F\_allocLocal(f, \text{FALSE})$ might create *InReg*$\langle t_{481} \rangle$.

The calls to *allocLocal* need not come immediately after the frame is created. In a language such as Tiger or C, there may be variable-declaration blocks nested inside the body of a function. For example,

```plaintext
function f() =
let var v := 6
  in print(v);
  let var v := 7
    in print(v);
  end;
print(v);
let var v := 8
  in print(v);
end;
print(v)
end
```

```plaintext
void f()
{int v=6;
  print(v);
  {int v=7;
    print(v);
  }
  print(v);
  {int v=8;
    print(v);
  }
  print(v);
}
```

In each of these cases, there are three different variables $v$. Either program will print the sequence 6 7 6 8 6. As each variable declaration is encountered in processing the Tiger program, *allocLocal* will be called to allocate a temporary or new space in the frame, associated with the name $v$. As each *end* (or closing brace) is encountered, the association with $v$ will be forgotten.
CHAPTER SIX. ACTIVATION RECORDS

– but the space is still reserved in the frame. Thus, there will be a distinct temporary or frame slot for every variable declared within the entire function.

The register allocator will use as few registers as possible to represent the temporaries. In this example, the second and third \( v \) variables (initialized to 7 and 8) could be held in the same temporary. A clever compiler might also optimize the size of the frame by noticing when two frame-resident variables could be allocated to the same slot.

CALCULATING ESCAPES
Local variables that do not escape can be allocated in a register; escaping variables must be allocated in the frame. A FindEscape function can look for escaping variables and record this information in the escape fields of the abstract syntax. The simplest way is to traverse the entire abstract syntax tree, looking for escaping uses of every variable. This phase must occur before semantic analysis begins, since Semant needs to know whether a variable escapes immediately upon seeing that variable for the first time.

The traversal function for FindEscape will be a mutual recursion on abstract syntax exp’s and var’s, just like the type-checker. And, just like the type-checker, it will use environments that map variables to bindings. But in this case the binding will be very simple: it will be the boolean flag that is to be set if the particular variable escapes:

```c
/* escape.h */
void Esc_findEscape(A_exp exp);

/* escape.c */
static void traverseExp(S_table env, int depth, A_exp e);
static void traverseDec(S_table env, int depth, A_dec d);
static void traverseVar(S_table env, int depth, A_var v);
```

Whenever a variable or formal-parameter declaration is found at static function-nesting depth \( d \), such as

```c
A_VarDec{name=symbol(“a”), escape=r,...}
```

then EscapeEntry(d, &(x->escape)) is entered into the environment, and \( x->escape \) is set to FALSE.

This new environment is used in processing expressions within the scope of the variable; whenever \( a \) is used at depth > \( d \), then the escape field of \( x \) is set to TRUE.
For a language where addresses of variables can be taken explicitly by the programmer, or where there are call-by-reference parameters, a similar FindEscape can find variables that escape in those ways.

**TEMPORARIES AND LABELS**
The compiler's semantic analysis phase will want to choose registers for parameters and local variables, and choose machine-code addresses for procedure bodies. But it is too early to determine exactly which registers are available, or exactly where a procedure body will be located. We use the word *temporary* to mean a value that is temporarily held in a register, and the word *label* to mean some machine-language location whose exact address is yet to be determined – just like a label in assembly language.

Temps are abstract names for local variables; labels are abstract names for static memory addresses. The Temp module manages these two distinct sets of names.

```c
/* temp.h */
typedef struct Temp_temp_ *Temp_temp;
Temp_temp Temp_newtemp(void);

typedef S_symbol Temp_label;
Temp_label Temp_newlabel(void);
Temp_label Temp_namedlabel(string name);
string Temp_labelstring(Temp_label s);

typedef struct Temp_tempList_ *Temp_tempList;
struct Temp_tempList_ {Temp_temp head; Temp_tempList tail;}
Temp_tempList Temp_TempList(Temp_temp head,
                           Temp_tempList tail);

typedef struct Temp_labelList_ *Temp_labelList;
struct Temp_labelList_ {Temp_label head; Temp_labelList tail;}
Temp_labelList Temp_LabelList(Temp_label head,
                           Temp_labelList tail);
...

/* Temp map type, and operations on it, described on page 207 */
```

Temp_newtemp() returns a new temporary from an infinite set of temps. Temp_newlabel() returns a new label from an infinite set of labels. And Temp_namedlabel(string) returns a new label whose assembly-language name is string.

When processing the declaration function f(...), a label for the address of f’s machine code can be produced by Temp_newlabel(). It’s tempt-
ing to call Temp_namedlabel("f") instead – the assembly-language program will be easier to debug if it uses the label $f$ instead of L213 – but unfortunately there could be two different functions named $f$ in different scopes.

**TWO LAYERS OF ABSTRACTION**

Our Tiger compiler will have two layers of abstraction between semantic analysis and frame-layout details:

```
  semant.c
translate.h
translate.c
  frame.h
temp.h
  µframe.c
temp.c
```

The `frame.h` and `temp.h` interfaces provide machine-independent views of memory-resident and register-resident variables. The `Translate` module augments this by handling the notion of nested scopes (via static links), providing the interface `translate.h` to the `Semant` module.

It is essential to have an abstraction layer at `frame.h`, to separate the source-language semantics from the machine-dependent frame layout ($\mu$ stands for a target machine such as mips, sparc, pentium). Separating `Semant` from `Translate` at the `translate.h` interface is not absolutely necessary: we do it to avoid a huge, unwieldy module that does both type-checking and semantic translation.

In Chapter 7, we will see how `Translate` provides C functions that are useful in producing intermediate representation from abstract syntax. Here, we need to know how `Translate` manages local variables and static function nesting for `Semant`.

```c
/* translate.h */

typedef struct Tr_access_ *Tr_access;

typedef ... Tr_accessList ...
Tr_accessList Tr_AccessList(Tr_access head,
                           Tr_accessList tail);

Tr_level Tr_outermost(void);
Tr_level Tr_newLevel(Tr_level parent, Temp_label name,
                    U_boolList formals);
Tr_accessList Tr_formals(Tr_level level);
Tr_access Tr_allocLocal(Tr_level level, bool escape);
```
In the semantic analysis phase of the Tiger compiler, transDec creates a new “nesting level” for each function by calling Tr_newLevel. That function in turn calls F_newFrame to make a new frame. Semant keeps this level in its FunEntry data structure for the function, so that when it comes across a function call it can pass the called function’s level back to Translate. The FunEntry also needs the label of the function’s machine-code entry point:

```c
/* new versions of VarEntry and FunEntry */
struct E_entry_ {
    enum {E_varEntry, E_funEntry} kind;
    union {
        struct {Tr_access access; Ty_ty ty;} var;
        struct {Tr_level level; Temp_label label;
                Ty_tyList formals; Ty_ty result;} fun;
    } u;
};

E_entry E_VarEntry(Tr_access access, Ty_ty ty);
E_entry E_FunEntry(Tr_level level, Temp_label label,
                    Ty_tyList formals, Ty_ty result);
```

When Semant processes a local variable declaration at level lev, it calls Tr_allocLocal(lev,esc) to create the variable in this level; the argument esc specifies whether the variable escapes. The result is a Tr_access, which is an abstract data type (not the same as F_access, since it must know about static links). Later, when the variable is used in an expression, Semant can hand this access back to Translate in order to generate the machine code to access the variable. Meanwhile, Semant records the access in each VarEntry in the value-environment.

The abstract data type Tr_access can be implemented as a pair consisting of the variable’s level and its F_access:

```c
/* inside translate.c */
struct Tr_access_ {Tr_level level; F_access access;};
```

so that Tr_allocLocal calls F_allocLocal, and also remembers what level the variable lives in. The level information will be necessary later for calculating static links, when the variable is accessed from a (possibly) different level.

**MANAGING STATIC LINKS**
The Frame module should be independent of the specific source language being compiled. Many source languages do not have nested function declara-
tions; thus, Frame should not know anything about static links. Instead, this is the responsibility of Translate.

Translate knows that each frame contains a static link. The static link is passed to a function in a register and stored into the frame. Since the static link behaves so much like a formal parameter, we will treat it as one (as much as possible). For a function with \( k \) “ordinary” parameters, let \( l \) be the list of booleans signifying whether the parameters escape. Then

\[
    l' = \text{U_BoolList}(\text{TRUE}, l)
\]

is a new list; the extra TRUE at the front signifies that the static link “extra parameter” does escape. Then \( \text{newFrame}(\text{label}, l') \) makes the frame whose formal parameter list includes the “extra” parameter.

Suppose, for example, function \( f(x, y) \) is nested inside function \( g \), and the level (previously created) for \( g \) is called \( \text{level}_g \). Then \( \text{transDec} \) (inside \text{semant.c}) can call

\[
    \text{Tr_newLevel}(\text{level}_g, f, \text{U_BoolList}(\text{FALSE}, \text{U_BoolList}(\text{FALSE}, \text{NULL})))
\]

assuming that neither \( x \) nor \( y \) escapes. Then \( \text{Tr_newLevel}(\text{label}, \text{fmls}) \) adds an extra element to the formal-parameter list (for the static link), and calls

\[
    \text{F_newFrame}(\text{label}, \text{U_BoolList}(\text{TRUE}, \text{fmls}))
\]

What comes back is a \( \text{F_frame} \). In this frame are three frame-offset values, accessible by calling \( \text{F_formals(frame)} \). The first of these is the static-link offset; the other two are the offsets for \( x \) and \( y \). When \( \text{Semant} \) calls \( \text{Tr_formals(level)} \), it will get these two offsets, suitably converted into access values.

**KEEPING TRACK OF LEVELS**

With every call to \( \text{Tr_newLevel} \), \( \text{Semant} \) must pass the enclosing level value. When creating the level for the “main” Tiger program (one not within any Tiger function), \( \text{Semant} \) should pass a special level value, obtained by calling \( \text{Tr_outermost()} \). This is not the level of the Tiger main program, it is the level within which that program is nested. All “library” functions are declared (as described at the end of Section 5.2) at this outermost level, which does not contain a frame or formal parameter list. \( \text{Tr_outermost()} \) returns
the same level every time it is called; it is a function just because initializing
global variables to heap-allocated values is difficult in C.

The function transDec will make a new level for each Tiger function
declaration. But Tr_newLevel must be told the enclosing function’s level.
This means that transDec must know, while processing each declaration,
the current static nesting level.

This is easy: transDec will now get an additional argument (in addition
to the type and value environments) that is the current level as given by
the appropriate call to newLevel. And transExp will also require this ar-
gument, so that transDec can pass a level to transExp, which passes it
in turn to transDec to process declarations of nested functions. For similar
reasons, transVar will also need a level argument.

PROGRAM FRAMES
Augment semant.c to allocate locations for local variables, and to keep
track of the nesting level. To keep things simple, assume every variable es-
capes.

Implement the Translate module as translate.c.

If you are compiling for the Sparc, implement the SparcFrame module
(matching frame.h) as sparcframe.c. If compiling for the MIPS, imple-
ment MipsFrame, and so on.

Try to keep all the machine-specific details in your machine-dependent
Frame module, not in Semant or Translate.

To keep things simple, handle only escaping parameters. That is, when
implementing newFrame, handle only the case where all “escape” indicators
are TRUE.

If you are working on a RISC machine (such as MIPS or Sparc) that passes
the first $k$ parameters in registers and the rest in memory, keep things simple
by handling only the case where there are $k$ or fewer parameters.

Optional: Implement FindEscape, the module that sets the escape field
of every variable in the abstract syntax. Modify your transDec function to
allocate nonescaping variables and formal parameters in registers.

Optional: Handle functions with more than $k$ formal parameters.

Supporting files available in $TIGER/chap6 include:

  temp.h, temp.c  The module supporting temporaries and labels.
CHAPTER SIX. ACTIVATION RECORDS

FURTHER READING

The use of a single contiguous stack to hold variables and return addresses dates from Lisp [McCarthy 1960] and Algol [Naur et al. 1963]. Block structure (the nesting of functions) and the use of static links are also from Algol.

Computers and compilers of the 1960s and '70s kept most program variables in memory, so that there was less need to worry about which variables escaped (needed addresses). The VAX, built in 1978, had a procedure-call instruction that assumed all arguments were pushed on the stack, and itself pushed program counter, frame pointer, argument pointer, argument count, and callee-save register mask on the stack [Leonard 1987].

With the RISC revolution [Patterson 1985] came the idea that procedure calling can be done with much less memory traffic. Local variables should be kept in registers by default; storing and fetching should be done as needed, driven by “spilling” in the register allocator [Chaitin 1982].

Most procedures don’t have more than five arguments and five local variables [Tanenbaum 1978]. To take advantage of this, Chow et al. [1986] and Hopkins [1986] designed calling conventions optimized for the common case: the first four arguments are passed in registers, with the (rare) extra arguments passed in memory; compilers use both caller- and callee-save registers for local variables; leaf procedures don’t even stack frames of their own if they can operate within the caller-save registers; and even the return address need not always be pushed on the stack.

EXERCISES

6.1 Using the C compiler of your choice (or a compiler for another language), compile some small test functions into assembly language. On Unix this is usually done by `cc -S`. Turn on all possible compiler optimizations. Then evaluate the compiled programs by these criteria:

a. Are local variables kept in registers?

b. If local variable $b$ is live across more than one procedure call, is it kept in a callee-save register? Explain how doing this would speed up the following program:

```c
int f(int a) {int b; b=a+1; g(); h(b); return b+2;}
```
c. If local variable \( x \) is never live across a procedure call, is it properly kept in a caller-save register? Explain how doing this would speed up the following program:

```c
void h(int y) { int x; x=y+1; f(y); f(2); }
```

6.2 If you have a C compiler that passes parameters in registers, make it generate assembly language for this function:

```c
eextern void h(int, int);
void m(int x, int y) { h(y,y); h(x,x); }
```

Clearly, if arguments to \( m(x, y) \) arrive in registers \( r_{\text{arg1}} \) and \( r_{\text{arg2}} \), and arguments to \( h \) must be passed in \( r_{\text{arg1}} \) and \( r_{\text{arg2}} \), then \( x \) cannot stay in \( r_{\text{arg1}} \) during the marshalling of arguments to \( h(y, y) \). Explain when and how your C compiler moves \( x \) out of the \( r_{\text{arg1}} \) register so as to call \( h(y, y) \).

6.3 For each of the variables \( a, b, c, d, e \) in this C program, say whether the variable should be kept in memory or a register, and why.

```c
int f(int a, int b)
{ int c[3], d, e;
  d=a+1;
  e=g(c, &b);
  return e+c[1]+b;
}
```

*6.4 How much memory should this program use?

```c
int f(int i) {int j,k; j=i*i; k=i?f(i-1):0; return k+j;}
void main() {f(100000);}
```

a. Imagine a compiler that passes parameters in registers, wastes no space providing “backup storage” for parameters passed in registers, does not use static links, and in general makes stack frames as small as possible. How big should each stack frame for \( f \) be, in words?

b. What is the maximum memory use of this program, with such a compiler?

c. Using your favorite C compiler, compile this program to assembly language and report the size of \( f \)'s stack frame.

d. Calculate the total memory use of this program with the real C compiler.

e. Quantitatively and comprehensively explain the discrepancy between (a) and (c).

f. Comment on the likelihood that the designers of this C compiler considered deeply recursive functions important in real programs.
6.5 Some Tiger functions do not need static links, because they do not make use of a particular feature of the Tiger language.

a. Characterize precisely those functions that do not need a static link passed to them.

b. Give an algorithm (perhaps similar to FindEscape) that marks all such functions.

6.6 Instead of (or in addition to) using static links, there are other ways of getting access to nonlocal variables. One way is just to leave the variable in a register!

    function f() : int =
       let var a := 5
       function g() : int =
          (a+1)
       in g()+g()
    end

If a is left in register r7 (for example) while g is called, then g can just access it from there.

What properties must a local variable, the function in which it is defined, and the functions in which it is used, have for this trick to work?

6.7 A display is a data structure that may be used as an alternative to static links for maintaining access to nonlocal variables. It is an array of frame pointers, indexed by static nesting depth. Element \( D_i \) of the display always points to the most recently called function whose static nesting depth is \( i \).

The bookkeeping performed by a function \( f \), whose static nesting depth is \( i \), looks like:

    Copy \( D_i \) to \textit{save location} in stack frame
    Copy frame pointer to \( D_i \)
    \cdots \text{body of } f \cdots
    Copy \textit{save location back to } \( D_i \)

In Program 6.3, function prettyprint is at depth 1, write and show are at depth 2, and so on.

a. Show the sequence of machine instructions required to fetch the variable output into a register at line 14 of Program 6.3, using static links.

b. Show the machine instructions required if a display were used instead.

c. When variable \( x \) is declared at depth \( d_1 \) and accessed at depth \( d_2 \), how many instructions does the static-link method require to fetch \( x \)?

d. How many does the display method require?
e. How many instructions does static-link maintenance require for a procedure entry and exit (combined)?

f. How many instructions does display maintenance require for procedure entry and exit?

Should we use displays instead of static links? Perhaps; but the issue is more complicated. For languages such as Pascal and Tiger with block structure but no function variables, displays work well.

But the full expressive power of block structure is obtained when functions can be returned as results of other functions, as in Scheme and ML. For such languages, there are more issues to consider than just variable-access time and procedure entry-exit cost: there is closure-building cost, and the problem of avoiding useless data kept live in closures. Chapter 15 explains some of the issues.
Translation to Intermediate Code

**translate**: to turn into one’s own or another language

*Webster’s Dictionary*

The semantic analysis phase of a compiler must translate abstract syntax into abstract machine code. It can do this after type-checking, or at the same time.

Though it is possible to translate directly to real machine code, this hinders portability and modularity. Suppose we want compilers for $N$ different source languages, targeted to $M$ different machines. In principle this is $N \cdot M$ compilers (Figure 7.1a), a large implementation task.

An intermediate representation (IR) is a kind of abstract machine language that can express the target-machine operations without committing to too much machine-specific detail. But it is also independent of the details of the source language. The *front end* of the compiler does lexical analysis, parsing, semantic analysis, and translation to intermediate representation. The *back end* does optimization of the intermediate representation and translation to machine language.

A portable compiler translates the source language into IR and then translates the IR into machine language, as illustrated in Figure 7.1b. Now only $N$ front ends and $M$ back ends are required. Such an implementation task is more reasonable.

Even when only one front end and one back end are being built, a good IR can modularize the task, so that the front end is not complicated with machine-specific details, and the back end is not bothered with information specific to one source language. Many different kinds of IR are used in compilers; for this compiler I have chosen simple expression trees.
7.1. INTERMEDIATE REPRESENTATION TREES

The intermediate representation tree language is defined by the interface `tree.h`, as shown in Figure 7.2.

A good intermediate representation has several qualities:

- It must be convenient for the semantic analysis phase to produce.
- It must be convenient to translate into real machine language, for all the desired target machines.
- Each construct must have a clear and simple meaning, so that optimizing transformations that rewrite the intermediate representation can easily be specified and implemented.

Individual pieces of abstract syntax can be complicated things, such as array subscripts, procedure calls, and so on. And individual “real machine” instructions can also have a complicated effect (though this is less true of modern RISC machines than of earlier architectures). Unfortunately, it is not always the case that complex pieces of the abstract syntax correspond exactly to the complex instructions that a machine can execute.

Therefore, the intermediate representation should have individual components that describe only extremely simple things: a single fetch, store, add, move, or jump. Then any “chunky” piece of abstract syntax can be translated into just the right set of abstract machine instructions; and groups of abstract machine instructions can be clumped together (perhaps in quite different clumps) to form “real” machine instructions.

Here is a description of the meaning of each tree operator. First, the ex-
/* tree.h *

FIGURE 7.2. Intermediate representation trees.
pressions \((T_{\text{exp}})\), which stand for the computation of some value (possibly with side effects):

- **CONST** \(i\) The integer constant \(i\). Written in C as \(T_{\text{Const}}(i)\).
- **NAME** \(n\) The symbolic constant \(n\) (corresponding to an assembly language label). Written in C as \(T_{\text{Name}}(n)\).
- **TEMP** \(t\) Temporary \(t\). A temporary in the abstract machine is similar to a register in a real machine. However, the abstract machine has an infinite number of temporaries.
- **BINOP** \(o, e_1, e_2\) The application of binary operator \(o\) to operands \(e_1, e_2\). Subexpression \(e_1\) is evaluated before \(e_2\). The integer arithmetic operators are PLUS, MINUS, MUL, DIV; the integer bitwise logical operators are AND, OR, XOR; the integer logical shift operators are LSHIFT, RSHIFT; the integer arithmetic right-shift is ARSHIFT. The Tiger language has no logical operators, but the intermediate language is meant to be independent of any source language; also, the logical operators might be used in implementing other features of Tiger.
- **MEM** \(e\) The contents of \(\text{wordSize}\) bytes of memory starting at address \(e\) (where \(\text{wordSize}\) is defined in the Frame module). Note that when MEM is used as the left child of a MOVE, it means “store,” but anywhere else it means “fetch.”
- **CALL** \(f, l\) A procedure call: the application of function \(f\) to argument list \(l\). The subexpression \(f\) is evaluated before the arguments which are evaluated left to right.
- **ESEQ** \(s, e\) The statement \(s\) is evaluated for side effects, then \(e\) is evaluated for a result.

The statements \((T_{\text{stm}})\) of the tree language perform side effects and control flow:

- **MOVE** \(\text{TEMP} \ t, \ e\) Evaluate \(e\) and move it into temporary \(t\).
- **MOVE** \(\text{MEM}(e_1), \ e_2\) Evaluate \(e_1\), yielding address \(a\). Then evaluate \(e_2\), and store the result into \(\text{wordSize}\) bytes of memory starting at \(a\).
- **EXP** \(e\) Evaluate \(e\) and discard the result.
- **JUMP** \(e, \ labs\) Transfer control (jump) to address \(e\). The destination \(e\) may be a literal label, as in \(\text{NAME}(\text{lab})\), or it may be an address calculated by any other kind of expression. For example, a C-language \text{switch}(i)\) statement may be implemented by doing arithmetic on \(i\). The list of labels \(\text{labs}\) specifies all the possible locations that the expression \(e\) can evaluate to; this is necessary for dataflow analysis later. The common case of jumping to a known label \(l\) is written as

\[
T_{\text{Jump}}(l, T_{\text{Temp LabelList}}(l, \text{NULL}));
\]

- **CJUMP** \(o, e_1, e_2, t, f\) Evaluate \(e_1, e_2\) in that order, yielding values \(a, b\). Then compare \(a, b\) using the relational operator \(o\). If the result is true, jump to
CHAPTER SEVEN. TRANSLATION TO INTERMEDIATE CODE

$t$; otherwise jump to $f$. The relational operators are $\text{EQ}$ and $\text{NE}$ for integer equality and nonequality (signed or unsigned); signed integer inequalities $\text{LT}$, $\text{GT}$, $\text{LE}$, $\text{GE}$; and unsigned integer inequalities $\text{ULT}$, $\text{ULE}$, $\text{UGT}$, $\text{UGE}$.

$\text{SEQ}(s_1, s_2)$ The statement $s_1$ followed by $s_2$.

$\text{LABEL}(n)$ Define the constant value of name $n$ to be the current machine code address. This is like a label definition in assembly language. The value $\text{NAME}(n)$ may be the target of jumps, calls, etc.

It is almost possible to give a formal semantics to the Tree language. However, there is no provision in this language for procedure and function definitions – we can specify only the body of each function. The procedure entry and exit sequences will be added later as special “glue” that is different for each target machine.

7.2 TRANSLATION INTO TREES

Translation of abstract syntax expressions into intermediate trees is reasonably straightforward; but there are many cases to handle.

KINDS OF EXPRESSIONS

What should the representation of an abstract syntax expression $\text{A\_exp}$ be in the Tree language? At first it seems obvious that it should be $\text{T\_exp}$. However, this is true only for certain kinds of expressions, the ones that compute a value. Expressions that return no value (such as some procedure calls, or $\text{while}$ expressions in the Tiger language) are more naturally represented by $\text{T\_stm}$. And expressions with Boolean values, such as $a > b$, might best be represented as a conditional jump – a combination of $\text{T\_stm}$ and a pair of destinations represented by $\text{Temp\_labels}$.

Therefore, we will make a union type (with kind tag, as usual) in the Translate module, to model these three kinds of expressions:

```c
/* in translate.h */
typedef struct Tr_exp_ *Tr_exp;
```
/* in translate.c */

struct Cx {patchList trues; patchList falses; T_stm stm;};

struct Tr_exp {
    enum {Tr_ex, Tr_nx, Tr_cx} kind;
    union {T_exp ex; T_stm nx; struct Cx cx; } u;
};

static Tr_exp Tr_Ex(T_exp ex);
static Tr_exp Tr_Nx(T_stm nx);
static Tr_exp Tr_Cx(patchList trues, patchList falses,
                     T_stm stm);

Ex stands for an “expression,” represented as a Tr_exp.
Nx stands for “no result,” represented as a Tree statement.
Cx stands for “conditional,” represented as a statement that may jump to a true-
label or false-label, but these labels have yet to be filled in. If you fill in
a true-destination and a false-destination, the resulting statement evaluates
some conditionals and then jumps to one of the destinations (the statement
will never “fall through”).

For example, the Tiger expression \(a > b | c < d\) might translate to the con-
ditional:

\[
\text{Temp_label } z = \text{Temp_newlabel();} \\
T\text{_stm } s1 = T\text{_Seq}(T\text{_Cjump}(T\text{_gt}, a, b, NULL, z), \\
   T\text{_Seq}(T\text{_Label(z),} \\
   T\text{_Cjump(T\text{_lt}, c, d, NULL, NULL))));
\]

The problem here is that \(t\) and \(f\) are not known yet, so the statement is full of
NULLs. We won’t know the true-destination and false-destination until much
later. We need to make a list of where all the NULLs are that need to be filled
in with \(t\) when it is known, and another list of all the places that need to be
filled in with \(f\).

To represent “a list of places where a label must be filled in” we use a
patchList:

```c
typedef struct patchList_ *patchList;
struct patchList_ {Temp_label *head; patchList tail;};
static patchList PatchList(Temp_label *head, patchList tail);
```

Therefore, we can complete the translation of \(a > b | c < d\) into a Tr_exp as
follows:
Sometimes we will have an expression of one kind and we will need to convert it to an equivalent expression of another kind. For example, the Tiger statement

\[ \text{flag := (a>b | c<d)} \]

requires the conversion of a Cx into an Ex so that a 1 (for true) or 0 (for false) can be stored into flag.

It is helpful to have three conversion functions:

\[
\begin{align*}
\text{static T_exp unEx(Tr_exp e);} \\
\text{static T_stm unNx(Tr_exp e);} \\
\text{static struct Cx unCx(Tr_exp e);} \\
\end{align*}
\]

Each of these behaves as if it were simply stripping off the corresponding constructor (Ex, Nx, or Cx), but the catch is that each conversion function must work no matter what constructor has been used!

Suppose \( e \) is the representation of \( a>b | c<d \), so

\[ e = \text{Tr}_\text{Cx}(\text{trues}, \text{false}, \text{stm}) \]

Then the assignment statement can be implemented as

\[ \text{MOVE(TEMP}_{\text{flag}}, \text{unEx} (e)). \]

We have “stripped off the Ex constructor” even though Cx was really there instead.

Program 7.3 is the implementation of unEx. To convert a “conditional” into a “value expression,” we invent a new temporary \( r \) and new labels \( t \) and \( f \). Then we make a T_stm that moves the value 1 into \( r \), and follow it with the statement \( e->u.cs.stm; \) it will jump to \( t \) if true, and \( f \) if false. If the condition is false, then 0 is moved into \( r \); if true, then execution proceeds at \( t \) and the second move is skipped. The result of the whole thing is just the temporary \( r \) containing zero or one.
static T_exp unEx(Tr_exp e) {
    switch (e->kind) {
    case Tr_ex:
        return e->u.ex;
    case Tr_cx:
        Temp_temp r = Temp_newtemp();
        Temp_label t = TempNewLabel(), f = TempNewLabel();
        doPatch(e->u.cx.trues, t);
        doPatch(e->u.cx.falses, f);
        return T_Eseq(T_Move(T_Temp(r), T_Const(1)),
                      T_Eseq(e->u.cx.stm,
                          T_Eseq(T_Label(f),
                              T_Eseq(T_Move(T_Temp(r), T_Const(0)),
                                  T_Eseq(T_Label(t),
                                      T_Temp(r))))));
    case Tr_nx:
        return T_Eseq(e->u.nx, T_Const(0));
    }
    assert(0); /* can’t get here */
}

PROGRAM 7.3. The conversion function unEx.

By calling doPatch(e->u.cx.trues, t) we fill in all the label-holes in
the trues patch list with the label t, and similarly for the falses list with
doPatch(e->u.cx.trues, f). The doPatch function is one of two useful
utility functions on patch lists:

void doPatch(patchList tList, Temp_label label) {
    for (; tList; tList=tList->tail)
        *(tList->head) = label;
}

patchList joinPatch(patchList first, patchListList second) {
    if (!first) return second;
    for (; first->tail; first=first->tail); /* go to end of list */
    first->tail = second;
    return first;
}

The functions unCx and unNx are left as an exercise. It’s helpful to have
unCx treat the cases of CONST 0 and CONST 1 specially, since they have
particularly simple and efficient translations. Also, unCx should never expect
to see a Tr_exp with a kind of Tr_nx—such a case should never occur in
compiling a well typed Tiger program.
SIMPLE VARIABLES

The semantic analysis phase has a function that type-checks a variable in the context of a type environment \texttt{tenv} and a value environment \texttt{venv}. This function \texttt{transVar} returns a struct \texttt{expty} containing a \texttt{Tr_exp} and a \texttt{Ty_ty}. In Chapter 5 the \texttt{exp} was merely a place-holder, but now \texttt{Semant} must be modified so that each \texttt{exp} holds the intermediate-representation translation of each Tiger expression.

For a simple variable \( v \) declared in the current procedure’s stack frame, we translate it as

\[
\text{MEM} \quad \text{BINOP} \quad \text{PLUS} \quad \text{TEMP} \, \text{fp} \quad \text{CONST} \, k
\]

\[
\text{MEM}(\text{BINOP}(\text{PLUS}, \text{TEMP} \, \text{fp}, \text{CONST} \, k))
\]

where \( k \) is the offset of \( v \) within the frame and \( \text{TEMP} \, \text{fp} \) is the frame pointer register. For the Tiger compiler we make the simplifying assumption that all variables are the same size – the natural word size of the machine.

Interface between Translate and Semant. The type \texttt{Tr_exp} is an abstract data type, whose \texttt{Ex} and \texttt{Nx} constructors are visible only within \texttt{Translate}.

The manipulation of \texttt{MEM} nodes should all be done in the \texttt{Translate} module, not in \texttt{Semant}. Doing it in \texttt{Semant} would clutter up the readability of that module and would make \texttt{Semant} dependent on the \texttt{Tree} representation.

We add a function

\[
\text{Tr_Exp} \, \text{Tr_simpleVar}(\text{Tr_Access}, \text{Tr_Level});
\]

to the \texttt{Translate} interface. Now \texttt{Semant} can pass the \texttt{access} of \( x \) (obtained from \texttt{Tr_allocLocal}) and the \texttt{level} of the function in which \( x \) is used and get back a \texttt{Tr_exp}.

With this interface, \texttt{Semant} never gets its hands dirty with a \texttt{T_exp} at all. In fact, this is a good rule of thumb in determining the interface between \texttt{Semant} and \texttt{Translate}: the \texttt{Semant} module should not contain any direct reference to the \texttt{Tree} or \texttt{Frame} module. Any manipulation of IR trees should be done by \texttt{Translate}. 
7.2. TRANSLATION INTO TREES

The Frame module holds all machine-dependent definitions; here we add to it a frame-pointer register FP and a constant whose value is the machine’s natural word size:

```c
/* frame.h */
;
Temp_temp F_FP(void);
extern const int F_wordSize;
T_exp F_Exp(F_access acc, T_exp framePtr);
```

In this and later chapters, I will abbreviate BINOP(PLUS, e₁, e₂) as +(e₁, e₂), so the tree above would be shown as

```
MEM
|
+
```
```
+ (TEMP fp, CONST k)
```

The function F_Exp is used by Translate to turn an F_access into the Tree expression. The T_exp argument is the address of the stack frame that the F_access lives in. Thus, for an access a such as InFrame(k), we have

```
F_Exp (a, T_Temp (F_FP ())) returns MEM (BINOP (PLUS, TEMP (FP), CONST (k)))
```

Why bother to pass the tree expression T_Temp (F_FP ()) as an argument? The answer is that the address of the frame is the same as the current frame pointer only when accessing the variable from its own level. When accessing a from an inner-nested function, the frame address must be calculated using static links, and the result of this calculation will be the T_exp argument to F_Exp.

If a is a register access such as InReg(t₈₃₂), then the frame-address argument to F_Exp will be discarded, and the result will be simply TEMP t₈₃₂.

An l-value such as v or a[i] or p.next can appear either on the left side or the right side of an assignment statement – l stands for left, to distinguish from r-values that can appear only on the right side of an assignment. Fortunately, only MEM and TEMP nodes can appear on the left of a MOVE node.
FOLLOWING STATIC LINKS
When a variable $x$ is declared at an outer level of static scope, static links must be used. The general form is

$$\text{MEM}(+(\text{CONST } k_n, \text{MEM}(+(\text{CONST } k_{n-1}, \ldots \text{MEM}(+(\text{CONST } k_1, \text{TEMP FP}) \ldots))))$$

where the $k_1, ..., k_{n-1}$ are the various static link offsets in nested functions, and $k_n$ is the offset of $x$ in its own frame.

To construct this expression, we need the level $l_f$ of the function $f$ in which $x$ is used, and the level $l_g$ of the function $g$ in which $x$ is declared. As we strip levels from $l_f$, we use the static link offsets $k_1, k_2, ...$ from these levels to construct the tree. Eventually we reach $l_g$, and we can stop.

$\text{Tr}_{\text{simpleVar}}$ must produce a chain of MEM and $+$ nodes to fetch static links for all frames between the level of use (the level passed to $\text{simpleVar}$) and the level of definition (the level within the variable’s access).

ARRAY VARIABLES
For the rest of this chapter I will not specify all the interface functions of $\text{Translate}$, as I have done for $\text{simpleVar}$. But the rule of thumb just given applies to all of them; there should be a $\text{Translate}$ function to handle array subscripts, one for record fields, one for each kind of expression, and so on.

Different programming languages treat array-valued variables differently.

In Pascal, an array variable stands for the contents of the array – in this case all 12 integers. The Pascal program

```pascal
var a, b : array[1..12] of integer
begin
  a := b
end;
```

copies the contents of array $a$ into array $b$.

In C, there is no such thing as an array variable. There are pointer variables; arrays are like “pointer constants.” Thus, this is illegal:

```c
{int a[12], b[12];
 a = b;
}
```

but this is quite legal:
The statement \( b = a \) does not copy the elements of \( a \); instead, it means that \( b \) now points to the beginning of the array \( a \).

In Tiger (as in Java and ML), array variables behave like pointers. Tiger has no named array constants as in C, however. Instead, new array values are created (and initialized) by the construct \( t_a[n] of i \), where \( t_a \) is the name of an array type, \( n \) is the number of elements, and \( i \) is the initial value of each element. In the program

```tiger
let
type intArray = array of int
var a := intArray[12] of 0
var b := intArray[12] of 7
in a := b
end
```

the array variable \( a \) ends up pointing to the same 12 sevens as the variable \( b \); the original 12 zeros allocated for \( a \) are discarded.

Tiger record values are also pointers. Record assignment, like array assignment, is pointer assignment and does not copy all the fields. This is also true of modern object-oriented and functional programming languages, which try to blur the syntactic distinction between pointers and objects. In C or Pascal, however, a record value is “big,” and record assignment means copying all the fields.

**STRUCTURED L-VALUES**

An \( l \)-value is the result of an expression that can occur on the left of an assignment statement, such as \( x \) or \( p.y \) or \( a[i+2] \). An \( r \)-value is one that can only appear on the right of an assignment, such as \( a+3 \) or \( f(x) \). That is, an \( l \)-value denotes a location that can be assigned to, and an \( r \)-value does not.

Of course, an \( l \)-value can occur on the right of an assignment statement; in this case the contents of the location are implicitly taken.

We say that an integer or pointer value is a “scalar,” since it has only one component. Such a value occupies just one word of memory and can fit in a register. All the variables and \( l \)-values in Tiger are scalar. Even a Tiger array or record variable is really a pointer (a kind of scalar); the *Tiger Language Reference Manual* does not say so explicitly, because it is talking about Tiger semantics instead of Tiger implementation.
In C or Pascal there are structured l-values – structs in C, arrays and records in Pascal – that are not scalar. To implement a language with “large” variables such as the arrays and records in C or Pascal requires a bit of extra work. In a C compiler, the access type would require information about the size of the variable. Then, the MEM operator of the TREE intermediate language would need to be extended with a notion of size:

$$T_{\text{exp}} \text{T\_Mem}(T_{\text{exp}}, \text{int size});$$

The translation of a local variable into an IR tree would look like

$$\text{MEM}(+(\text{TEMP fp}, \text{CONST } k_n), S)$$

where the $S$ indicates the size of the object to be fetched or stored (depending on whether this tree appears on the left or right of a MOVE).

Leaving out the size on MEM nodes makes the Tiger compiler easier to implement, but limits the generality of its intermediate representation.

**SUBSCRIPTING AND FIELD SELECTION**

To subscript an array in Pascal or C (to compute $a[i]$), just calculate the address of the $i$th element of $a$: $(i - l) \times s + a$, where $l$ is the lower bound of the index range, $s$ is the size (in bytes) of each array element, and $a$ is the base address of the array elements. If $a$ is global, with a compile-time constant address, then the subtraction $a - s \times l$ can be done at compile time.

Similarly, to select field $f$ of a record l-value $a$ (to calculate $a.f$), simply add the constant field offset of $f$ to the address $a$.

An array variable $a$ is an l-value; so is an array subscript expression $a[i]$, even if $i$ is not an l-value. To calculate the l-value $a[i]$ from $a$, we do arithmetic on the address of $a$. Thus, in a Pascal compiler, the translation of an l-value (particularly a structured l-value) should not be something like

$$\text{MEM}$$

but should instead be the Tree expression representing the base address of the array:

$$+(\text{TEMP fp}, \text{CONST } k)$$
7.2. TRANSLATION INTO TREES

What could happen to this \( l \)-value?

- A particular element might be subscripted, yielding a (smaller) \( l \)-value. A “+” node would add the index times the element size to the \( l \)-value for the base of the array.
- The \( l \)-value (representing the entire array) might be used in a context where an \( r \)-value is required (e.g., passed as a by-value parameter, or assigned to another array variable). Then the \( l \)-value is coerced into an \( r \)-value by applying the MEM operator to it.

In the Tiger language, there are no structured, or “large,” \( l \)-values. This is because all record and array values are really pointers to record and array structures. The “base address” of the array is really the contents of a pointer variable, so MEM is required to fetch this base address.

Thus, if \( a \) is a memory-resident array variable represented as \( \text{MEM}(e) \), then the contents of address \( e \) will be a one-word pointer value \( p \). The contents of addresses \( p, p+W, p+2W, \ldots \) (where \( W \) is the word size) will be the elements of the array (all elements are one word long). Thus, \( a[i] \) is just

\[
\text{MEM}(+(\text{MEM}(e), \text{BINOP}(\text{MUL}, i, \text{CONST W})))
\]

**L-values and MEM nodes.** Technically, an \( l \)-value (or assignable variable) should be represented as an *address* (without the top MEM node in the diagram above). Converting an \( l \)-value to an \( r \)-value (when it is used in an expression) means *fetching* from that address; assigning to an \( l \)-value means *storing* to that address. We are attaching the MEM node to the \( l \)-value before knowing whether it is to be fetched or stored; this works only because in the Tree intermediate representation, MEM means both *store* (when used as the left child of a MOVE) and *fetch* (when used elsewhere).
A SERMON ON SAFETY
Life is too short to spend time chasing down irreproducible bugs, and money is too valuable to waste on the purchase of flaky software. When a program has a bug, it should detect that fact as soon as possible and announce that fact (or take corrective action) before the bug causes any harm.

Some bugs are very subtle. But it should not take a genius to detect an out-of-bounds array subscript: if the array bounds are $L..H$, and the subscript is $i$, then $i < L \text{ or } i > H$ is an array bounds error. Furthermore, computers are well-equipped with hardware able to compute the condition $i > H$. For several decades now, we have known that compilers can automatically emit the code to test this condition. There is no excuse for a compiler that is unable to emit code for checking array bounds. Optimizing compilers can often safely remove the checks by compile-time analysis; see Section 18.4.

One might say, by way of excuse, “but the language in which I program has the kind of address arithmetic that makes it impossible to know the bounds of an array.” Yes, and the man who shot his mother and father threw himself upon the mercy of the court because he was an orphan.

In some rare circumstances, a portion of a program demands blinding speed, and the timing budget does not allow for bounds checking. In such a case, it would be best if the optimizing compiler could analyze the subscript expressions and prove that the index will always be within bounds, so that an explicit bounds check is not necessary. If that is not possible, perhaps it is reasonable in these rare cases to allow the programmer to explicitly specify an unchecked subscript operation. But this does not excuse the compiler from checking all the other subscript expressions in the program.

Needless to say, the compiler should check pointers for nil before dereferencing them, too.1

ARITHMETIC
Integer arithmetic is easy to translate: each Absyn arithmetic operator corresponds to a Tree operator.

The Tree language has no unary arithmetic operators. Unary negation of integers can be implemented as subtraction from zero; unary complement can be implemented as XOR with all ones.

Unary floating-point negation cannot be implemented as subtraction from zero, because many floating-point representations allow a negative zero. The

---

1A different way of checking for nil is to unmap page 0 in the virtual-memory page tables, so that attempting to fetch/store fields of a nil record results in a page fault.
negation of negative zero is positive zero, and vice versa. Some numerical programs rely on identities such as \(-0 < 0\). Thus, the Tree language does not support unary negation very well.

Fortunately, the Tiger language doesn’t support floating-point numbers; but in a real compiler, a new operator would have to be added for floating negation.

**CONDITIONALS**

The result of a comparison operator will be a \(C_x\) expression: a statement \(s\) that will jump to any true-destination and false-destination you specify.

Making “simple” \(C_x\) expressions from Absyn comparison operators is easy with the CJUMP operator. However, the whole point of the \(C_x\) representation is that conditional expressions can be combined easily with the Tiger operators \& and |. Therefore, an expression such as \(x<5\) will be translated as a \(C_x\) with

\[
\text{trues} = \{ t \} \\
\text{falses} = \{ f \} \\
\text{stm} = \text{CJUMP}(\lt, x, \text{CONST}(5), t, f).
\]

The \& and | operators of the Tiger language, which combine conditionals with short-circuit conjunction and disjunction (\(and\) and \(or\)) respectively, have already been translated into if-expressions in the abstract syntax.

The most straightforward thing to do with an if-expression

\[ \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \]

is to treat \(e_1\) as a \(C_x\) expression, and \(e_2\) and \(e_3\) as \(E_x\) expressions. That is, apply \(\text{unC}x\) to \(e_1\) and \(\text{unE}x\) to \(e_2\) and \(e_3\). Make two labels \(t\) and \(f\) to which the conditional will branch. Allocate a temporary \(r\), and after label \(t\), move \(e_2\) to \(r\); after label \(f\), move \(e_3\) to \(r\). Both branches should finish by jumping to a newly created “join” label.

This will produce perfectly correct results. However, the translated code may not be very efficient at all. If \(e_2\) and \(e_3\) are both “statements” (expressions that return no value), then their representation is likely to be \(N_x\), not \(E_x\). Applying \(\text{unE}x\) to them will work – a coercion will automatically be applied – but it might be better to recognize this case specially.

Even worse, if \(e_2\) or \(e_3\) is a \(C_x\) expression, then applying the \(\text{unE}x\) coercion to it will yield a horrible tangle of jumps and labels. It is much better to recognize this case specially.
For example, consider

\[\text{if } x < 5 \text{ then } a > b \text{ else } 0\]

As shown above, \(x < 5\) translates into \(\text{C}x(s_1)\); similarly, \(a > b\) will be translated as \(\text{C}x(s_2)\) for some \(s_2\). The whole if-statement should come out approximately as

\[
\text{SEQ(CJUMP(LT, x, CONST, 5), z, f)} \quad \text{SEQ(LABEL, z, CJUMP(GT, a, b, t, f)))}
\]

for some new label \(z\). The shorthand \(s_1(z, f)\) means the \(\text{C}x\) statement \(s_1\) with its trues labels filled in with \(z\) and its falses labels filled in with \(f\).

**String comparison.** Because the string equality operator is complicated (it must loop through the bytes checking byte-for-byte equality), the compiler should call a runtime-system function \(\text{stringEqual}\) that implements it. This function returns a 0 or 1 value (false or true), so the CALL tree is naturally contained within an \(\text{Ex}\) expression. String not-equals can be implemented by generating Tree code that complements the result of the function call.

**STRINGS**

A string literal in the Tiger (or C) language is the constant address of a segment of memory initialized to the proper characters. In assembly language a label is used to refer to this address from the middle of some sequence of instructions. At some other place in the assembly-language program, the definition of that label appears, followed by the assembly-language pseudo-instruction to reserve and initialize a block of memory to the appropriate characters.

For each string literal \(\text{lit}\), the Translate module makes a new label \(\text{lab}\), and returns the tree \(\text{T\_NAME(lab)}\). It also puts the assembly-language fragment \(\text{F\_string(lab, lit)}\) onto a global list of such fragments to be handed to the code emitter. “Fragments” are discussed further on page 172; translation of string fragments to assembly language, on page 269.
All string operations are performed in functions provided by the runtime system; these functions heap-allocate space for their results, and return pointers. Thus, the compiler (almost) doesn’t need to know what the representation is, as long as it knows that each string pointer is exactly one word long. I say “almost” because string literals must be represented.

But how are strings represented in Tiger? In Pascal, they are fixed-length arrays of characters; literals are padded with blanks to make them fit. This is not very useful. In C, strings are pointers to variable-length, zero-terminated sequences. This is much more useful, though a string containing a zero byte cannot be represented.

Tiger strings should be able to contain arbitrary 8-bit codes (including zero). A simple representation that serves well is to have a string pointer point to a one-word integer containing the length (number of characters), followed immediately by the characters themselves. Then the string function in the machine-specific Frame module (mipsframe.c, sparcframe.c, pentiumframe.c, etc.) can make a string with a label definition, an assembly-language pseudo-instruction to make a word containing the integer length, and a pseudo-instruction to emit character data.

**RECORD AND ARRAY CREATION**

The Tiger language construct \( a\{f_1 = e_1, f_2 = e_2, ..., f_n = e_n\} \) creates an \( n \)-element record initialized to the values of expressions \( e_i \). Such a record may outlive the procedure activation that creates it, so it cannot be allocated on the stack. Instead, it must be allocated on the heap. There is no provision for freeing records (or strings); industrial-strength Tiger systems should have a garbage collector to reclaim unreachable records (see Chapter 13).

The simplest way to create a record is to call an external memory-allocation function that returns a pointer to an \( n \)-word area into a new temporary \( r \). Then a series of MOVE trees can initialize offsets 0, 1\( W \), 2\( W \), ..., (\( n - 1 \))\( W \) from \( r \) with the translations of expressions \( e_i \). Finally the result of the whole expression is TEMP(\( r \)), as shown in Figure 7.4.

In an industrial compiler, calling malloc (or its equivalent) on every record creation might be too slow; see Section 13.7.

Array creation is very much like record creation, except that all the fields are initialized to the same value. The external initArray function can take the array length and the initializing value as arguments.
**FIGURE 7.4.** Record allocation.

**Calling runtime-system functions.** To call an external function named `initArray` with arguments `a, b`, simply generate a CALL such as

```c
CALL(NAME(Temp_namedlabel("initArray")),
     T_ExpList(a, T_ExpList(b, NULL)))
```

This refers to an external function `initArray` which is written in a language such as C or assembly language – it cannot be written in Tiger because Tiger has no mechanism for manipulating raw memory.

But on some operating systems, the C compiler puts an underscore at the beginning of each label; and the calling conventions for C functions may differ from those of Tiger functions; and C functions don’t expect to receive a static link, and so on. All these target-machine-specific details should be encapsulated into a function provided by the Frame structure:

```c
/* frame.h */

T_exp F_externalCall(string s, T_expList args);
```

where `F_externalCall` takes the name of the external procedure and the arguments to be passed.
7.2. TRANSLATION INTO TREES

The implementation of externalCall depends on the relationship between Tiger’s procedure-call convention and that of the external function. The simplest possible implementation looks like

```c
T_exp F_externalCall(string s, T_expList args) {
    return T_Call(T_Name(Temp_namedlabel(s)), args);
}
```

but may have to be adjusted for static links, or underscores in labels, and so on.

WHILE LOOPS

The general layout of a while loop is

```
test:
    if not(condition) goto done
body
    goto test
done:
```

If a break statement occurs within the body (and not nested within any interior while statements), the translation is simply a jump to done.

So that transExp can translate break statements, it will have a new formal parameter break that is the done label of the nearest enclosing loop. In translating a while loop, transExp is called upon body with the done label passed as the break parameter. When transExp is recursively calling itself in nonloop contexts, it can simply pass down the same break parameter that was passed to it.

The break argument must also be added to the transDec function.

FOR LOOPS

A for statement can be expressed using other kinds of statements:

```
for i := lo to hi
do body
```

```
let var i := lo
var limit := hi
in while i <= limit
do (body; i := i+1)
end
```

A very straightforward approach to the translation of for statements is to rewrite the abstract syntax into the abstract syntax of the let/while expression shown, and then call transExp on the result.
CHAPTER SEVEN. TRANSLATION TO INTERMEDIATE CODE

This is almost right, but consider the case where \( \text{limit} = \text{maxint} \). Then \( i + 1 \) will overflow; either a hardware exception will be raised, or \( i \leq \text{limit} \) will always be true! The solution is to put the test at the bottom of the loop, where \( i < \text{limit} \) can be tested before the increment. Then an extra test will be needed before entering the loop to check \( \text{lo} \leq \text{hi} \).

FUNCTION CALL
Translating a function call \( f(a_1, \ldots, a_n) \) is simple, except that the static link must be added as an implicit extra argument:

\[
\text{CALL}(\text{NAME } l_f, [sl, e_1, e_2, \ldots, e_n])
\]

Here \( l_f \) is the label for \( f \), and \( sl \) is the static link, computed as described in Chapter 6. To do this computation, both the level of \( f \) and the level of the function calling \( f \) are required. A chain of (zero or more) offsets found in successive level descriptors is fetched, starting with the frame pointer \( \text{TEMP}(\text{FP}) \) defined by the Frame module.

7.3 DECLARATIONS

The clause to type-check \texttt{let} expressions was shown on page 118. It is not hard to augment this clause to translate into Tree expressions. \texttt{TransExp} and \texttt{transDec} now take more arguments than before (as described elsewhere in this chapter), and \texttt{transDec} must now return an extra result – the Tr_exp resulting from the evaluation of the declaration (this will be explained below).

The call to \texttt{transDec} will now side-effect the frame data structure: for each variable declaration within the declaration, additional space will be reserved in the current level’s frame. Also, for each function declaration, a new “fragment” of Tree code will be kept for the function’s body.

VARIABLE DEFINITION
The \texttt{transDec} function, described in Chapter 5, updates the value environment and type environment that are used in processing the body of a \texttt{let} expression.

However, the initialization of a variable translates into a Tree expression that must be put just before the body of the \texttt{let}. Therefore, \texttt{transDec} must also return a Tr_exp containing assignment expressions that accomplish these initializations.
If \texttt{transDec} is applied to function and type declarations, the result will be a “no-op” expression such as \texttt{Ex(CONST(0))}.

\section*{FUNCTION DEFINITION}
Each Tiger function is translated into a segment of assembly language with a \textit{prologue}, a \textit{body}, and an \textit{epilogue}. The body of a Tiger function is an expression, and the \textit{body} of the translation is simply the translation of that expression.

The \textit{prologue}, which precedes the body in the assembly-language version of the function, contains
\begin{enumerate}
    \item pseudo-instructions, as needed in the particular assembly language, to announce the beginning of a function;
    \item a label definition for the function name;
    \item an instruction to adjust the stack pointer (to allocate a new frame);
    \item instructions to save “escaping” arguments – including the static link – into the frame, and to move nonescaping arguments into fresh temporary registers;
    \item store instructions to save any callee-save registers – including the return address register – used within the function.
\end{enumerate}

Then comes
\begin{enumerate}
    \item the function \textit{body}.
\end{enumerate}

The \textit{epilogue} comes after the body and contains
\begin{enumerate}
    \item an instruction to move the return value (result of the function) to the register reserved for that purpose;
    \item load instructions to restore the callee-save registers;
    \item an instruction to reset the stack pointer (to deallocate the frame);
    \item a return instruction (JUMP to the return address);
    \item pseudo-instructions, as needed, to announce the end of a function.
\end{enumerate}

Some of these items (1, 3, 9, and 11) depend on exact knowledge of the frame size, which will not be known until after the register allocator determines how many local variables need to be kept in the frame because they don’t fit in registers. So these instructions should be generated very late, in a FRAME function called \texttt{procEntryExit3} (see also page 269). Item 2 (and 10), nestled between 1 and 3 (and 9 and 11, respectively) are also handled at that time.

To implement 7, the \texttt{Translate} phase should generate a move instruction
\begin{verbatim}
MOVE(RV, body)
\end{verbatim}
CHAPTER SEVEN. TRANSLATION TO INTERMEDIATE CODE

that puts the result of evaluating the body in the return value (RV) location specified by the machine-specific frame structure:

```
/* frame.h */
:
Temp_temp F_RV(void);
```

Item 4 (moving incoming formal parameters), and 5 and 8 (the saving and restoring of callee-save registers), are part of the view shift described on page 137. They should be done by a function in the Frame module:

```
/* frame.h */
:
T_stm F_procEntryExit1(F_frame frame, T_stm stm);
```

The implementation of this function will be discussed on page 267. Translate should apply it to each procedure body (items 5–7) as it is translated.

FRAGMENTS

Given a Tiger function definition comprising a level and an already-translated body expression, the Translate phase should produce a descriptor for the function containing this necessary information:

**frame:** The frame descriptor containing machine-specific information about local variables and parameters;

**body:** The result returned from procEntryExit1.

Call this pair a fragment to be translated to assembly language. It is the second kind of fragment we have seen; the other was the assembly-language pseudo-instruction sequence for a string literal. Thus, it is useful to define (in the Translate interface) a frag datatype:

```
/* frame.h */
:
typedef struct F_frag_ *F_frag;
struct F_frag_ { enum {F_stringFrag, F_procFrag} kind;
union {
    struct {Temp_label label;
             string str;} stringg;
    struct {T_stm body; F_frame frame;} proc;
} u;
};
F_frag F_StringFrag(Temp_label label, string str);
```
PROGRAMMING EXERCISE

```c
F_frag F_ProcFrag(T_stm body, F_frame frame);

typedef struct F_fragList_ *F_fragList;
struct F_fragList_ {F_frag head; F_fragList tail;};
F_fragList F_FragList(F_frag head, F_fragList tail);

/************************** translate.h **************************
void Tr_procEntryExit(Tr_level level, Tr_exp body,
                      Tr_accessList formals);
F_fragList Tr_getResult(void);

The semantic analysis phase calls upon Tr_newLevel in processing a
function header. Later it calls other interface functions of Translate to
translate the body of the Tiger function; this has the side effect of remembering DataFrag fragments for any string literals encountered (see pages 166
and 269). Finally the semantic analyzer calls procEntryExit, which has the side effect of remembering a ProcFrag.

All the remembered fragments go into a private fragment list within
Translate; then getResult can be used to extract the fragment list.

TRANSLATION TO TREES
Design translate.h, implement translate.c, and rewrite the Semant
structure to call upon Translate appropriately. The result of calling
SEM_transProg should be a F_fragList.

To keep things simpler (for now), keep all local variables in the frame; do
not bother with FindEscape, and assume that every variable escapes.

In the Frame module, a “dummy” implementation

```c
T_stm F_procEntryExit1(F_frame frame, T_stm stm) {
    return stm;
}
```
A simpler Translate. To simplify the implementation of Translate, you may do without the Ex, Nx, Cx constructors. The entire Translate module can be done with ordinary value-expressions. This makes Tr_exp identical to T_exp. That is, instead of Ex(e), just use e. Instead of Nx(s), use the expression ESEQ(s, CONST 0). For conditionals, instead of a Cx, use an expression that just evaluates to 1 or 0.

The intermediate representation trees produced from this kind of naive translation will be bulkier and slower than a “fancy” translation. But they will work correctly, and in principle a fancy back-end optimizer might be able to clean up the clumsiness. In any case, a clumsy but correct Translate module is better than a fancy one that doesn’t work.

EXERCISES

7.1 Suppose a certain compiler translates all expressions and subexpressions into T_exp trees, and does not use the Nx and Cx constructors to represent expressions in different ways. Draw a picture of the IR tree that results from each of the following expressions. Assume all variables are nonescaping unless specified otherwise.

a. a+5

b. b[i+1]

c. p.z.x, where p is a Tiger variable whose type is

   type m = {x:int,y:int,z:m}

d. write(" "), as it appears on line 13 of Program 6.3.

e. a<b, which should be implemented by making an ESEQ whose left-hand side moves a 1 or 0 into some newly defined temporary, and whose right-hand side is the temporary.

f. if a then b else c, where a is an integer variable (true if \( \neq 0 \)); this should also be translated using an ESEQ.

g. a := x+y, which should be translated with an EXP node at the top.

h. if a<b then c:=a else c:=b, translated using the a<b tree from part (e) above; the whole statement will therefore be rather clumsy and inefficient.

i. if a<b then c:=a else c:=b, translated in a less clumsy way.

7.2 Translate each of these expressions into IR trees, but using the Ex, Nx, and Cx constructors as appropriate. In each case, just draw pictures of the trees; an Ex
EXERCISES

tree will be a Tree $\text{exp}$, an $\text{Nx}$ tree will be a Tree $\text{stm}$, and a $\text{Cx}$ tree will be a $\text{stm}$ with holes labeled $true$ and $false$ into which labels can later be placed.

a. $a + 5$

b. $\text{output} := \text{concat} (\text{output}, s)$, as it appears on line 8 of Program 6.3.

The $\text{concat}$ function is part of the standard library (see page 525), and for purposes of computing its static link, assume it is at the same level of nesting as the $\text{prettyprint}$ function.

c. $b[i+1] := 0$

d. $(c := a + 1; c * c)$

e. while $a > 0$ do $a := a - 1$

f. $a < b$ moves a 1 or 0 into some newly defined temporary, and whose right-hand side is the temporary.

g. if $a$ then $b$ else $c$, where $a$ is an integer variable ($true$ if $\neq 0$).

h. $a := x + y$

i. if $a < b$ then $a$ else $b$

j. if $a < b$ then $c := a$ else $c := b$

7.3 Using the C compiler of your choice (or a compiler for another language), translate some functions to assembly language. On Unix this is done with the -S option to the C compiler.

Then identify all the components of the calling sequence (items 1–11), and explain what each line of assembly language does (especially the pseudo-instructions that comprise items 1 and 11). Try one small function that returns without much computation (a leaf function), and one that calls another function before eventually returning.

7.4 The Tree intermediate language has no operators for floating-point variables. Show how the language would look with new binops for floating-point arithmetic, and new relops for floating-point comparisons. You may find it useful to introduce a variant of $\text{MEM}$ nodes to describe fetching and storing floating-point values.

*7.5 The Tree intermediate language has no provision for data values that are not exactly one word long. The C programming language has signed and unsigned integers of several sizes, with conversion operators among the different sizes. Augment the intermediate language to accommodate several sizes of integers, with conversions among them.

**Hint:** Do not distinguish signed values from unsigned values in the intermediate trees, but do distinguish between signed operators and unsigned operators. See also Fraser and Hanson [1995], sections 5.5 and 9.1.
Basic Blocks and Traces

**canonical**: reduced to the simplest or clearest schema possible

*Webster's Dictionary*

The trees generated by the semantic analysis phase must be translated into assembly or machine language. The operators of the Tree language are chosen carefully to match the capabilities of most machines. However, there are certain aspects of the tree language that do not correspond exactly with machine languages, and some aspects of the Tree language interfere with compile-time optimization analyses.

For example, it’s useful to be able to evaluate the subexpressions of an expression in any order. But the subexpressions of Tree.exp can contain side effects – ESEQ and CALL nodes that contain assignment statements and perform input/output. If tree expressions did not contain ESEQ and CALL nodes, then the order of evaluation would not matter.

Some of the mismatches between Trees and machine-language programs are:

- The CJUMP instruction can jump to either of two labels, but real machines’ conditional jump instructions fall through to the next instruction if the condition is false.
- ESEQ nodes within expressions are inconvenient, because they make different orders of evaluating subtrees yield different results.
- CALL nodes within expressions cause the same problem.
- CALL nodes within the argument-expressions of other CALL nodes will cause problems when trying to put arguments into a fixed set of formal-parameter registers.

Why does the Tree language allow ESEQ and two-way CJUMP, if they
are so troublesome? Because they make it much more convenient for the 
Translate (translation to intermediate code) phase of the compiler.

We can take any tree and rewrite it into an equivalent tree without any of 
the cases listed above. Without these cases, the only possible parent of a SEQ 
node is another SEQ; all the SEQ nodes will be clustered at the top of the tree. 
This makes the SEQs entirely uninteresting; we might as well get rid of them 
and make a linear list of $T_{\text{stms}}$.

The transformation is done in three stages: First, a tree is rewritten into a 
list of canonical trees without SEQ or ESEQ nodes; then this list is grouped 
into a set of basic blocks, which contain no internal jumps or labels; then 
the basic blocks are ordered into a set of traces in which every CJUMP is 
immediately followed by its false label.

Thus the module Canon has these tree-rearrangement functions:

/* canon.h */

typedef struct C_stmListList_ *C_stmListList;
struct C_block { C_stmListList stmLists; Temp_label label;};
struct C_stmListList_ { T_stmList head; C_stmListList tail;};

T_stmList C_linearize(T_stm stm);
struct C_block C_basicBlocks(T_stmList stmList);
T_stmList C_traceSchedule(struct C_block b);

Linearize removes the ESEQs and moves the CALLs to top level. Then 
BasicBlocks groups statements into sequences of straight-line code. Fi-
nally traceSchedule orders the blocks so that every CJUMP is followed by 
its false label.

## 8.1. CANONICAL TREES

Let us define canonical trees as having these properties:

1. No SEQ or ESEQ.
2. The parent of each CALL is either EXP(...) or MOVE(TEMP t, ...).

### TRANSFORMATIONS ON ESEQ

How can the ESEQ nodes be eliminated? The idea is to lift them higher and 
higher in the tree, until they can become SEQ nodes.

Figure 8.1 gives some useful identities on trees.
CHAPTER EIGHT. BASIC BLOCKS AND TRACES

\[ \text{ESEQ}(s_1, \text{ESEQ}(s_2, e)) = \text{ESEQ}(\text{SEQ}(s_1, s_2), e) \]

\[ \text{BINOP}(op, \text{ESEQ}(s, e_1), e_2) = \text{ESEQ}(s, \text{BINOP}(op, e_1, e_2)) \]

\[ \text{MEM} (\text{ESEQ}(s, e_1)) = \text{ESEQ}(s, \text{MEM}(e_1)) \]

\[ \text{JUMP} (\text{ESEQ}(s, e_1)) = \text{SEQ}(s, \text{JUMP}(e_1)) \]

\[ \text{CJUMP}(op, \text{ESEQ}(s, e_1), e_2, l_1, l_2) = \text{SEQ}(s, \text{CJUMP}(op, e_1, e_2, l_1, l_2)) \]

\[ \text{BINOP}(op, e_1, \text{ESEQ}(s, e_2)) = \text{ESEQ}(\text{MOVE}(\text{TEMP} t, e_1), \text{BINOP}(op, e_1, e_2)) \]

\[ \text{CJUMP}(op, e_1, \text{ESEQ}(s, e_2), l_1, l_2) = \text{SEQ}(\text{MOVE}(\text{TEMP} t, e_1), \text{SEQ}(s, \text{CJUMP}(op, e_1, e_2, l_1, l_2))) \]

\[ \text{if } s, e_1 \text{ commute} \]

\[ \text{BINOP}(op, e_1, \text{ESEQ}(s, e_2)) = \text{ESEQ}(s, \text{BINOP}(op, e_1, e_2)) \]

\[ \text{CJUMP}(op, e_1, \text{ESEQ}(s, e_2), l_1, l_2) = \text{SEQ}(s, \text{CJUMP}(op, e_1, e_2, l_1, l_2)) \]

**FIGURE 8.1.** Identities on trees (see also Exercise 8.1).
Identity (1) is obvious. So is identity (2): Statement $s$ is to be evaluated; then $e_1$; then $e_2$; then the sum of the expressions is returned. If $s$ has side effects that affect $e_1$ or $e_2$, then either the left-hand side or the right-hand side of the first equation will execute those side effects before the expressions are evaluated.

Identity (3) is more complicated, because of the need not to interchange the evaluations of $s$ and $e_1$. For example, if $s$ is MOVE(MEM($x$), $y$) and $e_1$ is BINOP(PLUS, MEM($x$), $z$), then the program will compute a different result if $s$ is evaluated before $e_1$ instead of after. Our goal is simply to pull $s$ out of the BINOP expression; but now (to preserve the order of evaluation) we must pull $e_1$ out of the BINOP with it. To do so, we assign $e_1$ into a new temporary $t$, and put $t$ inside the BINOP.

It may happen that $s$ causes no side effects that can alter the result produced by $e_1$. This will happen if the temporaries and memory locations assigned by $s$ are not referenced by $e_1$ (and $s$ and $e_1$ don’t both perform external I/O). In this case, identity (4) can be used.

We cannot always tell if two expressions commute. For example, whether MOVE(MEM($x$), $y$) commutes with MEM($z$) depends on whether $x = z$, which we cannot always determine at compile time. So we conservatively approximate whether statements commute, saying either “they definitely do commute” or “perhaps they don’t commute.” For example, we know that any statement “definitely commutes” with the expression CONST($n$), so we can use identity (4) to justify special cases like

\[
\text{BINOP}(\text{op}, \text{CONST} (n), \text{ESEQ}(s, e)) = \text{ESEQ}(s, \text{BINOP}(\text{op}, \text{CONST} (n), e)).
\]

The \texttt{commute} function estimates (very naively) whether two expressions commute:

\begin{verbatim}
static bool isNop(T_stm x) {
    return x->kind == T_EXP && x->u.EXP->kind == T_CONST;
}
static bool commute(T_stm x, T_exp y) {
    return isNop(x) || y->kind==T_NAME || y->kind==T_CONST;
}
\end{verbatim}

A constant commutes with any statement, and the empty statement commutes with any expression. Anything else is assumed not to commute.
GENERAL REWRITING RULES

In general, for each kind of Tree statement or expression we can identify the subexpressions. Then we can make rewriting rules, similar to the ones in Figure 8.1, to pull the ESEQs out of the statement or expression.

For example, in $[e_1, e_2, \text{ESEQ}(s, e_3)]$, the statement $s$ must be pulled leftward past $e_2$ and $e_1$. If they commute, we have $(s; [e_1, e_2, e_3])$. But suppose $e_2$ does not commute with $s$; then we must have

$$(\text{SEQ}((t_1, e_1), \text{SEQ}((t_2, e_2), s)); \ [\text{TEMP}(t_1), \text{TEMP}(t_2), e_3])$$

Or if $e_2$ commutes with $s$ but $e_1$ does not, we have

$$(\text{SEQ}((t_1, e_1), s); \ [\text{TEMP}(t_1), e_2, e_3])$$

The reorder function takes a list of expressions and returns a pair of (statement, expression-list). The statement contains all the things that must be executed before the expression-list. As shown in these examples, this includes all the statement-parts of the ESEQs, as well as any expressions to their left with which they did not commute. When there are no ESEQs at all we will use $\text{EXP}(\text{CONST} 0)$, which does nothing, as the statement.

**Algorithm.** Step one is to make a “subexpression-extraction” method for each kind. Step two is to make a “subexpression-insertion” method: given an ESEQ-clean version of each subexpression, this builds a new version of the expression or statement.

```c
typedef struct expRefList_ *expRefList;
struct expRefList_ {T_exp *head; expRefList tail;};

struct stmExp {T_stm s; T_exp e;};
static T_stm reorder(expRefList rlist);
static T_stm do_stm(T_stm stm);
static struct stmExp do_exp(T_exp exp);
```

The reorder function is supposed to pull all the ESEQs out of a list of expressions and combine the statement-parts of these ESEQ into one big $T\_stm$. The argument to reorder is a list of references to the immediate subexpressions of that statement. Figure 8.2 illustrates the use of a pointer to a pointer. If we call reorder($l_2$), we are saying, “please pull any ESEQs out of the children and grandchildren of this BINOP node $e_2$. For your convenience, the
places where it points to its children are at the locations pointed to by the list $l_2$. For each child that is an ESEQ($s_k$, $e_k$), you should update the child-pointer to point to $e_k$ instead and put $s_k$ on the big sequence of statements that you will return as a result.”

Reorder($l_2$) calls upon an auxiliary function do_exp on each expression in the list $l_2$, that is, the expressions $e_1$ and $e_3$. Do_exp($e_1$) returns a statement $s_1$ and an expression $e'_1$, where $e'_1$ contains no ESEQs, such that ESEQ($s$, $e'_1$) would be equivalent to the original expression $e_1$. In this case, since $e_1$ is so trivial, $s_1$ will be a no-op statement EXP(CONST(0)) and $e'_1 = e_1$. But if expression $e_3$’s MEM node pointed to ESEQ($s_x$, TEMP $a$), then do_exp($e_3$) will yield $s_3 = s_x$ and $e'_3 = MEM(TEMP a)$.

The implementation of do_exp is rather simple. For any kind of expression except ESEQ, do_exp just makes a list of the subexpression references and calls reorder:

```c
static struct stmExp do_exp(T_exp exp) {
    switch(exp->kind) {
    case T_BINOP:
        return StmExp(reorder(ExpRefList(&exp->u.BINOP.left,
                                         ExpRefList(&exp->u.BINOP.right, NULL))), exp);
    case T_MEM:
        return StmExp(reorder(ExpRefList(&exp->u.MEM,NULL)), exp);
    case T_ESEQ: {
        struct stmExp x = do_exp(exp->u.ESEQ.exp);
        return StmExp(seq(do_stm(exp->u.ESEQ.stm), x.s), x.e);
    }
    case T_CALL:
        return StmExp(reorder(get_call_rlist(exp)), exp);
    default:
        return StmExp(reorder(NULL), exp);  
    }}
}
```

The function seq($s_1$, $s_2$) just returns a statement equivalent to SEQ($s_1$, $s_2$), but in the very common case that $s_1$ or $s_2$ is a no-op, we can do something simpler:

```c
static T_stm seq(T_stm x, T_stm y) {
    if (isNop(x)) return y;
    if (isNop(y)) return x;
    return T_Seq(x,y);
}
```
The ESEQ case of do_exp must call do_stm, which pulls all the ESEQs out of a statement. It also works by making a list of all the subexpression references and calling reorder:

```c
static T_stm do_stm(T_stm stm) {
    switch (stm->kind) {
    case T_SEQ:
        return seq(do_stm(stm->u.SEQ.left),
                   do_stm(stm->u.SEQ.right));
    case T_JUMP:
        return seq(reorder(ExpRefList(&stm->u.JUMP.exp,NULL)), stm);
    case T_CJUMP:
        return seq(reorder(ExpRefList(&stm->u.CJUMP.left,
                                   ExpRefList(&stm->u.CJUMP.right,NULL))), stm);
    case T_MOVE:
        : see below
    case T_EXP:
        if (stm->u.EXP->kind == T_CALL)
            return seq(reorder(get_call_rlist(stm->u.EXP)), stm);
        else return seq(reorder(ExpRefList(&stm->u.EXP, NULL)),
                         stm);
    default:
        return stm;
    }
}
```

The left-hand operand of the MOVE statement is not considered a subexpression, because it is the destination of the statement – its value is not used.
by the statement. However, if the destination is a memory location, then the
address acts like a source. Thus we have,

```c
static T_stm do_stm(T_stm stm) {
    :
    case T_MOVE:
        if (stm->u.MOVE.dst->kind == T_TEMP &&
            stm->u.MOVE.src->kind == T_CALL)
            return seq(reorder(get_call_rlist(stm->u.MOVE.src)),
                        stm);
        else if (stm->u.MOVE.dst->kind == T_TEMP)
            return seq(reorder(ExpRefList(&stm->u.MOVE.src, NULL)),
                        stm);
        else if (stm->u.MOVE.dst->kind == T_MEM)
            return seq(reorder(ExpRefList(&stm->u.MOVE.dst->u.MEM,
                                        ExpRefList(&stm->u.MOVE.src, NULL))),
                        stm);
        else if (stm->u.MOVE.dst->kind == T_ESEQ) {
            T_stm s = stm->u.MOVE.dst->u.ESEQ.stm;
            stm->u.MOVE.dst = stm->u.MOVE.dst->u.ESEQ.exp;
            return do_stm(T_Seq(s, stm));
        }
    :
}
```

With the assistance of `do_exp` and `do_stm`, the `reorder` function can pull the statement $s_i$ out of each expression $e_i$ on its list of references, going from right to left.

**MOVING CALLS TO TOP LEVEL**

The `Tree` language permits `CALL` nodes to be used as subexpressions. However, the actual implementation of `CALL` will be that each function returns its result in the same dedicated return-value register `TEMP(RV)`. Thus, if we have

```
BINOP(PLUS, CALL(...), CALL(...))
```

the second call will overwrite the `RV` register before the `PLUS` can be executed.

We can solve this problem with a rewriting rule. The idea is to assign each return value immediately into a fresh temporary register, that is

```
CALL(fun, args) → ESEQ(MOVE(TEMP t, CALL(fun, args)), TEMP t)
```

Now the `ESEQ`-eliminator will percolate the `MOVE` up outside of its containing `BINOP` (etc.) expressions.
This technique will generate a few extra MOVE instructions, which the register allocator (Chapter 11) can clean up.

The rewriting rule is implemented as follows: reorder replaces any occurrence of CALL\( (f, \text{args}) \) by

\[
\text{ESEQ}(\text{MOVE}(\text{TEMP } t_{\text{new}}, \text{CALL}(f, \text{args})), \text{TEMP } t_{\text{new}})
\]

and calls itself again on the ESEQ. But do_stm recognizes the pattern

\[
\text{MOVE}(\text{TEMP } t_{\text{new}}, \text{CALL}(f, \text{args}))
\]

and does not call reorder on the CALL node in that case, but treats the \( f \) and \( \text{args} \) as the children of the MOVE node. Thus, reorder never “sees” any CALL that is already the immediate child of a MOVE. Occurrences of the pattern \( \text{EXP}(\text{CALL}(f, \text{args})) \) are treated similarly.

**A LINEAR LIST OF STATEMENTS**

Once an entire function body \( s_0 \) is processed with do_stm, the result is a tree \( s'_0 \) where all the SEQ nodes are near the top (never underneath any other kind of node). The linearize function repeatedly applies the rule

\[
\text{SEQ}(\text{SEQ}(a, b), c) = \text{SEQ}(a, \text{seq}(b, c))
\]

The result is that \( s'_0 \) is linearized into an expression of the form

\[
\text{SEQ}(s_1, \text{SEQ}(s_2, \ldots, \text{SEQ}(s_{n-1}, s_n))\ldots)
\]

Here the SEQ nodes provide no structuring information at all, and we can just consider this to be a simple list of statements,

\[s_1, s_2, \ldots, s_{n-1}, s_n\]

where none of the \( s_i \) contain SEQ or ESEQ nodes.

These rewrite rules are implemented by linearize, with an auxiliary function linear:

```c
static T_stmList linear(T_stm stm, T_stmList right) {
    if (stm->kind == T_SEQ)
        return linear(stm->u.SEQ.left,
                      linear(stm->u.SEQ.right,
                              right));
    else return T_StmList(stm, right);
}

T_stmList C_linearize(T_stm stm) {
    return linear(do_stm(stm), NULL);
}
```
8.2 TAMING CONDITIONAL BRANCHES

Another aspect of the Tree language that has no direct equivalent in most machine instruction sets is the two-way branch of the CJUMP instruction. The Tree language CJUMP is designed with two target labels for convenience in translating into trees and analyzing trees. On a real machine, the conditional jump either transfers control (on a true condition) or “falls through” to the next instruction.

To make the trees easy to translate into machine instructions, we will rearrange them so that every CJUMP(cond, lt, lf) is immediately followed by LABEL(lf), its “false branch.” Each such CJUMP can be directly implemented on a real machine as a conditional branch to label lt.

We will make this transformation in two stages: first, we take the list of canonical trees and form them into basic blocks; then we order the basic blocks into a trace. The next sections will define these terms.

BASIC BLOCKS

In determining where the jumps go in a program, we are analyzing the program’s control flow. Control flow is the sequencing of instructions in a program, ignoring the data values in registers and memory, and ignoring the arithmetic calculations. Of course, not knowing the data values means we cannot know whether the conditional jumps will go to their true or false labels; so we simply say that such jumps can go either way.

In analyzing the control flow of a program, any instruction that is not a jump has an entirely uninteresting behavior. We can lump together any sequence of non-branch instructions into a basic block and analyze the control flow between basic blocks.

A basic block is a sequence of statements that is always entered at the beginning and exited at the end, that is:

- The first statement is a LABEL.
- The last statement is a JUMP or CJUMP.
- There are no other LABELS, JUMPS, or CJUMPS.

The algorithm for dividing a long sequence of statements into basic blocks is quite simple. The sequence is scanned from beginning to end; whenever a LABEL is found, a new block is started (and the previous block is ended); whenever a JUMP or CJUMP is found, a block is ended (and the next block is started). If this leaves any block not ending with a JUMP or CJUMP, then
a JUMP to the next block’s label is appended to the block. If any block has been left without a LABEL at the beginning, a new label is invented and stuck there.

We will apply this algorithm to each function-body in turn. The procedure “epilogue” (which pops the stack and returns to the caller) will not be part of this body, but is intended to follow the last statement. When the flow of program execution reaches the end of the last block, the epilogue should follow. But it is inconvenient to have a “special” block that must come last and that has no JUMP at the end. Thus, we will invent a new label done – intended to mean the beginning of the epilogue – and put a JUMP(NAME done) at the end of the last block.

In the Tiger compiler, the function C_basicBlocks implements this simple algorithm.

TRACES
Now the basic blocks can be arranged in any order, and the result of executing the program will be the same – every block ends with a jump to the appropriate place. We can take advantage of this to choose an ordering of the blocks satisfying the condition that each CJUMP is followed by its false label.

At the same time, we can also arrange that many of the unconditional JUMPS are immediately followed by their target label. This will allow the deletion of these jumps, which will make the compiled program run a bit faster.

A trace is a sequence of statements that could be consecutively executed during the execution of the program. It can include conditional branches. A program has many different, overlapping traces. For our purposes in arranging CJUMPS and false-labels, we want to make a set of traces that exactly covers the program: each block must be in exactly one trace. To minimize the number of JUMPS from one trace to another, we would like to have as few traces as possible in our covering set.

A very simple algorithm will suffice to find a covering set of traces. The idea is to start with some block – the beginning of a trace – and follow a possible execution path – the rest of the trace. Suppose block \( b_1 \) ends with a JUMP to \( b_4 \), and \( b_4 \) has a JUMP to \( b_6 \). Then we can make the trace \( b_1, b_4, b_6 \).

But suppose \( b_6 \) ends with a conditional jump CJUMP\((\text{cond}, b_7, b_3)\). We cannot know at compile time whether \( b_7 \) or \( b_3 \) will be next. But we can assume that some execution will follow \( b_3 \), so let us imagine it is that execution that we are simulating. Thus, we append \( b_3 \) to our trace and continue with the rest
8.2. TAMING CONDITIONAL BRANCHES

Put all the blocks of the program into a list $Q$.

\begin{algorithm}
\textbf{while} $Q$ is not empty
\begin{itemize}
\item Start a new (empty) trace, call it $T$.
\item Remove the head element $b$ from $Q$.
\item \textbf{while} $b$ is not marked
\begin{itemize}
\item Mark $b$; append $b$ to the end of the current trace $T$.
\item Examine the successors of $b$ (the blocks to which $b$ branches);
\begin{itemize}
\item \textbf{if} there is any unmarked successor $c$
\item $b \leftarrow c$
\end{itemize}
\end{itemize}
(All the successors of $b$ are marked.)
\end{itemize}
End the current trace $T$.
\end{algorithm}

\textbf{Algorithm 8.3.} Generation of traces.

of the trace after $b_3$. The block $b_7$ will be in some other trace.

Algorithm 8.3 (which is similar to \texttt{c_traceSchedule}) orders the blocks into traces as follows: It starts with some block and follows a chain of jumps, marking each block and appending it to the current trace. Eventually it comes to a block whose successors are all marked, so it ends the trace and picks an unmarked block to start the next trace.

FINISHING UP

An efficient compiler will keep the statements grouped into basic blocks, because many kinds of analysis and optimization algorithms run faster on (relatively few) basic blocks than on (relatively many) individual statements. For the Tiger compiler, however, we seek simplicity in the implementation of later phases. So we will flatten the ordered list of traces back into one long list of statements.

At this point, most (but not all) CJUMP s will be followed by their true or false label. We perform some minor adjustments:

- Any CJUMP immediately followed by its false label we let alone (there will be many of these).
- For any CJUMP followed by its true label, we switch the true and false labels and negate the condition.
- For any CJUMP($cond$, $a$, $b$, $l_t$, $l_f$) followed by neither label, we invent a new false label $l'_f$ and rewrite the single CJUMP statement as three statements, just to achieve the condition that the CJUMP is followed by its false label:
**FIGURE 8.4.** Different trace coverings for the same program.

\[
\text{CJUMP} (\text{cond}, a, b, l_t, l'_f) \\
\text{LABEL } l'_f \\
\text{JUMP} (\text{NAME } l_f)
\]

The trace-generating algorithm will tend to order the blocks so that many of the unconditional JUMPs are immediately followed by their target labels. We can remove such jumps.

**OPTIMAL TRACES**

For some applications of traces, it is important that any frequently executed sequence of instructions (such as the body of a loop) should occupy its own trace. This helps not only to minimize the number of unconditional jumps, but also may help with other kinds of optimization such as register allocation and instruction scheduling.

Figure 8.4 shows the same program organized into traces in different ways. Figure 8.4a has a CJUMP and a JUMP in every iteration of the while-loop; Figure 8.4b uses a different trace covering, also with CJUMP and a JUMP in every iteration. But 8.4c shows a better trace covering, with no JUMP in each iteration.

The Tiger compiler’s Canon module doesn’t attempt to optimize traces around loops, but it is sufficient for the purpose of cleaning up the Tree-statement lists for generating assembly code.

**FURTHER READING**

The rewrite rules of Figure 8.1 are an example of a term rewriting system; such systems have been much studied [Dershowitz and Jouannaud 1990].
Fisher [1981] shows how to cover a program with traces so that frequently executing paths tend to stay within the same trace. Such traces are useful for program optimization and scheduling.

**EXERCISES**

*8.1* The rewriting rules in Figure 8.1 are a subset of the rules necessary to eliminate all ESEQs from expressions. Show the right-hand side for each of the following incomplete rules:

a. \(\text{MOVE}(\text{TEMP } t, \text{ ESEQ}(s, e)) \Rightarrow\)
b. \(\text{MOVE}(\text{MEM}(\text{ESEQ}(s, e_1)), e_2) \Rightarrow\)
c. \(\text{MOVE}(\text{MEM}(e_1), \text{ESEQ}(s, e_2)) \Rightarrow\)
d. \(\text{EXP}(\text{ESEQ}(s, e)) \Rightarrow\)
e. \(\text{EXP}(\text{CALL}(\text{ESEQ}(s, e), \text{args})) \Rightarrow\)
f. \(\text{MOVE}(\text{TEMP } t, \text{ CALL}(\text{ESEQ}(s, e), \text{args})) \Rightarrow\)
g. \(\text{EXP}(\text{CALL}(e_1, [e_2, \text{ESEQ}(s, e_3), e_4])) \Rightarrow\)

In some cases, you may need two different right-hand sides depending on whether something commutes (just as parts (3) and (4) of Figure 8.1 have different right-hand sides for the same left-hand sides).

**8.2** Draw each of the following expressions as a tree diagram, and then apply the rewriting rules of Figure 8.1 and Exercise 8.1, as well as the \texttt{CALL} rule on page 183.

a. \(\text{MOVE}(\text{MEM}(\text{ESEQ}(\text{SEQ}((\text{CJUMP}(\text{LT}, \text{TEMP}_i, \text{CONST } 0), \text{Lout}, \text{Lok}, \text{LABEL}_{ok}), \text{TEMP}_i)), \text{CONST } 1))\)
b. \(\text{MOVE}(\text{MEM}(\text{NAME}_a), \text{MEM}(\text{CALL}(\text{TEMP}_f, [])))\)
c. \(\text{BINOP}(\text{PLUS}, \text{CALL}(\text{NAME}_f, [\text{TEMP}_x]), \text{CALL}(\text{NAME}_g, [\text{ESEQ}(\text{MOVE}(\text{TEMP}_x, \text{CONST}_0), \text{TEMP}_x)]))\)

*8.3* The directory \texttt{STIGER/chap8} contains an implementation of every algorithm described in this chapter. Read and understand it.

**8.4** A primitive form of the \texttt{commute} test is shown on page 179. This function is conservative: if interchanging the order of evaluation of the expressions will change the result of executing the program, this function will definitely return false; but if an interchange is harmless, \texttt{commute} might return true or false.

Write a more powerful version of \texttt{commute} that returns true in more cases, but is still conservative. Document your program by drawing pictures of (pairs of) expression trees on which it will return true.
CHAPTER EIGHT. BASIC BLOCKS AND TRACES

*8.5 The left-hand side of a MOVE node really represents a destination, not an expression. Consequently, the following rewrite rule is not a good idea:

\[
\text{MOVE}(e_1, \text{ESEQ}(s, e_2)) \rightarrow \text{SEQ}(s, \text{MOVE}(e_1, e_2)) \text{ if } s, e_1 \text{ commute}
\]

Write an statement matching the left side of this rewrite rule that produces a different result when rewritten.

**Hint:** It is very reasonable to say that the statement \(\text{MOVE}(\text{TEMP}_a, \text{TEMP}_b)\) commutes with expression \(\text{TEMP}_b\) (if \(a\) and \(b\) are not the same), since \(\text{TEMP}_b\) yields the same value whether executed before or after the MOVE.

Conclusion: The only subexpression of \(\text{MOVE}(\text{TEMP}_a, e)\) is \(e\), and the subexpressions of \(\text{MOVE}(\text{MEM}(e_1), e_2)\) are \([e_1, e_2]\); we should not say that \(a\) is a subexpression of \(\text{MOVE}(a, b)\).

8.6 Break this program into basic blocks.

```
1 m ← 0
2 v ← 0
3 if v ≥ n goto 15
4 r ← v
5 s ← 0
6 if r < n goto 9
7 v ← v + 1
8 goto 3
9 x ← M[r]
10 s ← s + x
11 if s ≤ m goto 13
12 m ← s
13 r ← r + 1
14 goto 6
15 return m
```

8.7 Express the basic blocks of Exercise 8.6 as statements in the Tree intermediate form, and use Algorithm 8.3 to generate a set of traces.
Instruction Selection

**Instruction**: a code that tells a computer to perform a particular operation

*Webster's Dictionary*

The intermediate representation (Tree) language expresses only one operation in each tree node: memory fetch or store, addition or subtraction, conditional jump, and so on. A real machine instruction can often perform several of these primitive operations. For example, almost any machine can perform an add and a fetch in the same instruction, corresponding to the tree

![Tree diagram](image)

Finding the appropriate machine instructions to implement a given intermediate representation tree is the job of the *instruction selection* phase of a compiler.

**TREE PATTERNS**

We can express a machine instruction as a fragment of an IR tree, called a *tree pattern*. Then instruction selection becomes the task of tiling the tree with a minimal set of tree patterns.

For purposes of illustration, we invent an instruction set: the *Jouette* architecture. The arithmetic and memory instructions of *Jouette* are shown in Figure 9.1. On this machine, register $r_0$ always contains zero.
### FIGURE 9.1.

</tbody>
</table>

Each instruction above the double line in Figure 9.1 produces a result in a register. The very first entry is not really an instruction, but expresses the idea that a TEMP node is implemented as a register, so it can “produce a result in a register” without executing any instructions at all. The instructions below the double line do not produce results in registers, but are executed only for side effects on memory.

For each instruction, the tree-patterns it implements are shown. Some instructions correspond to more than one tree pattern; the alternate patterns are obtained for commutative operators (+ and \( \times \)), and in some cases where a register or constant can be zero (LOAD and STORE). In this chapter we abbre-
violate the tree diagrams slightly: BINOP\((\text{PLUS}, x, y)\) nodes will be written as \(+ (x, y)\), and the actual values of CONST and TEMP nodes will not always be shown.

The fundamental idea of instruction selection using a tree-based intermediate representation is tiling the IR tree. The tiles are the set of tree patterns corresponding to legal machine instructions, and the goal is to cover the tree with nonoverlapping tiles.

For example, the Tiger-language expression such as \(a[i] := x\), where \(i\) is a register variable and \(a\) and \(x\) are frame-resident, results in a tree that can be tiled in many different ways. Two tilings, and the corresponding instruction sequences, are shown in Figure 9.2 (remember that \(a\) is really the frame offset of the pointer to an array). In each case, tiles 1, 3, and 7 do not correspond to any machine instructions, because they are just registers (TEMPS) already containing the right values.

Finally – assuming a “reasonable” set of tile-patterns – it is always possible to tile the tree with tiny tiles, each covering only one node. In our example, such a tiling looks like this:

![Image of a tree tiled in two ways]
CHAPTER NINE. INSTRUCTION SELECTION

```plaintext
ADDI   r1 ← r0 + a
ADD    r1 ← fp + r1
LOAD   r1 ← M[r1 + 0]
ADDI   r2 ← r0 + 4
MUL    r2 ← ri × r2
ADD    r1 ← r1 + r2
ADDI   r2 ← r0 + x
ADD    r2 ← fp + r2
LOAD   r2 ← M[r2 + 0]
STORE  M[r1 + 0] ← r2
```

For a reasonable set of patterns, it is sufficient that each individual Tree node correspond to some tile. It is usually possible to arrange for this; for example, the LOAD instruction can be made to cover just a single MEM node by using a constant of 0, and so on.

OPTIMAL AND OPTIMUM TILINGS

The best tiling of a tree corresponds to an instruction sequence of least cost: the shortest sequence of instructions. Or if the instructions take different amounts of time to execute, the least-cost sequence has the lowest total time.

Suppose we could give each kind of instruction a cost. Then we could define an optimum tiling as the one whose tiles sum to the lowest possible value. An optimal tiling is one where no two adjacent tiles can be combined into a single tile of lower cost. If there is some tree pattern that can be split into several tiles of lower combined cost, then we should remove that pattern from our catalog of tiles before we begin.

Every optimum tiling is also optimal, but not vice versa. For example, suppose every instruction costs one unit, except for MOVEM which costs m units. Then either Figure 9.2a is optimum (if m > 1) or Figure 9.2b is optimum (if m < 1) or both (if m = 1); but both trees are optimal.

Optimum tiling is based on an idealized cost model. In reality, instructions are not self-contained with individually attributable costs; nearby instructions interact in many ways, as discussed in Chapter 20.

9.1 ALGORITHMS FOR INSTRUCTION SELECTION

There are good algorithms for finding optimum and optimal tilings, but the algorithms for optimal tilings are simpler, as you might expect.
9.1. ALGORITHMS FOR INSTRUCTION SELECTION

Complex Instruction Set Computers (CISC) have instructions that accomplish several operations each. The tiles for these instructions are quite large, and the difference between optimum and optimal tilings – while never very large – is at least sometimes noticeable.

Most architectures of modern design are Reduced Instruction Set Computers (RISC). Each RISC instruction accomplishes just a small number of operations (all the Jouette instructions except MOVEM are typical RISC instructions). Since the tiles are small and of uniform cost, there is usually no difference at all between optimum and optimal tilings. Thus, the simpler tiling algorithms suffice.

MAXIMAL MUNCH

The algorithm for optimal tiling is called Maximal Munch. It is quite simple. Starting at the root of the tree, find the largest tile that fits. Cover the root node – and perhaps several other nodes near the root – with this tile, leaving several subtrees. Now repeat the same algorithm for each subtree.

As each tile is placed, the instruction corresponding to that tile is generated. The Maximal Munch algorithm generates the instructions in reverse order – after all, the instruction at the root is the first to be generated, but it can only execute after the other instructions have produced operand values in registers.

The “largest tile” is the one with the most nodes. For example, the tile for ADD has one node, the tile for SUBI has two nodes, and the tiles for STORE and MOVEM have three nodes each.

If two tiles of equal size match at the root, then the choice between them is arbitrary. Thus, in the tree of Figure 9.2, STORE and MOVEM both match, and either can be chosen.

Maximal Munch is quite straightforward to implement in C. Simply write two recursive functions, munchStm for statements and munchExp for expressions. Each clause of munchExp will match one tile. The clauses are ordered in order of tile preference (biggest tiles first).

Programs 9.3 and 9.4 sketch a partial example of a Jouette code-generator based on the Maximal Munch algorithm. Executing this program on the tree of Figure 9.2 will match the first clause of munchStm; this will call munchExp to emit all the instructions for the operands of the STORE, followed by the STORE itself. Program 9.3 does not show how the registers are chosen and operand syntax is specified for the instructions; we are concerned here only with the pattern-matching of tiles.
static void munchStmt(T_stm s) {
    switch(s->kind) {
    case T_MOVE: {
        T_exp dst = s->u.MOVE.dst, src = s->u.MOVE.src;
        if (dst->kind==T_MEM) {
            if (dst->u.MEM->kind==T_BINOP
                && dst->u.MEM->u.BINOP.op==T_plus
                && dst->u.MEM->u.BINOP.right->kind==T_CONST) {
                T_exp e1 = dst->u.MEM->u.BINOP.left, e2=src;
                /* MOVE(MEM(BINOP(PLUS,e1,CONST(i))),e2) */
                munchExp(e1); munchExp(e2); emit("STORE");
            }
            else if (dst->u.MEM->kind==T_BINOP
                && dst->u.MEM->u.BINOP.op==T_plus
                && dst->u.MEM->u.BINOP.left->kind==T_CONST) {
                T_exp e1 = dst->u.MEM->u.BINOP.right, e2=src;
                /* MOVE(MEM(BINOP(PLUS,CONST(i)),e1),e2) */
                munchExp(e1); munchExp(e2); emit("STORE");
            }
            else if (src->kind==T_MEM) {
                T_exp e1 = dst->u.MEM, e2=src->u.MEM;
                /* MOVE(MEM(e1),MEM(e2)) */
                munchExp(e1); munchExp(e2); emit("MOVEM");
            }
            else {
                T_exp e1 = dst->u.MEM, e2=src;
                /* MOVE(MEM(e1),e2) */
                munchExp(e1); munchExp(e2); emit("STORE");
            }
        }
        else if (dst->kind==T_TEMP) {
            T_exp e2=src;
            /* MOVE(TEMP˜,e2) */
            munchExp(e2); emit("ADD");
        }
        else assert(0);
        /* destination of MOVE must be MEM or TEMP */
        break;
    }
    case T_JUMP: ...
    case T_CUMP: ...
    case T_NAME: ...
    }

PROGRAM 9.3. Maximal Munch in C.

If, for each node-type in the Tree language, there exists a single-node tile pattern, then Maximal Munch cannot get “stuck” with no tile to match some subtree.
DYNAMIC PROGRAMMING

Maximal Munch always finds an optimal tiling, but not necessarily an optimum. A dynamic-programming algorithm can find the optimum. In general, dynamic programming is a technique for finding optimum solutions for a whole problem based on the optimum solution of each subproblem; here the subproblems are the tilings of the subtrees.

The dynamic-programming algorithm assigns a cost to every node in the tree. The cost is the sum of the instruction-costs of the best instruction sequence that can tile the subtree rooted at that node.

This algorithm works bottom-up, in contrast to Maximal Munch, which works top-down. First, the costs of all the children (and grandchildren, etc.) of node $n$ are found recursively. Then, each tree-pattern (tile kind) is matched against node $n$.

Each tile has zero or more leaves. In Figure 9.1 the leaves are represented as edges whose bottom ends exit the tile. The leaves of a tile are places where subtrees can be attached.

For each tile $t$ of cost $c$ that matches at node $n$, there will be zero or more subtrees $s_i$ corresponding to the leaves of the tile. The cost $c_i$ of each subtree has already been computed (because the algorithm works bottom-up). So the cost of matching tile $t$ is just $c + \sum c_i$.

Of all the tiles $t_j$ that match at node $n$, the one with the minimum-cost match is chosen, and the (minimum) cost of node $n$ is thus computed. For example, consider this tree:

```
  MEM
    |
    +
  CONST 1  CONST 2
```

```
static void munchStm(T_stm s)
MEM(BINOP(PLUS, e1, CONST(i))) ⇒ munchExp(e1); emit("LOAD");
MEM(BINOP(PLUS, CONST(i), e1)) ⇒ munchExp(e1); emit("LOAD");
MEM(CONST(i)) ⇒ emit("LOAD");
MEM(e1) ⇒ munchExp(e1); emit("LOAD");
BINOP(PLUS, e1, CONST(i)) ⇒ munchExp(e1); emit("ADDI");
BINOP(PLUS, CONST(i), e1) ⇒ munchExp(e1); emit("ADDI");
CONST(i) ⇒ munchExp(e1); emit("ADDI");
BINOP(PLUS, e1, CONST(i)) ⇒ munchExp(e1); emit("ADD");
TEMP(t) ⇒ {}
The only tile that matches \texttt{CONST 1} is an \texttt{ADDI} instruction with cost 1. Similarly, \texttt{CONST 2} has cost 1. Several tiles match the + node:

<table>
<thead>
<tr>
<th>Tile</th>
<th>Instruction</th>
<th>Tile Cost</th>
<th>Leaves Cost</th>
<th>Total Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>+</td>
<td>ADD</td>
<td>1</td>
<td>1+1</td>
<td>3</td>
</tr>
<tr>
<td>+</td>
<td>ADDI</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>CONST</td>
<td>+</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>+</td>
<td>ADDI</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>CONST</td>
<td>+</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>MEM</td>
<td>LOAD</td>
<td>1</td>
<td>2</td>
<td>3</td>
</tr>
<tr>
<td>+</td>
<td>LOAD</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>MEM</td>
<td>LOAD</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

The \texttt{ADD} tile has two leaves, but the \texttt{ADDI} tile has only one leaf. In matching the first \texttt{ADDI} pattern, we are saying “though we computed the cost of tiling \texttt{CONST 2}, we are not going to use that information.” If we choose to use the first \texttt{ADDI} pattern, then \texttt{CONST 2} will not be the root of any tile, and its cost will be ignored. In this case, either of the two \texttt{ADDI} tiles leads to the minimum cost for the + node, and the choice is arbitrary. The + node gets a cost of 2.

Now, several tiles match the MEM node:

<table>
<thead>
<tr>
<th>Tile</th>
<th>Instruction</th>
<th>Tile Cost</th>
<th>Leaves Cost</th>
<th>Total Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>MEM</td>
<td>LOAD</td>
<td>1</td>
<td>2</td>
<td>3</td>
</tr>
<tr>
<td>+</td>
<td>LOAD</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>MEM</td>
<td>LOAD</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

Either of the last two matches will be optimum.

Once the cost of the root node (and thus the entire tree) is found, the instruction emission phase begins. The algorithm is as follows:

Emission(node \( n \)): for each leaf \( l_i \) of the tile selected at node \( n \), perform Emission\((l_i)\). Then emit the instruction matched at node \( n \).

Emission\((n)\) does \textit{not} recur on the children of node \( n \), but on the \textit{leaves of the tile} that matched at \( n \). For example, after the dynamic programming
algorithm finds the optimum cost of the simple tree above, the Emission phase emits

\[
\begin{align*}
\text{ADDI} & \quad r_1 \leftarrow r_0 + 1 \\
\text{LOAD} & \quad r_1 \leftarrow M[r_1 + 2]
\end{align*}
\]

but no instruction is emitted for any tile rooted at the + node, because this was not a leaf of the tile matched at the root.

**TREE GRAMMARS**

For machines with complex instruction sets and several classes of registers and addressing modes, there is a useful generalization of the dynamic programming algorithm. Suppose we make a brain-damaged version of *Jouette* with two classes of registers: *a* registers for addressing, and *d* registers for “data.” The instruction set of the *Schizo-Jouette* machine (loosely based on the Motorola 68000) is shown in Figure 9.5.

The root and leaves of each tile must be marked with *a* or *d* to indicate which kind of register is implied. Now, the dynamic programming algorithm must keep track, for each node, of the min-cost match as an *a* register, and also the min-cost match as a *d* register.

At this point it is useful to use a context-free grammar to describe the tiles; the grammar will have nonterminals *s* (for statements), *a* (for expressions calculated into an *a* register), and *d* (for expressions calculated into a *d* register). Section 3.1 describes the use of context-free grammars for source-language syntax; here we use them for quite a different purpose.

The grammar rules for the LOAD, MOVEA, and MOVED instructions might look like this:

\[
\begin{align*}
\text{d} & \rightarrow \text{MEM}(+(a, \text{CONST})) \\
\text{d} & \rightarrow \text{MEM}(+(\text{CONST}, a)) \\
\text{d} & \rightarrow \text{MEM}(\text{CONST}) \\
\text{d} & \rightarrow \text{MEM}(a) \\
\text{d} & \rightarrow a \\
\text{a} & \rightarrow d
\end{align*}
\]

Such a grammar is highly ambiguous: there are many different parses of the same tree (since there are many different instruction sequences implementing the same expression). For this reason, the parsing techniques described in Chapter 3 are not very useful in this application. However, a generalization of the dynamic programming algorithm works quite well: the
## Figure 9.5

The Schizo-Jouette architecture.
minimum-cost match at each node for each nonterminal of the grammar is computed.

Though the dynamic programming algorithm is conceptually simple, it becomes messy to write down directly in a general-purpose programming language such as C. Thus, several tools have been developed. These code-generator generators process grammars that specify machine instruction sets; for each rule of the grammar, a cost and an action are specified. The costs are used to find the optimum tiling, and then the actions of the matched rules are used in the emission phase.

Like Yacc and Lex, the output of a code-generator generator is usually a program in C that operates a table-driven matching engine with the action fragments (written in C) inserted at the appropriate points.

Such tools are quite convenient. Grammars can specify addressing modes of treelike CISC instructions quite well. A typical grammar for the VAX has 112 rules and 20 nonterminal symbols; and one for the Motorola 68020 has 141 rules and 35 nonterminal symbols. However, instructions that produce more than one result – such as autoincrement instructions on the VAX – are difficult to express using tree patterns.

Code-generator generators are probably overkill for RISC machines. The tiles are quite small, there aren’t very many of them, and there is little need for a grammar with many nonterminal symbols.

**FAST MATCHING**

Maximal Munch and the dynamic programming algorithm must examine, for each node, all the tiles that match at that node. A tile matches if each nonleaf node of the tile is labeled with the same operator (MEM, CONST, etc.) as the corresponding node of the tree.

The naive algorithm for matching would be to examine each tile in turn, checking each node of the tile against the corresponding part of the tree. However, there are better approaches. To match a tile at node $n$ of the tree, the label at $n$ can be used in a case statement:

```c
match(n) {
    switch (label(n)) {
    case MEM: ···
    case BINOP: ···
    case CONST: ···
    }
}
```

Once the clause for one label (such as MEM) is selected, only those patterns
rooted in that label remain in consideration. Another case statement can use the label of the child of \( n \) to begin distinguishing among those patterns.

The organization and optimization of decision trees for pattern matching is beyond the scope of this book. However, for better performance the naive sequence of clauses in function \( \text{munchExp} \) should be rewritten as a sequence of comparisons that never looks twice at the same tree node.

**EFFICIENCY OF TILING ALGORITHMS**

How expensive are Maximal Munch and dynamic programming?

Let us suppose that there are \( T \) different tiles, and that the average matching tile contains \( K \) nonleaf (labeled) nodes. Let \( K' \) be the largest number of nodes that ever need to be examined to see which tiles match at a given subtree; this is approximately the same as the size of the largest tile. And suppose that, on the average, \( T' \) different patterns (tiles) match at each tree node. For a typical RISC machine we might expect \( T = 50, K = 2, K' = 4, T' = 5. \)

Suppose there are \( N \) nodes in the input tree. Then Maximal Munch will have to consider matches at only \( N/K \) nodes because, once a “munch” is made at the root, no pattern-matching needs to take place at the nonleaf nodes of the tile.

To find all the tiles that match at one node, at most \( K' \) tree nodes must be examined; but (with a sophisticated decision tree) each of these nodes will be examined only once. Then each of the successful matches must be compared to see if its cost is minimal. Thus, the matching at each node costs \( K' + T' \), for a total cost proportional to \( (K' + T')N/K \).

The dynamic programming algorithm must find all the matches at every node, so its cost is proportional to \( (K' + T')N \). However, the constant of proportionality is higher than that of Maximal Munch, since dynamic programming requires two tree-walks instead of one.

Since \( K, K', \) and \( T' \) are constant, the running time of all of these algorithms is linear. In practice, measurements show that these instruction selection algorithms run very quickly compared to the other work performed by a real compiler – even lexical analysis is likely to take more time than instruction selection.

### 9.2 CISC MACHINES

A typical modern RISC machine has
9.2. CISC MACHINES

1. 32 registers,
2. only one class of integer/pointer registers,
3. arithmetic operations only between registers,
4. “three-address” instructions of the form $r_1 \leftarrow r_2 \oplus r_3$,
5. load and store instructions with only the $M[\text{reg+const}]$ addressing mode,
6. every instruction exactly 32 bits long,
7. one result or effect per instruction.

Many machines designed between 1970 and 1985 are Complex Instruction Set Computers (CISC). Such computers have more complicated addressing modes that encode instructions in fewer bits, which was important when computer memories were smaller and more expensive. Typical features found on CISC machines include

1. few registers (16, or 8, or 6),
2. registers divided into different classes, with some operations available only on certain registers,
3. arithmetic operations can access registers or memory through “addressing modes,”
4. “two-address” instructions of the form $r_1 \leftarrow r_1 \oplus r_2$,
5. several different addressing modes,
6. variable-length instructions, formed from variable-length opcode plus variable-length addressing modes,
7. instructions with side effects such as “auto-increment” addressing modes.

Most computer architectures designed since 1990 are RISC machines, but most general-purpose computers installed since 1990 are CISC machines: the Intel 80386 and its descendants (486, Pentium).

The Pentium, in 32-bit mode, has six general-purpose registers, a stack pointer, and a frame pointer. Most instructions can operate on all six registers, but the multiply and divide instructions operate only on the $\text{eax}$ register. In contrast to the “3-address” instructions found on RISC machines, Pentium arithmetic instructions are generally “2-address,” meaning that the destination register must be the same as the first source register. Most instructions can have either two register operands ($r_1 \leftarrow r_1 \oplus r_2$), or one register and one memory operand, for example $M[r_1 + c] \leftarrow M[r_1 + c] \oplus r_2$ or $r_1 \leftarrow r_1 \oplus M[r_2 + c]$, but not $M[r_1 + c_1] \leftarrow M[r_1 + c_1] \oplus M[r_2 + c_2]$

We will cut through these Gordian knots as follows:

1. **Few registers:** we continue to generate TEMP nodes freely, and assume that the register allocator will do a good job.
2. **Classes of registers:** The multiply instruction on the Pentium requires that its left operand (and therefore destination) must be the eax register. The high-order bits of the result (useless to a Tiger program) are put into register edx. The solution is to move the operands and result explicitly; to implement \( t_1 \leftarrow t_2 \times t_3 \):

\[
\begin{align*}
\text{mov } &\text{ eax, } t_2 &\text{ eax }&\leftarrow t_2 \\
\text{mul } &\text{ t}_3 &\text{ eax }&\leftarrow \text{eax} \times t_3; \quad \text{edx }&\leftarrow \text{garbage} \\
\text{mov } &\text{ t}_1, \text{ eax} &\text{ t}_1 &\leftarrow \text{eax}
\end{align*}
\]

This looks very clumsy; but one job that the register allocator performs is to eliminate as many move instructions as possible. If the allocator can assign \( t_1 \) or \( t_3 \) (or both) to register eax, then it can delete one or both of the move instructions.

3. **Two-address instructions:** We solve this problem in the same way as we solve the previous one: by adding extra move instructions. To implement \( t_1 \leftarrow t_2 + t_3 \)

\[
\begin{align*}
\text{mov } &\text{ t}_1, t_2 &\text{ t}_1 &\leftarrow t_2 \\
\text{add } &\text{ t}_1, t_3 &\text{ t}_1 &\leftarrow t_1 + t_3
\end{align*}
\]

Then we hope that the register allocator will be able to allocate \( t_1 \) and \( t_2 \) to the same register, so that the move instruction will be deleted.

4. **Arithmetic operations can address memory:** The instruction selection phase turns every TEMP node into a “register” reference. Many of these “registers” will actually turn out to be memory locations. The spill phase of the register allocator must be made to handle this case efficiently; see Chapter 11.

The alternative to using memory-mode operands is simply to fetch all the operands into registers before operating and store them back to memory afterwards. For example, these two sequences compute the same thing:

\[
\begin{align*}
\text{mov } &\text{ eax, } [\text{ebp }- 8] \\
\text{add } &\text{ eax, ecx} &\text{ add } &\text{[ebp }- 8], \text{ecx} \\
\text{mov } &\text{ [ebp }- 8], \text{ eax}
\end{align*}
\]

The sequence on the right is more concise (and takes less machine-code space), but the two sequences are equally fast. The load, register-register add, and store take 1 cycle each, and the memory-register add takes 3 cycles. On a highly pipelined machine such as the Pentium Pro, simple cycle counts are not the whole story, but the result will be the same: the processor has to perform the load, add, and store, no matter how the instructions specify them.

The sequence on the left has one significant disadvantage: it trashes the value in register eax. Therefore, we should try to use the sequence on the right when possible. But the issue here turns into one of register allocation, not of instruction speed; so we defer its solution to the register allocator.
5. **Several addressing modes:** An addressing mode that accomplishes six things typically takes six steps to execute. Thus, these instructions are often no faster than the multi-instruction sequences they replace. They have only two advantages: they “trash” fewer registers (such as the register eax in the previous example), and they have a shorter instruction encoding. With some work, tree-matching instruction selection can be made to select CISC addressing modes, but programs can be just as fast using the simple RISC-like instructions.

6. **Variable-length instructions:** This is not really a problem for the compiler; once the instructions are selected, it is a trivial (though tedious) matter for the assembler to emit the encodings.

7. **Instructions with side effects:** Some machines have an “autoincrement” memory fetch instruction whose effect is

   \[ r_2 \leftarrow M[r_1]; \quad r_1 \leftarrow r_1 + 4 \]

This instruction is difficult to model using tree patterns, since it produces two results. There are three solutions to this problem:

(a) Ignore the autoincrement instructions, and hope they go away. This is an increasingly successful solution, as few modern machines have multiple-side-effect instructions.

(b) Try to match special idioms in an ad hoc way, within the context of a tree pattern-matching code generator.

(c) Use a different instruction algorithm entirely, one based on DAG-patterns instead of tree-patterns.

Several of these solutions depend critically on the register allocator to eliminate move instructions and to be smart about spilling; see Chapter 11.

---

**INSTRUCTION SELECTION FOR THE Tiger COMPILER**

Pattern-matching of “tiles” is simple (if tedious) in C, as shown in Program 9.3. But this figure does not show what to do with each pattern match. It is all very well to print the name of the instruction, but which registers should these instructions use?

In a tree tiled by instruction patterns, the root of each tile will correspond to some intermediate result held in a register. Register allocation is the act of assigning register-numbers to each such node.

The instruction selection phase can simultaneously do register allocation. However, many aspects of register allocation are independent of the particular target-machine instruction set, and it is a shame to duplicate the register-
CHAPTER NINE. INSTRUCTION SELECTION

allocation algorithm for each target machine. Thus, register allocation should come either before or after instruction selection.

Before instruction selection, it is not even known which tree nodes will need registers to hold their results, since only the roots of tiles (and not other labeled nodes within tiles) require explicit registers. Thus, register allocation before instruction selection cannot be very accurate. But some compilers do it anyway, to avoid the need to describe machine instructions without the real registers filled in.

We will do register allocation after instruction selection. The instruction selection phase will generate instructions without quite knowing which registers the instructions use.

ABSTRACT ASSEMBLY-LANGUAGE INSTRUCTIONS
We will invent a data type for “assembly language instruction without register assignments,” called AS_instr:

/* assem.h */

typedef struct {Temp_labelList labels;} *AS_targets;
AS_targets AS_Targets(Temp_labelList labels);

typedef struct {
    enum {I_OPER, I_LABEL, I_MOVE} kind;
    union {struct {string assem; Temp_tempList dst, src; AS_targets jumps;} OPER;
            struct {string assem; Temp_label label;} LABEL;
            struct {string assem; Temp_tempList dst, src;} MOVE;
        } u;
} *AS_instr;

AS_instr AS_Oper(string a, Temp_tempList d,
                  Temp_tempList s, AS_targets j);
AS_instr AS_Label(string a, Temp_label label);
AS_instr AS_Move(string a, Temp_tempList d, Temp_tempList s);

void AS_print(FILE *out, AS_instr i, Temp_map m);

An OPER holds an assembly-language instruction assem, a list of operand registers src, and a list of result registers dst. Either of these lists may be empty. Operations that always fall through to the next instruction have
jump=NULL; other operations have a list of “target” labels to which they may jump (this list must explicitly include the next instruction if it is possible to fall through to it).

A LABEL is a point in a program to which jumps may go. It has an assem component showing how the label will look in the assembly-language program, and a label component identifying which label-symbol was used.

A MOVE is like an OPER, but must perform only data transfer. Then, if the dst and src temporaries are assigned to the same register, the MOVE can later be deleted.

Calling AS_print(f, i, m) formats an assembly instruction as a string and prints it to the file f; m is a temp mapping that tells the register assignment (or perhaps just the name) of every temp.

The temp.h interface describes functions for operating on temp mappings:

/* temp.h */

typedef struct Temp_map_ *Temp_map;
Temp_map Temp_empty(void); /* create a new, empty map */
Temp_map Temp_layerMap(Temp_map over, Temp_map under);
void Temp_enter(Temp_map m, Temp_temp t, string s);
string Temp_look(Temp_map m, Temp_temp t);

Temp_map Temp_name(void);

A Temp_map is just a table whose keys are Temp_temps and whose bindings are strings. However, one mapping can be layered over another; if \( \sigma_3 = \text{layer}(\sigma_1, \sigma_2) \), this means that \( \text{look}(\sigma_3, t) \) will first try \( \text{look}(\sigma_1, t) \), and if that fails it will try \( \text{look}(\sigma_2, t) \). Also, \( \text{enter}(\sigma_3, t, a) \) will have the effect of entering \( t \mapsto a \) into \( \sigma_2 \).

The primary users of these Temp_map operations will be the register allocator, which will decide which register name to use for each temporary. But the Frame module makes a Temp_map to describe the names of all the preallocated registers (such as the frame-pointer, stack-pointer, etc.); and for debugging purposes it’s useful to have a special Temp_name mapping that just maps each temporary (such as \( t_{182} \)) to its “name” (such as “\( t_{182} \)”).

**Machine-independence.** The AS_instr type is independent of the chosen target-machine assembly language (though it is tuned for machines with only one class of register). If the target machine is a Sparc, then the assem strings
will be Sparc assembly language. I will use Jouette assembly language for illustration.

For example, the tree

```
MEM
+  
TEMP fp  CONST 8
```

could be translated into Jouette assembly language as

```
AS_Oper("LOAD 'd0 <- M['s0+8]",
    Temp_TempList(Temp_newtemp(), NULL),
    Temp_TempList(T_Temp(F_FP()), NULL),
    NULL)
```

This instruction needs some explanation. The actual assembly language of Jouette, after register allocation, might be

```
LOAD r1 <- M[r27+8]
```

assuming that register $r_{27}$ is the frame pointer $fp$ and that the register allocator decided to assign the new temp to register $r_1$. But the Assem instruction does not know about register assignments; instead, it just talks of the sources and destination of each instruction. This LOAD instruction has one source register, which is referred to as `$s0$`; and one destination register, referred to as `$d0$.

Another example will be useful. The tree

```
*  
+  
TEMP t87  CONST 3  MEM
      TEMP t92
```

could be translated as

```
<table>
<thead>
<tr>
<th>assem</th>
<th>dst</th>
<th>src</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADDI 'd0 &lt;- 's0+3</td>
<td>t908</td>
<td>t87</td>
</tr>
<tr>
<td>LOAD 'd0 &lt;- M['s0+0]</td>
<td>t909</td>
<td>t92</td>
</tr>
<tr>
<td>MUL 'd0 &lt;- 's0*'s1</td>
<td>t910</td>
<td>t908,t909</td>
</tr>
</tbody>
</table>
```

where $t_{908}$, $t_{909}$, and $t_{910}$ are temporaries newly chosen by the instruction selector.

After register allocation the assembly language might look like:
ADDI  r1 <- r12+3
LOAD  r2 <- M[r13+0]
MUL   r1 <- r1 * r2

The string of an instr may refer to source registers ‘s0, ‘s1, ... ‘s(k-1), and destination registers ‘d0, ‘d1, etc. Jumps are OPER instructions that refer to labels ‘j0, ‘j1, etc. Conditional jumps, which may branch away or fall through, typically have two labels in the jump list but refer to only one of them in the assem string.

Two-address instructions. Some machines have arithmetic instructions with two operands, where one of the operands is both a source and a destination. The instruction add t1,t2, which has the effect of \( t_1 \leftarrow t_1 + t_2 \), can be described as

\[
\text{assem} \quad \text{dst} \quad \text{src} \\
\text{add} \quad 'd0,'s1 \quad t1 \quad t1,t2
\]

where ‘s0 is implicitly, but not explicitly, mentioned in the assem string.

PRODUCING ASSEMBLY INSTRUCTIONS

Now it is a simple matter to write the right-hand sides of the pattern-matching clauses that “munch” Tree expressions into Assem instructions. I will show some examples from the Jouette code generator, but the same ideas apply to code generators for real machines.

The functions munchStm and munchExp will produce Assem instructions, bottom-up, as side effects. MunchExp returns the temporary in which the result is held.

\[
\text{static Temp_temp munchExp(T_exp e);} \\
\text{static void munchStm(T_stm s);} \\
\]

The “actions” of the munchExp clauses of Program 9.3 can be written as shown in Programs 9.7 and 9.6.

The emit function just accumulates a list of instructions to be returned later, as shown in Program 9.8. The assem.h interface contains data structures and functions for lists of instructions, AS_instrList:
static Temp_temp munchExp(T_exp e) {
    switch(e)
    case MEM(BINOP(PLUS,e1,CONST(i))):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("LOAD \texttt{d0} <- M[\texttt{s0}+i] \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case MEM(BINOP(PLUS,CONST(i),e1)):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("LOAD \texttt{d0} <- M[\texttt{s0}+i] \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case MEM(CONST(i)):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("LOAD \texttt{d0} <- M[\texttt{r0}+i] \\n",
                   L(r,NULL), NULL, NULL));
        return r;
    case MEM(e1):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("LOAD \texttt{d0} <- M[\texttt{s0}+0] \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case BINOP(PLUS,e1,CONST(i)):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("ADDI \texttt{d0} <- \texttt{s0}+i \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case BINOP(PLUS,CONST(i),e1):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("ADDI \texttt{d0} <- \texttt{s0}+i \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case BINOP(PLUS,e1,e2):
        Temp_temp r = Temp_newtemp();
        emit(AS_Oper("ADD \texttt{d0} <- \texttt{s0}+\texttt{s1} \\n",
                   L(r,NULL), L(munchExp(e1),NULL), NULL));
        return r;
    case TEMP(t):
        return t;
    
    PROGRAM 9.6. Assem-instructions for munchExp.

    Temp_map m);

typedef struct {
    string prolog; AS_instrList body; string epilog;
} *AS_proc;
CHAPTER NINE. INSTRUCTION SELECTION

/* codegen.c */
:
static AS_instrList iList=NULL, last=NULL;
static void emit(AS_instr inst) {
    if (last!=NULL)
        last = last->tail = AS_InstrList(inst,NULL);
    else last = iList = AS_InstrList(inst,NULL);
}

AS_instrList F_codegen(F_frame f, T_stmList stmList) {
    AS_instrList list; T_stmList sl;
    :
    for (sl=stmList; sl; sl=sl->tail) munchStm(sl->head);
    list=iList; iList=last=NULL; return list;
}

PROGRAM 9.8. The codegen function.

PROCEDURE CALLS

Procedure calls are represented by EXP(CALL(f, args)), and function calls by
MOVE(TEMP t, CALL(f, args)). These trees can be matched by tiles such as

   case EXP(CALL(e, args)): {
       Temp_temp r = munchExp(e);
       Temp_tempList l = munchArgs(0, args);
       emit(AS_Oper("CALL 's0\n", calldefs, L(r,l), NULL));
   }

In this example, munchArgs generates code to move all the arguments to
their correct positions, in outgoing parameter registers and/or in memory. The
integer parameter to munchArgs is i for the i\textsuperscript{th} argument; munchArgs will
recur with i + 1 for the next argument, and so on.

What munchArgs returns is a list of all the temporaries that are to be
passed to the machine’s CALL instruction. Even though these temps are never
written explicitly in assembly language, they should be listed as “sources” of
the instruction, so that liveness analysis (Chapter 10) can see that their values
need to be kept up to the point of call.

A CALL is expected to “trash” certain registers – the caller-save registers,
the return-address register, and the return-value register. This list of
calldefs should be listed as “destinations” of the CALL, so that the later
phases of the compiler know that something happens to them here.

In general, any instruction that has the side effect of writing to another reg-
ister requires this treatment. For example, the Pentium’s multiply instruction
writes to register edx with useless high-order result bits, so edx and eax are both listed as destinations of this instruction. (The high-order bits can be very useful for programs written in assembly language to do multiprecision arithmetic, but most programming languages do not support any way to access them.)

**IF THERE’S NO FRAME POINTER**

In a stack frame layout such as the one shown in Figure 6.2, the frame pointer points at one end of the frame and the stack pointer points at the other. At each procedure call, the stack pointer register is copied to the frame pointer register, and then the stack pointer is incremented by the size of the new frame.

Many machines’ calling conventions do not use a frame pointer. Instead, the “virtual frame pointer” is always equal to stack pointer plus frame size. This saves time (no copy instruction) and space (one more register usable for other purposes). But our Translate phase has generated trees that refer to this fictitious frame pointer. The codegen function must replace any reference to FP+k with SP+k+fs, where fs is the frame size. It can recognize these patterns as it munches the trees.

However, to replace them it must know the value of fs, which cannot yet be known because register allocation is not known. Assuming the function \( f \) is to be emitted at label L14 (for example), codegen can just put sp+L14_framesize in its assembly instructions and hope that the prologue for \( f \) (generated by F_procEntryExit3) will include a definition of the assembly-language constant L14_framesize. Codegen is passed the frame argument (Program 9.8) so that it can learn the name L14.

Implementations that have a “real” frame pointer won’t need this hack and can ignore the frame argument to codegen. But why would an implementation use a real frame pointer when it wastes time and space to do so? The answer is that this permits the frame size to grow and shrink even after it is first created; some languages have permitted dynamic allocation of arrays within the stack frame (e.g., using alloca in C). Calling-convention designers now tend to avoid dynamically adjustable frame sizes, however.
PROGRAM INSTRUCTION SELECTION

/* codegen.h */
AS_instrList F_codegen(F_frame f, T_stmList stmList);

Implement the translation to Assem-instructions for your favorite instruction set (let \( \mu \) stand for Sparc, Mips, Alpha, Pentium, etc.) using Maximal Munch. If you would like to generate code for a RISC machine, but you have no RISC computer on which to test it, you may wish to use SPIM (a MIPS simulator implemented by James Larus), described on the Web page for this book.

First write the module \( \mu \)codegen.c that implements the codegen.h interface using the “Maximal Munch” translation algorithm from IR trees to the Assem data structure.

Use the Canon module (described in Chapter 8) to simplify the trees before applying your Codegen module to them. Use the AS_printInstrList function to translate the resulting Assem trees to \( \mu \) assembly language. Since you won’t have done register assignment, just pass Temp_name to AS_print as the translation function from temporaries to strings.

This will produce “assembly” language that does not use register names at all: the instructions will use names such as \( t3 \), \( t283 \), and so on. But some of these temps are the “built-in” ones created by the Frame module to stand for particular machine registers (see page 159), such as Frame.FP. The assembly language will be easier to read if these registers appear with their natural names (e.g., \( fp \) instead of \( t1 \)).

The Frame module must provide a mapping from the special temps to their names, and nonspecial temps to NULL:

/* frame.h */
;
Temp_map F_tempMap;

Then, for the purposes of displaying your assembly language prior to register allocation, use Temp_layerMap to make a new function that first tries F_tempMap, and if that returns NULL, resorts to Temp_name.

REGISTER LISTS
Make the following lists of registers; for each register, you will need a string for its assembly-language representation and a Temp_temp for referring to it in Tree and Assem data structures.
specialregs a list of \( \mu \) registers used to implement “special” registers such as RV and FP and also the stack pointer SP, the return-address register RA, and (on some machines) the zero register ZERO. Some machines may have other special registers;
argregs a list of \( \mu \) registers in which to pass outgoing arguments (including the static link);
calleesaves a list of \( \mu \) registers that the called procedure (callee) must preserve unchanged (or save and restore);
callersaves a list of \( \mu \) registers that the callee may trash.

The four lists of registers must not overlap, and must include any register that might show up in \textit{Assem} instructions. These lists are not exported through the \texttt{frame.h} interface, but they are useful internally for both \texttt{Frame} and \texttt{Codegen} – for example, to implement \texttt{munchArgs} and to construct the calldefs list.

Implement the \texttt{F_procEntryExit2} function of the \texttt{frame.h} interface.

```c
/* frame.h */

AS_instrList F_procEntryExit2(AS_instrList body);
```

This function appends a “sink” instruction to the function body to tell the register allocator that certain registers are live at procedure exit. In the case of the \textit{Jouette} machine, this is simply:

```c
static Temp_tempList returnSink = NULL;

AS_instrList F_procEntryExit2(AS_instrList body) {
    if (!returnSink) returnSink =
        Temp_TempList(ZERO, Temp_TempList(RA,
            Temp_TempList(SP, calleeSaves)));
    return AS_splice(body, AS_InstrList(
        AS_Oper("", NULL, returnSink, NULL), NULL));
}
```

meaning that the temporaries zero, return-address, stack-pointer, and all the callee-saves registers are still live at the end of the function. Having zero live at the end means that it is live throughout, which will prevent the register allocator from trying to use it for some other purpose. The same trick works for any other special registers the machine might have.

Files available in \$TIGER/chap9 include:

\texttt{canon.c} Canonicalization and trace-generation.
assem.c The Assem module.
main.c A Main module that you may wish to adapt.

Your code generator will handle only the body of each procedure or function, but not the procedure entry/exit sequences. Use a “scaffold” version of F_procEntryExit3 function:

```c
AS_proc F_procEntryExit3(F_frame frame, AS_instrList body) {
    char buf[100];
    sprintf(buf,"PROCEDURE %s
", S_name(frame->name));
    return AS_Proc(String(buf), body, "END\n");
}
```

FURTHER READING

Cattell [1980] expressed machine instructions as tree patterns, invented the Maximal Munch algorithm for instruction selection, and built a code generator generator to produce an instruction-selection function from a tree-pattern description of an instruction set. Glanville and Graham [1978] expressed the tree patterns as productions in LR(1) grammars, which allows the Maximal Munch algorithm to use multiple nonterminal symbols to represent different classes of registers and addressing modes. But grammars describing instruction sets are inherently ambiguous, leading to problems with the LR(1) approach; Aho et al. [1989] use dynamic programming to parse the tree grammars, which solves the ambiguity problem, and describe the Twig automatic code-generator generator. The dynamic programming can be done at compiler-construction time instead of code-generation time [Pelegri-Llopard and Graham 1988]; using this technique, the BURG tool [Fraser et al. 1992] has an interface similar to Twig’s but generates code much faster.
9.1 For each of the following expressions, draw the tree and generate Jouette-machine instructions using Maximal Munch. Circle the tiles (as in Figure 9.2), but number them in the order that they are munched, and show the sequence of Jouette instructions that results.

a. MOVE(MEM(+((CONST$1000$, MEM(TEMP$x$)), TEMP$f$)), CONST$0$)
b. BINOP(MUL, CONST$5$, MEM(CONST$100$))

*9.2 Consider a machine with the following instruction:
\[
\text{mult const1(src1), const2(src2), dst3}
\]
\[
r_3 \leftarrow M[r_1 + \text{const1}] \ast M[r_2 + \text{const2}]
\]
On this machine, $r_0$ is always 0, and $M[1]$ always contains 1.

a. Draw all the tree patterns corresponding to this instruction (and its special cases).
b. Pick one of the bigger patterns and show how to write a C if-statement to match it, with the Tree representation used for the Tiger compiler.

9.3 The Jouette machine has control-flow instructions as follows:

- **BRANCHGE** if $r_i \geq 0$ goto $L$
- **BRANCHLT** if $r_i < 0$ goto $L$
- **BRANCHEQ** if $r_i = 0$ goto $L$
- **BRANCHNE** if $r_i \neq 0$ goto $L$
- **JUMP** goto $r_i$

where the **JUMP** instruction goes to an address contained in a register.

Use these instructions to implement the following tree patterns:

```
   JUMP
     |   JUMP
     |     GT
     |     NAME
     |   NAME
```

Assume that a **CJUMP** is always followed by its false label. Show the best way to implement each pattern; in some cases you may need to use more than one instruction or make up a new temporary. How do you implement **CJUMP(GT, . . .)** without a **BRANCHGT** instruction?
10 Liveness Analysis

live: of continuing or current interest

Webster’s Dictionary

The front end of the compiler translates programs into an intermediate language with an unbounded number of temporaries. This program must run on a machine with a bounded number of registers. Two temporaries $a$ and $b$ can fit into the same register, if $a$ and $b$ are never “in use” at the same time. Thus, many temporaries can fit in few registers; if they don’t all fit, the excess temporaries can be kept in memory.

Therefore, the compiler needs to analyze the intermediate-representation program to determine which temporaries are in use at the same time. We say a variable is live if it holds a value that may be needed in the future, so this analysis is called liveness analysis.

To perform analyses on a program, it is often useful to make a control-flow graph. Each statement in the program is a node in the flow graph; if statement $x$ can be followed by statement $y$, there is an edge from $x$ to $y$. Graph 10.1 shows the flow graph for a simple loop.

Let us consider the liveness of each variable (Figure 10.2). A variable is live if its current value will be used in the future, so we analyze liveness by working from the future to the past. Variable $b$ is used in statement 4, so $b$ is live on the $3 \rightarrow 4$ edge. Since statement 3 does not assign into $b$, then $b$ is also live on the $2 \rightarrow 3$ edge. Statement 2 assigns into $b$. That means that the contents of $b$ on the $1 \rightarrow 2$ edge are not needed by anyone; $b$ is dead on this edge. So the live range of $b$ is $\{2 \rightarrow 3, 3 \rightarrow 4\}$.

The variable $a$ is an interesting case. It’s live from $1 \rightarrow 2$, and again from $4 \rightarrow 5 \rightarrow 2$, but not from $2 \rightarrow 3 \rightarrow 4$. Although $a$ has a perfectly
a ← 0
$L_1: b ← a + 1$
c ← c + b
a ← b * 2
if a < N goto $L_1$
return c

**GRAPH 10.1.** Control-flow graph of a program.

**FIGURE 10.2.** Liveness of variables $a, b, c$. 
well defined value at node 3, that value will not be needed again before \( a \) is assigned a new value.

The variable \( c \) is live on entry to this program. Perhaps it is a formal parameter. If it is a local variable, then liveness analysis has detected an uninitialized variable; the compiler could print a warning message for the programmer.

Once all the live ranges are computed, we can see that only two registers are needed to hold \( a, b, \) and \( c \), since \( a \) and \( b \) are never live at the same time. Register 1 can hold both \( a \) and \( b \), and register 2 can hold \( c \).

10.1 SOLUTION OF DATAFLOW EQUATIONS

Liveness of variables “flows” around the edges of the control-flow graph; determining the live range of each variable is an example of a dataflow problem. Chapter 17 will discuss several other kinds of dataflow problems.

**Flow graph terminology.** A flow-graph node has *out-edges* that lead to *successor* nodes, and *in-edges* that come from *predecessor* nodes. The set \( \text{pred}[n] \) is all the predecessors of node \( n \), and \( \text{succ}[n] \) is the set of successors.

In Graph 10.1 the out-edges of node 5 are \( 5 \rightarrow 6 \) and \( 5 \rightarrow 2 \), and \( \text{succ}[5] = \{2, 6\} \). The in-edges of 2 are \( 5 \rightarrow 2 \) and \( 1 \rightarrow 2 \), and \( \text{pred}[2] = \{1, 5\} \).

**Uses and defs.** An assignment to a variable or temporary *defines* that variable. An occurrence of a variable on the right-hand side of an assignment (or in other expressions) *uses* the variable. We can speak of the *def* of a variable as the set of graph nodes that define it; or the *def* of a graph node as the set of variables that it defines; and similarly for the *use* of a variable or graph node. In Graph 10.1, \( \text{def}(3) = \{c\}, \text{use}(3) = \{b, c\} \).

**Liveness.** A variable is *live* on an edge if there is a directed path from that edge to a *use* of the variable that does not go through any *def*. A variable is *live-in* at a node if it is live on any of the in-edges of that node; it is *live-out* at a node if it is live on any of the out-edges of the node.

**CALCULATION OF LIVENESS**

Liveness information (*live-in* and *live-out*) can be calculated from *use* and *def* as follows:
10.1. SOLUTION OF DATAFLOW EQUATIONS

\[ \text{in}[n] = \text{use}[n] \cup (\text{out}[n] - \text{def}[n]) \]
\[ \text{out}[n] = \bigcup_{s \in \text{succ}[n]} \text{in}[s] \]

EQUATIONS 10.3. Dataflow equations for liveness analysis.

\begin{align*}
\text{for each } n \\
\text{in}[n] & \leftarrow \{\}; \text{ out}[n] \leftarrow \{} \\
\text{repeat} \\
\text{for each } n \\
\quad \text{in}'[n] & \leftarrow \text{in}[n]; \text{ out}'[n] \leftarrow \text{out}[n] \\
\quad \text{in}[n] & \leftarrow \text{use}[n] \cup (\text{out}[n] - \text{def}[n]) \\
\quad \text{out}[n] & \leftarrow \bigcup_{s \in \text{succ}[n]} \text{in}[s] \\
\text{until} \text{ in}'[n] = \text{in}[n] \text{ and out}'[n] = \text{out}[n] \text{ for all } n
\end{align*}

ALGORITHM 10.4. Computation of liveness by iteration.

1. If a variable is in use[n], then it is live-in at node n. That is, if a statement uses a variable, the variable is live on entry to that statement.
2. If a variable is live-in at a node n, then it is live-out at all nodes m in pred[n].
3. If a variable is live-out at node n, and not in def[n], then the variable is also live-in at n. That is, if someone needs the value of a at the end of statement n, and n does not provide that value, then a’s value is needed even on entry to n.

These three statements can be written as Equations 10.3 on sets of variables. The live-in sets are an array in[n] indexed by node, and the live-out sets are an array out[n]. That is, in[n] is all the variables in use[n], plus all the variables in out[n] and not in def[n]. And out[n] is the union of the live-in sets of all successors of n.

Algorithm 10.4 finds a solution to these equations by iteration. As usual, we initialize in[n] and out[n] to the the empty set {}, for all n, then repeatedly treat the equations as assignment statements until a fixed point is reached.

Table 10.5 shows the results of running the algorithm on Graph 10.1. The columns 1st, 2nd, etc. are the values of in and out on successive iterations of the repeat loop. Since the 7th column is the same as the 6th, the algorithm terminates.

We can speed the convergence of this algorithm significantly by ordering the nodes properly. Suppose there is an edge 3 \rightarrow 4 in the graph. Since in[4]

**TABLE 10.6.** Liveness calculation following reverse control-flow edges.

is computed from \(\text{out}[4]\), and \(\text{out}[3]\) is computed from \(\text{in}[4]\), and so on, we should compute the in and out sets in the order \(\text{out}[4] \rightarrow \text{in}[4] \rightarrow \text{out}[3] \rightarrow \text{in}[3]\). But in Table 10.5, just the opposite order is used in each iteration! We have waited as long as possible (in each iteration) to make use of information gained from the previous iteration.

Table 10.6 shows the computation, in which each **for** loop iterates from 6 to 1 (approximately following the reversed direction of the flow-graph arrows), and in each iteration the out sets are computed before the in sets. By the end of the second iteration, the fixed point has been found; the third iteration just confirms this.

When solving dataflow equations by iteration, the order of computation should follow the “flow.” Since liveness flows backward along control-flow arrows, and from “out” to “in,” so should the computation.

Ordering the nodes can be done easily by depth-first search, as shown in Section 17.4.
10.1. SOLUTION OF DATAFLOW EQUATIONS

**Basic blocks.** Flow-graph nodes that have only one predecessor and one successor are not very interesting. Such nodes can be merged with their predecessors and successors; what results is a graph with many fewer nodes, where each node represents a basic block. The algorithms that operate on flow graphs, such as liveness analysis, go much faster on the smaller graphs. Chapter 17 explains how to adjust the dataflow equations to use basic blocks. In this chapter we keep things simple.

**One variable at a time.** Instead of doing dataflow “in parallel” using set equations, it can be just as practical to compute dataflow for one variable at a time as information about that variable is needed. For liveness, this would mean repeating the dataflow traversal once for each temporary. Starting from each *use* site of a temporary $t_i$, and tracing backward (following *predecessor* edges of the flow graph) using depth-first search, we note the liveness of $t_i$ at each flow-graph node. The search stops at any definition of the temporary. Although this might seem expensive, many temporaries have very short live ranges, so the searches terminate quickly and do not traverse the entire flow graph for most variables.

**REPRESENTATION OF SETS**

There are at least two good ways to represent sets for dataflow equations: as arrays of bits or as sorted lists of variables.

If there are $N$ variables in the program, the bit-array representation uses $N$ bits for each set. Calculating the union of two sets is done by *or*-ing the corresponding bits at each position. Since computers can represent $K$ bits per word (with $K = 32$ typical), one set-union operation takes $N/K$ operations.

A set can also be represented as a linked list of its members, sorted by any totally ordered key (such as variable name). Calculating the union is done by merging the lists (discarding duplicates). This takes time proportional to the size of the sets being unioned.

Clearly, when the sets are sparse (fewer than $N/K$ elements, on the average), the sorted-list representation is asymptotically faster; when the sets are dense, the bit-array representation is better.

**TIME COMPLEXITY**

How fast is iterative dataflow analysis?

A program of size $N$ has at most $N$ nodes in the flow graph, and at most $N$ variables. Thus, each live-in set (or live-out set) has at most $N$ elements;
each set-union operation to compute live-in (or live-out) takes \( O(N) \) time.

The \textbf{for} loop computes a constant number of set operations per flow-graph node; there are \( O(N) \) nodes; thus, the \textbf{for} loop takes \( O(N^2) \) time.

Each iteration of the \textbf{repeat} loop can only make each in or out set larger, never smaller. This is because the in and out sets are \textit{monotonic} with respect to each other. That is, in the equation \( \text{in}[n] = \text{use}[n] \cup (\text{out}[n] - \text{def}[n]) \), a larger \( \text{out}[n] \) can only make \( \text{in}[n] \) larger. Similarly, in \( \text{out}[n] = \bigcup_{s \in \text{succ}[n]} \text{in}[s] \), a larger \( \text{in}[s] \) can only make \( \text{out}[n] \) larger.

Each iteration must add something to the sets; but the sets cannot keep growing infinitely; at most every set can contain every variable. Thus, the sum of the sizes of all in and out sets is \( 2N^2 \), which is the most that the repeat loop can iterate.

Thus, the worst-case run time of this algorithm is \( O(N^4) \). Ordering the nodes using depth-first search (Algorithm 17.5, page 396) usually brings the number of \textbf{repeat}-loop iterations to two or three, and the live-sets are often sparse, so the algorithm runs between \( O(N) \) and \( O(N^2) \) in practice.

Section 17.4 discusses more sophisticated ways of solving dataflow equations quickly.

**LEAST FIXED POINTS**

Table 10.7 illustrates two solutions (and a nonsolution!) to the Equations 10.3; assume there is another program variable \( d \) not used in this fragment of the program.

In solution \( Y \), the variable \( d \) is carried uselessly around the loop. But in fact, \( Y \) satisfies Equations 10.3 just as \( X \) does. What does this mean? Is \( d \) live or not?

**TABLE 10.7.** \( X \) and \( Y \) are solutions to the liveness equations; \( Z \) is not a solution.
The answer is that any solution to the dataflow equations is a *conservative approximation*. If the value of variable $a$ will truly be needed in some execution of the program when execution reaches node $n$ of the flow graph, then we can be assured that $a$ is live-out at node $n$ in any solution of the equations. But the converse is not true; we might calculate that $d$ is live-out, but that doesn’t mean that its value will really be used.

Is this acceptable? We can answer that question by asking what use will be made of the dataflow information. In the case of liveness analysis, if a variable is *thought to be live* then we will make sure to have its value in a register. A conservative approximation of liveness is one that may erroneously believe a variable is live, but will never erroneously believe it is dead. The consequence of a conservative approximation is that the compiled code might use more registers than it really needs; but it will compute the right answer.

Consider instead the live-in sets $Z$, which fail to satisfy the dataflow equations. Using this $Z$ we think that $b$ and $c$ are never live at the same time, and we would assign them to the same register. The resulting program would use an optimal number of registers but *compute the wrong answer*.

A dataflow equation used for compiler optimization should be set up so that any solution to it provides conservative information to the optimizer; imprecise information may lead to suboptimal but never incorrect programs.

**Theorem.** Equations 10.3 have more than one solution.

**Proof.** $X$ and $Y$ are both solutions.

**Theorem.** All solutions to Equations 10.3 contain solution $X$. That is, if $in_X[n]$ and $in_Y[n]$ are the live-in sets for some node $n$ in solutions $X$ and $Y$, then $in_X[n] \subseteq in_Y[n]$.

**Proof.** See Exercise 10.2.

We say that $X$ is the *least solution* to Equations 10.3. Clearly, since a bigger solution will lead to using more registers (producing suboptimal code), we want to use the least solution. Fortunately, Algorithm 10.4 always computes the least fixed point.

**STATIC VS. DYNAMIC LIVENESS**

A variable is live “if its value will be used in the future.” In Graph 10.8, we know that $b \times b$ must be nonnegative, so that the test $c \geq b$ will be true. Thus,
node 4 will never be reached, and \( a \)'s value will not be used after node 2; \( a \) is not live-out of node 2.

But Equations 10.3 say that \( a \) is live-in to node 4, and therefore live-out of nodes 3 and 2. The equations are ignorant of which way the conditional branch will go. “Smarter” equations would permit \( a \) and \( c \) to be assigned the same register.

Although we can prove here that \( b \times b \geq 0 \), and we could have the compiler look for arithmetic identities, no compiler can ever fully understand how all the control flow in every program will work. This is a fundamental mathematical theorem, derivable from the halting problem.

**Theorem.** There is no program \( H \) that takes as input any program \( P \) and input \( X \) and (without infinite-looping) returns true if \( P(X) \) halts and false if \( P(X) \) infinite-loops.

**Proof.** Suppose that there were such a program \( H \); then we could arrive at a contradiction as follows. From the program \( H \), construct the function \( F \),

\[
F(Y) = \text{if } H(Y, Y) \text{ then (while true do ()) else true}
\]

By the definition of \( H \), if \( F(F) \) halts, then \( H(F, F) \) is true; so the \textbf{then} clause is taken; so the \textbf{while} loop executes forever; so \( F(F) \) does not halt. But if \( F(F) \) loops forever, then \( H(F, F) \) is false; so the \textbf{else} clause is taken; so \( F(F) \) halts. The program \( F(F) \) halts if it doesn’t halt, and doesn’t halt if
it halts: a contradiction. Thus there can be no program \( H \) that tests whether another program halts (and always halts itself).

**Corollary.** No program \( H'(X, L) \) can tell, for any program \( X \) and label \( L \) within \( X \), whether the label \( L \) is ever reached on an execution of \( X \).

**Proof.** From \( H' \) we could construct \( H \). In some program that we want to test for halting, just let \( L \) be the end of the program, and replace all instances of the \texttt{halt} command with \texttt{goto} \( L \).

**Conservative approximation.** This theorem does not mean that we can never tell if a given label is reached or not, just that there is not a general algorithm that can always tell. We could improve our liveness analysis with some special-case algorithms that, in some cases, calculate more information about run-time control flow. But any such algorithm will come up against many cases where it simply cannot tell exactly what will happen at run time.

Because of this inherent limitation of program analysis, no compiler can really tell if a variable’s value is truly needed – whether the variable is truly live. Instead, we have to make do with a conservative approximation. We assume that any conditional branch goes both ways. Thus, we have a dynamic condition and its static approximation:

**Dynamic liveness** A variable \( a \) is dynamically live at node \( n \) if some execution of the program goes from \( n \) to a use of \( a \) without going through any definition of \( a \).

**Static liveness** A variable \( a \) is statically live at node \( n \) if there is some path of control-flow edges from \( n \) to some use of \( a \) that does not go through a definition of \( a \).

Clearly, if \( a \) is dynamically live it is also statically live. An optimizing compiler must allocate registers, and do other optimizations, on the basis of static liveness, because (in general) dynamic liveness cannot be computed.

**INTERFERENCE GRAPHS**
Liveness information is used for several kinds of optimization in a compiler. For some optimizations, we need to know exactly which variables are live at each node in the flow graph.

One of the most important applications of liveness analysis is for register allocation: we have a set of temporaries \( a, b, c, \ldots \) that must be allocated to
registers $r_1, \ldots, r_k$. A condition that prevents $a$ and $b$ being allocated to the same register is called an *interference*.

The most common kind of interference is caused by overlapping live ranges: when $a$ and $b$ are both live at the same program point, then they cannot be put in the same register. But there are some other causes of interference: for example, when $a$ must be generated by an instruction that cannot address register $r_1$, then $a$ and $r_1$ interfere.

Interference information can be expressed as a matrix; Figure 10.9a has an $x$ marking interferences of the variables in Graph 10.1. The interference matrix can also be expressed as an undirected graph (Figure 10.9b), with a node for each variable, and edges connecting variables that interfere.

**Special treatment of MOVE instructions.** In static liveness analysis, we can give MOVE instructions special consideration. It is important not to create artificial interferences between the source and destination of a move. Consider the program:

\[
\begin{align*}
    t & \leftarrow s \quad \text{ (copy)} \\
    : & \\
    x & \leftarrow \ldots s \ldots \quad \text{ (use of } s) \\
    : & \\
    y & \leftarrow \ldots t \ldots \quad \text{ (use of } t)
\end{align*}
\]

After the copy instruction both $s$ and $t$ are live, and normally we would make an interference edge $(s, t)$ since $t$ is being defined at a point where $s$ is live. But we do not need separate registers for $s$ and $t$, since they contain the same value. The solution is just not to add an interference edge $(t, s)$ in this case. Of course, if there is a later (nonmove) definition of $t$ while $s$ is still live, that will create the interference edge $(t, s)$.

Therefore, the way to add interference edges for each new definition is:
1. At any nonmove instruction that defines a variable $a$, where the live-out variables are $b_1, \ldots, b_j$, add interference edges $(a, b_1), \ldots, (a, b_j)$.
2. At a move instruction $a \leftarrow c$, where variables $b_1, \ldots, b_j$ are live-out, add interference edges $(a, b_1), \ldots, (a, b_j)$ for any $b_i$ that is not the same as $c$.

10.2 LIVENESS IN THE Tiger COMPILER

The flow analysis for the Tiger compiler is done in two stages: first, the control flow of the Assem program is analyzed, producing a control-flow graph; then, the liveness of variables in the control-flow graph is analyzed, producing an interference graph.

**GRAPHS**

To represent both kinds of graphs, let’s make a Graph abstract data type (Program 10.10).

The function $G_{\text{Graph}}()$ creates an empty directed graph; $G_{\text{Node}}(g, x)$ makes a new node within a graph $g$, where $x$ is any extra information that the caller wants to keep “attached” to the new node. A directed edge from $n$ to $m$ is created by $G_{\text{addEdge}}(n, m)$; after that, $m$ will be found in the list $g_{\text{succ}}(n)$ and $n$ will be in $G_{\text{pred}}(m)$. When working with undirected graphs, the function $\text{adj}$ is useful: $G_{\text{adj}}(m) = G_{\text{succ}}(m) \cup G_{\text{pred}}(m)$.

To delete an edge, use $G_{\text{rmEdge}}$. To test whether $m$ and $n$ are the same node, use $m == n$.

When using a graph in an algorithm, we want each node to represent something (an instruction in a program, for example). To make mappings from nodes to the things they are supposed to represent, we use a $G_{\text{table}}$. The following idiom associates information $x$ with node $n$ in a mapping $\text{mytable}$.

$$G_{\text{enter}}(\text{mytable}, n, x)$$

Instead of keeping a separate table mapping $n \mapsto x$, we can put $x$ directly inside $n$. Executing $n = G_{\text{Node}}(g, x)$ creates a new node $n$ with “associated information” $x$. Calling $G_{\text{nodeInfo}}(n)$ retrieves $x$.

**CONTROL-FLOW GRAPHS**

The Flowgraph module manages control-flow graphs. Each instruction (or basic block) is represented by a node in the flow graph. If instruction $m$ can be followed by instruction $n$ (either by a jump or by falling through), then there will be an edge $(m, n)$ in the graph.
Program 10.10. The Graph abstract data type.

/* flowgraph.h */
Temp_tempList FG_def(G_node n);
Temp_tempList FG_use(G_node n);
bool FG_isMove(G_node n);

G_graph FG_AsemFlowGraph(AS_instrList il);

A flow graph is just a G_graph with some extra (hidden) information in each node. From this information it is possible to learn three things about each node n:

FG_def(n) a list of the temporaries defined at node n (destination registers of the instruction);
FG_use(n) a list of the temporaries used at n (source registers of the instruction);
FG_isMove(n) tells whether n represents a MOVE instruction, that could be deleted if the def and use are identical.
The Flowgraph module is an abstract data type; clients cannot see the information inside the nodes. The implementation – flowgraph.h – contains a function FG_AsemmFlowGraph that takes a list of instructions and returns a flow graph in which the info of each G_node is actually a pointer to an AS_instr. In making the flow graph, the jump fields of the instrs are used in creating control-flow edges, and the use and def information is obtained from the src and dst fields of the instructions. Clients of Flowgraph should never call G_nodeInfo directly, but go through the operations provided in flowgraph.h.

Information associated with the nodes. For a flow graph, we want to associate some use and def information with each node in the graph. Then the liveness-analysis algorithm will also want to remember live-in and live-out information at each node. We have made room in the G_node struct to store all of this information – this is the “associated information” accessed by G_nodeInfo(). This works well and is quite efficient. However, it may not be very modular. Eventually we may want to do other analyses on flow graphs, which remember other kinds of information about each node. We may not want to modify the data structure (which is a widely used interface) for each new analysis.

Instead of storing the information in the nodes, a more modular approach is to say that a graph is a graph, and that a flow graph is a graph along with separately packaged auxiliary information (tables, or functions mapping nodes to whatever). Similarly, a dataflow algorithm on a graph does not need to modify dataflow information in the nodes, but modifies its own privately held mappings.

There may be a trade-off here between efficiency and modularity, since it may be faster to keep the information in the nodes, accessibly by a simple pointer-traversal instead of a hash-table or search-tree lookup.

We will compromise by putting the “permanent” information about a node – that is, the Assem instruction it represents – into the info, and making up a G_table for each dataflow analysis that needs to keep additional information about the nodes.

LIVENESS ANALYSIS
The Liveness module takes a flow graph and produces two things: an interference graph, and a list of node-pairs (representing MOVE instructions) that should be assigned the same register if possible (so that the MOVE can be deleted).
For an interference-graph node \( n \), \texttt{Live_gtemp} tells what temporary variable is represented by \( n \). It is implemented, of course, by making the \texttt{info} field of each graph node point to a \texttt{Temp_temp}.

In the implementation of the \texttt{Liveness} module, it is useful to maintain a data structure that remembers what is live at the exit of each flow-graph node:

```c
static void enterLiveMap(G_table t, G_node flowNode,
                           Temp_tempList temps) {
    G_enter(t, flowNode, temps);
}
static Temp_tempList lookupLiveMap(G_table t,
                                  G_node flownode) {
    return (Temp_tempList)G_look(t, flownode);
}
```

Given a flow-graph node \( n \), the set of live temporaries at that node can be looked up in a global \texttt{liveMap}.

Having calculated a complete \texttt{liveMap}, we can now construct an interference graph. At each flow node \( n \) where there is a newly defined temporary \( d \in \text{def}(n) \), and where temporaries \{\texttt{t}_1, \texttt{t}_2, \ldots\} are in the \texttt{liveMap}, we just add interference edges \((d, \texttt{t}_1), (d, \texttt{t}_2), \ldots\). For \texttt{MOVE}s, these edges will be safe but suboptimal; pages 228–229 describe a better treatment.

What if a newly defined temporary is not live just after its definition? This would be the case if a variable is defined but never used. It would seem that there’s no need to put it in a register at all; thus it would not interfere with any other temporaries. But if the defining instruction is going to execute (perhaps
it is necessary for some other side effect of the instruction), then it will write to some register, and that register had better not contain any other live variable. Thus, zero-length live ranges do interfere with any live ranges that overlap them.

**PROGRAM CONSTRUCTING FLOW GRAPHS**

Implement `flowgraph.c` that turns a list of `Assem` instructions into a flow graph. Use the interfaces `graph.h` and `flowgraph.h`, and the implementation of `graph.c`, provided in `$TIGER/chap10`.

**PROGRAM LIVENESS**

Implement the Liveness module. Use either the set-equation algorithm with the array-of-boolean or sorted-list-of-temporaries representation of sets, or the one-variable-at-a-time method.

**EXERCISES**

10.1 Perform flow analysis on the program of Exercise 8.6:
   a. Draw the control-flow graph.
   b. Calculate live-in and live-out at each statement.
   c. Construct the register interference graph.

**10.2** Prove that Equations 10.3 have a least fixed point and that Algorithm 10.4 always computes it.

**Hint:** We know the algorithm refuses to terminate until it has a fixed point. The questions are whether (a) it must eventually terminate, and (b) the fixed point it computes is smaller than all other fixed points. For (a) show that the sets can only get bigger. For (b) show by induction that at any time, the `in` and `out` sets are subsets of those in any possible fixed point. This is clearly true initially, when `in` and `out` are both empty; show that each step of the algorithm preserves the invariant.

**10.3** Analyze the asymptotic complexity of the one-variable-at-a-time method of computing dataflow information.

**10.4** Analyze the worst-case asymptotic complexity of making an interference graph, for a program of size $N$ (with at most $N$ variables and at most $N$ control-flow nodes). Assume the dataflow analysis is already done and that `use`, `def`, and `live-out` information for each node can be queried in constant time. What representation of graph adjacency matrices should be used for efficiency?
10.5 The DEC Alpha architecture places the following restrictions on floating-point instructions, for programs that wish to recover from arithmetic exceptions:

1. Within a basic block (actually, in any sequence of instructions not separated by a *trap-barrier* instruction), no two instructions should write to the same destination register.
2. A source register of an instruction cannot be the same as the destination register of that instruction or any later instruction in the basic block.

\[
\begin{align*}
    r_1 + r_5 &\rightarrow r_4 \\
    r_3 \times r_2 &\rightarrow r_4 \\
    r_1 + r_5 &\rightarrow r_3 \\
    r_4 \times r_2 &\rightarrow r_4
\end{align*}
\]

violates rule 1. violates rule 2. violates rule 2. OK

Show how to express these restrictions in the register interference graph.
Register Allocation

\textbf{reg-is-ter:} a device for storing small amounts of data
\textbf{al-lo-cate:} to apportion for a specific purpose

\textit{Webster's Dictionary}

The Translate, Canon, and Codegen phases of the compiler assume that there are an infinite number of registers to hold temporary values and that \texttt{MOVE} instructions cost nothing. The job of the register allocator is to assign the many temporaries to a small number of machine registers, and, where possible, to assign the source and destination of a \texttt{MOVE} to the same register so that the \texttt{MOVE} can be deleted.

From an examination of the control and dataflow graph, we derive an \textit{interference graph}. Each node in the interference graph represents a temporary value; each edge \((t_1, t_2)\) indicates a pair of temporaries that cannot be assigned to the same register. The most common reason for an interference edge is that \(t_1\) and \(t_2\) are live at the same time. Interference edges can also express other constraints; for example, if a certain instruction \(a \leftarrow b \oplus c\) cannot produce results in register \(r_{12}\) on our machine, we can make \(a\) interfere with \(r_{12}\).

Next we color the interference graph. We want to use as few colors as possible, but no pair of nodes connected by an edge may be assigned the same color. Graph coloring problems derive from the old mapmakers’ rule that adjacent countries on a map should be colored with different colors. Our “colors” correspond to registers: if our target machine has \(K\) registers, and we can \(K\)-color the graph (color the graph with \(K\) colors), then the coloring is a valid register assignment for the interference graph. If there is no \(K\)-coloring, we will have to keep some of our variables and temporaries in memory instead of registers; this is called spilling.
11.1 COLORING BY SIMPLIFICATION

Register allocation is an $NP$-complete problem (except in special cases, such as expression trees); graph coloring is also $NP$-complete. Fortunately there is a linear-time approximation algorithm that gives good results; its principal phases are Build, Simplify, Spill, and Select.

**Build**: Construct the interference graph. We use dataflow analysis to compute the set of temporaries that are simultaneously live at each program point, and we add an edge to the graph for each pair of temporaries in the set. We repeat this for all program points.

**Simplify**: We color the graph using a simple heuristic. Suppose the graph $G$ contains a node $m$ with fewer than $K$ neighbors, where $K$ is the number of registers on the machine. Let $G'$ be the graph $G - \{m\}$ obtained by removing $m$. If $G'$ can be colored, then so can $G$, for when $m$ is added to the colored graph $G'$, the neighbors of $m$ have at most $K - 1$ colors among them so a free color can always be found for $m$. This leads naturally to a stack-based (or recursive) algorithm for coloring: we repeatedly remove (and push on a stack) nodes of degree less than $K$. Each such simplification will decrease the degrees of other nodes, leading to more opportunity for simplification.

**Spill**: Suppose at some point during simplification the graph $G$ has nodes only of significant degree, that is, nodes of degree $\geq K$. Then the simplify heuristic fails, and we mark some node for spilling. That is, we choose some node in the graph (standing for a temporary variable in the program) and decide to represent it in memory, not registers, during program execution. An optimistic approximation to the effect of spilling is that the spilled node does not interfere with any of the other nodes remaining in the graph. It can therefore be removed and pushed on the stack, and the simplify process continued.

**Select**: We assign colors to nodes in the graph. Starting with the empty graph, we rebuild the original graph by repeatedly adding a node from the top of the stack. When we add a node to the graph, there must be a color for it, as the premise for removing it in the simplify phase was that it could always be assigned a color provided the remaining nodes in the graph could be successfully colored.

When potential spill node $n$ that was pushed using the Spill heuristic is
COLORING BY SIMPLIFICATION

live-in: \[ k \ j \]
\[ g := \text{mem}[j+12] \]
\[ h := k - 1 \]
\[ f := g \times h \]
\[ e := \text{mem}[j+8] \]
\[ m := \text{mem}[j+16] \]
\[ b := \text{mem}[f] \]
\[ c := e + 8 \]
\[ d := c \]
\[ k := m + 4 \]
\[ j := b \]

live-out: \[ d \ k \ j \]

GRAPH 11.1. Interference graph for a program. Dotted lines are not interference edges but indicate move instructions.

popped, there is no guarantee that it will be colorable: its neighbors in the graph may be colored with \( K \) different colors already. In this case, we have an actual spill. We do not assign any color, but we continue the Select phase to identify other actual spills.

But perhaps some of the neighbors are the same color, so that among them there are fewer than \( K \) colors. Then we can color \( n \), and it does not become an actual spill. This technique is known as optimistic coloring.

**Start over:** If the Select phase is unable to find a color for some node(s), then the program must be rewritten to fetch them from memory just before each use, and store them back after each definition. Thus, a spilled temporary will turn into several new temporaries with tiny live ranges. These will interfere with other temporaries in the graph. So the algorithm is repeated on this rewritten program. This process iterates until simplify succeeds with no spills; in practice, one or two iterations almost always suffice.

**EXAMPLE**

Graph 11.1 shows the interferences for a simple program. The nodes are labeled with the temporaries they represent, and there is an edge between two nodes if they are simultaneously live. For example, nodes \( d, k, \) and \( j \) are all connected since they are live simultaneously at the end of the block. Assuming that there are four registers available on the machine, then the simplify phase can start with the nodes \( g, h, c, \) and \( f \) in its working set, since they
CHAPTER ELEVEN. REGISTER ALLOCATION

have less than four neighbors each. A color can always be found for them if the remaining graph can be successfully colored. If the algorithm starts by removing h and g and all their edges, then node k becomes a candidate for removal and can be added to the work-list. Graph 11.2 remains after nodes g, h, and k have been removed. Continuing in this fashion a possible order in which nodes are removed is represented by the stack shown in Figure 11.3a, where the stack grows upward.

The nodes are now popped off the stack and the original graph reconstructed and colored simultaneously. Starting with m, a color is chosen arbitrarily since the graph at this point consists of a singleton node. The next node to be put into the graph is c. The only constraint is that it be given a color different from m, since there is an edge from m to c. A possible assignment of colors for the reconstructed original graph is shown in Figure 11.3b.
11.2. COALESCING

11.2 COALESCING

It is easy to eliminate redundant move instructions with an interference graph. If there is no edge in the interference graph between the source and destination of a move instruction, then the move can be eliminated. The source and destination nodes are coalesced into a new node whose edges are the union of those of the nodes being replaced.

In principle, any pair of nodes not connected by an interference edge could be coalesced. This aggressive form of copy propagation is very successful at eliminating move instructions. Unfortunately, the node being introduced is more constrained than those being removed, as it contains a union of edges. Thus, it is quite possible that a graph, colorable with $K$ colors before coalescing, may no longer be $K$-colorable after reckless coalescing. We wish to coalesce only where it is safe to do so, that is, where the coalescing will not render the graph uncolorable. Both of the following strategies are safe:

Briggs: Nodes $a$ and $b$ can be coalesced if the resulting node $ab$ will have fewer than $K$ neighbors of significant degree (i.e., having $\geq K$ edges). The coalescing is guaranteed not to turn a $K$-colorable graph into a non-$K$-colorable graph, because after the simplify phase has removed all the insignificant-degree nodes from the graph, the coalesced node will be adjacent only to those neighbors that were of significant degree. Since there are fewer than $K$ of these, simplify can then remove the coalesced node from the graph. Thus if the original graph was colorable, the conservative coalescing strategy does not alter the colorability of the graph.

George: Nodes $a$ and $b$ can be coalesced if, for every neighbor $t$ of $a$, either $t$ already interferes with $b$ or $t$ is of insignificant degree. This coalescing is safe, by the following reasoning. Let $S$ be the set of insignificant-degree neighbors of $a$ in the original graph. If the coalescing were not done, simplify could remove all the nodes in $S$, leaving a reduced graph $G_1$. If the coalescing is done, then simplify can remove all the nodes in $S$, leaving a graph $G_2$. But $G_2$ is a subgraph of $G_1$ (the node $ab$ in $G_2$ corresponds to the node $b$ in $G_1$), and thus must be at least as easy to color.

These strategies are conservative, because there are still safe situations in which they will fail to coalesce. This means that the program may perform some unnecessary MOVE instructions – but this is better than spilling!

Interleaving simplification steps with conservative coalescing eliminates most move instructions, while still guaranteeing not to introduce spills. The coalesce, simplify, and spill procedures should be alternated until the graph is empty, as shown in Figure 11.4.
These are the phases of a register allocator with coalescing:

**Build:** Construct the interference graph, and categorize each node as either *move-related* or *non-move-related*. A move-related node is one that is either the source or destination of a move instruction.

**Simplify:** One at a time, remove non-move-related nodes of low (< K) degree from the graph.

**Coalesce:** Perform conservative coalescing on the reduced graph obtained in the simplification phase. Since the degrees of many nodes have been reduced by *simplify*, the conservative strategy is likely to find many more moves to coalesce than it would have in the initial interference graph. After two nodes have been coalesced (and the move instruction deleted), if the resulting node is no longer move-related it will be available for the next round of simplification. *Simplify* and *coalesce* are repeated until only significant-degree or move-related nodes remain.

**Freeze:** If neither *simplify* nor *coalesce* applies, we look for a move-related node of low degree. We *freeze* the moves in which this node is involved: that is, we give up hope of coalescing those moves. This causes the node (and perhaps other nodes related to the frozen moves) to be considered non-move-related, which should enable more simplification. Now, *simplify* and *coalesce* are resumed.

**Spill:** If there are no low-degree nodes, we select a significant-degree node for potential spilling and push it on the stack.

**Select:** Pop the entire stack, assigning colors.

Consider *Graph 11.1*; nodes b, c, d, and j are the only move-related nodes. The initial work-list used in the simplify phase must contain only non-move-
related nodes and consists of nodes g, h, and f. Once again, after removal of g, h, and k we obtain Graph 11.2.

We could continue the simplification phase further; however, if we invoke a round of coalescing at this point, we discover that c and d are indeed coalescable as the coalesced node has only two neighbors of significant degree: m and b. The resulting graph is shown in Graph 11.5a, with the coalesced node labeled as c&d.

From Graph 11.5a we see that it is possible to coalesce b and j as well. Nodes b and j are adjacent to two neighbors of significant degree, namely m and e. The result of coalescing b and j is shown in Graph 11.5b.

After coalescing these two moves, there are no more move-related nodes, and therefore no more coalescing is possible. The simplify phase can be invoked one more time to remove all the remaining nodes. A possible assignment of colors is shown in Figure 11.6.

Some moves are neither coalesced nor frozen. Instead, they are constrained. Consider the graph x, y, z, where (x, z) is the only interference edge and there are two moves x ← y and y ← z. Either move is a candidate for coalescing. But after x and y are coalesced, the remaining move xy ← z cannot
be coalesced because of the interference edge \((xy, z)\). We say this move is \textit{constrained}, and we remove it from further consideration: it no longer causes nodes to be treated as move-related.

\textbf{SPILLING}

If spilling is necessary, \textit{build} and \textit{simplify} must be repeated on the whole program. The simplest version of the algorithm discards any coalescences found if \textit{build} must be repeated. Then it is easy to see that coalescing does not increase the number of spills in any future round of \textit{build}. A more efficient algorithm preserves any coalescences done before the first potential spill was discovered, but discards (uncoalesces) any coalescences done after that point.

\textbf{Coalescing of spills.} On a machine with many registers (> 20), there will usually be few spilled nodes. But on a six-register machine (such as the Intel Pentium), there will be many spills. The front end may have generated many temporaries, and transformations such as SSA (described in Chapter 19) may split them into many more temporaries. If each spilled temporary lives in its own stack-frame location, then the frame may be quite large.

Even worse, there may be many move instructions involving pairs of spilled nodes. But to implement \(a \leftarrow b\) when \(a\) and \(b\) are both spilled temporaries requires a fetch-store sequence, \(t \leftarrow M[a_{\text{loc}}]; \quad M[b_{\text{loc}}] \leftarrow t\). This is expensive, and also defines a temporary \(t\) that itself may cause other nodes to spill.

But many of the spill pairs are never live simultaneously. Thus, they may be graph-colored, with coalescing! In fact, because there is no fixed limit to the number of stack-frame locations, we can coalesce aggressively, without worrying about how many high-degree neighbors the spill-nodes have. The algorithm is thus:

1. Use liveness information to construct the interference graph for spilled nodes.
2. While there is any pair of non-interfering spilled nodes connected by a move instruction, coalesce them.
3. Use \textit{simplify} and \textit{select} to color the graph. There is no (further) spilling in this coloring; instead, \textit{simplify} just picks the lowest-degree node, and \textit{select} picks the first available color, without any predetermined limit on the number of colors.
4. The colors correspond to activation-record locations for the spilled variables.

This should be done \textit{before} generating the spill instructions and regenerating the register-temporary interference graph, so as to avoid creating fetch-store sequences for coalesced moves of spilled nodes.
11.3 PRECOLORED NODES

Some temporaries are *precolored* – they represent machine registers. The front end generates these when interfacing to standard calling conventions across module boundaries, for example. For each actual register that is used for some specific purpose, such as the frame pointer, standard-argument-1-register, standard-argument-2-register, and so on, the Codegen or Frame module should use the particular temporary that is permanently bound to that register (see also page 267). For any given color (that is, for any given machine register) there should be only one precolored node of that color.

The *select* and *coalesce* operations can give an ordinary temporary the same color as a precolored register, as long as they don’t interfere, and in fact this is quite common. Thus, a standard calling-convention register can be reused inside a procedure as a temporary variable. Precolored nodes may be coalesced with other (non-precolored) nodes using conservative coalescing.

For a $K$-register machine, there will be $K$ precolored nodes that all interfere with each other. Those of the precolored nodes that are not used explicitly (in a parameter-passing convention, for example) will not interfere with any ordinary (non-precolored) nodes; but a machine register used explicitly will have a live range that interferes with any other variables that happen to be live at the same time.

We cannot *simplify* a precolored node – this would mean pulling it from the graph in the hope that we can assign it a color later, but in fact we have no freedom about what color to assign it. And we should not spill precolored nodes to memory, because the machine registers are by definition *registers*. Thus, we should treat them as having “infinite” degree.

TEMPORARY COPIES OF MACHINE REGISTERS

The coloring algorithm works by calling *simplify*, *coalesce*, and *spill* until only the precolored nodes remain, and then the *select* phase can start adding the other nodes (and coloring them).

Because precolored nodes do not spill, the front end must be careful to keep their live ranges short. It can do this by generating MOVE instructions to move values to and from precolored nodes. For example, suppose $r_7$ is a callee-save register; it is “defined” at procedure entry and “used” at procedure exit. Instead of being kept in a precolored register throughout the procedure (Figure 11.7a), it can be moved into a fresh temporary and then moved back.
CALLER-SAVE AND CALLEE-SAVE REGISTERS

The most basic of spill heuristics can achieve the effect of allocating variables live across calls to callee-save registers. A local variable or compiler temporary that is not live across any procedure call should usually be allocated to a caller-save register, because in this case no saving and restoring of the register will be necessary at all. On the other hand, any variable that is live across several procedure calls should be kept in a callee-save register, since then only one save/restore will be necessary (on entry/exit from the calling procedure).

The register allocator should allocate variables to registers using this criterion. Fortunately, a graph-coloring allocator with spilling can do this very easily. The CALL instructions in the Assembl language have been annotated to define (interfere with) all the caller-save (precolored) registers. If a variable is not live across a procedure call, it will tend to be allocated to a caller-save register.

If a variable \( x \) is live across a procedure call, then it interferes with all the caller-save (precolored) registers, \emph{and} it interferes with all the new temporaries (such as \( t_{231} \) in Figure 11.7) created for callee-save registers. Thus, a spill will occur. Using the common spill-cost heuristic that spills a node with high degree but few uses, the node chosen for spilling will not be \( x \) but \( t_{231} \). Since \( t_{231} \) is spilled, \( r_7 \) will be available for coloring \( x \) (or some other variable).

EXAMPLE WITH PRECOLORED NODES

A worked example will illustrate the issues of register allocation with precolored nodes, callee-save registers, and spilling.

A C compiler is compiling Program 11.8a for a target machine with three
11.3. PRECOLORED NODES

**Program 11.8.** A C function and its translation into instructions

```c
int f(int a, int b) {
    int d=0;
    int e=a;
    do {d = d+b;
         e = e-1;
    } while (e>0);
    return d;
}
```

**enter:**

```
c ← r3
a ← r1
b ← r2
d ← 0
e ← a
```

**loop:**

```
d ← d + b
```

if e > 0 goto loop

```
r1 ← d
r3 ← c
```

return 

(r₁, r₃ live out)

---

registers; r₁ and r₂ are caller-save, and r₃ is callee-save. The code generator
has therefore made arrangements to preserve the value of r₃ explicitly, by
copying it into the temporary c and back again.

The instruction-selection phase has pro-
duced the instruction-list of Program 11.8b.
The interference graph for this function is
shown at right.

The register allocation proceeds as follows (with K = 3):

1. In this graph, there is no opportunity for simplify or freeze (because all the
   non-precolored nodes have degree ≥ K). Any attempt to coalesce would pro-
duce a coalesced node adjacent to K or more significant-degree nodes. There-
fore we must spill some node. We calculate spill priorities as follows:

<table>
<thead>
<tr>
<th>Node</th>
<th>Uses+Defs outside loop</th>
<th>Uses+Defs within loop</th>
<th>Degree</th>
<th>Spill priority</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>( 2 + 10 × 0 ) / 4</td>
<td>4</td>
<td>0.50</td>
<td></td>
</tr>
<tr>
<td>b</td>
<td>( 1 + 10 × 1 ) / 4</td>
<td>4</td>
<td>2.75</td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>( 2 + 10 × 0 ) / 6</td>
<td>6</td>
<td>0.33</td>
<td></td>
</tr>
<tr>
<td>d</td>
<td>( 2 + 10 × 2 ) / 4</td>
<td>4</td>
<td>5.50</td>
<td></td>
</tr>
<tr>
<td>e</td>
<td>( 1 + 10 × 3 ) / 3</td>
<td>3</td>
<td>10.33</td>
<td></td>
</tr>
</tbody>
</table>
Node $c$ has the lowest priority – it interferes with many other temporaries but is rarely used – so it should be spilled first. Spilling $c$, we obtain the graph at right.

2. We can now coalesce $a$ and $e$, since the resulting node will be adjacent to fewer than $K$ significant-degree nodes (after coalescing, node $d$ will be low-degree, though it is significant-degree right now). No other simplify or coalesce is possible now.

3. Now we could coalesce $ae & r_1$ or coalesce $b & r_2$. Let us do the latter.

4. We can now coalesce either $ae & r_1$ or coalesce $d & r_1$. Let us do the former.

5. We cannot now coalesce $r_1ae & d$ because the move is constrained: the nodes $r_1ae$ and $d$ interfere. We must simplify $d$.

6. Now we have reached a graph with only precolored nodes, so we pop nodes from the stack and assign colors to them. First we pick $d$, which can be assigned color $r_3$. Nodes $a$, $b$, $e$ have already been assigned colors by coalescing. But node $c$, which was a potential spill, turns into an actual spill when it is popped from the stack, since no color can be found for it.

7. Since there was spilling in this round, we must rewrite the program to include spill instructions. For each use (or definition) of $c$, we make up a new temporary, and fetch (or store) it immediately afterward (or beforehand).

```
enter:
c_1 ← r_3
M[c_{loc}] ← c_1
a ← r_1
b ← r_2
d ← 0
e ← a

loop:
d ← d + b
e ← e - 1
if e > 0 goto loop
r_1 ← d
c_2 ← M[c_{loc}]
r_3 ← c_2
return
```
11.3. PRECOLORED NODES

8. Now we build a new interference graph:

9. Graph coloring proceeds as follows. We can immediately coalesce \( c_1 & r_3 \) and then \( c_2 & r_3 \).

10. Then, as before, we can coalesce \( a & e \) and then \( b & r_2 \).

11. As before, we can coalesce \( a & e \) and then simplify \( d \).

12. Now we start popping from the stack: we select color \( r_3 \) for \( d \), and this was the only node on the stack – all other nodes were coalesced or precolored. The coloring is shown at right.

<table>
<thead>
<tr>
<th>Node</th>
<th>Color</th>
</tr>
</thead>
<tbody>
<tr>
<td>( a )</td>
<td>( r_1 )</td>
</tr>
<tr>
<td>( b )</td>
<td>( r_2 )</td>
</tr>
<tr>
<td>( c )</td>
<td>( r_3 )</td>
</tr>
<tr>
<td>( d )</td>
<td>( r_3 )</td>
</tr>
<tr>
<td>( e )</td>
<td>( r_1 )</td>
</tr>
</tbody>
</table>

13. Now we can rewrite the program using the register assignment.

```plaintext
enter:
\( r_3 \leftarrow r_3 \)
\( M[\text{loc}] \leftarrow r_3 \)
\( r_1 \leftarrow r_1 \)
\( r_2 \leftarrow r_2 \)
\( r_3 \leftarrow 0 \)
\( r_1 \leftarrow r_1 \)

loop:
\( r_3 \leftarrow r_3 + r_2 \)
\( r_1 \leftarrow r_1 - 1 \)
if \( r_1 > 0 \) goto loop
\( r_1 \leftarrow r_3 \)
\( r_3 \leftarrow M[\text{loc}] \)
\( r_3 \leftarrow r_3 \)
return
```
14. Finally, we can delete any move instruction whose source and destination are the same; these are the result of coalescing.

```
enter:  M[c.loc] ← r3
r3 ← 0

loop:
r3 ← r3 + r2
r1 ← r1 - 1
if r1 > 0 goto loop
r1 ← r3
r3 ← M[c.loc]
return
```

The final program has only one uncoalesced move instruction.

11.4 GRAPH COLORING IMPLEMENTATION

The graph coloring algorithm needs to query the interference-graph data structure frequently. There are two kinds of queries:

1. Get all the nodes adjacent to node $X$; and
2. Tell if $X$ and $Y$ are adjacent.

An adjacency list (per node) can answer query 1 quickly, but not query 2 if the lists are long. A two-dimensional bit matrix indexed by node numbers can answer query 2 quickly, but not query 1. Therefore, we need both data structures to (redundantly) represent the interference graph. If the graph is very sparse, a hash table of integer pairs may be better than a bit matrix.

The adjacency lists of machine registers (precolored nodes) can be very large; because they’re used in standard calling conventions they interfere with any temporaries that happen to be live near any of the procedure-calls in the program. But we don’t need to represent the adjacency list for a precolored node, because adjacency lists are used only in the select phase (which does not apply to precolored nodes) and in the Briggs coalescing test. To save space and time, we do not explicitly represent the adjacency lists of the machine registers. We coalesce an ordinary node $a$ with a machine register $r$ using the George coalescing test, which needs the adjacency list of $a$ but not of $r$.

To test whether two ordinary (non-precolored) nodes can be coalesced, the algorithm shown here uses the Briggs coalescing test.

Associated with each move-related node is a count of the moves it is involved in. This count is easy to maintain and is used to test if a node is no longer move-related. Associated with all nodes is a count of the number of neighbors currently in the graph. This is used to determine whether a node is
11.4. GRAPH COLORING IMPLEMENTATION

of significant degree during coalescing, and whether a node can be removed from the graph during simplification.

It is important to be able to quickly perform each simplify step (removing a low-degree non-move-related node), each coalesce step, and each freeze step. To do this, we maintain four work-lists:

- Low-degree non-move-related nodes (simplifyWorklist);
- Move instructions that might be coalesceable (worklistMoves);
- Low-degree move-related nodes (freezeWorklist);
- High-degree nodes (spillWorklist).

Using these work-lists, we avoid quadratic time blowup in finding coalesceable nodes.

MOVE-WORK-LIST MANAGEMENT

When a node \( x \) changes from significant to low degree, the moves associated with its neighbors must be added to the move work-list. Moves that were blocked with too many significant neighbors might now be enabled for coalescing. Moves are added to the move work-list in only a few places:

- During simplify the degree of a node \( x \) might make the transition as a result of removing another node. Moves associated with neighbors of \( x \) are added to the worklistMoves.
- When \( u \) and \( v \) are coalesced, there may be a node \( x \) that interferes with both \( u \) and \( v \). The degree of \( x \) is decremented as it now interferes with the single coalesced node. Moves associated with neighbors of \( x \) are added. If \( x \) is move-related, then moves associated with \( x \) itself are also added as both \( u \) and \( v \) may have been significant degree nodes.
- When \( u \) is coalesced into \( v \), moves associated with \( u \) are added to the move work-list. This will catch other moves from \( u \) to \( v \).

DATA STRUCTURES

The algorithm maintains these data structures to keep track of graph nodes and move edges:

Node work-lists, sets, and stacks. The following lists and sets are always mutually disjoint and every node is always in exactly one of the sets or lists.

precolored: machine registers, preassigned a color.
initial: temporary registers, not precolored and not yet processed.
simplifyWorklist: list of low-degree non-move-related nodes.
freezeWorklist: low-degree move-related nodes.
spillWorklist: high-degree nodes.
spilledNodes: nodes marked for spilling during this round; initially empty.
coalescedNodes: registers that have been coalesced; when \( u \leftarrow v \) is coalesced, \( v \)
is added to this set and \( u \) put back on some work-list (or vice versa).
cooredNodes: nodes successfully colored.
selectStack: stack containing temporaries removed from the graph.

Since membership in these sets is often tested, the representation of each
node should contain an enumeration value telling which set it is in. Since
nodes must frequently be added to and removed from these sets, each set
can be represented by a doubly linked list of nodes. Initially (on entry to
Main), and on exiting RewriteProgram, only the sets precolored and initial
are nonempty.

Move sets. There are five sets of move instructions, and every move is in
exactly one of these sets (after Build through the end of Main).

coalescedMoves: moves that have been coalesced.
constrainedMoves: moves whose source and target interfere.
frozenMoves: moves that will no longer be considered for coalescing.
worklistMoves: moves enabled for possible coalescing.
activeMoves: moves not yet ready for coalescing.

Like the node work-lists, the move sets should be implemented as dou-
bly linked lists, with each move containing an enumeration value identifying
which set it belongs to.

Other data structures.

adjSet: the set of interference edges \((u, v)\) in the graph. If \((u, v) \in \text{adjSet}\) then
\((v, u) \in \text{adjSet}\).
adjList: adjacency list representation of the graph; for each non-precolored
temporary \( u \), \( \text{adjList}[u] \) is the set of nodes that interfere with \( u \).
dergee: an array containing the current degree of each node.
movelist: a mapping from a node to the list of moves it is associated with.
alias: when a move \((u, v)\) has been coalesced, and \( v \) put in coalescedNodes,
then alias\((v) = u\).
color: the color chosen by the algorithm for a node; for precolored nodes this is
initialized to the given color.
11.4. GRAPH COLORING IMPLEMENTATION

**Invariants.** After Build, the following invariants always hold:

**Degree invariant.**

\[(u \in \text{simplifyWorklist} \cup \text{freezeWorklist} \cup \text{spillWorklist}) \Rightarrow \\]
\[\text{degree}(u) = |\text{adjList}(u) \cap (\text{precolored} \cup \text{simplifyWorklist} \cup \text{freezeWorklist} \cup \text{spillWorklist})|\]

**Simplify worklist invariant.**

\[(u \in \text{simplifyWorklist}) \Rightarrow \text{degree}(u) < K \land \text{moveList}[u] \cap (\text{activeMoves} \cup \text{worklistMoves}) = {}\]

**Freeze worklist invariant.**

\[(u \in \text{freezeWorklist}) \Rightarrow \text{degree}(u) < K \land \text{moveList}[u] \cap (\text{activeMoves} \cup \text{worklistMoves}) \neq {}\]

**Spill worklist invariant.**

\[(u \in \text{spillWorklist}) \Rightarrow \text{degree}(u) \geq K\]

**PROGRAM CODE**

The algorithm is invoked using the procedure `Main`, which loops (via tail recursion) until no spills are generated.

```
procedure Main()
    LivenessAnalysis()
    Build()
    MakeWorklist()
    repeat
        if `simplifyWorklist` \(\neq\) {} then Simplify()
        else if `worklistMoves` \(\neq\) {} then Coalesce()
        else if `freezeWorklist` \(\neq\) {} then Freeze()
        else if `spillWorklist` \(\neq\) {} then SelectSpill()
    until `simplifyWorklist` = {} \(\land\) `worklistMoves` = {} \(\land\) `freezeWorklist` = {} \(\land\) `spillWorklist` = {}
    AssignColors()
    if `spilledNodes` \(\neq\) {} then
        RewriteProgram(`spilledNodes`)
        Main()
```

If `AssignColors` spills, then `RewriteProgram` allocates memory locations for the spilled temporaries and inserts store and fetch instructions to access them. These stores and fetches are to newly created temporaries (with tiny live ranges), so the main loop must be performed on the altered graph.
procedure Build ()
    forall b ∈ blocks in program
        let live = liveOut(b)
        forall I ∈ instructions(b) in reverse order
            if isMoveInstruction(I) then
                live ← live \ use(I)
                forall n ∈ def(I) ∪ use(I)
                    moveList[n] ← moveList[n] ∪ {I}
                    worklistMoves ← worklistMoves ∪ {I}
                live ← live ∪ def(I)
            forall d ∈ def(I)
                forall l ∈ live
                    AddEdge(l, d)
                live ← use(I) ∪ (live \ def(I))

Procedure Build constructs the interference graph (and bit matrix) using the results of static liveness analysis, and also initializes the worklistMoves to contain all the moves in the program.

procedure AddEdge(u, v)
    if ((u, v) ∉ adjSet) ∧ (u ≠ v) then
        adjSet ← adjSet ∪ {(u, v), (v, u)}
    if u ∉ precolored then
        adjList[u] ← adjList[u] ∪ {v}
        degree[u] ← degree[u] + 1
    if v ∉ precolored then
        adjList[v] ← adjList[v] ∪ {u}
        degree[v] ← degree[v] + 1

procedure MakeWorklist()
    forall n ∈ initial
        initial ← initial \ {n}
    if degree[n] ≥ K then
        spillWorklist ← spillWorklist ∪ {n}
    else if MoveRelated(n) then
        freezeWorklist ← freezeWorklist ∪ {n}
    else
        simplifyWorklist ← simplifyWorklist ∪ {n}

function Adjacent(n)
    adjList[n] \ (selectStack ∪ coalescedNodes)
11.4. GRAPH COLORING IMPLEMENTATION

function NodeMoves (n)
moveList[n] \cap (activeMoves \cup worklistMoves)

function MoveRelated(n)
NodeMoves(n) \neq \{

procedure Simplify()
let n \in simplifyWorklist
simplifyWorklist \leftarrow simplifyWorklist \setminus \{n\}
push(n, selectStack)
forall m \in Adjacent(n)
DecrementDegree(m)

Removing a node from the graph involves decrementing the degree of its current neighbors. If the degree of a neighbor is already less than $K - 1$ then the neighbor must be move-related, and is not added to the simplifyWorklist. When the degree of a neighbor transitions from $K$ to $K - 1$, moves associated with its neighbors may be enabled.

procedure DecrementDegree(m)
let d = degree[m]
degree[m] \leftarrow d-1
if d = K then
EnableMoves(\{m\} \cup Adjacent(m))
spillWorklist \leftarrow spillWorklist \setminus \{m\}
if MoveRelated(m) then
freezeWorklist \leftarrow freezeWorklist \cup \{m\}
else
simplifyWorklist \leftarrow simplifyWorklist \cup \{m\}

procedure EnableMoves(nodes)
forall n \in nodes
forall m \in NodeMoves(n)
if m \in activeMoves then
activeMoves \leftarrow activeMoves \setminus \{m\}
worklistMoves \leftarrow worklistMoves \cup \{m\}

Only moves in the worklistMoves are considered in the coalesce phase. When a move is coalesced, it may no longer be move-related and can be added to the simplify work-list by the procedure AddWorkList. OK implements the heuristic used for coalescing a precolored register. Conservative implements the conservative coalescing heuristic.
procedure Coalesce()
  let $m(x,y) \in \text{worklistMoves}$
  $x \leftarrow \text{GetAlias}(x)$
  $y \leftarrow \text{GetAlias}(y)$
  if $y \in \text{precolored}$ then
    let $(u, v) = (y, x)$
  else
    let $(u, v) = (x, y)$
  worklistMoves $\leftarrow$ worklistMoves $\setminus \{m\}$
  if $(u = v)$ then
    coalescedMoves $\leftarrow$ coalescedMoves $\cup \{m\}$
    AddWorkList(u)
  else if $v \in \text{precolored} \lor (u, v) \in \text{adjSet}$ then
    constrainedMoves $\leftarrow$ constrainedMoves $\cup \{m\}$
    AddWorkList(u)
    AddWorkList(v)
  else if $u \in \text{precolored} \land (\forall t \in \text{Adjacent}(v), \text{OK}(t, u))$ \lor $u \not\in \text{precolored}$ \land 
    $\text{Conservative}(\text{Adjacent}(u) \cup \text{Adjacent}(v))$ then
    coalescedMoves $\leftarrow$ coalescedMoves $\cup \{m\}$
    Combine(u, v)
    AddWorkList(u)
  else
    activeMoves $\leftarrow$ activeMoves $\cup \{m\}$

procedure AddWorkList(u)
  if $(u \not\in \text{precolored} \land \not\text{MoveRelated}(u) \land \text{degree}[u] < K)$ then
    freezeWorklist $\leftarrow$ freezeWorklist $\setminus \{u\}$
    simplifyWorklist $\leftarrow$ simplifyWorklist $\cup \{u\}$

function OK(t, r)
  degree[t] $< K \lor t \in \text{precolored} \lor (t, r) \in \text{adjSet}$

function Conservative(nodes)
  let $k = 0$
  forall $n \in$ nodes
    if degree[$n$] $\geq K$ then $k \leftarrow k + 1$
  return $(k < K)$

function GetAlias(n)
  if $n \in \text{coalescedNodes}$ then
    GetAlias(alias[n])
  else $n$
procedure Combine(u,v)
    if v ∈ freezeWorklist then
        freezeWorklist ← freezeWorklist \ {v}
    else
        spillWorklist ← spillWorklist \ {v}
        coalescedNodes ← coalescedNodes ∪ {v}
        alias[v] ← u
        nodeMoves[u] ← nodeMoves[u] ∪ nodeMoves[v]
    forall t ∈ Adjacent(v)
        AddEdge(t,u)
        DecrementDegree(t)
    if degree[u] ≥ K ∧ u ∈ freezeWorkList
        freezeWorkList ← freezeWorkList \ {u}
        spillWorkList ← spillWorkList ∪ {u}

procedure Freeze()
    let u ∈ freezeWorklist
    freezeWorklist ← freezeWorklist \ {u}
    simplifyWorklist ← simplifyWorklist ∪ {u}
    FreezeMoves(u)

procedure FreezeMoves(u)
    forall m(=copy(x,y)) ∈ NodeMoves(u)
        if GetAlias(y)=GetAlias(u) then
            v ← GetAlias(x)
        else
            v ← GetAlias(y)
        activeMoves ← activeMoves \ {m}
        frozenMoves ← frozenMoves ∪ {m}
    if NodeMoves(v) = {} ∧ degree[v] < K then
        freezeWorklist ← freezeWorklist \ {v}
        simplifyWorklist ← simplifyWorklist ∪ {v}

procedure SelectSpill()
    let m ∈ spillWorklist selected using favorite heuristic
    Note: avoid choosing nodes that are the tiny live ranges resulting from the fetches of previously spilled registers
    spillWorklist ← spillWorklist \ {m}
    simplifyWorklist ← simplifyWorklist ∪ {m}
    FreezeMoves(m)
**procedure** AssignColors()
  **while** SelectStack not empty
    **let** n = pop(SelectStack)
    okColors ← {0, …, K-1}
    **forall** w ∈ adjList[n]
      if GetAlias(w) ∈ (coloredNodes U precolored) **then**
        okColors ← okColors \ {color[GetAlias(w)]}
      **if** okColors = {} **then**
        spilledNodes ← spilledNodes U {n}
      **else**
        coloredNodes ← coloredNodes U {n}
        **let** c ∈ okColors
        color[n] ← c
    **forall** n ∈ coalescedNodes
      color[n] ← color[GetAlias(n)]

**procedure** RewriteProgram()
  Allocate memory locations for each v ∈ spilledNodes,
  Create a new temporary v_i for each definition and each use,
  In the program (instructions), insert a store after each
  definition of a v_i, a fetch before each use of a v_i.
  Put all the v_i into a set newTemps.
  spilledNodes ← {}  
  initial ← coloredNodes U coalescedNodes U newTemps  
  coloredNodes ← {}  
  coalescedNodes ← {}  

I show a variant of the algorithm in which all coalesces are discarded if
the program must be rewritten to incorporate spill fetches and stores. For a
faster algorithm, keep all the coalesces found before the first call to Select-
Spill and rewrite the program to eliminate the coalesced move instructions
and temporaries.

In principle, a heuristic could be used to select the freeze node; the Freeze
shown above picks an arbitrary node from the freeze work-list. But freezes
are not common, and a selection heuristic is unlikely to make a significant
difference.
11.5. REGISTER ALLOCATION FOR TREES

Register allocation for expression trees is much simpler than for arbitrary flow graphs. We do not need global dataflow analysis or interference graphs. Suppose we have a tiled tree such as in Figure 9.2a. This tree has two trivial tiles, the TEMP nodes \( f_p \) and \( i \), which we assume are already in registers \( r_{f_p} \) and \( r_i \). We wish to label the roots of the nontrivial tiles (the ones corresponding to instructions, i.e., 2, 4, 5, 6, 8) with registers from the list \( r_1, r_2, \ldots, r_k \).

Algorithm 11.9 traverses the tree in postorder, assigning a register to the root of each tile. With \( n \) initialized to zero, this algorithm applied to the root (tile 9) produces the allocation \( \{ {\text{tile2 }} \mapsto r_1, {\text{tile4 }} \mapsto r_2, {\text{tile5 }} \mapsto r_2, {\text{tile6 }} \mapsto r_1, {\text{tile8 }} \mapsto r_2, {\text{tile9 }} \mapsto r_1 \} \). The algorithm can be combined with Maximal Munch, since both algorithms are doing the same bottom-up traversal.

But this algorithm will not always lead to an optimal allocation. Consider the following tree, where each tile is shown as a single node:

```
+  *
/ \ /
MEM(NAME a)  MEM(NAME b)  MEM(NAME c)
```

The SimpleAlloc function will use three registers for this expression (as shown at left below), but by reordering the instructions we can do the computation
CHAPTER ELEVEN. REGISTER ALLOCATION

function Label(t)
    for each tile u that is a child of t
        Label(u)
    if t is trivial
        then need[t] ← 0
    else if t has two children, u_left and u_right
        then if need[u_left] = need[u_right]
            then need[t] ← 1 + need[u_left]
        else need[t] ← max(1, need[u_left], need[u_right])
    else if t has one child, u
        then need[t] ← max(1, need[u])
    else if t has no children
        then need[t] ← 1

ALGORITHM 11.10. Sethi-Ullman labeling algorithm.

using only two registers (as shown at right):

\[
\begin{align*}
    r_1 &\leftarrow M[a] & r_1 &\leftarrow M[b] \\
    r_2 &\leftarrow M[b] & r_2 &\leftarrow M[c] \\
    r_3 &\leftarrow M[c] & r_1 &\leftarrow r_1 \times r_2 \\
    r_2 &\leftarrow r_2 \times r_3 & r_2 &\leftarrow M[a] \\
    r_1 &\leftarrow r_1 + r_2 & r_1 &\leftarrow r_2 + r_1
\end{align*}
\]

Using dynamic programming, we can find the optimal ordering for the instructions. The idea is to label each tile with the number of registers it needs during its evaluation. Suppose a tile t has two nontrivial children u_left and u_right that require n and m registers, respectively, for their evaluation. If we evaluate u_left first, and hold its result in one register while we evaluate u_right, then we have needed max(n, 1 + m) registers for the whole expression rooted at t. Conversely, if we evaluate u_right first, then we need max(1 + n, m) registers. Clearly, if n > m we should evaluate u_left first, and if n < m we should evaluate u_right first. If n = m we will need n + 1 registers no matter which subexpression is evaluated first.

Algorithm 11.10 labels each tile t with need[t], the number of registers needed to evaluate the subtree rooted at t. It can be generalized to handle tiles with more than two children. Maximal Munch should identify – but not emit
11.5. REGISTER ALLOCATION FOR TREES

function SethiUllman(t)
  if t has two children, u_left and u_right
    if need[u_left] ≥ K ∧ need[u_right] ≥ K
      SethiUllman(t_right)
      n ← n − 1
      spill: emit instruction to store reg[t_right]
      SethiUllman(t_left)
      unspill: reg[t_right] ← “r_{n+1}”; emit instruction to fetch reg[t_right]
  else if need[u_left] ≥ need[u_right]
    SethiUllman(t_left)
    SethiUllman(t_right)
    n ← n − 1
  else need[u_left] < need[u_right]
    SethiUllman(t_right)
    SethiUllman(t_left)
    n ← n − 1
    reg[t] ← “r_n”
    emit OPER(instruction[t], reg[t], [reg[t_left], reg[t_right]])
  else if t has one child, u
    SethiUllman(u)
    reg[t] ← “r_n”
    emit OPER(instruction[t], reg[t], [reg[u]])
  else if t is nontrivial but has no children
    n ← n + 1
    reg[t] ← “r_n”
    emit OPER(instruction[t], reg[t], [ ])
  else if t is a trivial node TEMP(r_i)
    reg[t] ← “r_i”

ALGORITHM 11.11. Sethi-Ullman register allocation for trees.

– the tiles, simultaneously with the labeling of Algorithm 11.10. The next pass emits Assem instructions for the tiles; wherever a tile has more than one child, the subtrees must be emitted in decreasing order of register need.

Algorithm 11.10 can profitably be used in a compiler that uses graph-coloring register allocation. Emitting the subtrees in decreasing order of need
CHAPTER ELEVEN. REGISTER ALLOCATION

will minimize the number of simultaneously live temporaries and reduce the number of spills.

In a compiler without graph-coloring register allocation, Algorithm 11.10 is used as a pre-pass to Algorithm 11.11, which assigns registers as the trees are emitted and also handles spilling cleanly. This takes care of register allocation for the internal nodes of expression trees; allocating registers for explicit TEMPS of the Tree language would have to be done in some other way. In general, such a compiler would keep almost all program variables in the stack frame, so there would not be many of these explicit TEMPS to allocate.

PROGRAM GRAPH COLORING

Implement graph coloring register allocation as two modules: Color, which does just the graph coloring itself, and RegAlloc, which manages spilling and calls upon Color as a subroutine. To keep things simple, do not implement spilling or coalescing; this simplifies the algorithm considerably.

```c
/* color.h */
struct COL_result {Temp_map coloring; Temp_tempList spills;};
struct COL_result COL_color(G_graph ig,
                           Temp_map initial,
                           Temp_tempList registers);

/* regalloc.h */
struct RA_result {Temp_map coloring; AS_instrList il;};
struct RA_result RA_regAlloc(F_frame f, AS_instrList il);
```

Given an interference graph, an initial allocation (precoloring) of some temporaries imposed by calling conventions, and a list of colors (registers), color produces an extension of the initial allocation. The resulting allocation assigns all temps used in the flow graph, making use of registers from the registers list.

The initial allocation is the F_tempMap provided by the Frame structure; the registers argument is just the list of all machine registers, F_registers() (see page 267). The registers in the initial allocation can also appear in the registers argument to COL_color(), since it’s OK to use them to color other nodes as well.

The result of COL_color is a Temp_map describing the register allocation, along with a list of spills. The result of RegAlloc – if there were no spills – is an identical Temp_map, which can be used in final assembly-code emission as an argument to AS_print.
A better \texttt{COL\_color} interface would have a \texttt{spillCost} argument that specifies the spilling cost of each temporary. This can be just the number of uses and defs, or better yet, uses and defs weighted by occurrence in loops and nested loops. A naive \texttt{spillCost} that just returns 1 for every temporary will also work.

A simple implementation of the coloring algorithm without coalescing requires only one work-list: the \texttt{simplifyWorklist}, which contains all non-precolored, nonsimplified nodes of degree less than $K$. Obviously, no \texttt{freezeWorklist} is necessary. No \texttt{spillWorklist} is necessary either, if we are willing to look through all the nodes in the original graph for a spill candidate every time the \texttt{simplifyWorklist} becomes empty.

With only a \texttt{simplifyWorklist}, the doubly linked representation is not necessary: this work-list can be implemented as a singly linked list or a stack, since it is never accessed “in the middle.”

\textbf{ADVANCED PROJECT: SPILLING}

Implement spilling, so that no matter how many parameters and locals a Tiger program has, you can still compile it.

\textbf{ADVANCED PROJECT: COALESCING}

Implement coalescing, to eliminate practically all the \texttt{MOVE} instructions from the program.

Kempe [1879] invented the simplification algorithm that colors graphs by removing vertices of degree $< K$. Chaitin [1982] formulated register allocation as a graph-coloring problem – using Kempe’s algorithm to color the graph – and performed copy propagation by (nonconservatively) coalescing non-interfering move-related nodes before coloring the graph. Briggs et al. [1994] improved the algorithm with the idea of optimistic spilling, and also avoided introducing spills by using the conservative coalescing heuristic before coloring the graph. George and Appel [1996] found that there are more opportunities for coalescing if conservative coalescing is done during simplification instead of beforehand, and developed the work-list algorithm presented in this chapter.
Ershov [1958] developed the algorithm for optimal register allocation on expression trees; Sethi and Ullman [1970] generalized this algorithm and showed how it should handle spills.

### EXERCISES

#### 11.1

The following program has been compiled for a machine with three registers $r_1, r_2, r_3$; $r_1$ and $r_2$ are (caller-save) argument registers and $r_3$ is a callee-save register. Construct the interference graph and show the steps of the register allocation process in detail, as on pages 244–248. When you coalesce two nodes, say whether you are using the Briggs or George criterion.

**Hint:** When two nodes are connected by an interference edge and a move edge, you may delete the move edge; this is called constrain and is accomplished by the first else if clause of procedure Coalesce.

```plaintext
f :  c ← r_3  
p ← r_1  
if p = 0 goto L_1  
r_1 ← M[p]  
call f (uses r_1, defines r_1, r_2)  
s ← r_1  
r_1 ← M[p + 4]  
call f (uses r_1, defines r_1, r_2)  
t ← r_1  
u ← s + t  
goto L_2  
L_1 :  u ← 1  
L_2 :  r_1 ← u  
r_3 ← c  
return (uses r_1, r_3)
```

#### 11.2

The table below represents a register-interference graph. Nodes 1–6 are precolored (with colors 1–6), and nodes A–H are ordinary (non-precolored). Every pair of precolored nodes interferes, and each ordinary node interferes with nodes where there is an x in the table.
The following pairs of nodes are related by \texttt{MOVE} instructions:

\((A, 3) \quad (H, 3) \quad (G, 3) \quad (B, 2) \quad (C, 1) \quad (D, 6) \quad (E, 4) \quad (F, 5)\)

Assume that register allocation must be done for an 8-register machine.

a. Ignoring the \texttt{MOVE} instructions, and without using the \texttt{coalesce} heuristic, color this graph using \texttt{simplify} and \texttt{spill}. Record the sequence (stack) of \texttt{simplify} and potential-spill decisions, show which potential spills become actual spills, and show the coloring that results.

b. Color this graph using coalescing. Record the sequence of \texttt{simplify}, \texttt{coalesce}, freeze, and \texttt{spill} decisions. Identify each \texttt{coalesce} as Briggs- or George-style. Show how many \texttt{MOVE} instructions remain.

c. Another coalescing heuristic is \textit{biased coloring}. Instead of using a \textit{conservative coalescing} heuristic during simplification, run the \texttt{simplify-spill} part of the algorithm as in part (a), but in the \texttt{select} part of the algorithm,

i. When selecting a color for node \(X\) that is move-related to node \(Y\), when a color for \(Y\) has already been selected, use the same color if possible (to eliminate the \texttt{MOVE}).

ii. When selecting a color for node \(X\) that is move-related to node \(Y\), when a color for \(Y\) has not yet been selected, use a color that is \textit{not} the same as the color of any of \(Y\)'s neighbors (to increase the chance of heuristic (i) working when \(Y\) is colored).

Conservative coalescing (in the \texttt{simplify} phase) has been found more effective than biased coloring, in general; but it might not be on this particular graph. Since the two coalescing algorithms are used in different phases, they can both be used in the same register allocator.

d. Use both conservative coalescing and biased coloring in allocating registers. Show where biased coloring helps make the right decisions.

\textit{Conservative coalescing} is so called because it will not introduce any (potential) spills. But can it avoid spills? Consider this graph, where the solid edges represent interferences and the dashed edge represents a \texttt{MOVE}:
a. 4-color the graph without coalescing. Show the select-stack, indicating the order in which you removed nodes. Is there a potential spill? Is there an actual spill?

b. 4-color the graph with conservative coalescing. Did you use the Briggs or George criterion? Is there a potential spill? Is there an actual spill?

11.4 It has been proposed that the conservative coalescing heuristic could be simplified. In testing whether MOVE($a, b$) can be coalesced, instead of asking whether the combined node $ab$ is adjacent to $< K$ nodes of significant degree, we could simply test whether $ab$ is adjacent to $< K$ nodes of any degree. The theory is that if $ab$ is adjacent to many low-degree nodes, they will be removed by simplification anyway.

a. Show that this kind of coalescing cannot create any new potential spills.

b. Demonstrate the algorithm on this graph (with $K = 3$):

```
\begin{center}
\begin{tikzpicture}
\node (a) at (0,0) {a};
\node (b) at (1,1) {b};
\node (c) at (1,-1) {c};
\node (d) at (2,0) {d};
\node (e) at (3,0) {e};
\node (f) at (4,0) {f};
\node (g) at (3,-1) {g};
\node (h) at (4,-1) {h};
\node (i) at (5,0) {i};
\node (j) at (6,0) {j};
\draw (a) -- (b);
\draw (a) -- (c);
\draw (b) -- (d);
\draw (c) -- (d);
\draw (d) -- (e);
\draw (e) -- (f);
\draw (f) -- (g);
\draw (g) -- (h);
\draw [dashed] (i) -- (j);
\end{tikzpicture}
\end{center}
```

c. Show that this test is less effective than standard conservative coalescing. **Hint:** Use the graph of Exercise 11.3, with $K = 4$. 

Putting It All Together

de-bug: to eliminate errors in or malfunctions of

Webster’s Dictionary

Chapters 2–11 have described the fundamental components of a good compiler: a front end, which does lexical analysis, parsing, construction of abstract syntax, type-checking, and translation to intermediate code; and a back end, which does instruction selection, dataflow analysis, and register allocation.

What lessons have we learned? I hope that the reader has learned about the algorithms used in different components of a compiler and the interfaces used to connect the components. But the author has also learned quite a bit from the exercise.

My goal was to describe a good compiler that is, to use Einstein’s phrase, “as simple as possible – but no simpler.” I will now discuss the thorny issues that arose in designing Tiger and its compiler.

Nested functions. Tiger has nested functions, requiring some mechanism (such as static links) for implementing access to nonlocal variables. But many programming languages in widespread use – C, C++, Java – do not have nested functions or static links. The Tiger compiler would become simpler without nested functions, for then variables would not escape, and the FindEscape phase would be unnecessary. But there are two reasons for explaining how to compile nonlocal variables. First, there are programming languages where nested functions are extremely useful – these are the functional languages described in Chapter 15. And second, escaping variables and the mechanisms necessary to handle them are also found in languages where addresses can be taken (such as C) or with call-by-reference (such as C++).
Structured l-values. Tiger has no record or array variables, as C, C++, and Pascal do. Instead, all record and array values are really just pointers to heap-allocated data. This omission is really just to keep the compiler simple; implementing structured l-values requires some care but not too many new insights.

Tree intermediate representation. The Tree language has a fundamental flaw: it does not describe procedure entry and exit. These are handled by opaque procedures inside the Frame module that generate Tree code. This means that a program translated to Trees using, for example, the Pentium-Frame version of Frame will be different from the same program translated using SparcFrame – the Tree representation is not completely machine-independent.

Also, there is not enough information in the trees themselves to simulate the execution of an entire program, since the view shift (page 137) is partly done implicitly by procedure prologues and epilogues that are not represented as Trees. Consequently, there is not enough information to do whole-program optimization (across function boundaries).

The Tree representation is useful as a low-level intermediate representation, useful for instruction selection and intraprocedural optimization. A high-level intermediate representation would preserve more of the source-program semantics, including the notions of nested functions, nonlocal variables, record creation (as distinguished from an opaque external function call), and so on. Such a representation would be more tied to a particular family of source languages than the general-purpose Tree language is.

Register allocation. Graph-coloring register allocation is widely used in real compilers, but does it belong in a compiler that is supposed to be “as simple as possible”? After all, it requires the use of global dataflow (liveness) analysis, construction of interference graphs, and so on. This makes the back end of the compiler significantly bigger.

It is instructive to consider what the Tiger compiler would be like without it. We could keep all local variables in the stack frame (as we do now for variables that escape), fetching them into temporaries only when they are used as operands of instructions. The redundant loads within a single basic block can be eliminated by a simple intrablock liveness analysis. Internal nodes of Tree expressions could be assigned registers using Algorithms 11.10 and 11.9. But other parts of the compiler would become much uglier: The TEMPS introduced in canonicalizing the trees (eliminating ESEQs) would have to be
dealt with in an ad hoc way, by augmenting the Tree language with an operator that provides explicit scope for temporary variables; the Frame interface, which mentions registers in many places, would now have to deal with them in more complicated ways. To be able to create arbitrarily many temps and moves, and rely on the register allocator to clean them up, greatly simplifies procedure calling sequences and code generation.

**PROGRAM**

**PROCEDURE ENTRY/EXIT**

Implement the rest of the Frame module, which contains all the machine-dependent parts of the compiler: register sets, calling sequences, activation record (frame) layout.

Program 12.1 shows frame.h. Most of this interface has been described elsewhere. What remains is:

- **registers**  A list of all the register names on the machine, which can be used as “colors” for register allocation.
- **tempMap**  For each machine register, the Frame module maintains a particular Temp_temp that serves as the “precolored temporary” that stands for the register. These temps appear in the Assem instructions generated from CALL nodes, in procedure entry sequences generated by procEntryExit1, and so on. The tempMap tells the “color” of each of these precolored temps.
- **procEntryExit1**  For each incoming register parameter, move it to the place from which it is seen from within the function. This could be a frame location (for escaping parameters) or a fresh temporary. One good way to handle this is for newFrame to create a sequence of T_MOVE statements as it creates all the formal parameter “accesses.” newFrame can put this into the frame data structure, and procEntryExit1 can just concatenate it onto the procedure body.

  Also concatenated to the body are statements for saving and restoring of callee-save registers (including the return-address register). If your register allocator does not implement spilling, all the callee-save (and return-address) registers should be written to the frame at the beginning of the procedure body and fetched back afterward. Therefore, procEntryExit1 should call allocLocal for each register to be saved, and generate T_MOVE instructions to save and restore the registers. With luck, saving and restoring the callee-save registers will give the register allocator enough headroom to work with, so that some nontrivial programs can be compiled. Of course, some programs just cannot be compiled without spilling.

  If your register allocator implements spilling, then the callee-save registers should not always be written to the frame. Instead, if the register allocator needs the space, it may choose to spill only some of the callee-save registers.
CHAPTER TWELVE. PUTTING IT ALL TOGETHER

#include <frame.h>

PROGRAM 12.1. Interface frame.h.
But “precolored” temporaries are never spilled; so `procEntryExit1` should make up new temporaries for each callee-save (and return-address) register. On entry, it should move all these registers to their new temporary locations, and on exit, it should move them back. Of course, these moves (for nonspilled registers) will be eliminated by register coalescing, so they cost nothing.

`procEntryExit3` Creates the procedure prologue and epilogue assembly language. First (for some machines) it calculates the size of the `outgoing parameter space` in the frame. This is equal to the maximum number of outgoing parameters of any `CALL` instruction in the procedure body. Unfortunately, after conversion to `Assem` trees the procedure calls have been separated from their arguments, so the outgoing parameters are not obvious. Either `procEntryExit2` should scan the body and record this information in some new component of the `frame` type, or `procEntryExit3` should use the maximum legal value.

Once this is known, the assembly language for procedure entry, stack-pointer adjustment, and procedure exit can be put together; these are the prologue and epilogue.

`string` A string literal in Tiger, translated into a `F_StringFrag` fragment, must eventually be translated into machine-dependent assembly language that reserves and initializes a block of memory. The `F_string` function returns a string containing the assembly-language instructions required to define and initialize a string literal. For example,

```
F_string(Temp_namedlabel("L3"),"hello")
```

would yield “L3: .ascii "hello"
" in a typical assembly language. The `Translate` module might make a `F_StringFrag(L3,hello)` (page 172); the `Main` module (see below) would process this fragment by calling `F_string`.

---

**PROGRAM**

**MAKING IT WORK**

Make your compiler generate working code that runs.

The file `$TIGER/chap12/runtime.c` is a C-language file containing several external functions useful to your Tiger program. These are generally reached by `externalCall` from code generated by your compiler. You may modify this as necessary.

Write a module `main.c` that calls on all the other modules to produce an assembly language file `prog.s` for each input program `prog.tig`. This assembly language program should be assembled (producing `prog.o`) and linked with `runtime.o` to produce an executable file.
Programming projects
After your Tiger compiler is done, here are some ideas for further work:

12.1 Write a garbage collector (in C) for your Tiger compiler. You will need to make some modifications to the compiler itself to add descriptors to records and stack frames (see Chapter 13).

12.2 Implement first-class function values in Tiger, so that functions can be passed as arguments and returned as results (see Chapter 15).

12.3 Make the Tiger language object-oriented, so that instead of records there are objects with methods. Make a compiler for this object-oriented Tiger (see Chapter 14).

12.4 Implement dataflow analyses such as reaching definitions and available expressions and use them to implement some of the optimizations discussed in Chapter 17.

12.5 Figure out other approaches to improving the assembly-language generated by your compiler. Discuss; perhaps implement.

12.6 Implement instruction scheduling to fill branch-delay and load-delay slots in the assembly language. Or discuss how such a module could be integrated into the existing compiler; what interfaces would have to change, and in what ways?

12.7 Implement “software pipelining” (instruction scheduling around loop iterations) in your compiler.

12.8 Analyze how adequate the Tiger language itself would be for writing a compiler. What are the smallest possible additions/changes that would make it a much more useful language?

12.9 In the Tiger language, some record types are recursive and must be implemented as pointers; others are not recursive and could be implemented without pointers. Modify your compiler to take advantage of this by keeping nonrecursive, nonescaping records in the stack frame instead of on the heap.

12.10 Similarly, some arrays have bounds known at compile time, are not recursive, and are not assigned to other array variables. Modify your compiler so that these arrays are implemented right in the stack frame.

12.11 Implement inline expansion of functions (see Section 15.4).

12.12 Suppose an ordinary Tiger program were to run on a parallel machine (a multiprocessor)? How could the compiler automatically make a parallel program out of the original sequential one? Research the approaches.
PART TWO

Advanced Topics
Garbage Collection

**garbage**: unwanted or useless material

*Webster's Dictionary*

Heap-allocated records that are not reachable by any chain of pointers from program variables are *garbage*. The memory occupied by garbage should be reclaimed for use in allocating new records. This process is called *garbage collection*, and is performed not by the compiler but by the runtime system (the support programs linked with the compiled code).

Ideally, we would say that any record that is not dynamically live (will not be used in the future of the computation) is garbage. But, as Section 10.1 explains, it is not always possible to know whether a variable is live. So we will use a conservative approximation: we will require the compiler to guarantee that any *live* record is *reachable*; we will ask the compiler to minimize the number of reachable records that are *not* live; and we will preserve all reachable records, even if some of them might not be live.

Figure 13.1 shows a Tiger program ready to undergo garbage collection (at the point marked *garbage-collect here*). There are only three program variables in scope: \( p \), \( q \), and \( r \).

### 13.1 MARK-AND-SWEEP COLLECTION

Program variables and heap-allocated records form a directed graph. The variables are *roots* of this graph. A node \( n \) is reachable if there is a path of directed edges \( r \rightarrow \cdots \rightarrow n \) starting at some root \( r \). A graph-search algorithm such as *depth-first search* (Algorithm 13.2) can *mark* all the reachable nodes.
let
  type list = {link: list,
               key: int}
  type tree = {key: int,
                left: tree,
                right: tree}
function maketree() = ...
function showtree(t: tree) = ...
in
  let var x := list{link=nil,key=7}
  var y := list{link=x,key=9}
  in x.link := y
end;
let var p := maketree()
  var r := p.right
  var q := r.key
in garbage-collect here
  showtree(r)
end

function DFS(x)
  if x is a pointer into the heap
    if record x is not marked
      mark x
      for each field $f_i$ of record x
        DFS($x.f_i$)

ALGORITHM 13.2. Depth-first search.

Any node not marked must be garbage, and should be reclaimed. This can be done by a sweep of the entire heap, from its first address to its last, looking for nodes that are not marked (Algorithm 13.3). These are garbage and can be linked together in a linked list (the freelist). The sweep phase should also unmark all the marked nodes, in preparation for the next garbage collection.

After the garbage collection, the compiled program resumes execution. Whenever it wants to heap-allocate a new record, it gets a record from the freelist. When the freelist becomes empty, that is a good time to do another garbage collection to replenish the freelist.
13.1. MARK-AND-SWEEP COLLECTION

Mark phase:  
for each root \( v \)  
DFS\((v)\)  

Sweep phase:  
\( p \leftarrow \) first address in heap  
while \( p < \) last address in heap  
if record \( p \) is marked  
unmark \( p \)  
else let \( f_1 \) be the first field in \( p \)  
\( p.f_1 \leftarrow \) freelist  
freelist \( \leftarrow p \)  
\( p \leftarrow p+\) (size of record \( p \) )  

Cost of garbage collection. Depth-first search takes time proportional to the number of nodes it marks, that is, time proportional to the amount of reachable data. The sweep phase takes time proportional to the size of the heap. Suppose there are \( R \) words of reachable data in a heap of size \( H \). Then the cost of one garbage collection is \( c_1 R + c_2 H \) for some constants \( c_1 \) and \( c_2 \); for example, \( c_1 \) might be 10 instructions and \( c_2 \) might be 3 instructions.

The “good” that collection does is to replenish the freelist with \( H - R \) words of usable memory. Therefore, we can compute the amortized cost of collection by dividing the time spent collecting by the amount of garbage reclaimed. That is, for every word that the compiled program allocates, there is an eventual garbage-collection cost of

\[
\frac{c_1 R + c_2 H}{H - R}
\]

If \( R \) is close to \( H \), this cost becomes very large: each garbage collection reclaims only a few words of garbage. If \( H \) is much larger than \( R \), then the cost per allocated word is approximately \( c_2 \), or about three instructions of garbage-collection cost per word allocated.

The garbage collector can measure \( H \) (the heap size) and \( H - R \) (the freelist size) directly. After a collection, if \( R / H \) is larger than 0.5 (or some other criterion), the collector should increase \( H \) by asking the operating system for more memory. Then the cost per allocated word will be approximately \( c_1 + 2c_2 \), or perhaps 16 instructions per word.

Using an explicit stack. The DFS algorithm is recursive, and the maximum depth of its recursion is as long as the longest path in the graph of reachable
data. There could be a path of length $H$ in the worst case, meaning that the stack of activation records would be larger than the entire heap!

To attack this problem, we use an explicit stack (instead of recursion), as in Algorithm 13.5. Now the stack could still grow to size $H$, but at least this is $H$ words and not $H$ activation records. Still, it is unacceptable to require auxiliary stack memory as large as the heap being collected.

**Pointer reversal.** After the contents of field $x.f_i$ has been pushed on the stack, Algorithm 13.5 will never again look the original location $x.f_i$. This means we can use $x.f_i$ to store one element of the stack itself! This all-too-clever idea is called *pointer reversal*, because $x.f_i$ will be made to point back to the record from which $x$ was reached. Then, as the stack is popped, the field $x.f_i$ will be restored to its original value.

Algorithm 13.6 requires a field in each record called *done*, which indicates how many fields in that record have been processed. This takes only a few
function DFS(x)
    if x is a pointer and record x is not marked
        t ← 1
        stack[t] ← x
    while t > 0
        x ← stack[t];  t ← t − 1
        for each field fi of record x
            if x.fi is a pointer and record x.fi is not marked
                mark x.fi
                t ← t + 1;  stack[t] ← x.fi

ALGORITHM 13.5. Depth-first search using an explicit stack.

bits per record (and it can also serve as the mark field).

The variable t serves as the top of the stack; every record x on the stack is already marked, and if i = done[x] then x.fi is the “stack link” to the next node down. When popping the stack, x.fi is restored to its original value.

An array of freelists. The sweep phase is the same no matter which marking algorithm is used: it just puts the unmarked records on the freelist, and unmarks the marked records. But if records are of many different sizes, a simple linked list will not be very efficient for the allocator. When allocating a record of size n, it may have to search a long way down the list for a free block of that size.

A good solution is to have an array of several freelists, so that freelist[i] is a linked list of all records of size i. The program can allocate a node of size i just by taking the head of freelist[i]; the sweep phase of the collector can put each node of size j at the head of freelist[j].

If the program attempts to allocate from an empty freelist[i], it can try to grab a larger record from freelist[j] (for j > i) and split it (putting the unused portion back on freelist[j − i]). If this fails, it is time to call the garbage collector to replenish the freelists.

Fragmentation. It can happen that the program wants to allocate a record of size n, and there are many free records smaller than n but none of the right size. This is called external fragmentation. On the other hand, internal fragmentation occurs when the program uses a too-large record without splitting it, so that the unused memory is inside the record instead of outside.
function DFS(x)
    if x is a pointer and record x is not marked
        t ← nil
        mark x; done[x] ← 0
    while true
        i ← done[x]
        if i < # of fields in record x
            y ← x.f_i
            if y is a pointer and record y is not marked
                x.f_i ← t; t ← x; x ← y
                mark x; done[x] ← 0
            else
                done[x] ← i + 1
        else
            y ← x; x ← t
            if x = nil then return
            i ← done[x]
            t ← x.f_i; x.f_i ← y
            done[x] ← i + 1

ALGORITHM 13.6. Depth-first search using pointer reversal.

13.2 Reference Counts

One day a student came to Moon and said: “I understand how to make a better garbage collector. We must keep a reference count of the pointers to each cons.”

Moon patiently told the student the following story:

“One day a student came to Moon and said: ‘I understand how to make a better garbage collector ...’”

(MIT-AI koan by Danny Hillis)

Mark-sweep collection identifies the garbage by first finding out what is reachable. Instead, it can be done directly by keeping track of how many pointers point to each record: this is the reference count of the record, and it is stored with each record.
13.2. REFERENCE COUNTS

The compiler emits extra instructions so that whenever \( p \) is stored into \( x.f_i \), the reference count of \( p \) is incremented, and the reference count of what \( x.f_i \) previously pointed to is decremented. If the decremented reference count of some record \( r \) reaches zero, then \( r \) is put on the freelist and all the other records that \( r \) points to have their reference counts decremented.

Instead of decrementing the counts of \( r.f_i \) when \( r \) is put on the freelist, it is better to do this “recursive” decrementing when \( r \) is removed from the freelist, for two reasons:

1. It breaks up the “recursive decrementing” work into shorter pieces, so that the program can run more smoothly (this is important only for interactive or real-time programs).
2. The compiler must emit code (at each decrement) to check whether the count has reached zero and put the record on the freelist, but the recursive decrementing will be done only in one place, in the allocator.

Reference counting seems simple and attractive. But there are two major problems:

1. Cycles of garbage cannot be reclaimed. In Figure 13.1, for example, there is a loop of list cells (whose keys are 7 and 9) that are not reachable from program variables; but each has a reference count of 1.
2. Incrementing the reference counts is very expensive indeed. In place of the single machine instruction \( x.f_i \leftarrow p \), the program must execute

\[
\begin{align*}
z & \leftarrow x.f_i \\
c & \leftarrow z.\text{count} \\
c & \leftarrow c - 1 \\
z.\text{count} & \leftarrow c \\
\text{if } c = 0 \text{ call } \text{putOnFreelist} \\
x.f_i & \leftarrow p \\
c & \leftarrow p.\text{count} \\
c & \leftarrow c + 1 \\
p.\text{count} & \leftarrow c
\end{align*}
\]

A naive reference counter will increment and decrement the counts on every assignment to a program variable. Because this would be extremely expensive, many of the increments and decrements are eliminated using dataflow analysis: As a pointer value is fetched and then propagated through local variables, the compiler can aggregate the many changes in the count to a single increment, or (if the net change is zero) no extra instructions at all. However, even with this technique there are many ref-count increments and decrements that remain, and their cost is very high.
There are two possible solutions to the “cycles” problem. The first is simply to require the programmer to explicitly break all cycles when she is done with a data structure. This is less annoying than putting explicit free calls (as would be necessary without any garbage collection at all), but it is hardly elegant. The other solution is to combine reference counting (for eager and nondisruptive reclamation of garbage) with an occasional mark-sweep collection (to reclaim the cycles).

On the whole, the problems with reference counting outweigh its advantages, and it is rarely used for automatic storage management in programming language environments.

13.3 COPYING COLLECTION

The reachable part of the heap is a directed graph, with records as nodes, and pointers as edges, and program variables as roots. Copying garbage collection traverses this graph (in a part of the heap called from-space), building an isomorphic copy in a fresh area of the heap (called to-space). The to-space copy is compact, occupying contiguous memory without fragmentation (that is, without free records interspersed with the reachable data). The roots are made to point at the to-space copy; then the entire from-space (garbage, plus the previously reachable graph) is unreachable.

Figure 13.7 illustrates the situation before and after a copying collection. Before the collection, from-space is full of reachable nodes and garbage; there is no place left to allocate, since next has reached limit. After the collection, the area of to-space between next and limit is available for the compiled program to allocate new records. Because the new-allocation area is contiguous, allocating a new record of size \( n \) into pointer \( p \) is very easy: just copy next to \( p \), and increment next by \( n \). Copying collection does not have a fragmentation problem.

Eventually, the program will allocate enough that next reaches limit; then another garbage collection is needed. The roles of from-space and to-space are swapped, and the reachable data are again copied.

**Initiating a collection.** To start a new collection, the pointer next is initialized to point at the beginning of to-space; as each reachable record in from-space is found, it is copied to to-space at position next, and next incremented by the size of the record.
13.3. COPYING COLLECTION

The basic operation of copying collection is *forwarding* a pointer; that is, given a pointer $p$ that points to from-space, make $p$ point to to-space (Algorithm 13.8).

There are three cases:

1. If $p$ points to a from-space record that has already been copied, then $p.f_1$ is a special *forwarding pointer* that indicates where the copy is. The forwarding pointer can be identified just by the fact that it points within the to-space, as no ordinary from-space field could point there.

2. If $p$ points to a from-space record that has not yet been copied, then it is copied to location $\text{next}$; and the forwarding pointer is installed into $p.f_1$. It’s...
CHAPTER THIRTEEN. GARBAGE COLLECTION

\[
\text{scan} \leftarrow \text{next} \leftarrow \text{beginning of to-space} \\
\text{for each root } r \\
\quad r \leftarrow \text{Forward}(r) \\
\text{while } \text{scan} < \text{next} \\
\quad \text{for each field } f_i \text{ of record at } \text{scan} \\
\quad \quad \text{scan}.f_i \leftarrow \text{Forward}([\text{scan}.f_i]) \\
\quad \text{scan} \leftarrow \text{scan} + \text{size of record at } \text{scan}
\]

all right to overwrite the \( f_1 \) field of the old record, because all the data have already been copied to the to-space at next.

3. If \( p \) is not a pointer at all, or if it points outside from-space (to a record outside the garbage-collected arena, or to to-space), then forwarding \( p \) does nothing.

Cheney's algorithm. The simplest algorithm for copying collection uses breadth-first search to traverse the reachable data (Algorithm 13.9, illustrated in Figure 13.10). First, the roots are forwarded. This copies a few records (those reachable directly from root pointers) to to-space, thereby incrementing next.

The area between scan and next contains records that have been copied to to-space, but whose fields have not yet been forwarded: in general, these fields point to from-space. The area between the beginning of to-space and scan contains records that have been copied and forwarded, so that all the pointers in this area point to to-space. The while loop of (Algorithm 13.9) moves scan toward next, but copying records will cause next to move also. Eventually, scan catches up with next after all the reachable data are copied to to-space.

Cheney's algorithm requires no external stack, and no pointer reversal: it uses the to-space area between scan and next as the queue of its breadth-first search. This makes it considerably simpler to implement than depth-first search with pointer reversal.

Locality of reference. However, pointer data structures copied by breadth-first have poor locality of reference: If a record at address \( a \) points to another record at address \( b \), it is likely that \( a \) and \( b \) will be far apart. Conversely, the record at \( a + 8 \) is likely to be unrelated to the one at \( a \). Records that are copied near each other are those whose distance from the roots are equal.
In a computer system with virtual memory, or with a memory cache, good locality of reference is important. After the program fetches address \( a \), then the memory subsystem expects addresses near \( a \) to be fetched soon. So it ensures that the entire page or cache line containing \( a \) and nearby addresses can be quickly accessed.

Suppose the program is fetching down a chain of \( n \) pointers in a linked list. If the records in the list are scattered around memory, each on a page (or cache line) containing completely unrelated data, then we expect \( n \) difference pages or cache lines to be active. But if successive records in the chain are at adjacent addresses, then only \( n/k \) pages (cache lines) need to be active, where \( k \) records fit on each page (cache line).

Depth-first copying gives better locality, since each object \( a \) will tend to be adjacent to its first child \( b \); unless \( b \) is adjacent to another “parent” \( a' \). Other children of \( a \) may not be adjacent to \( a \), but if the subtree \( b \) is small, then they should be nearby.

But depth-first copy requires pointer-reversal, which is inconvenient and
function Forward(p)
    if p points to from-space
        then if p.f1 points to to-space
            then return p.f1
        else Chase(p); return p.f1
    else return p

function Chase(p)
    repeat
        q ← next
        next ← next+ size of record p
        r ← nil
        for each field f_i of record p
            q.f_i ← p.f_i
            if q.f_i points to from-space and q.f_i.f_1 does not point to to-space
                then r ← q.f_i
        p.f_1 ← q
        p ← r
        until p = nil

**Algorithm 13.11.** Semi-depth-first forwarding.

slow. A hybrid, partly depth-first and partly breadth-first algorithm can provide acceptable locality. The basic idea is to use breadth-first copying, but whenever an object is copied, see if some child can be copied near it (Algorithm 13.11).

**Cost of garbage collection.** Breadth-first search (or the semi-depth-first variant) takes time proportional to the number of nodes it marks; that is, \(c_3 R\) for some constant \(c_3\) (perhaps equal to 10 instructions). There is no sweep phase, so \(c_3 R\) is the total cost of collection. The heap is divided into two semi-spaces, so each collection reclaims \(H/2 - R\) words that can be allocated before the next collection. The amortized cost of collection is thus

\[
\frac{c_3 R}{\frac{H}{2} - R}
\]

instructions per word allocated.
As $H$ grows much larger than $R$, this cost approaches zero. That is, there is no inherent lower bound to the cost of garbage collection. In a more realistic setting, where $H = 4R$, the cost would be about 10 instructions per word allocated. This is rather costly in space and time: it requires four times as much memory as reachable data, and requires 40 instructions of overhead for every 4-word object allocated. To reduce both space and time costs significantly, we use generational collection.

### 13.4 GENERATIONAL COLLECTION

In many programs, newly created objects are likely to die soon; but an object that is still reachable after many collections will probably survive for many collections more. Therefore the collector should concentrate its effort on the “young” data, where there is a higher proportion of garbage.

We divide the heap into generations, with the youngest objects in generation $G_0$; every object in generation $G_1$ is older than any object in $G_0$; everything in $G_2$ is older than anything in $G_1$ and so on.

To collect (by mark-and-sweep or by copying) just $G_0$, just start from the roots and do either depth-first marking or breadth-first copying (or semi-depth-first copying). But now the roots are not just program variables: they...
include any pointer within \( G_1, G_2, \ldots \) that points into \( G_0 \). If there are too many of these, then processing the roots will take longer than the traversal of reachable objects within \( G_0 \)!

Fortunately, it is rare for an older object to point to a much younger object. In many common programming styles, when an object \( a \) is created its fields are immediately initialized; for example, they might be made to point to \( b \) and \( c \). But \( b \) and \( c \) already exist; they are older than \( a \). So we have a newer object pointing to an older object. The only way that an older object \( b \) could point to a newer object \( a \) is if some field of \( b \) is updated long after \( b \) is created; this turns out to be rare.

To avoid searching all of \( G_1, G_2, \ldots \) for roots of \( G_0 \), we make the compiled program remember where there are pointers from old objects to new ones. There are several ways of remembering:

**Remembered list:** The compiler generates code, after each update store of the form \( b.f_i \leftarrow a \), to put \( b \) into a vector of updated objects. Then, at each garbage collection, the collector scans the remembered list looking for old objects \( b \) that point into \( G_0 \).

**Remembered set:** Like the remembered list, but uses a bit within object \( b \) to record that \( b \) is already in the vector. Then the code generated by the compiler can check this bit to avoid duplicate references to \( b \) in the vector.

**Card marking:** Divide memory into logical “cards” of size \( 2^k \) bytes. An object can occupy part of a card or can start in the middle of one card and continue onto the next. Whenever address \( b \) is updated, the card containing that address is marked. There is an array of bytes that serve as marks; the byte index can be found by shifting address \( b \) right by \( k \) bits.

**Page marking:** This is like card marking, but if \( 2^k \) is the page size, then the computer’s virtual memory system can be used instead of extra instructions generated by the compiler. Updating an old generation sets a dirty bit for that page. If the operating system does not make dirty bits available to user programs, then the user program can implement this by write-protecting the page and asking the operating system to refer protection violations to a user-mode fault handler that records the dirtiness and unprotected the page.

When a garbage collection begins, the remembered set tells which objects (or cards, or pages) of the old generation can possibly contain pointers into \( G_0 \); these are scanned for roots.

**Algorithm 13.3** or **13.9** can be used to collect \( G_0 \): “heap” or “from-space” means \( G_0 \), “to-space” means a new area big enough to hold the reachable objects in \( G_0 \), and “roots” include program variables and the remembered set. Pointers to older generations are left unchanged: the marking algorithm
13.5. INCREMENTAL COLLECTION

does not mark old-generation records, and the copying algorithm copies them verbatim without forwarding them.

After several collections of $G_0$, generation $G_1$ may have accumulated a significant amount of garbage that should be collected. Since $G_0$ may contain many pointers into $G_1$, it is best to collect $G_0$ and $G_1$ together. As before, the remembered set must be scanned for roots contained in $G_2, G_3, \ldots$. Even more rarely, $G_2$ will be collected, and so on.

Each older generation should be exponentially bigger than the previous one. If $G_0$ is half a megabyte, then $G_1$ should be two megabytes, $G_2$ should be eight megabytes, and so on. An object should be promoted from $G_i$ to $G_{i+1}$ when it survives two or three collections of $G_i$.

Cost of generational collection. Without detailed empirical information about the distribution of object lifetimes, we cannot analyze the behavior of generational collection. In practice, however, it is common for the youngest generation to be less than 10% live data. With a copying collector, this means that $H/R$ is 10 in this generation, so that the amortized cost per word reclaimed is $c_3 R/(10R - R)$, or about 1 instruction. If the amount of reachable data in $G_0$ is about 50 to 100 kilobytes, then the amount of space “wasted” by having $H = 10R$ in the youngest generation is about a megabyte. In a 50-megabyte multigeneration system, this is a small space cost.

Collecting the older generations can be more expensive. To avoid using too much space, a smaller $H/R$ ratio can be used for older generations. This increases the time cost of an older-generation collection, but these are sufficiently rare that the overall amortized time cost is still good.

Maintaining the remembered set also takes time, approximately 10 instructions per pointer update to enter an object into the remembered set and then process that entry in the remembered set. If the program does many more updates than fresh allocations, then generational collection may be more expensive than nongenerational collection.

13.5 INCREMENTAL COLLECTION

Even if the overall garbage collection time is only a few percent of the computation time, the collector will occasionally interrupt the program for long periods. For interactive or real-time programs this is undesirable. Incremental or concurrent algorithms interleave garbage collection work with program execution to avoid long interruptions.
while there are any grey objects
    select a grey record $p$
    for each field $f_i$ of $p$
    if record $p.f_i$ is white
        color record $p.f_i$ grey
    color record $p$ black

**Algorithm 13.13.** Basic tricolor marking.

**Terminology.** The *collector* tries to collect the garbage; meanwhile, the compiled program keeps changing (mutating) the graph of reachable data, so it is called the *mutator*. An *incremental* algorithm is one in which the collector operates only when the mutator requests it; in a *concurrent* algorithm the collector can operate between or during any instructions executed by the mutator.

**Tricolor marking.** In a mark-sweep or copying garbage collection, there are three classes of records:

- **White** objects are not yet visited by the depth-first or breadth-first search.
- **Grey** objects have been visited (marked or copied), but their children have not yet been examined. In mark-sweep collection, these objects are on the stack; in Cheney’s copying collection, they are between *scan* and *next*.
- **Black** objects have been marked, and their children also marked. In mark-sweep collection, they have already been popped off the stack; in Cheney’s algorithm, have already been scanned.

The collection starts with all objects white; the collector executes Algorithm 13.13, blackening grey objects and greying their white children. Implicit in changing an object from grey to black is removing it from the stack or queue; implicit in greying an object is putting it into the stack or queue. When there are no grey objects, then all white objects must be garbage.

All these algorithms preserve two natural invariants:

1. No black object points to a white object.
2. Every grey object is on the collector’s (stack or queue) data structure (which we will call the *grey-set*).

While the collector operates, the mutator creates new objects (of what color?) and updates pointer fields of existing objects. If the mutator breaks one of the
invariants, then the collection algorithm will not work.

Most incremental and concurrent collection algorithms are based on techniques to allow the mutator to get work done while preserving the invariants. For example:

**Dijkstra, Lamport, et al.** Whenever the mutator stores a white pointer \( a \) into a black object \( b \), it colors \( a \) grey. (The compiler generates extra instructions at each store to check for this.)

**Steele.** Whenever the mutator stores a white pointer \( a \) into a black object \( b \), it colors \( b \) grey (using extra instructions generated by the compiler).

**Boehm, Demers, Shenker.** All-black pages are marked read-only in the virtual memory system. Whenever the mutator stores any value into an all-black page, a page fault marks all objects on that page grey (and makes the page writable).

**Baker.** Whenever the mutator fetches a pointer \( b \) to a white object, it colors \( b \) grey. The mutator never possesses a pointer to a white object, so it cannot violate invariant 1. The instructions to check the color of \( b \) are generated by the compiler after every fetch.

**Appel, Ellis, Li.** Whenever the mutator fetches a pointer \( b \) from any virtual-memory page containing any nonblack object, a page-fault handler colors every object on the page black (making children of these objects grey). Thus the mutator never possesses a pointer to a white object.

The first three of these are *write-barrier* algorithms, meaning that each *write* (store) by the mutator must be checked to make sure an invariant is preserved. The last two are *read-barrier* algorithms, meaning that *read* (fetch) instructions are the ones that must be checked. We have seen write barriers before, for generational collection: remembered lists, remembered sets, card marking, and page marking are all different implementations of the write barrier. Similarly, the read barrier can be implemented in software (as in Baker’s algorithm) or using the virtual-memory hardware.

Any implementation of a write or read barrier must synchronize with the collector. For example, a Dijkstra-style collector might try to change a white node to grey (and put it into the grey-set) at the same time the mutator is also greying the node (and putting it into the grey-set). Thus, software implementations of the read or write barrier will need to use explicit synchronization instructions, which can be expensive.

But implementations using virtual-memory hardware can take advantage of the synchronization implicit in a page fault: if the mutator faults on a page, the operating system will ensure that no other process has access to that page before processing the fault.
13.6 BAKER’S ALGORITHM

Baker’s algorithm illustrates the details of incremental collection. It is based on Cheney’s copying collection algorithm, so it forwards reachable objects from from-space to to-space. Baker’s algorithm is compatible with generational collection, so that the from-space and to-space might be for generation $G_0$, or might be $G_0 + \cdots + G_k$.

To initiate a garbage collection (which happens when an allocate request fails for lack of unused memory), the roles of the (previous) from-space and to-space are swapped, and all the roots are forwarded; this is called the flip. Then the mutator is resumed; but each time the mutator calls the allocator to get a new record, a few pointers at scan are scanned, so that scan advances toward next. Then a new record is allocated at the end of the to-space by decrementing limit by the appropriate amount.

The invariant is that the mutator has pointers only to to-space (never to from-space). Thus, when the mutator allocates and initializes a new record, that record need not be scanned; when the mutator stores a pointer into an old record, it is only storing a to-space pointer.

If the mutator fetches a field of a record, it might break the invariant. So each fetch is followed by two or three instructions that check whether the fetched pointer points to from-space. If so, that pointer must be forwarded immediately, using the standard forward algorithm.

For every word allocated, the allocator must advance scan by at least one word. When scan = next, the collection terminates until the next time the allocator runs out of space. If the heap is divided into two semi-spaces of size $H/2$, and $R < H/4$, then scan will catch up with next before next reaches halfway through the to-space; also by this time, no more than half the to-space will be occupied by newly allocated records.

Baker’s algorithm copies no more data than is live at the flip. Records allocated during collection are not scanned, so they do not add to the cost of collection. The collection cost is thus $c_3 R$. But there is also a cost to check (at every allocation) whether incremental scanning is necessary; this is proportional to $H/2 - R$.

But the largest cost of Baker’s algorithm is the extra instructions after every fetch, required to maintain the invariant. If one in every 10 instructions fetches from a heap record, and each of these fetches requires two extra instructions to test whether it is a from-space pointer, then there is at least a
20% overhead cost just to maintain the invariant. All of the incremental or concurrent algorithms that use a software write or read barrier will have a significant cost in overhead of ordinary mutator operations.

### 13.7 INTERFACE TO THE COMPILER

The compiler for a garbage-collected language interacts with the garbage collector by generating code that allocates records, by describing locations of roots for each garbage-collection cycle, and by describing the layout of data records on the heap. For some versions of incremental collection, the compiler must also generate instructions to implement a read barrier or write barrier.

### FAST ALLOCATION

Some programming languages, and some programs, allocate heap data (and generate garbage) very rapidly. This is especially true of programs in functional languages, where updating old data is discouraged.

The most allocation (and garbage) one could imagine a reasonable program generating is one word of allocation per store instruction; this is because each word of a heap-allocated record is usually initialized. Empirical measurements show that about one in every seven instructions executed is a store, almost regardless of programming language or program. Thus, we have (at most) \( \frac{1}{7} \) word of allocation per instruction executed.

Supposing that the cost of garbage collection can be made small by proper tuning of a generational collector, there may still be a considerable cost to create the heap records. To minimize this cost, copying collection should be used so that the allocation space is a contiguous free region; the next free location is \( \text{next} \) and the end of the region is \( \text{limit} \). To allocate one record of size \( N \), the steps are:

1. Call the allocate function.
2. Test \( \text{next} + N < \text{limit} \) ? (If the test fails, call the garbage collector.)
3. Move \( \text{next} \) into result
4. Clear \( M[\text{next}], M[\text{next} + 1], \ldots, M[\text{next} + N - 1] \)
5. \( \text{next} \leftarrow \text{next} + N \)
6. Return from the allocate function.

A. Move result into some computationally useful place.
B. Store useful values into the record.
Steps 1 and 6 should be eliminated by *inline expanding* the allocate function at each place where a record is allocated. Step 3 can often be eliminated by combining it with step A, and step 4 can be eliminated in favor of step B (steps A and B are not numbered because they are part of the useful computation; they are not allocation overhead).

Steps 2 and 5 cannot be eliminated, but if there is more than one allocation in the same basic block (or in the same *trace*, see Section 8.2) the comparison and increment can be shared among multiple allocations. By keeping *next* and *limit* in registers, steps 2 and 5 can be done in a total of three instructions.

By this combination of techniques, the cost of allocating a record – and then eventually garbage collecting it – can be brought down to about four instructions. This means that programming techniques such as the *persistent binary search tree* (page 108) can be efficient enough for everyday use.

**DESCRIBING DATA LAYOUTS**

The collector must be able to operate on records of all types: *list, tree,* or whatever the program has declared. It must be able to determine the number of fields in each record, and whether each field is a pointer.

For statically typed languages such as Tiger or Pascal, or for object-oriented languages such as Java or Modula-3, the simplest way to identify heap objects is to have the first word of every object point to a special type- or class-descriptor record. This record tells the total size of the object and the location of each pointer field.

For statically typed languages this is an overhead of one word per record to serve the garbage collector. But object-oriented languages need this descriptor-pointer in every object just to implement dynamic method lookup, so that there is no additional per-object overhead attributable to garbage collection.

The type- or class-descriptor must be generated by the compiler from the static type information calculated by the semantic analysis phase of the compiler. The descriptor-pointer will be the argument to the runtime system’s *alloc* function.

In addition to describing every heap record, the compiler must identify to the collector every pointer-containing temporary and local variable, whether it is in a register or in an activation record. Because the set of live temporaries can change at every instruction, the *pointer map* is different at every point in the program. Therefore, it is simpler to describe the pointer map only at points where a new garbage collection can begin. These are at calls to the
alloc function; and also, since any function-call might be calling a function which in turn calls alloc, the pointer map must be described at each function call.

The pointer map is best keyed by return addresses: a function call at location $a$ is best described by its return address immediately after $a$, because the return address is what the collector will see in the very next activation record. The data structure maps return addresses to live-pointer sets; for each pointer that is live immediately after the call, the pointer map tells its register or frame location.

To find all the roots, the collector starts at the top of the stack and scans downward, frame by frame. Each return address keys the pointer-map entry that describes the next frame. In each frame, the collector marks (or forwards, if copying collection) from the pointers in that frame.

Callee-save registers need special handling. Suppose function $f$ calls $g$, which calls $h$. Function $h$ knows that it saved some of the callee-save registers in its frame and mentions this fact in its pointer map; but $h$ does not know which of these registers are pointers. Therefore the pointer map for $g$ must describe which of its callee-save registers contain pointers at the call to $h$ and which are “inherited” from $f$.

**DERIVED POINTERS**

Sometimes a compiled program has a pointer that points into the middle of a heap record, or that points before or after the record. For example, the expression $a[i-2000]$ can be calculated internally as $M[a-2000+i]$:

$$
\begin{align*}
  t_1 & \leftarrow a - 2000 \\
  t_2 & \leftarrow t_1 + i \\
  t_3 & \leftarrow M[t_2]
\end{align*}
$$

If the expression $a[i-2000]$ occurs inside a loop, the compiler might choose to hoist $t_1 \leftarrow a - 2000$ outside the loop to avoid recalculating it in each iteration. If the loop also contains an alloc, and a garbage collection occurs while $t_1$ is live, will the collector be confused by a pointer $t_1$ that does not point to the beginning of an object, or (worse yet) points to an unrelated object?

We say that the $t_1$ is derived from the base pointer $a$. The pointer map must identify each derived pointer and tell the base pointer from which it is derived. Then, when the collector relocates $a$ to address $a'$, it must adjust $t_1$ to point to address $t_1 + a' - a$. 

293
Of course, this means that $a$ must remain live as long as $t_1$ is live. Consider the loop at left, implemented as shown at right:

```plaintext
let
    var a := intarray[100] of 0
in
    for i := 1930 to 1990
    do f(a[i-2000])
end

r_1 ← 100
r_2 ← 0
call alloc
    a ← r_1
t_1 ← a - 2000
    i ← 1930
L_1:  r_1 ← M[t_1 + i]
call f
L_2:  if i ≤ 1990 goto L_1
```

If there are no other uses of $a$, then the temporary $a$ appears dead after the assignment to $t_1$. But then the pointer map associated with the return address $L_2$ would not be able to “explain” $t_1$ adequately. Therefore, for purposes of the compiler’s liveness analysis, a derived pointer implicitly keeps its base pointer live.

**PROGRAM DESCRIPTORS**

Implement record descriptors and pointer maps for the Tiger compiler.

For each record-type declaration, make a string literal to serve as the record descriptor. The length of the string should be equal to the number of fields in the record. The $i$th byte of the string should be $p$ if the $i$th field of the record is a pointer (string, record, or array); or $n$ if the $i$th field is a nonpointer.

The `allocRecord` function should now take the record descriptor string (pointer) instead of a length; the allocator can obtain the length from the string literal. Then `allocRecord` should store this descriptor pointer at field zero of the record. Modify the runtime system appropriately.

The user-visible fields of the record will now be at offsets 1, 2, 3, ... instead of 0, 1, 2, ...; adjust the compiler appropriately.

Design a descriptor format for arrays, and implement it in the compiler and runtime system.

Implement a temp-map with a boolean for each temporary: is it a pointer or not? Also make a similar map for the offsets in each stack frame, for frame-resident pointer variables. You will not need to handle derived pointers, as your Tiger compiler probably does not keep derived pointers live across function calls.

For each procedure call, put a new return-address label $L_{\text{ret}}$ immediately after the `call` instruction. For each one, make a data fragment of the form...
PROGRAMMING EXERCISE

\[ L_{\text{ptrmap}327} : \text{.word} \quad L_{\text{ptrmap}326} \quad \text{link to previous ptr-map entry} \]
\[ .\text{word} \quad L_{\text{ret}327} \quad \text{key for this entry} \]
\[ .\text{word} \quad \ldots \quad \text{pointer map for} \]
\[ .\text{word} \quad \ldots \quad \text{this return address} \]

and then the runtime system can traverse this linked list of pointer-map entries, and perhaps build it into a data structure of its own choosing for fast lookup of return addresses. The data-layout pseudo-instructions (.word, etc.) are, of course, machine dependent.

PROGRAM GARBAGE COLLECTION

Implement a mark-sweep or copying garbage collector in the C language, and link it into the runtime system. Invoke the collector from allocRecord or initArray when the free space is exhausted.

FURTHER READING

Reference counting [Collins 1960] and mark-sweep collection [McCarthy 1960] are almost as old as languages with pointers. The pointer-reversal idea is attributed by Knuth [1967] to Peter Deutsch and to Herbert Schorr and W. M. Waite.

Fenichel and Yochelson [1969] designed the first two-space copying collector, using depth-first search; Cheney [1970] designed the algorithm that uses the unscanned nodes in to-space as the queue of a breadth-first search, and also the semi-depth-first copying that improves the locality of a linked list.

Steele [1975] designed the first concurrent mark-and-sweep algorithm. Dijkstra et al. [1978] formalized the notion of tricolor marking, and designed a concurrent algorithm that they could prove correct, trying to keep the synchronization requirements as weak as possible. Baker [1978] invented the incremental copying algorithm in which the mutator sees only to-space pointers.

Generational garbage collection, taking advantage of the fact that newer objects die quickly and that there are few old-to-new pointers, was invented by Lieberman and Hewitt [1983]; Ungar [1986] developed a simpler and more efficient remembered set mechanism.
The Symbolics Lisp Machine [Moon 1984] had special hardware to assist with incremental and generational garbage collection. The microcoded memory-fetch instructions enforced the invariant of Baker’s algorithm; the microcoded memory-store instructions maintained the remembered set for generational collection. This collector was the first to explicitly improve locality of reference by keeping related objects on the same virtual-memory page.

As modern computers rarely use microcode, and a modern general-purpose processor embedded in a general-purpose memory hierarchy tends to be an order of magnitude faster and cheaper than a computer with special-purpose instructions and memory tags, attention turned in the late 1980s to algorithms that could be implemented with standard RISC instructions and standard virtual-memory hardware. Appel et al. [1988] use virtual memory to implement a read barrier in a truly concurrent variant of Baker’s algorithm. Shaw [1988] uses virtual memory dirty bits to implement a write barrier for generational collection, and Boehm et al. [1991] make the same simple write barrier serve for concurrent generational mark-and-sweep. Write barriers are cheaper to implement than read barriers, because stores to old pages are rarer than fetches from to-space, and a write barrier merely needs to set a dirty bit and continue with minimal interruption of the mutator. Sobalvarro [1988] invented the card marking technique, which uses ordinary RISC instructions without requiring interaction with the virtual-memory system.

Appel and Shao [1996] describe techniques for fast allocation of heap records and discuss several other efficiency issues related to garbage-collected systems.

Branquart and Lewi [1971] describe pointer maps communicated from a compiler to its garbage collector; Diwan et al. [1992] tie pointer maps to return addresses, show how to handle derived pointers, and compress the maps to save space.

Appel [1992, Chapter 12] shows that compilers for functional languages must be careful about closure representations; using simple static links (for example) can keep enormous amounts of data reachable, preventing the collector from reclaiming it.

Boehm and Weiser [1988] describe conservative collection, where the compiler does not inform the collector which variables and record-fields contain pointers, so the collector must “guess.” Any bit-pattern pointing into the allocated heap is assumed to be a possible pointer and keeps the pointed-to record live. However, since the bit-pattern might really be meant as an inte-
ger, the object cannot be moved (which would change the possible integer), and some garbage objects may not be reclaimed. Wentworth [1990] points out that such an integer may (coincidentally) point to the root of a huge garbage data structure, which therefore will not be reclaimed; so conservative collection will occasionally suffer from a disastrous space leak. Boehm [1993] describes several techniques for making these disasters unlikely: for example, if the collector ever finds an integer pointing to address $X$ that is not a currently allocated object, it should blacklist that address so that the allocator will never allocate an object there. Boehm [1996] points out that even a conservative collector needs some amount of compiler assistance: if a derived pointer can point outside the bounds of an object, then its base pointer must be kept live as long as the derived pointer exists.

Page 515 discusses some of the literature on improving the cache performance of garbage-collected systems.

**EXERCISES**

13.1 Analyze the cost of mark-sweep versus copying collection. Assume that every record is exactly two words long, and every field is a pointer. Some pointers may point outside the collectible heap, and these are to be left unchanged.

- a. Analyze Algorithm 13.6 to estimate $c_1$, the cost (in instructions per reachable word) of depth-first marking.
- b. Analyze Algorithm 13.3 to estimate $c_2$, the cost (in instructions per word in the heap) of sweeping.
- c. Analyze Algorithm 13.9 to estimate $c_3$, the cost per reachable word of copying collection.
- d. There is some ratio $\gamma$ so that with $H = \gamma R$ the cost of copying collection equals the cost of mark-sweep collection. Find $\gamma$.
- e. For $H > \gamma R$, which is cheaper, mark-sweep or copying collection?

13.2 Run Algorithm 13.6 (pointer reversal) on the heap of Figure 13.1. Show the state of the heap, the done flags, and variables $t$, $x$, and $y$ at the time the node containing 59 is first marked.

13.3 Assume main calls $\ell$ with callee-save registers all containing 0. Then $\ell$ saves the callee-save registers it is going to use; puts pointers into some callee-save
registers, integers into others, and leaves the rest untouched; then calls \texttt{g}. Now \texttt{g} saves some of the callee-save registers, puts some pointers and integers into them, and calls \texttt{alloc}, which starts a garbage collection.

a. Write functions \texttt{f} and \texttt{g} matching this description.
b. Illustrate the pointer maps of functions \texttt{f} and \texttt{g}.
c. Show the steps that the collector takes to recover the exact locations of all the pointers.

**13.4** Every object in the Java language supports a \texttt{hashCode()} method that returns a “hash code” for that object. Hash codes need not be unique – different objects can return the same hash code – but each object must return the same hash code every time it is called, and two objects selected at random should have only a small chance of having the same hash code.

The Java language specification says that “This is typically implemented by converting the address of the object to an integer, but this implementation technique is not required by the Java language.”

Explain the problem in implementing \texttt{hashCode()} this way in a Java system with copying garbage collection, and propose a solution.
A useful software-engineering principle is *information hiding* or *encapsulation*. A module may provide values of a given type, but the representation of that type is known only to the module. Clients of the module may manipulate the values only through *operations* provided by the module. In this way, the module can assure that the values always meet consistency requirements of its own choosing.

*Object-oriented* programming languages are designed to support information hiding. Because the “values” may have internal state that the operations will modify, it makes sense to call them *objects*. Because a typical “module” manipulates only one type of object, we can eliminate the notion of module and (syntactically) treat the operations as fields of the objects, where they are called *methods*.

Another important characteristic of object-oriented languages is the notion of *extension* or *inheritance*. If some program context (such as the formal parameter of a function or method) expects an object that supports methods $m_1, m_2, m_3$, then it will also accept an object that supports $m_1, m_2, m_3, m_4$.

### 14.1 CLASSES

To illustrate the techniques of compiling object-oriented languages I will use a simple class-based object-oriented language called Object-Tiger.
We extend the Tiger language with new declaration syntax to create classes:

\[
\begin{align*}
\text{dec} & \rightarrow \text{classdec} \\
\text{classdec} & \rightarrow \text{class} \ \text{class-id} \ \text{extends} \ \text{class-id} \ \{ \ \{ \text{classfield} \} \} \\
\text{classfield} & \rightarrow \text{vardec} \\
\text{method} & \rightarrow \text{method} \ \text{id}(\text{tyfields}) = \text{exp} \\
\text{method} & \rightarrow \text{method} \ \text{id}(\text{tyfields}) : \text{type-id} = \text{exp}
\end{align*}
\]

The declaration `class B extends A { · · · }` declares a new class `B` that extends the class `A`. This declaration must be in the scope of the `let`-expression that declares `A`. All the fields and methods of `A` implicitly belong to `B`. Some of the `A` methods may be overridden (have new declarations) in `B`, but the fields may not be overridden. The parameter and result types of an overriding method must be identical to those of the overridden method.

There is a predefined class identifier `Object` with no fields or methods.

Methods are much like functions, with formal parameters and bodies. However, each method within `B` has an implicit formal parameter `self` of type `B`. But `self` is not a reserved word, it is just an identifier automatically bound in each method.

The responsibility for initializing object data fields rests with the class, not with the client. Thus, object-field declarations look more like variable declarations than like record-field declarations.

We make new expression syntax to create objects and invoke methods:

\[
\begin{align*}
\text{exp} & \rightarrow \text{new} \ \text{class-id} \\
& \rightarrow \text{lvalue} . \ \text{id}() \\
& \rightarrow \text{lvalue} . \ \text{id}(\text{exp}[., \text{exp}])
\end{align*}
\]

The expression `new B` makes a new object of type `B`; the data fields are initialized by evaluating their respective initialization expressions from the class declaration of `B`.

The `l-value b.x`, where `b` is an `l-value` of type `B`, denotes the field `x` of object `b`; this is similar to record-field selection and requires no new syntax.

The expression `b.f(x,y)`, where `b` is an `l-value` of type `B`, denotes a call to the `f` method of object `b` with explicit actual parameters `x` and `y`, and the value `b` for the implicit `self` parameter of `f`.

Program 14.1 illustrates the use of the Object-Tiger language. Every `Vehicle` is an `Object`; every `Car` is a `Vehicle`; thus every `Car` is also an
let start := 10

class Vehicle extends Object {
    var position := start
    method move(int x) = (position := position + x)
}
class Car extends Vehicle {
    var passengers := 0
    method await(v: Vehicle) =
        if (v.position < position)
            then v.move(position - v.position)
        else self.move(10)
}
class Truck extends Vehicle {
    method move(int x) =
        if x <= 55 then position := position + x
}

var t := new Truck
var c := new Car
var v : Vehicle := c

in
    c.passengers := 2;
    c.move(60);
    v.move(70);
    c.await(t)
end

Object. Every Vehicle (and thus every Car and Truck) has an integer position field and a move method.

In addition, a Car has an integer passengers field and an await method. The variables in scope on entry to await are

start By normal Tiger language scoping rules.
passengers Because it is a field of Car.
position Because it is (implicitly) a field of Car.
v Because it is a formal parameter of await.
self Because it is (implicitly) a formal parameter of await.

In the main program, the expression new Truck has type Truck, so the type of t is Truck (in the normal manner of variable declarations in Tiger). Variable c has type Car, and variable v is explicitly declared to have type Vehicle. It is legal to use c (of type Car) in a context where type Vehicle is required (the initialization of v), because class Car is a subclass of Vehicle.
CHAPTER FOURTEEN. OBJECT-ORIENTED LANGUAGES

```
class A extends Object {
    var a := 0
}
class B extends A {var b := 0
                       var c := 0}
class C extends A {var d := 0}
class D extends B {var e := 0}
```

**FIGURE 14.2.** Single inheritance of data fields.

Class Truck overrides the `move` method of Vehicle, so that any attempt to move a truck “faster” than 55 has no effect.

At the call to `c.await(t)`, the truck `t` is bound to the formal parameter `v` of the `await` method. Then when `v.move` is called, this activates the `Truck_move` method body, not `Vehicle_move`.

We use the notation `A_m` to indicate a `method instance` `m` declared within a class `A`. This is not part of the Object-Tiger syntax, it is just for use in discussing the semantics of Object-Tiger programs. Each different declaration of a method is a different method instance. Two different method instances could have the same method name if, for example, one overrides the other.

14.2 SINGLE INHERITANCE OF DATA FIELDS

To evaluate the expression `v.position`, where `v` belongs to class Vehicle, the compiler must generate code to fetch the field `position` from the object (record) that `v` points to.

This seems simple enough: the environment entry for variable `v` contains (among other things) a pointer to the type (class) description of Vehicle; this has a list of fields and their offsets. But at run time the variable `v` could also contain a pointer to a Car or Truck; where will the `position` field be in a Car or Truck object?

**Single inheritance.** For *single-inheritance* languages, in which each class extends just one parent class, the simple technique of *prefixing* works well. Where `B` extends `A`, those fields of `B` that are inherited from `A` are laid out in a `B` record *at the beginning, in the same order they appear in `A` records*. Fields of `B` not inherited from `A` are placed afterward, as shown in **Figure 14.2**.
14.2. SINGLE INHERITANCE OF DATA FIELDS

```
class A extends Object {
    var x := 0
    method f()
}
class B extends A {method g()
}
class C extends B {method g()
}
class D extends C {var y := 0
    method f()
}
```

**Program 14.3.** Class descriptors for dynamic method lookup.

**METHODS**

A method instance is compiled much like a function: it turns into machine code that resides at a particular address in the instruction space. Let us say, for example, that the method instance `Truck_move` has an entry point at machine-code label `Truck_move`. In the semantic-analysis phase of the compiler, each variable’s environment entry contains a pointer to its class descriptor; each class descriptor contains a pointer to its parent class, and also a list of method instances; each method instance has a machine-code label.

**Static methods.** Some object-oriented languages allow some methods to be declared `static`. The machine code that executes when `c.f()` is called depends on the type of the `variable c`, not the type of the `object` that `c` holds. To compile a method-call of the form `c.f()`, the compiler finds the class of `c`; let us suppose it is class `C`. Then it searches in class `C` for a method `f`; suppose none is found. Then it searches the parent class of `C`, class `B`, for a method `f`; then the parent class of `B`; and so on. Suppose in some ancestor class `A` it finds a static method `f`; then it can compile a function call to label `A_f`.

**Dynamic methods.** But this technique will not work for dynamic methods. If method `f` in `A` is a dynamic method, then it might be overridden in some class `D` which is a subclass of `C` (see Figure 14.3). But there is no way to tell at compile time if the variable `c` is pointing to an object of class `D` (in which case `D_f` should be called) or class `C` (in which case `A_f` should be called).

To solve this problem, the class descriptor must contain a vector with a method instance for each (nonstatic) method name. When class `B` inherits from `A`, the method table starts with entries for all method names known to `A`, and then continues with new methods declared by `B`. This is very much like the arrangement of fields in objects with inheritance.

Figure 14.3 shows what happens when class `D` overrides method `f`. Al-
class A extends Object {var a := 0}
class B extends Object {var b := 0
var c := 0}
class C extends A {var d := 0}
class D extends A,B,C {var e := 0}

**FIGURE 14.4.** Multiple inheritance of data fields.

though the entry for $f$ is at the beginning of $D$’s method table, as it is also at the beginning of the ancestor class $A$’s method table, it points to a different method-instance label because $f$ has been overridden.

To execute $c.f()$, where $f$ is a dynamic method, the compiled code must execute these instructions:

1. Fetch the class descriptor $d$ at offset 0 from object $c$.
2. Fetch the method-instance pointer $p$ from the (constant) $f$ offset of $d$.
3. Jump to address $p$, saving return address (that is, call $p$).

### 14.3 MULTIPLE INHERITANCE

In languages that permit a class $D$ to extend several parent classes $A,B,C$ (that is, where $A$ is not a subclass of $B$ or vice versa), finding field offsets and method instances is more difficult. It is impossible to put all the $A$ fields at the beginning of $D$ and to put all the $B$ fields at the beginning of $D$.

**Global graph coloring.** One solution to this problem is to statically analyze all classes at once, finding some offset for each field name that can be used in every record containing that field. We can model this as a graph-coloring problem: there is a node for each distinct field name, and an edge for any two fields which coexist (perhaps by inheritance) in the same class. The offsets 0, 1, 2, ... are the colors. Figure 14.4 shows an example.

The problem with this approach is that it leaves empty slots in the middle of objects, since it cannot always color the $N$ fields of each class with colors with the first $N$ colors. To eliminate the empty slots in objects, we pack the fields of each object and have the class descriptor tell where each field is. *Figure 14.5* shows an example. We have done graph coloring on all the field

---

1 *Distinct field name* does not mean simple equivalence of strings. Each fresh declaration of field or method $x$ (where it is not overriding the $x$ of a parent class) is really a distinct name.
names, as before, but now the “colors” are not the offsets of those fields within the objects but within the descriptors. To fetch a field \( a \) of object \( x \), we fetch the \( a \)-word from \( x \)’s descriptor; this word contains a small integer telling the position of the actual \( a \) data within \( x \).

In this scheme, class descriptors have empty slots, but the objects do not; this is acceptable because a system with millions of objects is likely to have only dozens of class descriptors. But each data fetch (or store) requires three instructions instead of one:

1. Fetch the descriptor-pointer from the object.
2. Fetch the field-offset value from the descriptor.
3. Fetch (or store) the data at the appropriate offset in the object.

In practice, it is likely that other operations on the object will have fetched the descriptor-pointer already, and multiple operations on the same field (e.g., fetch then store) won’t need to re-fetch the offset from the descriptor; common-subexpression elimination can remove much of this redundant overhead.

**Method lookup.** Finding method instances in a language with multiple inheritance is just as complicated as finding field offsets. The global graph-coloring approach works well: the method names can be mixed with the field names to form nodes of a large interference graph. Descriptor entries for fields give locations within the objects; descriptor entries for methods give machine-code addresses of method instances.
Problems with dynamic linking. Any global approach suffers from the problem that the coloring (and layout of class descriptors) can be done only at link-time; the job is certainly within the capability of a special-purpose linker.

However, many object-oriented systems have the capability to load new classes into a running system; these classes may be extensions (subclasses) of classes already in use. Link-time graph coloring poses many problems for a system that allows dynamic incremental linking.

Hashing. Instead of global graph coloring, we can put a hash table in each class descriptor, mapping field names to offsets and method names to method instances. This works well with separate compilation and dynamic linking.

The characters of the field names are not hashed at run time. Instead, each field name $a$ is hashed at compile time to an integer hash$\_a$ in the range $[0, N − 1]$. Also, for each field name a unique run-time record (pointer) $ptr\_a$ is made for each field.

Each class descriptor has a field-offset table $F\_\text{tab}$ of size $N$ containing field-offsets and method instances, and (for purposes of collision detection) a parallel key table $K\_\text{tab}$ containing field-name pointers. If the class has a field $x$, then field-offset-table slot number hash$\_x$ contains the offset for $x$, and key-table slot number hash$\_x$ contains the pointer $ptr\_x$.

To fetch a field $x$ of object $c$, the compiler generates code to

1. Fetch the class descriptor $d$ at offset 0 from object $c$.
2. Fetch the field-name $f$ from the address offset $d + K\_\text{tab} + \text{hash}_x$.
3. Test whether $f = \text{ptr}_x$; if so
4. Fetch the field offset $k$ from $d + F\_\text{tab} + \text{hash}_x$.
5. Fetch the contents of the field from $c + k$.

This algorithm has four instructions of overhead, which may still be tolerable. A similar algorithm works for dynamic method-instance lookup.

The algorithm as described does not say what to do if the test at line 3 fails. Any hash-table collision-resolution technique can be used.

14.4 TESTING CLASS MEMBERSHIP

Some object-oriented languages allow the program to test membership of an object in a class at run time, as summarized in Table 14.6.

Since each object points to its class descriptor, the address of the class descriptor can serve as a “type-tag.” However, if $x$ is an instance of $D$, and $D$
14.4. TESTING CLASS MEMBERSHIP

<table>
<thead>
<tr>
<th>Test whether object ( x ) belongs class ( C ), or to any subclass of ( C ).</th>
<th>Modula-3</th>
<th>Java</th>
</tr>
</thead>
<tbody>
<tr>
<td>ISTYPE ((x,C))</td>
<td>( x ) instanceof ( C )</td>
<td></td>
</tr>
</tbody>
</table>

Given a variable \( x \) of class \( C \), where \( x \) actually points to an object of class \( D \) that extends \( C \), yield an expression whose compile-time type is class \( D \).

\[
NARROW \( (x,D) \) \quad (D) \times
\]

**TABLE 14.6.** Facilities for type testing and safe casting.

extends \( C \), then \( x \) is also an instance of \( C \). Assuming there is no multiple inheritance, a simple way to implement \( x \) instanceof \( C \) is to generate code that performs the following loop at run time:

\[
t_1 \leftarrow x.\text{descriptor} \\
L_1 : \quad \text{if} \ t_1 = C \ \text{goto} \ \text{true} \\
\quad \quad t_1 \leftarrow t_1.\text{super} \\
\quad \quad \text{if} \ t_1 = \text{nil} \ \text{goto} \ \text{false} \\
\quad \quad \text{goto} \ L_1
\]

where \( t_1.\text{super} \) is the superclass (parent class) of class \( t_1 \).

However, there is a faster approach using a *display* of parent classes. Assume that the class nesting depth is limited to some constant, such as 20. Reserve a 20-word block in each class descriptor. In the descriptor for a class \( D \) whose nesting depth is \( j \), put a pointer to descriptor \( D \) in the \( j \)th slot, a pointer to \( D.\text{super} \) in the \((j-1)\)th slot, a pointer to \( D.\text{super}.\text{super} \) in slot \( j-2 \), and so on up to \text{Object} in slot 0. In all slots numbered greater than \( j \), put \text{nil}.

Now, if \( x \) is an instance of \( D \), or of any subclass of \( D \), then the \( j \)th slot of \( x \)'s class descriptor will point to the class descriptor \( D \). Otherwise it will not. So \( x \) instanceof \( D \) requires

1. Fetch the class descriptor \( d \) at offset 0 from object \( c \).
2. Fetch the \( j \)th class-pointer slot from \( d \).
3. Compare with the class descriptor \( D \).

This works because the class-nesting depth of \( D \) is known at compile time.

**Type coercions.** Given a variable \( c \) of type \( C \), it is always legal to treat \( c \) as any supertype of \( C \) – if \( C \) extends \( B \), and variable \( b \) has type \( B \), then the assignment \( b \leftarrow c \) is legal and safe.

But the reverse is not true. The assignment \( c \leftarrow b \) is safe only if \( b \) is really (at run time) an instance of \( C \), which is not always the case. If we have
CHAPTER FOURTEEN. OBJECT-ORIENTED LANGUAGES

$b \leftarrow \text{new } B, c \leftarrow b$, followed by fetching some field of $c$ that is part of class $C$ but not class $B$, then this fetch will lead to unpredictable behavior.

Thus, safe object-oriented languages (such as Modula-3 and Java) accompany any coercion from a superclass to a subclass with a run-time type-check that raises an exception unless the run-time value is really an instance of the subclass (e.g. unless $b$ instanceof $C$).

It is a common idiom to write

Modula-3:  
```java
IF ISTYPE(b,C) THEN f(NARROW(b,C)) ELSE ...
```

Java:  
```java
if (b instanceof C) f((C)b) else ... 
```

Now there are two consecutive, identical type tests: one explicit (ISTYPE or instanceof) and one implicit (in NARROW or the cast). A good compiler will do enough flow analysis to notice that the then-clause is reached only if $b$ is in fact an instance of $C$, so that the type-check in the narrowing operation can be eliminated.

C++ is an unsafe object-oriented language. It has a static cast mechanism without run-time checking; careless use of this mechanism can make the program “go wrong” in unpredictable ways. C++ also has dynamic_cast with run-time checking, which is like the mechanisms in Modula-3 and Java.

**Typcase.** Explicit instanceof testing, followed by a narrowing cast to a subclass, is not a wholesome “object-oriented” style. Instead of using this idiom, programmers are expected to use dynamic methods that accomplish the right thing in each subclass. Nevertheless, the test-then-narrow idiom is fairly common.

Modula-3 has a typcase facility that makes the idiom more beautiful and efficient (but not any more “object-oriented”):

```java
TYPECASE expr
OF $C_1$ ($v_1$) => $S_1$
| $C_2$ ($v_2$) => $S_2$
| ...
| $C_n$ ($v_n$) => $S_n$
ELSE $S_0$
END
```

If the $expr$ evaluates to an instance of class $C_i$, then a new variable $v_i$ of type $C_i$ points to the result of the $expr$, and statement $S_i$ is executed. The
declaration of \( v_i \) is implicit in the TYPECASE, and its scope covers only \( S_i \).

If more than one of the \( C_i \) match (which can happen if, for example, one is a superclass of another), then only the first matching clause is taken. If none of the \( C_i \) match, then the ELSE clause is taken (statement \( S_0 \) is executed).

**Typecase** can be converted straightforwardly to a chain of **else-ifs**, with each if doing an instance test, a narrowing, and a local variable declaration. However, if there are very many clauses, then it can take a long time to go through all the **else-ifs**. Therefore it is attractive to treat it like a case (switch) statement on integers, using an indexed jump (computed goto).

That is, an ordinary case statement on integers:

```ml
case i
  of 0 => s0
  | 1 => s1
  | 2 => s2
  | 3 => s3
  | 4 => s4
  | _ => sd
```

```c,java
switch (i) {
  case 0: s0; break;
  case 1: s1; break;
  case 2: s2; break;
  case 3: s3; break;
  case 4: s4; break;
  default: sd;
}
```

is compiled as follows: first a range-check comparison is made to ensure that \( i \) is within the range of case labels (0–4, in this case); then the address of the \( i \)th statement is fetched from the \( i \)th slot of a table, and control jumps to \( s_i \).

This approach will not work for **typecase**, because of subclassing. That is, even if we could make class descriptors be small integers instead of pointers, we cannot do an indexed jump based on the class of the object, because we will miss clauses that match superclasses of that class. Thus, Modula-3 **typecase** is implemented as a chain of **else-ifs**.

Assigning integers to classes is not trivial, because separately compiled modules can each define their own classes, and we do not want the integers to clash. But a sophisticated linker might be able to assign the integers at link time.

If all the classes in the **typecase** were **final** classes (in the sense used by Java, that they cannot be extended), then this problem would not apply. Modula-3 does not have final classes; and Java does not have **typecase**. But a clever Java system might be able to recognize a chain of **else-ifs** that do **instanceof** tests for a set of final classes, and generate a indexed jump.
14.5 PRIVATE FIELDS AND METHODS

True object-oriented languages can protect fields of objects from direct manipulation by other objects’ methods. A private field is one that cannot be fetched or updated from any function or method declared outside the object; a private method is one that cannot be called from outside the object.

Privacy is enforced by the type-checking phase of the compiler. In the symbol table of C, along with each field offset and method offset, is a boolean flag indicating whether the field is private. When compiling the expression c.f() or c.x, it is a simple matter to check that field and reject accesses to private fields from any method outside the object declaration.

There are many varieties of privacy and protection. Different languages allow

- Fields and methods which are accessible only to the class that declares them.
- Fields and methods accessible to the declaring class, and to any subclasses of that class.
- Fields and methods accessible only within the same module (package, namespace) as the declaring class.
- Fields that are read-only from outside the declaring class, but writable by methods of the class.

In general, these varieties of protection can be statically enforced by compile-time type-checking, for class-based languages.

14.6 CLASSLESS LANGUAGES

Some object-oriented languages do not use the notion of class at all. In such a language, each object implements whatever methods and has whatever data fields it wants. Type-checking for such languages is usually dynamic (done at run time) instead of static (done at compile time).

Many objects are created by cloning: copying an existing object (or template object) and then modifying some of the fields. Thus, even in a classless language there will be groups (“pseudo-classes”) of similar objects that can share descriptors. When b is created by cloning a, it can share a descriptor with a. Only if a new field is added or a method field is updated (overridden) does b require a new descriptor.

The techniques used in compiling classless languages are similar to those
for class-based languages with multiple inheritance and dynamic linking: pseudo-class descriptors contain hash tables that yield field offsets and method instances.

The same kinds of global program analysis and optimization that are used for class-based languages – finding which method instance will be called from a (dynamic) method call site – are just as useful for classless languages.

14.7. OPTIMIZING OBJECT-ORIENTED PROGRAMS

An optimization of particular importance to object-oriented languages (which also benefit from most optimizations that apply to programming languages in general) is conversion of dynamic method calls to static method-instance calls.

Compared with an ordinary function call, at each method call site there is a dynamic method lookup to determine the method instance. For single-inheritance languages, method lookup takes only two instructions. This seems like a small cost, but:

- Modern machines can jump to constant addresses more efficiently than to addresses fetched from tables. When the address is manifest in the instruction stream, the processor is able to pre-fetch the instruction cache at the destination and direct the instruction-issue mechanism to fetch at the target of the jump. Unpredictable jumps stall the instruction-issue and -execution pipeline for several cycles.
- An optimizing compiler that does inline expansion or interprocedural analysis will have trouble analyzing the consequences of a call if it doesn’t even know which method instance is called at a given site.

For multiple-inheritance and classless languages, the dynamic method-lookup cost is even higher.

Thus, optimizing compilers for object-oriented languages do global program analysis to determine those places where a method call is always calling the same method instance; then the dynamic method call can be replaced by a static function call.

For a method call $c.f()$, where $c$ is of class $C$, type hierarchy analysis is used to determine which subclasses of $C$ contain methods $f$ that may override $C.f$. If there is no such method, then the method instance must be $C.f$.

This idea is combined with type propagation, a form of static dataflow analysis similar to reaching definitions (see Section 17.2). After an assign-
ment \( c \leftarrow \text{new } C \), the exact class of \( c \) is known. This information can be propagated through the assignment \( d \leftarrow c \), and so on. When \( d.f() \) is encountered, the type-propagation information limits the range of the type hierarchy that might contribute method instances to \( d \).

Suppose a method \( f \) defined in class \( C \) calls method \( g \) on \texttt{self}. But \( g \) is a dynamic method and may be overridden, so this call requires a dynamic method lookup. An optimizing compiler may make a different copy of a method instance \( C_f \) for each subclass (e.g. \( D, E \)) that extends \( C \). Then when the (new copy) \( D_f \) calls \( g \), the compiler knows to call the instance \( D_g \) without a dynamic method lookup.

### PROGRAM

#### OBJECT-Tiger

Implement the Object-Tiger object-oriented extensions to your Tiger compiler.

This chapter’s description of the Object-Tiger language leaves many things unspecified: if method \( f \) is declared before method \( g \), can \( f \) call \( g \)? Can a method access all the class variables, or just the ones declared above it? Can the initializer of a class variable (field) call a method of the class (and can the method therefore see an uninitialized field)? You will need to refine and document the definition of the Object-Tiger language.

### FURTHER READING

Dahl and Nygaard’s Simula-67 language [Birtwistle et al. 1973] introduced the notion of classes, objects, single inheritance, static methods, instance testing, typecase, and the \texttt{prefix} technique to implement static single inheritance. In addition it had coroutines and garbage collection.

Cohen [1991] suggested the \texttt{display} for constant-time testing of class membership.

Chambers et al. [1991] describe several techniques to make classless, dynamically typed languages perform efficiently: pseudo-class descriptors, multiple versions of method instances, and other optimizations. Diwan et al. [1996] describe optimizations for statically typed languages that can replace dynamic method calls by static function calls.

Conventional object-oriented languages choose a method instance for a call \(a.f(x, y)\) based only on the class of the method receiver \((a)\) and not other arguments \((x, y)\). Languages with multimethods [Bobrow et al. 1989] allow dynamic method lookup based on the types of all arguments. Chambers and Leavens [1995] show how to do static type-checking for multimethods; Amiel et al. [1994] and Chen and Turau [1994] show how to do efficient dynamic multimethod lookup.

**EXERCISES**

*14.1* A problem with the *display* technique (as explained on page 307) for testing class membership is that the maximum class nesting depth \(N\) must be fixed in advance, and every class descriptor needs \(N\) words of space even if most classes are not deeply nested. Design a variant of the *display* technique that does not suffer from these problems; it will be a couple of instructions more costly than the one described on page 307.

14.2 The hash-table technique for finding field offsets and method instances in the presence of multiple inheritance is shown incompletely on page 306 – the case of \(f \neq \text{ptr}_x\) is not resolved. Choose a collision-resolution technique, explain how it works, and analyze the extra cost (in instructions) in the case that \(f = \text{ptr}_x\) (no collision) and \(f \neq \text{ptr}_x\) (collision).

*14.3* Consider the following class hierarchy, which contains five method-call sites. The task is to show which of the method-call sites call known method instances, and (in each case) show which method instance. For example, you might say that “method-instance \(X\_g\) always calls \(Y\_f\); method \(Z\_g\) may call more than one instance of \(f\).”
class A extends Object { method f() = print("1") }
class B extends A { method g() = (f(); print("2")) }
class C extends B { method f() = (g(); print("3")) }
class D extends C { method g() = (f(); print("4")) }
class E extends A { method g() = (f(); print("5")) }
class F extends E { method g() = (f(); print("6")) }

Do this analysis for each of the following assumptions:

a. This is the entire program, and there are no other subclasses of these modules.

b. This is part of a large program, and any of these classes may be extended elsewhere.

c. Classes C and E are local to this module, and cannot be extended elsewhere; the other classes may be extended.

*14.4 Use method replication to improve your analysis of the program in Exercise 14.3. That is, make every class override f and g. For example, in class B (which does not already override f), put a copy of method A_f, and in D put a copy of C_F:

class B extends A { ... method f() = (print("1")) }
class D extends C { ... method f() = (g(); print("3")) }

Similarly, add new instances E_f, F_f, and C_g. Now, for each set of assumptions (a), (b), and (c), show which method calls go to known static instances.

**14.5 Devise an efficient implementation mechanism for any typecase that only mentions final classes. A final class is one that cannot be extended. (In Java, there is a final keyword; but even in other object-oriented languages, a class that is not exported from a module is effectively final, and a link-time whole-program analysis can discover which classes are never extended, whether declared final or not.)

You may make any of the following assumptions, but state which assumptions you need to use:

a. The linker has control over the placement of class-descriptor records.

b. Class descriptors are integers managed by the linker that index into a table of descriptor records.

c. The compiler explicitly marks final classes (in their descriptors).

d. Code for typecase can be generated at link time.

e. After the program is running, no other classes and subclasses are dynamically linked into the program.
15

Functional Programming Languages

**function**: a mathematical correspondence that assigns exactly one element of one set to each element of the same or another set

*Webster’s Dictionary*

The mathematical notion of function is that if \( f(x) = a \) “this time,” then \( f(x) = a \) “next time”; there is no other value equal to \( f(x) \). This allows the use of *equational reasoning* familiar from algebra: that if \( a = f(x) \) then \( g(f(x), f(x)) \) is equivalent to \( g(a, a) \). *Pure functional* programming languages encourage a kind of programming in which equational reasoning works, as it does in mathematics.

*Imperative* programming languages have similar syntax: \( a \leftarrow f(x) \). But if we follow this by \( b \leftarrow f(x) \) there is no guarantee that \( a = b \); the function \( f \) can have *side effects* on global variables that make it return a different value each time. Furthermore, a program might assign into variable \( x \) between calls to \( f(x) \), so \( f(x) \) really means a different thing each time.

**Higher-order functions.** Functional programming languages also allow functions to be passed as arguments to other functions, or returned as results. Functions that take functional arguments are called *higher-order* functions.

Higher-order functions become particularly interesting if the language also supports *nested functions* with *lexical scope* (also called *block structure*). As in Tiger, lexical scope means that each function can refer to variables and parameters of any function in which it is nested. A *higher-order functional language* is one with nested scope and higher-order functions.

What is the essence of functional programming: is it equational reasoning or is it higher-order functions? There is no clear agreement about the answer.
to this question. In this chapter I will discuss three different flavors of “functional” language:

**Fun-Tiger** The Tiger language with higher-order functions. Because side effects are still permitted (and thus, equational reasoning won’t work), this is an *impure, higher-order functional language*; other such languages are Scheme, ML, and Smalltalk.

**PureFun-Tiger** A language with higher-order functions and no side effects, capturing the essence of *strict, pure functional languages* (like the pure functional subset of ML).

**Lazy-Tiger** A *non-strict, pure functional language* that uses lazy evaluation like the language Haskell. Non-strict pure functional languages support equational reasoning very well (see Section 15.7).

A *first-order, pure functional language* such as SISAL supports equational reasoning but not higher-order functions.

## 15.1 A SIMPLE FUNCTIONAL LANGUAGE

To make the new language Fun-Tiger, we add *function types* to Tiger:

\[
\begin{align*}
\text{ty} & \rightarrow \text{ty} \rightarrow \text{ty} \\
& \rightarrow (\text{ty} \rightarrow \text{ty}) \\
& \rightarrow (\text{ty} \rightarrow (\text{ty} \rightarrow \text{ty}))
\end{align*}
\]

The type \text{int} \rightarrow \text{string} is the type of functions that take a single integer argument and return a string result. The type \text{int,string} \rightarrow \text{intarray} describes functions that take two arguments (one integer, one string) and return an \text{intarray} result. The getchar function has type \((\text{} \rightarrow \text{string})

Any variable can have a functional type; functions can be passed as arguments and returned as results. Thus, the type \text{int} \rightarrow \text{int} \rightarrow \text{int} is perfectly legal; the \rightarrow operator is right-associative, so this is the type of functions that take an \text{int} \rightarrow \text{int} argument and return an \text{int} \rightarrow \text{int} result.

We also modify the format of a CALL expression, so that the function being called is an arbitrary expression, not just an identifier:

\[
\begin{align*}
\text{exp} & \rightarrow \text{exp} (\text{exp}, \text{exp}) \\
\text{exp} & \rightarrow \text{exp} ()
\end{align*}
\]
let
  type intfun = int -> int
  function add(n: int) : intfun =
    let function h(m: int) : int = n+m
    in h
  end

var addFive : intfun := add(5)
var addSeven : intfun := add(7)
var twenty := addFive(15)
var twentyTwo := addSeven(15)

function twice(f: intfun) : intfun =
  let function g(x: int) : int = f(f(x))
  in g
  end

var addTen : intfun := twice(addFive)

var seventeen := twice(add(5))(7)
var addTwentyFour := twice(twice(add(6)))

  in addTwentyFour(seventeen)
end

PROGRAM 15.1.  A Fun-Tiger program.

Program 15.1 illustrates the use of function types. The function add takes an integer argument \( n \) and returns a function \( h \). Thus, addFive is a version of \( h \) whose \( n \) variable is 5, but addSeven is a function \( h(x) = 7 + x \). The need for each different instance of \( h \) to “remember” the appropriate value for a nonlocal variable \( n \) motivates the implementation technique of closures, which is described later.

The function twice takes an argument \( f \) that is a function from int to int, and the result of twice(\( f \)) is a function \( g \) that applies \( f \) twice. Thus, addTen is a function \( g(x) = addFive(addFive(x)) \). Each instance of \( g(x) \) needs to remember the right \( f \) value, just as each instance of \( h \) needs to remember \( n \).
CLOSURES

In languages (such as C) without nested functions, the run-time representation of a function value can be the address of the machine code for that function. This address can be passed as an argument, stored in a variable, and so on; when it is time to call the function, the address is loaded into a machine register, and the “call to address contained in register” instruction is used.

In the Tree intermediate representation, this is easy to express. Suppose the function starts at label $L_{123}$; we assign the address into a variable $t_{57}$ using

\[
\text{MOVE}(\text{TEMP}(t_{57}), \text{NAME}(L_{123}))
\]

and then call the function with something like

\[
\text{CALL}(\text{TEMP}(t_{57}), \ldots \text{parameters} \ldots).
\]

But this will not work for nested functions; if we represent the $h$ function by an address, in what outer frame can it access the variable $n$? Similarly, how does the $g$ function access the variable $f$?

The solution is to represent a function-variable as closure: a record that contains the machine-code pointer and a way to access the necessary nonlocal variables. One simple kind of closure is just a pair of code pointer and static link; the nonlocal variables can be accessed by following the static link. The portion of the closure giving access to values of variables is often called the environment.

Closures need not be based on static links; any other data structure that gives access to nonlocal variables will do. Using static links has some serious disadvantages: it takes a chain of pointer dereferences to get to the outermost variables, and the garbage collector cannot collect the intermediate links along this chain even if the program is going to use only the outermost variables. However, in this chapter I will use static-link closures for simplicity.

HEAP-ALLOCATED ACTIVATION RECORDS

Using static links in closures means that the activation record for $\text{add}$ must not be destroyed when $\text{add}$ returns, because it still serves as the environment for $h$. To solve this problem, we could create activation records on the heap instead of on the stack. Instead of explicitly destroying $\text{add}$’s frame when $\text{add}$ returns, we would wait until the garbage collector determines that it is safe to reclaim the frame; this would happen when all the pointers to $h$ disappear.
A refinement of this technique is to save on the heap only those variables that *escape* (that are used by inner-nested functions). The stack frame will hold spilled registers, return address, and so on, and also a pointer to the *escaping-variable record*. The escaping-variable record holds (1) any local variables that an inner-nested procedure might need and (2) a static link to the environment (escaping-variable record) provided by the enclosing function; see Figure 15.2.

**Modifications to the Tiger compiler.** In each Fun-Tiger function we make a temporary called the *escaping-variables pointer* or EP that will point to the record of escaping variables. All static link computations, whether to access nonlocal variables or to compute a static link to pass to some other function, will be based on the EP, not the FP. The EP itself is a nonescaping local temporary that will be spilled as needed, just like any other temporary. The static-link formal parameter passed to this function escapes (as does the static link of an ordinary Tiger function) since inner nested functions need to access it; thus, the static link is stored into the escaping-variables record.

In the Frame module of the compiler, the interface functions that create formals and locals (newFrame and allocLocal) must be modified to make accesses (for escaping variables) that are offsets from EP instead of FP. The escaping-variables record must be allocated by instructions produced in procEntryExit1.

---

### 15.3. IMMUTABLE VARIABLES

The Fun-Tiger language has higher-order functions with nested scope, but it is still not really possible to use *equational reasoning* about Fun-Tiger programs. That is, $f(3)$ may return a different value each time. To remedy this situation, we prohibit *side effects* of functions: when a function is called, it must return a result without changing the “world” in any observable way.

Thus, we make a new *pure functional programming* language PureFun-Tiger, in which the following are prohibited:

- Assignments to variables (except as initializations in var declarations);
- Assignments to fields of heap-allocated records;
- Calls to external functions that have visible effects: print, flush, getchar, exit.

This seems rather Draconian: how is the program to get any work done?
FIGURE 15.2. Closures for execution of \( \text{twice}(\text{add}(5)) \). SL=static link; RV=return value; EP=escaping-variables-pointer or environment-pointer.
type key = string
type binding = int
type tree = {key: key,
            binding: binding,
            left: tree,
            right: tree}

function look(t: tree, k: key) : binding =
if k < t.key
    then look(t.left,k)
else if k > t.key
    then look(t.right,k)
else t.binding

function enter(t: tree, k: key, b: binding) :
if k < t.key
    then if t.left=nil
        then t.left :=
            tree{key=k,
            binding=b,
            left=nil,
            right=nil}
        else enter(t.left,k,b)
    else if k > t.key
        then if t.right=nil
            then t.right :=
                tree{key=k,
                binding=b,
                left=nil,
                right=nil}
            else enter(t.right,k,b)
    else t.binding := b

(a) Imperative

FUNCTIONAL

function look(t: tree, k: key) : binding =
if k < t.key
    then look(t.left,k)
else if k > t.key
    then look(t.right,k)
else t.binding

function enter(t: tree, k: key, b: binding) :
if k < t.key
    then
        tree{key=t.key,
        binding=t.binding,
        left=enter(t.left,k,b),
        right=t.right}
else if k > t.key
    then
        tree{key=t.key,
        binding=t.binding,
        left=t.left,
        right=enter(t.right,k,b)
    else tree{key=t.key,
                binding=b,
                left=t.left,
                right=t.right}

(b) Functional

PROGRAM 15.3. Binary search trees implemented in two ways.
To program without assignments, in a functional style, you produce new values instead of updating old ones. For example, Program 15.3 shows the implementation of binary search trees in imperative and functional styles. As explained in Section 5.1 (page 108), the imperative program updates a tree-node, but the functional program returns a new tree much like the old one, though the path from the root to a “new” leaf has been copied. If we let \( t_1 \) be the tree in Figure 5.4a on page 108, we can say

```plaintext
var t2 := enter(t1, "mouse", 4)
```

and now \( t_1 \) and \( t_2 \) are both available for the program to use. On the other hand, if the program returns \( t_2 \) as the result of a function and discards \( t_1 \), then the root node of \( t_1 \) will be reclaimed by the garbage collector (the other nodes of \( t_1 \) will not be reclaimed, because they are still in use by tree \( t_2 \)).

Similar techniques can allow functional programs to express the same wide variety of algorithms that imperative programs can, and often more clearly, expressively and concisely.

**CONTINUATION-BASED I/O**

Producing new data structures instead of updating old ones makes it possible to obey the “no assignments” rules, but how is the program to do input/output? The technique of *continuation-based I/O* expresses input/output in a functional framework. As shown in Program 15.4, the predefined types and functions in PureFun-Tiger rely on the notion of an answer: this is the “result” returned by the entire program.

The built-in `getchar` function does not return a string (as in Tiger); instead, `getchar` takes an argument that is a `stringConsumer` and passes the newly read character to that consumer. Whatever answer the consumer produces will also be the answer of the `getchar`.
let
  type intConsumer = int -> answer

function isDigit(s : string) : int =
  ord(s)>=ord("0") & ord(s)<=ord("9")

function getInt(done: intConsumer) =
  let function nextDigit(accum: int) =
    let function eatChar(dig: string) =
      if isDigit(dig)
        then nextDigit(accum*10+ord(dig))
        else done(accum)
    in getchar(eatChar)
  end
  in nextDigit(0)
end

function putInt(i: int, c: cont) =
  if i=0 then c()
  else let var rest := i/10
    var dig := i - rest * 10
    function doDigit() = print(chr(dig), c)
    in putInt(rest, doDigit)
  end

function factorial(i: int) : int =
  if i=0 then 1 else i * factorial(i-1)

function loop(i) =
  if i > 12 then exit()
  else let function next() = getInt(loop)
    in putInt(factorial(i), next)
  end
in
  getInt(loop)
end

PROGRAM 15.5. PureFun-Tiger program to read \( i \), print \( i! \).

Similarly, \texttt{print} takes a string to print as well as a \textit{continuation} (\texttt{cont}); \texttt{print} outputs a string and then calls the \texttt{cont} to produce an answer.

The point of these arrangements is to allow input/output while preserving equational reasoning. Interestingly, input/output is now “visible” to the type-checker: any function which does I/O will have \texttt{answer} in its result type.
LANGUAGE CHANGES
The following modifications of Fun-Tiger make the new language PureFun-Tiger:

- Add the predefined types `answer`, `stringConsumer`, and `cont`; and modify the types of the predefined I/O functions – as shown in Program 15.4.
- A “procedure” (a function without an explicit return type) is now considered to return type `answer`.
- Assignment statements, `while` loops, `for` loops, and compound statements (with semicolon) are deleted from the language.

Program 15.5 shows a complete PureFun-Tiger program that loops, reading integers and printing the factorial of each integer, until an integer larger than 12 is input.

OPTIMIZATION OF PURE FUNCTIONAL LANGUAGES
Because we have only deleted features from Fun-Tiger, and not added any new ones (except changing some predefined types), our Fun-Tiger compiler can compile PureFun-Tiger right away. And, in general, functional-language compilers can make use of the same kinds of optimizations as imperative-language compilers: inline expansion, instruction selection, loop-invariant analysis, graph-coloring register allocation, copy propagation, and so on. Calculating the control-flow graph can be a bit more complicated, however, because much of the control flow is expressed through function calls, and some of these calls may be function-variables instead of statically defined functions.

A PureFun-Tiger compiler can also make several kinds of optimizations that a Fun-Tiger compiler cannot, because it can take advantage of equational reasoning.

Consider this program fragment, which builds a record `r` and then later fetches fields from it:

```plaintext
type recrd = {a: ⋯, b: ⋯}

var a1 := 5
var b1 := 7
var r := recrd{a := a1, b := b1}

var x := f(r)
var y := r.a + r.b
```
let
  type list = {head: int, tail: list}
  type observeInt = (int, cont) -> answer

function doList(f: observeInt, l: list, c: cont) =
  if l=nil then c()
  else let function doRest() = doList(f, l.tail, c)
         in f(l.head, doRest)
   end

function double(j: int) : int = j+j

function printDouble(i: int, c: cont) =
  let function again() = putInt(double(i),c)
         in putInt(i, again)
   end

function printTable(l: list, c: cont) =
  doList(printDouble, l, c)

var mylist :=

in printTable(mylist, exit)
end

PROGRAM 15.6. printTable in PureFun-Tiger.

In a pure functional language, the compiler knows that when the computation
of y refers to r.a and r.b, it is going to get the values a1 and b1. In an im-
perative (or impure functional) language, the computation f(r) might assign
new values to the fields of r, but not in PureFun-Tiger.

Thus, within the scope of r every occurrence of r.a can be replaced with
a1, and similarly b1 can be substituted for r.b. Also, since no other part of
the program can assign any new value to a1, it will contain the same value (5)
for all time. Thus, 5 can be substituted for a1 everywhere, and 7 for b1. Thus,
we end up with var y := 5+7 which can be turned into var y := 12;
thus, 12 can be substituted for y throughout its scope.

The same kind of substitution works for imperative languages too; it’s just
that a compiler for an imperative language is often not sure whether a field or
variable is updated between the point of definition and the point of use. Thus,
it must conservatively approximate – assuming that the variable may have
been modified – and thus, in most cases, the substitution cannot be performed.
See also alias analysis (Section 17.5).
let
  type list = {head: int,
               tail: list}

function double(j: int): int = j+j

function printDouble(i: int) =
  (putInt(i);
   putInt(double(i)))

function printTable(l: list) =
  while l <> nil
  do (printDouble(l.head);
      l := l.tail)

var mylist := ···
in printTable(mylist)
end
(a) As written

let
  type list = {head: int,
               tail: list}

function printTable(l: list) =
  while l <> nil
  do let var i := l.head
      in putInt(i);
         putInt(i+i);
         l := l.tail
      end

var mylist := ···
in printTable(mylist)
end
(b) Optimized

PROGRAM 15.7. Regular Tiger printTable.

The ML language has pure-functional records, which cannot be updated and on which this substitution transformation is always valid, and also has updatable reference cells, which can be assigned to and which behave like records in a conventional imperative language.

15.4 INLINE EXPANSION

Because functional programs tend to use many small functions, and especially because they pass functions from one place to another, an important optimization technique is inline expansion of function calls: replacing a function call with a copy of the function body.

For example, in Program 15.6, an observeInt is any function (like the putInt of Program 15.5) that “observes” an integer and then continues. doList is a function that applies an observer $f$ to a list $l$, and then continues. In this case, the observer is not putInt but printDouble, which prints $i$ followed by $2i$. Thus, printTable prints a table of integers, each followed by its double.

For comparison, Program 15.7a is a regular Tiger program that does the same thing.
Program 15.6 uses a generic list-traverser, doList, for which any function can be plugged in. Although in this case printDouble is used, the same program could reuse doList for other purposes that print or “observe” all the integers in the list. But Program 15.7a lacks this flexibility – it calls printDouble directly, because the ordinary Tiger language lacks the ability to pass functions as arguments.

If compiled naively, the pure-functional program – which passed printDouble as an argument – will do many more function calls than the imperative program. By using inline expansion and tail-call optimizations (described in Section 15.6), Program 15.6 can be optimized into machine instructions equivalent to the efficient loop of Program 15.7b.

Avoiding variable capture. We must be careful about variable names when doing inlining in Tiger (or C) where a local declaration creates a “hole” in the scope of an outer variable:

```
1 let var x := 5
2   function g(y: int): int =
3       y+x
4   function f(x: int): int =
5       g(1)+x
6   in f(2)+x
7 end
```

The formal parameter x on line 4 creates a hole in the scope of the variable x declared on line 1, so that the x on line 5 refers to the formal parameter, not the variable. If we were to inline-expand the call to g(1) on line 5 by substituting the body of g for the call, we could not simply write 1+x, for then we’d have

```
4   function f(x: int) : int =
5       (1+x)+x
```

but the first x on line 5 is now incorrectly referring to f’s parameter instead of the variable declared on line 1.

To solve this problem, we could first rename, or α-convert, the formal parameter of f, then perform the substitution:

```
1 let var x := 5
2   function g(y: int): int=
3       y+x
4   function f(a: int): int=
5       g(1)+a
6   in f(2)+a
7 end
```

```
1 let var x := 5
2   function g(y: int): int=
3       y+x
4   function f(a: int): int=
5       (1+x)+a
6   in f(2)+a
7 end
```
(a) When the actual parameters are simple variables \(i_1, \ldots, i_n\).

Within the scope of:

\[
\text{function } f(a_1, \ldots, a_n) = B
\]

the expression

\[
f(i_1, \ldots, i_n)
\]

rewrites to

\[
B[a_1 \mapsto i_1, \ldots, a_n \mapsto i_n]
\]

(b) When the actual parameters are non-trivial expressions, not just variables.

Within the scope of:

\[
\text{function } f(a_1, \ldots, a_n) = B
\]

the expression

\[
f(E_1, \ldots, E_n)
\]

rewrites to

\[
\text{let } \text{var } i_1 := E_1 \\
\quad \vdots \\
\quad \text{var } i_n := E_n \\
\text{in } B[a_1 \mapsto i_1, \ldots, a_n \mapsto i_n]
\]

end

where \(i_1, \ldots, i_n\) are previously unused names.

**Algorithm 15.8.** Inline expansion of function bodies. We assume that no two declarations declare the same name.

Alternately, we can rename the actual parameters instead of the formal parameters, and define the substitution function to avoid substituting for \(x\) inside the scope of a new definition of \(x\).

But the best solution of all for avoiding variable capture is to have an earlier pass of the compiler rename all variables so that the same variable-name is never declared twice. This simplifies reasoning about, and optimizing, the program.

**Rules for inlining.** Algorithm 15.8 gives the rules for inline expansion, which can apply to imperative or functional programs. The function body \(B\) is used in place of the function call \(f(\ldots)\), but within this copy of \(B\), each actual parameter is substituted for the corresponding formal parameter. When the actual parameter is just a variable or a constant, the substitution is very simple (Algorithm 15.8a). But when the actual parameter is a nontrivial expression, we must first assign it to a new variable (Algorithm 15.8b).

For example, in Program 15.6 the function-call \(\text{double}(i)\) can be replaced by a copy of \(j + j\) in which each \(j\) is replaced by the actual parameter
15.4. INLINE EXPANSION

i. Here we have used Algorithm 15.8a, since i is a variable, not a more complicated expression.

Suppose we wish to inline expand \( \text{double}(g(x)) \); if we improperly use Algorithm 15.8a, we obtain \( g(x) + g(x) \), which computes \( g(x) \) twice. Even though the principle of equational reasoning assures that we will compute the same result each time, we do not wish to slow down the computation by repeating the (potentially expensive) computation \( g(x) \). Instead, Algorithm 15.8b yields

\[
\text{let } i := g(x) \text{ in } i + i \text{ end}
\]

which computes \( g(x) \) only once.

In an imperative program, not only is \( g(x) + g(x) \) slower than

\[
\text{let } i := g(x) \text{ in } i + i \text{ end}
\]

but – because \( g \) may have side effects – it may compute a different result! Again, Algorithm 15.8b does the right thing.

**Dead function elimination.** If all the calls to a function (such as \( \text{double} \)) have been inline expanded, and if the function is not passed as an argument or referenced in any other way, the function itself can be deleted.

**Inlining recursive functions.** Inlining \( \text{doList} \) into \( \text{printTable} \) yields this new version of \( \text{printTable} \):

```plaintext
function printTable(l: list, c: cont) =
    if l=nil then c()
    else let function doRest() =
            doList(printDouble, l.tail, c)
        in printDouble(l.head, doRest)
    end
```

This is not so good: \( \text{printTable} \) calls \( \text{printDouble} \) on \( l.\text{head} \), but to process \( l.\text{tail} \) it calls \( \text{doList} \) as before. Thus, we have inline expanded only the first iteration of the loop. We would rather have a fully customized version of \( \text{doRest} \); therefore, we do not inline expand in this way.

For recursive functions we use a *loop-preheader* transformation (Algorithm 15.9). The idea is to split \( f \) into two functions: a *prelude* called from outside, and a *loop header* called from inside. Every call to the loop header will be a recursive call from within itself, except for a single call from the prelude. Applying this transformation to \( \text{doList} \) yields
If every use of \( f' \) within \( B \) is of the form \( f'(E_1, \ldots, E_i-1, a_i, E_{i+1}, \ldots, E_n) \) such that the \( i \)th argument is always \( a_i \), then rewrite

\[
\begin{align*}
\text{function } f(a_1', \ldots, a_n') &= \\
&\text{let function } f'(a_1', \ldots, a_n') = B[a \mapsto f'] \\
&\in f'(a_1', \ldots, a_n') \\
\text{end}
\end{align*}
\]

where every call \( f'(E_1, \ldots, E_{i-1}, a_i, E_{i+1}, \ldots, E_n) \) within \( B \) is rewritten as \( f'(E_{i+1}, \ldots, E_n) \).

**Algorithm 15.10. Loop-invariant hoisting.**

```
function doList(fX: observeInt, lX: list, cX: cont) =
  let function doListX(f: observeInt, l: list, c: cont) =
    if l=nil then c()
    else let function doRest() = doListX(f, l.tail, c)
    in f(l.head, doRest)
  end
  in doListX(fX,lX,cX)
end
```

where the new `doList` is the prelude, and `doListX` is the loop header. Notice that the prelude function contains the entire loop as an internal function, so that when any call to `doList` is inline expanded, a new copy of `doListX` comes along with it.

**Loop-invariant arguments.** In this example, the function `doListX` is passing around the values `f` and `c` that are invariant – they are the same in every recursive call. In each case, \( f \) is \( fX \) and \( c \) is \( cX \). A loop-invariant hoisting transformation (Algorithm 15.10) can replace every use of \( f \) with \( fX \), and \( c \) with \( cX \).

Applying this transformation to `doList` yields
15.4. INLINE EXPANSION

```plaintext
function doList(f: observeInt, lx: list, c: cont) =
    let function doListX(l: list) =
        if l=nil then c()
        else let function doRest() = doListX(l.tail)
            in f(l.head, doRest)
        end
    in doListX(lx)
end
```

Finally, in printTable when the call doList(printDouble, l, c) is inlined, we obtain:

```plaintext
function printTable(l: list, c: cont) =
    let function doListX(l: list) =
        if l=nil then c()
        else let function doRest() = doListX(l.tail)
            in printDouble(l.head, doRest)
        end
    in doListX(l)
end
```

**Cascading inlining.** In this version of printTable, we have printDouble applied to arguments (instead of just passed to doList), so we can inline expand that call, yielding

```plaintext
function printTable(l: list, c: cont) =
    let function doListX(l: list) =
        if l=nil then c()
        else let function doRest() = doListX(l.tail)
            in let var i := l.head
                in let function again() = putInt(i+i, doRest)
                    in putInt(i, again)
                end
            end
        end
    in doListX(l)
end
```

**Avoiding code explosion.** Inline expansion copies function bodies. This generally makes the program bigger. If done indiscriminantly, the size of the program explodes; in fact, it is easy to construct cases where expanding one function call creates new instances that can also be expanded, ad infinitum.
function printTable(l: list, c: cont) =
  let function doListX(l: list) =
    if l=nil then c()
    else let function doRest() =
      doListX(l.tail)
      var i := l.head
      function again() =
        putInt(i+i,doRest)
        in putInt(i,again)
    in doListX(l)
end

PROGRAM 15.11. printTable as automatically specialized.

There are several heuristics that can be used to control inlining:

1. Expand only those function-call sites that are very frequently executed; determine frequency either by static estimation (loop-nest depth) or by feedback from an execution profiler.
2. Expand functions with very small bodies, so that the copied function body is not much larger than the instructions that would have called the function.
3. Expand functions called only once; then dead function elimination will delete the original copy of the function body.

Unnesting lets. Since the Tiger expression

let dec₁ in let dec₂ in exp end end

is exactly equivalent to

let dec₁ dec₂ in exp end

we end up with Program 15.11.

The optimizer has taken a program written with abstraction (with a general-purpose doList) and transformed it into a more efficient, special-purpose program (with a special-purpose doListX that calls putInt directly).

15.5 CLOSURE CONVERSION

A function passed as an argument is represented as a closure: a combination of a machine-code pointer and a means of accessing the nonlocal variables (also called free variables).
Chapter 6 explained the method of static links for accessing free variables, where the static links point directly to the enclosing functions’ stack frames. Figure 15.2 shows that the free variables can be kept in a heap-allocated record, separate from the stack frame. Now, for the convenience of the back end of the compiler, we would like to make the creation and access of those free-variable records explicit in the program.

The closure conversion phase of a functional-language compiler transforms the program so that none of the functions appears to access free (nonlocal) variables. This is done by turning each free-variable access into a formal-parameter access.

Given a function \( f(a_1, \ldots, a_n) = B \) at nesting depth \( d \) with escaping local variables (and formal parameters) \( x_1, x_2, \ldots, x_n \) and nonescaping variables \( y_1, \ldots, y_n \); rewrite into

\[
f(a_0, a_1, \ldots, a_n) = \text{let } \text{var } r := \{a_0, x_1, x_2, \ldots, x_n\} \text{ in } B' \text{ end}
\]

The new parameter \( a_0 \) is the static link, now made into an explicit argument. The variable \( r \) is a record containing all the escaping variables and the enclosing static link. This \( r \) becomes the static-link argument when calling functions of depth \( d + 1 \).

Any use of a nonlocal variable (one that comes from nesting depth \(< d\)) within \( B \) must be transformed into an access of some offset within the record \( a_0 \) (in the rewritten function body \( B' \)).

**Function values.** Function values are represented as closures, comprising a code pointer and environment. Instead of heap allocating a two-word record to hold these two, when the programmer passes a function as an argument, the compiler should pass the code pointer and environment as two adjacent arguments.

Program 15.12 is the result of closure-converting Program 15.11. We can see that each function creates an explicit record to hold escaping variables. In fact, the function doListX creates two different records \( r_2 \) and \( r_3 \), because the variables \( i \) and doRestC are not available at the time \( r_2 \) must be created. Functions in closure-converted programs access only local variables, so that later phases of the compiler need not worry about nonlocal-variable access or static links.

**Unknown types of static links in closures.** The types of all escaping-variable records are given by record declarations at the top of Program 15.12. But
type mainLink = { ⋯ }
type printTableLink = {SL: mainLink, cFunc: cont, cSL: ?}
type cont = ? -> answer
type doListXLink1 = {SL: printTableLink, l: list}
type doListXLink2 = {SL: doListXLink1, i: int,
   doRestFunc: cont, doRestSL: doListXLink1}

function printTable(SL: mainLink, l: list, cFunc: cont, cSL: ?) =
   let var r1 := printTableLink{SL=SL, cFunc=cFunc, cSL=cSL}
   function doListX(SL: printTableLink, l: list) =
      let var r2 := doListXLink1{SL: printTableLink, l=l}
      in if r2.l=nil then SL.cFunc(SL.cSL)
         else let function doRest(SL: doListXLink1) =
               doListX(SL.SL, SL.l.tail)
               var i := r2.l.head
               var r3 := doListXLink2{SL=r2, i=i,
                      doRestFunc=doRest, doRestSL=r2}
               function again(SL: doListXLink2) =
                  putInt(SL.SL.SL, SL.i+SL.i,
                      SL.doRest.func, SL.doRestSL)
               in putInt(SL.SL, i, again,r3)
            end
      in doListX(r1,l)
   end

PROGRAM 15.12. printTable after closure conversion.

what is the type of cont’s static link argument? It must be the type of the
escaping-variable record of the function that encloses the cont function.

But there are several different functions of type cont:

• the c argument of printTable, which comes from main (examination of
  Program 15.6 shows that this will in fact be the exit function);
• doRest;
• and again.

Each of these functions has a different kind of static link record. Thus, the
type of the SL field of contClosure varies, and cannot always be known by
the caller. The type of the static-link argument of the cont type is shown as a
question-mark. That is, although we can write closure-converted Fun-Tiger or
PureFun-Tiger programs in Tiger syntax, these programs do not type-check in
a conventional sense.
15.6 EFFICIENT TAIL RECURSION

Functional programs express loops and other control flow by function calls. Where Program 15.7b has a **while** loop, Program 15.12 has a function call to doListX. Where Program 15.7b’s putInt simply returns to its two points of call within printTable, Program 15.11 has continuation functions. The Fun-Tiger compiler must compile the calls to doListX, doRest, and again as efficiently as the Tiger compiler compiles loops and function returns.

Many of the function calls in Program 15.11 are in **tail position**. A function call \( f(x) \) within the body of another function \( g(y) \) is in tail position if “calling \( f \) is the last thing that \( g \) will do before returning.” More formally, in each of the following expressions, the \( B_i \) are in tail contexts, but the \( C_i \) are not:

1. \( \text{let var } x := C_1 \text{ in } B_1 \text{ end} \)
2. \( C_1(C_2) \)
3. \( \text{if } C_1 \text{ then } B_1 \text{ else } B_2 \)
4. \( C_1 + C_2 \)

For example, \( C_2 \) in expression 4 is not in a tail context, even though it seems to be “last,” because after \( C_2 \) completes there will still need to be an **add** instruction. But \( B_1 \) in expression 3 is in a tail context, even though it is not “last” syntactically.

If a function call \( f(x) \) is in a tail context with respect to its enclosing expression, and that expression is in a tail context, and so on all the way to the body of the enclosing function definition \( \text{function } g(y) = B \), then \( f(x) \) is a tail call.

Tail calls can be implemented more efficiently than ordinary calls. Given

\[
g(y) = \text{let var } x := h(y) \text{ in } f(x) \text{ end}
\]

Then \( h(y) \) is not a tail call, but \( f(x) \) is. When \( f(x) \) returns some result \( z \), then \( z \) will also be the result returned from \( g \). Instead of pushing a new return address for \( f \) to return to, \( g \) could just give \( f \) the return address given to \( g \), and have \( f \) return there directly.

That is, a tail call can be implemented more like a jump than a call. The steps for a tail call are:

1. Move actual parameters into argument registers.
2. Restore callee-save registers.
3. Pop the stack frame of the calling function, *if it has one.*
4. Jump to the callee.
In many cases, item 1 (moving parameters) is eliminated by the copy-propagation (coalescing) phase of the compiler. Often, items 2 and 3 are eliminated because the calling function has no stack frame – any function that can do all its computation in caller-save registers needs no frame. Thus, a tail call can be as cheap as a jump instruction.

In Program 15.12, every call is a tail call! Also, none of the functions in this program needs a stack frame. This need not have been true; for example, the call to double in Program 15.6 is not in tail position, and this nontail call only disappeared because the inline expander did away with it.

Tail calls implemented as jumps. The compilation of Programs 15.12 and 15.7b is instructive. Figure 15.13 shows that the pure-functional program and the imperative program are executing almost exactly the same instructions! The figure does not show the functional program’s fetching from static-link records; and it does not show the imperative program’s saving and restoring callee-save registers.

The remaining inefficiency in the functional program is that it creates three heap-allocated records, r1, r2, r3, while the imperative program creates only one stack frame. However, more advanced closure-conversion algorithms can succeed in creating only one record (at the beginning of printTable). So the difference between the two programs would be little more than a heap-record creation versus a stack-frame creation.

Allocating a record on the garbage-collected heap may be more expensive.
than pushing and popping a stack frame. Optimizing compilers for functional languages solve this problem in different ways:

- Compile-time *escape analysis* can identify which closure records do not outlive the function that creates them. These records can be stack-allocated. In the case of `printTable`, this would make the “functional” code almost identical to the “imperative” code.
- Or heap allocation and garbage collection can be made extremely cheap. Then creating (and garbage-collecting) a heap-allocated record takes only four or five instructions, making the functional `printTable` almost as fast as the imperative one (see Section 13.7).

### 15.7 LAZY EVALUATION

Equational reasoning aids in understanding functional programs. One important principle of equational reasoning is *β-substitution*: if \( f(x) = B \) with some function body \( B \) then any application \( f(E) \) to an expression \( E \) is equivalent to \( B \) with every occurrence of \( x \) replaced with \( E \):

\[
f(x) = B \quad \text{implies that} \quad f(E) \equiv B[x \mapsto E]
\]

But consider the PureFun-Tiger program fragments,

```plaintext
let
  function loop(z:int):int=
    if z>0 then z
    else loop(z)
function f(x:int):int=
  if y>8 then x
  else -y
in
  f(loop(y))
end
```

If the expression \( B \) is \( \text{if } y>8 \text{ then } x \text{ else } -y \), and expression \( E \) is \( \text{loop}(y) \), then clearly the program on the left contains \( f(E) \) and the program on the right contains \( B[x \mapsto E] \). So these programs are equivalent, using equational reasoning.

However, *the programs do not always behave the same!* If \( y = 0 \), then the program on the right will return 0, but the program on the left will first get stuck in a call to \( \text{loop}(0) \), which infinite-loops.
Clearly, if we want to claim that two programs are equivalent then they
must behave the same. In PureFun-Tiger, if we obtain program \( A \) by doing
substitution on program \( B \), then \( A \) and \( B \) will never give different results if they
both halt; but \( A \) or \( B \) might not halt on the same set of inputs.

To remedy this (partial) failure of equational reasoning, we can introduce
\textit{lazy evaluation} into the programming language. Haskell and Miranda are the
most widely used lazy languages. A program compiled with lazy evaluation
will not evaluate any expression unless its value is demanded by some other
part of the computation. In contrast, \textit{strict} languages such as Tiger, PureFun-
Tiger, ML, C, and Java evaluate each expression as the control flow of the
program reaches it.

To explore the compilation of lazy functional languages, we will use the
Lazy-Tiger language. Its syntax is identical to PureFun-Tiger, and its seman-
tics are almost identical, except that lazy evaluation is used in compiling it.

**CALL-BY-NAME EVALUATION**

Most programming languages (Pascal, C, ML, Java, Tiger, PureFun-Tiger) use
\textit{call-by-value} to pass function arguments: to compute \( f (g(x)) \), first \( g(x) \)
is computed, and this value is passed to \( f \). But if \( f \) did not actually need to
use its argument, then computing \( g(x) \) will have been unnecessary.

To avoid computing expressions before their results are needed, we can use
\textit{call-by-name} evaluation. Essentially, each variable is not a simple value,
but is a \textit{thunk}: a function that computes the value on demand. The compiler
replaces each expression of type \texttt{int} with a function value of type \texttt{() -> int},
and similarly for all other types.

At each place where a variable is created, the compiler creates a function
value; and everywhere a variable is used, the compiler puts a function appli-
cation.

Thus the Lazy-Tiger program

\begin{verbatim}
let var a := 5+7 in a + 10 end
\end{verbatim}

is automatically transformed to

\begin{verbatim}
let function a() = 5+7 in a() + 10 end
\end{verbatim}

Where are variables created? At \texttt{var} declarations and at function-parameter
bindings. Thus, each \texttt{var} turns into a \texttt{function}, and at each function-call
site, we need a little \texttt{function} declaration for each actual-parameter expres-
sion.
15.7. LAZY EVALUATION

```plaintext
type tree = {key: () -> key,
            binding: () -> binding,
            left: () -> tree,
            right: () -> tree}

function look(t: () -> tree, k: () -> key) : () -> binding =
    if k() < t().key() then look(t().left, k)
    else if k() > t().key() then look(t().right, k)
    else t().binding
```

PROGRAM 15.14. Call-by-name transformation applied to Program 15.3a.

Program 15.14 illustrates this transformation applied to the `look` function of Program 15.3a.

The problem with call-by-name is that each thunk may be executed many times, each time (redundantly) yielding the same value. For example, suppose there is a tree represented by a thunk `t1`. Each time `look(t1, k)` is called, `t1()` is evaluated, which rebuilds the (identical) tree every time!

CALL-BY-NEED

Lazy evaluation, also called `call-by-need`, is a modification of call-by-name that never evaluates the same thunk twice. Each thunk is equipped with a `memo` slot to store the value. When the thunk is first created, the memo slot is empty. Each evaluation of the thunk checks the memo slot: if full, it returns the memo-ized value; if empty, it calls the thunk function.

To streamline this process, we will represent a lazy thunk as a two-element record containing a `thunk function` and a `memo slot`. An unevaluated thunk contains an arbitrary thunk function, and the memo slot is a static link to be used in calling the thunk function. An evaluated thunk has the previously computed value in its memo slot, and its thunk function just returns the memo-slot value.

For example, the Lazy-Tiger declaration `var twenty:=addFive(15)` (in Program 15.1) is compiled in a context where the environment pointer `EP` will point to a record containing the `addFive` function. The representation of `addFive(15)` is not a function call that will go and compute the answer now, but a thunk that will remember how to compute it on demand, later. We might translate this fragment of the Lazy-Tiger program into Fun-Tiger as follows:

```plaintext
/* EP already points to a record containing addFive */
var twenty := intThunk{func=twentyFunc, memo=EP}
```
which is supported by the auxiliary declarations

```plaintext
type intThunk = {func: ?->int, memo: ?}
type intfunc = {func: (?,intThunk)->int, SL: ?}
type intfuncThunk = {func: ?->intfunc, memo: ?}
```

```plaintext
function evaluatedFunc(th: intThunk) : int =
    th.memo

function twentyFunc(mythunk: intThunk) : int =
    let var EP := mythunk.memo
        var add5thunk : intfuncThunk := EP.addFive
        var add5 : intfunc := add5thunk.func(add5thunk)
        var fifteenThunk:=intThunk{func=evaluatedFunc,memo=15}
        var result : int := add5.func(add5.SL, fifteenThunk)
    in mythunk.memo := result;
        mythunk.func := evaluatedFunc;
        result
end
```

To touch a lazy thunk \( t \), we just compute \( t . func(t) \). For \( t = twenty \), the first time \( t \) is touched, \( twentyFunc(twenty) \) will execute, making \( twenty.memo \) point at the integer result computed by \( addFive(15) \) and making \( twenty.func \) point to the special function \( evaluatedFunc \). Any subsequent time that \( twenty \) is touched, \( evaluatedFunc \) will simply return the \( twenty.memo \) field, which will contain the integer 20.

**EVALUATION OF A LAZY PROGRAM**

Here is a program that uses the `enter` function of Program 15.3b to build a tree mapping \{ three \( \mapsto \) 3!, minusOne \( \mapsto \) \((-1)!)\}:

```plaintext
let function fact(i: int) : int =
    if i=0 then 1 else i * fact(i-1)
    var t1 := enter(nil, "minusOne", fact(-1))
    var t2 := enter(t1, "three", fact(3))
    in putInt(look(t2,"three"), exit)
end
```

A curious thing about this program is that \( fact(-1) \) is undefined. Thus, if this program is compiled by a (strict) PureFun-Tiger compiler, it will infinite-loop (or will eventually overflow the machine’s arithmetic as it keeps subtracting 1 from a negative number).

But if compiled by a Lazy-Tiger compiler, the program will succeed, returning three factorial! First, variable \( t_1 \) is defined; but this does not actually
call enter—it merely makes a thunk which will do so on demand. Then, \texttt{t2} is defined, which also does nothing but make a thunk. Then a thunk is created for \texttt{look(t2,"three")} (but \texttt{look} is not actually called).

Finally, a thunk for the expression \texttt{putInt(...,exit)} is created. This is the result of the program. But the runtime system then “demands” an answer from this program, which can be computed only by calling the outermost thunk. So the body of \texttt{putInt} executes, which immediately demands the integer value of its first argument; this causes the \texttt{look(t2,"three")} thunk to evaluate.

The body of \texttt{look} needs to compare \texttt{k} with \texttt{t.key}. Since \texttt{k} and \texttt{t} are each thunks, we can compute an integer by evaluating \texttt{k()} and a tree by evaluating \texttt{t()}. From the tree we can extract the \texttt{key} field, but each field is a thunk, so we must actually do \texttt{(t().key)()} to get the integer.

The \texttt{t.key} value will turn out to be \texttt{-1}, so \texttt{look(t().right,k)} is called. The program never evaluates the binding thunk in the \texttt{minusOne node}, so \texttt{fact(-1)} is never given a chance to infinite-loop.

### OPTIMIZATION OF LAZY FUNCTIONAL PROGRAMS

Lazy functional programs are subject to many of the same kinds of optimizations as strict functional programs, or even imperative programs. Loops can be identified (these are simply tail-recursive functions), induction variables can be identified, common subexpressions can be eliminated, and so on.

In addition, lazy compilers can do some kinds of optimizations that strict-functional or imperative compilers cannot, using equational reasoning.

**Invariant hoisting.** For example, given a loop

```plaintext
type intfun = int->int

function f(i: int) : intfun =
  let function g(j: int) = h(i) * j
      in g
  end
```

an optimizer might like to hoist the invariant computation \texttt{h(i)} out of the function \texttt{g}. After all, \texttt{g} may be called thousands of times, and it would be better not to recompute \texttt{h(i)} each time. Thus we obtain
type intfun = int->int

function f(i: int) : intfun =
    let var hi := h(i)
        function g(j: int) = hi * j
    in g
end

and now each time g is called, it runs faster.

This is valid in a lazy language. But in a strict language, this transformation is invalid! Suppose after var a := f(8) the function a is never called at all; and suppose h(8) infinite-loops; before the “optimization” the program would have terminated successfully, but afterward we get a nonterminating program. Of course, the transformation is also invalid in an impure functional language, because h(8) might have side effects, and we are changing the number of times h(8) is executed.

**Dead-code removal.** Another subtle problem with strict programming languages is the removal of dead code. Suppose we have

function f(i: int) : int =
    let var d := g(x)
    in i+2
end

The variable d is never used; it is *dead* at its definition. Therefore, the call to g(x) should be removed. In a conventional programming language, such as Tiger or Fun-Tiger, we cannot remove g(x) because it might have side effects that are necessary to the operation of the program.

In a strict, purely functional language such as PureFun-Tiger, removing the computation g(x) could optimize a nonterminating computation into a terminating one! Though this seems benign, it can be very confusing to the programmer. We do not want programs to change their input/output behavior when compiled with different levels of optimization.

In a lazy language, it is perfectly safe to remove dead computations such as g(x).

**Deforestation.** In any language, it is common to break a program into one module that produces a data structure and another module that consumes it. Program 15.15 is a simple example; range(i,j) generates a list of the integers from i to j, squares(l) returns the square of each number, and sum(l) adds up all the numbers.
15.7. LAZY EVALUATION

type intList = {head: int, tail: intList}
type intfun = int->int
type int2fun = (int,int) -> int

function sumSq(inc: intfun, mul: int2fun, add: int2fun) : int =
  let
    function range(i: int, j: int) : intList =
      if i>j then nil else intList{head=i, tail=range(inc(i),j)}
    function squares(l: intList) : intList =
      if l=nil then nil
      else intList{head=mul(l.head,l.head), tail=squares(l.tail)}
    function sum(accum: int, l: intList) : int =
      if l=nil then accum else sum(add(accum,l.head), l.tail)
  in sum(0,squares(range(1,100)))
end

PROGRAM 15.15. Summing the squares.

First range builds a list of 100 integers; then squares builds another list
of 100 integers; finally sum traverses this list.

It is wasteful to build these lists. A transformation called deforestation
removes intermediate lists and trees (hence the name) and does everything in
one pass. The deforested sumSq program looks like this:

function sumSq(inc:intfun, mul:int2fun, add:int2fun):int =
  let function f(accum: int, i: int, j: int) : int =
    if i>j then accum else f(add(accum,mul(i,i)),inc(i))
  in f(0,1,100)
end

In impure functional languages (where functions can have side effects) de-
forestation is not usually valid. Suppose, for example, that the functions inc,
mul, and add alter global variables, or print on an output file. The defor-
estation transformation has rearranged the order of calling these functions;
instead of

inc(1), inc(2), ... inc(100),
mul(1,1), mul(2,2), ... mul(100,100),
add(0,1), add(1,4), ... add(328350,10000)
the functions are called in the order

\[
\begin{align*}
\text{mul}(1, 1), & \quad \text{add}(0, 1), & \quad \text{inc}(1), \\
\text{mul}(2, 2), & \quad \text{add}(1, 4), & \quad \text{inc}(2), \\
\quad & \quad \ldots \\
\text{mul}(100, 100), & \quad \text{add}(328350, 10000), & \quad \text{inc}(100)
\end{align*}
\]

Only in a pure functional language is it always legal to make this transformation.

**STRICTNESS ANALYSIS**

Although laziness allows certain new optimizations, the overhead of thunk creation and thunk evaluation is very high. If no attention is paid to this problem, then the lazy program will run slowly no matter what other optimizations are enabled.

The solution is to put thunks only where they are needed. If a function \( f(x) \) is certain to evaluate its argument \( x \), then there is no need to pass a thunk for \( x \); we can just pass an evaluated \( x \) instead. We are trading an evaluation now for a certain eventual evaluation.

**Definition of strictness.** We say a function \( f(x) \) is *strict in* \( x \) if, whenever some actual parameter \( a \) would fail to terminate, then \( f(a) \) would also fail to terminate. A multi-argument function \( f(x_1, \ldots, x_n) \) is strict in \( x_i \) if, whenever \( a \) would fail to terminate, then \( f(b_1, \ldots, b_{i-1}, a, b_{i+1}, \ldots, b_n) \) also fails to terminate, regardless of whether the \( b_j \) terminate.

Let us take an example:

\[
\begin{align*}
\text{function } f(x: \text{int}, y: \text{int}) : \text{int} & = x + x + y \\
\text{function } g(x: \text{int}, y: \text{int}) : \text{int} & = \text{if } x>0 \text{ then } y \text{ else } x \\
\text{function } h(x: \text{string}, y: \text{int}) : \text{tree} & = \\
& \quad \text{tree\{key=x, binding=y, left=nil, right=nil\}} \\
\text{function } j(x: \text{int}) : \text{int} & = j(0)
\end{align*}
\]

The function \( f \) is *strict* in its argument \( x \), since if the result \( f(x, y) \) is demanded then \( f \) will certainly touch (demand the value of) \( x \). Similarly, \( f \) is strict in argument \( y \), and \( g \) is strict in argument \( x \). But \( g \) is not strict in its second argument, because \( g \) can sometimes compute its result without touching \( y \).
function look(t: tree, k: key) : () -> binding =  
  if k < t.key() then look(t.left(),k)  
  else if k > t.key() then look(t.right(),k)  
  else t.binding

PROGRAM 15.16. Partial call-by-name using the results of strictness analysis; compare with Program 15.14.

The function $h$ is not strict in either argument. Even though it appears to “use” both $x$ and $y$, it does not demand (string or integer) values from them; instead it just puts them into a data structure, and it could be that no other part of the program will ever demand values from the key or binding fields of that particular tree.

Curiously, by our definition of strictness, the function $j$ is strict in $x$ even though it never uses $x$. But the purpose of strictness analysis is to determine whether it is safe to evaluate $x$ before passing it to the function $j$: will this cause a terminating program to become nonterminating? In this case, if $j$ is going to be called, it will infinite-loop anyway, so it doesn’t matter if we perform a (possibly nonterminating) evaluation of $x$ beforehand.

Using the result of strictness analysis. Program 15.16 shows the result of transforming the look function (of Program 15.3a) using strictness information. A call-by-name transformation has been applied here, as in Program 15.14, but the result would be similar using call-by-need. Function look is strict in both its arguments $t$ and key. Thus, when comparing $k < t.key$, it does not have to touch $k$ and $t$. However, the $t.key$ field still points to a thunk, so it must be touched.

Since look is strict, callers of look are expected to pass evaluated values, not thunks. This is illustrated by the recursive calls, which must explicitly touch $t.left$ and $t.right$ to turn them from thunks to values.

Approximate strictness analysis. In some cases, such as the functions $f, g, h$ above, the strictness or nonstrictness of a function is obvious – and easily determined by an optimizing compiler. But in general, exact strictness analysis is not computable – like exact dynamic liveness analysis (see page 225) and many other dataflow problems.

Thus, compilers must use a conservative approximation; where the exact strictness of a function argument cannot be determined, the argument must be assumed nonstrict. Then a thunk will be created for it; this slows down the
Function $M$:

\[
M(7, \sigma) = 1 \\
M(x, \sigma) = x \in \sigma \\
M(E_1 + E_2, \sigma) = M(E_1, \sigma) \land M(E_2, \sigma) \\
M(\text{record}(E_1, \ldots, E_n), \sigma) = 1 \\
M(\text{if } E_1 \text{ then } E_2 \text{ else } E_3, \sigma) = M(E_1, \sigma) \land (M(E_2, \sigma) \lor M(E_3, \sigma)) \\
M(f(E_1, \ldots, E_n), \sigma) = (f, (M(E_1, \sigma), \ldots, M(E_n, \sigma))) \in H
\]

Calculation of $H$:

$H \leftarrow \{\}$

repeat

\[
done \leftarrow \text{true}
\]

for each function $f(x_1, \ldots, x_n) = B$

for each sequence $(b_1, \ldots, b_n)$ of booleans (all $2^n$ of them)

if $(f, (b_1, \ldots, b_n)) \notin H$

\[
\sigma \leftarrow \{x_i \mid b_i = 1\} \\
\begin{aligned}
\sigma & \text{ is the set of } x \text{’s corresponding to } 1 \text{’s in the } b \text{ vector} \\
done & \leftarrow \text{false}
\end{aligned}
\]

$H \leftarrow H \cup \{(f, (b_1, \ldots, b_n))\}$

until $done$

Strictness (after the calculation of $H$ terminates):

$f$ is strict in its $i$th argument if

\[
(f, 1, 1, \ldots, 1, 0, 1, 1, \ldots, 1) \notin H
\]

**Algorithm 15.17.** First-order strictness analysis.

program a bit, but at least the optimizer will not have turned a terminating program into an infinite-looping program.

Algorithm 15.17 shows an algorithm for computing strictness. It maintains a set $H$ of tuples of the form $(f, (b_1, \ldots, b_n))$, where $n$ is the number of arguments of $f$ and the $b_i$ are booleans. The meaning of a tuple $(f, (1, 1, 0))$ is this: if $f$ is called with three arguments (thunks), and the first two may halt but the third never halts, then $f$ may halt.
If \((f, (1, 1, 0))\) is in the set \(H\), then \(f\) might not be strict in its third argument. If \((f, (1, 1, 0))\) is never put into \(H\), then \(f\) must be strict in its third argument.

We also need an auxiliary function to calculate whether an expression may terminate. Given an expression \(E\) and a set of variables \(\sigma\), we say that \(M(E, \sigma)\) means “\(E\) may terminate if all the variables in \(\sigma\) may terminate.” If \(E_1\) is \(i+j\), and there is some possibility that the thunks \(i\) and \(j\) may halt, then it is also possible that \(E_1\) will halt too: \(M(i + j, \{i, j\})\) is true. But if \(E_2\) is \(\text{if } k \text{ then } i \text{ else } j\), where \(i\) and \(j\) could conceivably halt but \(k\) never does, then certainly \(E_2\) will not halt, so \(M(E_2, \{i, j\})\) is false.

Algorithm 15.17 will not work on the full Lazy-Tiger language, because it does not handle functions passed as arguments or returned as results. But for first-order programs (without higher-order functions), it does a good job of computing (static) strictness. More powerful algorithms for strictness analysis handle higher-order functions.

Church [1941] developed the \(\lambda\)-calculus, a “programming language” of nested functions that can be passed as arguments and returned as results. He was hampered by having no machines to compile for.

**Closures.** Landin [1964] showed how to interpret \(\lambda\)-calculus on an abstract machine, using closures allocated on a heap. Steele [1978] used closure representations specialized to different patterns of function usage, so that in many cases nonlocal variables are passed as extra arguments to an inner function to avoid heap allocating a record. Cousineau et al. [1985] showed how closure conversion can be expressed as a transformation back into the source language, so that closure analysis can be cleanly separated from other phases of code generation.

Static links are actually not the best basis for doing closure conversion; for many reasons it is better to consider each nonlocal variable separately, instead of always grouping together all the variables at the same nesting level. Kranz et al. [1986] performed escape analysis to determine which closures can be stack-allocated because they do not outlive their creating function and also integrated closure analysis with register allocation to make a high-performance optimizing compiler. Shao and Appel [1994] integrate closures with the use of callee-save registers to minimize the load/store traffic caused by accessing...
local and nonlocal variables. Appel [1992, Chapters 10 and 12] has a good overview of closure conversion.

**Continuations.** Tail calls are particularly efficient and easy to analyze. Stra-chey and Wadsworth [1974] showed that the control flow of any program (even an imperative one) can be expressed as function calls, using the notion of continuations. Steele [1978] transformed programs into continuation-passing style early in compilation, turning all function calls into tail calls, to simplify all the analysis and optimization phases of the compiler. Kranz et al. [1986] built an optimizing compiler for Scheme using continuation-passing style; Appel [1992] describes a continuation-based optimizing compiler for ML.

**Inline expansion.** Cocke and Schwartz [1970] describe inline expansion of function bodies; Scheifler [1977] shows that it is particularly useful for languages supporting data abstraction, where there tend to be many tiny functions implementing operations on an abstract data type. Appel [1992] describes practical heuristics for controlling code explosion.

**Continuation-based I/O.** Wadler [1995] describes the use of monads to generalize the notion of continuation-based interaction.

Several lazy pure-functional languages were developed in the 1980s; the community of researchers in this area designed and adopted the language Haskell [Hudak et al. 1992] as a standard. Peyton Jones [1987; 1992] describes many implementation and optimization techniques for lazy functional languages; Peyton Jones and Partain [1993] describe a practical algorithm for higher-order strictness analysis. Wadler [1990] describes deforestation.

**PROGRAM COMPILING FUNCTIONAL LANGUAGES**

a. Implement Fun-Tiger. A function value can be allocated as a heap-allocated
EXERCISES

two-element record, containing function-address and static-link fields.
b. Implement PureFun-Tiger. This is just like Fun-Tiger, except that several “im-
pure” features are removed and the predefined functions have different inter-
faces.
c. Implement optimizations on PureFun-Tiger. This requires changing the Tree
intermediate language so that it can represent an entire program, including
function entry and exit, in a machine-independent way. After inline expansion
(and other) optimizations, the program can be converted into the standard
Tree intermediate representation of Chapter 7.
d. Implement Lazy-Tiger.

EXERCISES

15.1 Draw a picture of the closure data structures representing add24 and a in
Program 15.1 just at the point where add24 (a) is about to be called. Label all
the components.

*15.2 Figure 15.13 summarizes the instructions necessary to implement printTable
in a functional or an imperative style. But it leaves out the MOVE instructions
that pass parameters to the calls. Flesh out both the functional and imperative
versions with all omitted instructions, writing pseudo-assembly language in the
style of the program accompanying Graph 11.1 on page 237. Show which
MOVE instructions you expect to be deleted by copy propagation.

*15.3 Explain why there are no cycles in the graph of closures and records of
a PureFun-Tiger program. Comment on the applicability of reference-count
garbage collection to such a program. Hint: Under what circumstances are
records or closures updated after they are initialized?

15.4 a. Perform Algorithm 15.9 (loop-preheader transformation) on the look
function of Program 15.3a.
b. Perform Algorithm 15.10 (loop-invariant hoisting) on the result.
c. Perform Algorithm 15.8 (inline expansion) on the following call to look
(assuming the previous two transformations have already been applied):
look(mytree, a+1)

15.5 Perform Algorithm 15.17 (strictness analysis) on the following program, showing
the set $H$ on each pass through the repeat loop.

function f(w: int, x: int, y: int, z: int) =
    if z=0 then w+y else f(x,0,0,z-1) + f(y,y,0,z-1)

In which arguments is $f$ strict?
Polymorphic Types

poly-mor-phi c: able to assume different forms

Webster’s Dictionary

Some functions execute in a way that’s independent of the data type on which they operate. Some data structures are structured in the same way regardless of the types of their elements.

As an example, consider a function to concatenate linked lists in Tiger. We first define a linked-list data type, and then an `append` function:

```plaintext
type elem = int
type intlist = {head: elem, tail: intlist}

function append(a: intlist, b: intlist) : intlist =
  if a=nil
    then b
  else intlist{head= a.head, tail= append(a.tail,b)}
```

There’s nothing about the code for the `intlist` data type or the `append` function that would be any different if the `elem` type were `string` or `tree` instead. We might like `append` to be able to work on any kind of list.

A function is polymorphic (from the Greek many+shape) if it can operate on arguments of different types. There are two main kinds of polymorphism:

**Parametric polymorphism.** A function is parametrically polymorphic if it follows the same algorithm regardless of the type of its argument. The Ada or Modula-3 generic mechanism, C++ templates, or ML type schemes are examples of parametric polymorphism.

**Overloading.** A function identifier is overloaded if it stands for different algorithms depending on the type of its argument. For example, in most languages...
+ is overloaded, meaning integer addition on integer arguments and floating-point addition (which is quite a different algorithm) on floating-point arguments. In many languages, including Ada, C++, and Java, programmers can make overloaded functions of their own.

These two kinds of polymorphism are quite different – almost unrelated – and require different implementation techniques.

### 16.1. PARAMETRIC POLYMORPHISM

A polymorphic function $f(x : t)$ takes some parameter $x$ of type $t$, where $t$ can be instantiated at different actual types. In an *explicit* style of parametric polymorphism, we pass the type as an argument to the function, so we write something like $f<t>(x : t)$, and a function call might look like $f<int>(3)$ or $f<string>("three")$. In a language with *implicit* parametric polymorphism, we simply write the definition as $f(x)$, and the call as $f(3)$ or $f("three")$ – the type-parameter $t$ is unstated. Reasonable programming languages can be designed either way.

Even when compiling an implicitly typed language, it makes sense to use an explicitly typed language as the intermediate representation, as shown in [Figure 16.1](#). One of the biggest advantages of an *explicitly typed intermediate language* is that the intermediate representation is type-checkable, unlike the Read language described in Chapter 7. This means that after each optimization phase the type-checker can be run again – not to debug the program being compiled, but to debug the compiler!

**Trust, but verify.** A typed intermediate form allows the recipient of a partially compiled (and optimized) program to check it for safety and security; this is an important principle of Web applets. A Java program, for example,
can be compiled into an intermediate form called Java virtual machine byte codes; the semi-compiled program is transmitted to a user’s machine, where it can still be type-checked by a byte-code verifier. Then the byte-code program is either interpreted or translated to native machine code. Type-checking of byte codes (or other transmitted intermediate representation) means that the user of an applet does not have to take it on faith that the applet will not subvert security by violating the type system. But Java does not have parametric polymorphism; in this chapter we will show a typed intermediate form for a polymorphic programming language.

To investigate polymorphism, let us make an explicitly polymorphic language Poly-Tiger, and an implicitly polymorphic language ImplicitPoly-Tiger, both based on the functional language Fun-Tiger described in Chapter 15. The explicitly typed abstract syntax for both languages will be similar to Poly-Tiger.

AN EXPLICITLY TYPED POLYMORPHIC LANGUAGE
Poly-Tiger is the Tiger language described in Appendix A, but with different syntax for declarations and types, and two new kinds of expressions, as shown in Grammar 16.2. Like Fun-Tiger, Poly-Tiger has function types ty->ty (as shown in the function type, multi-argument function type, and no-argument function type rules of Grammar 16.2), and function-calling syntax exp_f (exp_1, ..., exp_n) that allows exp_f to be an expression, not just an identifier.

For Poly-Tiger we add several new kinds of types ty. A polymorphic type poly<a>T can behave like type T for any a. For example, poly<a>a->a is the type of a function that, for any a, can take a parameter of type a and return a result of type a.

We also need a way to build polymorphic data structures. Therefore we add new rules for parametric type constructor and type construction: the declaration type id tyvars = ty declares a parameterized type id; any type variables occurring in the right-hand-side ty must be from the explicit type parameters tyvars.

With this, we can make the “list of anything:”

```
type list<e> = {head: e, tail: list<e>}
```

Note that list is not a type – it is a type constructor (tycon for short), declared by the programmer as shown here. But for any type T, list<T> is a type.
16.1. PARAMETRIC POLYMORPHISM

\[ \begin{align*}
\text{ty} & \rightarrow \text{id} & \text{Type identifier} \\
\text{ty} & \rightarrow \text{ty -> ty} & \text{Function type} \\
\text{ty} & \rightarrow (\text{ty}, \text{ty}) \rightarrow \text{ty} & \text{Multi-argument function type} \\
\text{ty} & \rightarrow () \rightarrow \text{ty} & \text{No-argument function type} \\
\text{ty} & \rightarrow \text{poly tyvars ty} & \text{Polymorphic type} \\
\text{ty} & \rightarrow ty \text{tyargs} & \text{Type construction} \\
\text{tyvars} & \rightarrow <\text{id}, \text{id}> & \text{Formal type parameters} \\
\text{tyargs} & \rightarrow \epsilon & \text{No type parameters} \\
\text{tyargs} & \rightarrow <\text{ty}, \text{ty}> & \text{Type arguments} \\
\text{vardec} & \rightarrow \text{var id : ty := exp} & \text{Variable declaration with type} \\
\text{tydec} & \rightarrow \text{type id tyvars = ty} & \text{Parametric type constructor} \\
\text{tydec} & \rightarrow \text{type id tyvars = array of ty} & \text{Array type expression} \\
\text{tydec} & \rightarrow \text{type id tyvars = { tyfields } } & (\text{these braces stand for themselves}) \\
\text{tyfields} & \rightarrow \epsilon & \text{Empty record type} \\
\text{tyfields} & \rightarrow id : ty \{, id : ty \} & \text{Record type fields} \\
\text{fundec} & \rightarrow \text{function id tyvars ( tyfields ) = exp} & \text{Polymorphic procedure declaration} \\
\text{fundec} & \rightarrow \text{function id tyvars ( tyfields ) : id = exp} & \text{Polymorphic function declaration} \\
\text{exp} & \rightarrow \ldots & \text{all the Tiger expressions, plus \ldots} \\
\text{exp} & \rightarrow \text{exp tyargs ( exp \{, exp \} )} & \text{Function call with instantiation} \\
\text{exp} & \rightarrow \text{type-id tyargs \{id=exp\{, id=exp\}\} } & \text{Record creation with type instantiation}
\end{align*} \]

To construct a record from a polymorphic record-type constructor, the record creation with type instantiation rule requires a type argument before the record-field initializers. Thus, for example, we can make a list<int> record by

\[ \text{list\{int\}\{head=4, tail=nil\}} \]

The function call with instantiation allows us to call a polymorphic function. Now we are prepared to write a polymorphic append function:

\[ \begin{align*}
\text{type list<e> = \{head: e, tail: list<e>\}} \\
\text{function append<e>(a: list<e>, b: list<e>) : list<e> =} \\
\text{if a=nil} \\
\text{then b} \\
\text{else list<e>{head= a.head, tail= append<e>(a.tail,b)}}
\end{align*} \]
polymorphic types

(a) Monomorphic

(b) Polymorphic

FIGURE 16.3. Types module. (a) Summary of Program 5.8; the word unique in the Record and Array types indicates that we used a pointer-equality test to distinguish one type from another. (b) With new App, Var, Poly types, and with type constructors.

The type of append is poly<e>(list<e>, list<e>) -> list<e>. Now let’s build a list of two 4’s:

var one4 : list<int> := list<int>{head=4, tail=nil}
var two4s : list<int> := append<int>(one4, one4)

We can even build a list of int-lists:

list<list<int>>{head=two4s, tail=nil}

POLYMORPHIC TYPE-CHECKING

Type-checking for a polymorphic language is not as straightforward as for a monomorphic language. Before embarking on an implementation, we must be clear about what the typing rules are.

For Tiger, we used a Types module (Program 5.8) to describe monomorphic types. To describe the types of Poly-Tiger, we use a new Types module as summarized in Figure 16.3.

There are some important differences. We now have an App type to apply a tycon (such as list) to type arguments (such as <int>). To simplify the internal representation of types, we think of int as a type constructor that takes zero type arguments; so even though it’s not written this way in Poly-Tiger syntax, internally we represent it as App(Int, []). The two-argument Arrow tycon represents functions, so that $a \rightarrow b$ is represented as App(Arrow, [a, b]).
16.1. Parametric Polymorphism

Substitution. The type-constructor \( \text{TyFun}(\alpha_1, \ldots, \alpha_n, t) \) represents a type function. Type \( t \) may mention \( \alpha_1 \ldots \alpha_n \), and the meaning of any \( \text{App} \) type using this \( \text{tycon} \) is found by expanding \( t \), substituting actual type arguments for the formal parameters \( \alpha_i \). The rules for this substitution are given in Algorithm 16.4.

The basic idea of substitution is that substituting \( t_1 \) for \( \beta_1 \) in a type expression \( t \) replaces all the occurrences of \( \beta_1 \) within \( t \) by \( t_1 \). But this must be done subject to scope rules to avoid variable capture. If the type \( t \) is \( \text{Poly}(\beta_1, \text{list}<\beta_1>) \), then the formal parameter \( \beta_1 \) of the \( \text{Poly} \) is a new variable whose scope is the body of the \( \text{Poly} \) (e.g. \( \text{list}<\beta_1> \)), and no substitution for \( \beta_1 \) should occur within that scope.

The problem of variable capture for expressions is described in Section 15.4 (page 327). Type substitution requires \( \alpha \)-conversion in the same way as term (i.e., expression) substitution. To avoid capture, we introduce the new variables \( \gamma_1, \ldots, \gamma_n \) in the \( \text{Poly} \) rule of Algorithm 16.4.

Equivalence of types. Given the declarations

```latex
type number = int
type transformer<e> = e -> e
```

then number means just the same as int, and transformer<int> means the same as int->int; we can freely substitute the definitions of these types for their uses. This is called **structural equivalence of types**.

The internal representation of these type constructors is

\[
\begin{align*}
\text{number} & \mapsto \text{Int} \\
\text{transformer} & \mapsto \text{TyFun}([e], \text{App}(	ext{Arrow}, [\text{Var}(e), \text{Var}(e)]))
\end{align*}
\]

In Poly-Tiger we wish to preserve the “record distinction” rule of the Tiger language (page 519), that each record-type declaration creates a “new” type. This is called **occurrence equivalence of types**. That is, given the declarations

\[
\begin{align*}
type \text{pair}<a>&=\{\text{first}: a, \text{second}: a\} \\
type \text{twosome}<a>&=\{\text{first}: a, \text{second}: a\}
\end{align*}
\]

the types pair<int> and twosome<int> are *not* the same. Structural versus occurrence equivalence is a decision that each language designer must make; record types in ML, for example, use structural equivalence.

In ordinary Tiger, **Record** types are distinguished by the pointer values of the Ty_record structures that represent them internally. But in a polymorphic language, we may need to copy record descriptions when we apply them to arguments. In the following program,

\[
\begin{align*}
\text{let type \text{pair}<z>&=\{\text{first}: z, \text{second}: z\} \\
&\text{function } f(a: \text{pair<int>}) : \text{pair<int>} = a \\
&\text{in } f \\
&\text{end}
\end{align*}
\]

the first line creates a new **type constructor** pair, not a new type. We want pair<int> (the parameter type) to be the same type as pair<int> (the result type); but pair<string> must be recognized as a different type.

To express the internal structure of the pair type-constructor, we could write,

\[
\begin{align*}
tycon_{p} &= \text{TyFun}([z], \text{App}(	ext{Record}([\text{first}, \text{second}]), [\text{Var}(z), \text{Var}(z)]))
\end{align*}
\]

but this would not distinguish pair from twosome. Therefore, we wrap a **Unique** tycon around it:

\[
\begin{align*}
tycon_{\text{pair}} &= \text{Unique}(tycon_{p}, q_{323}) \\
tycon_{\text{twosome}} &= \text{Unique}(tycon_{p}, q_{324})
\end{align*}
\]

\footnote{Sometimes this has been called *name equivalence*, but in fact it is the occurrence of a definition that “generates” the new type, not the name to which it is bound.}
16.1. PARAMETRIC POLYMORPHISM

**Algorithm 16.5.** Testing for equivalence of types. This function may print an error message but has no other side effect on the global state. It is called `unify` because—when we extend it to do type inference in an implicitly typed language—it will not only check that two types are the same but will make them the same if possible, modifying global state.

\[
\text{unify}(\text{App}(\text{tycon}_1, [t_1, \ldots, t_n]), \text{App}(\text{tycon}_1, [u_1, \ldots, u_n])) = \begin{cases} \text{if } \text{tycon}_1 \text{ is } \text{Int}, \text{String}, \text{Void}, \\
\text{Arrow, Array, or Record}([\text{id}_1, \ldots, \text{id}_n]) \\
\text{unify}(t_1, u_1); \ldots \text{unify}(t_n, u_n) \\
\end{cases}
\]

\[
\text{unify}(\text{App}(\text{TyFun}([\alpha_1, \ldots, \alpha_n], u), [t_1, \ldots, t_n]), t) = \\
\text{unify}(\text{subst}(u, [\alpha_1 \mapsto t_1, \ldots, \alpha_n \mapsto t_n]), t)
\]

\[
\text{unify}(t, \text{App}(\text{TyFun}([\alpha_1, \ldots, \alpha_n], u), [t_1, \ldots, t_n])) = \\
\text{unify}(t, \text{subst}(u, [\alpha_1 \mapsto t_1, \ldots, \alpha_n \mapsto t_n]))
\]

\[
\text{unify}(\text{App}(\text{Unique}(u, [t_1, \ldots, t_n]), \text{App}(\text{Unique}(u', [t'_1, \ldots, t'_n]))) = \\
\text{if } z \neq z' \text{ then error;} \\
\text{unify}(t_1, t'_1); \ldots \text{unify}(t_n, t'_n)
\]

\[
\text{unify}(\text{Poly}([\alpha_1, \ldots, \alpha_n], u), \text{Poly}([\alpha'_1, \ldots, \alpha'_n], u')) = \\
\text{unify}(u, \text{subst}(u', [\alpha'_1 \mapsto \text{Var}(\alpha_1), \ldots, \alpha'_n \mapsto \text{Var}(\alpha_n)]))
\]

\[
\text{unify}(\text{Var}(\beta), \text{Var}(\beta)) = \text{OK}
\]

\[
\text{unify}(\text{Nil}, \text{App}(\text{Record}(\ldots), \ldots)) = \text{OK}
\]

\[
\text{unify}(\text{App}(\text{Record}(\ldots), \ldots), \text{Nil}) = \text{OK}
\]

\[
\text{unify}(t, u) = \text{error} \quad \text{in all other cases}
\]

**Algorithm 16.6.** Expanding a type to see its internal structure.

The tags \(q_{321}\) and \(q_{324}\) distinguish pair types from twosome types (in practice we might use the pointer-address of the Ty_unique structure to identify occurrences).

**Testing type equivalence.** In type-checking, we often need to test whether one type is equivalent to another. To test equivalence of types containing \(\text{App}(\text{TyFun} \ldots, \ldots)\) we may need to expand the TyFun, substituting actual parameters for formal parameters. But to compare types containing \(\text{App}(\text{Unique}(\text{tycon}, z), \ldots)\) we should not expand \(\text{tycon}\), but instead test the
transdec\((\sigma_v, \sigma_t, \text{type } id = \text{array of } ty) = \)
\[

\end{align*}

\begin{align*}
\text{transsty}(\sigma_t, \text{poly < a > ty}) &= \beta \leftarrow \text{newtyvar()}
\]
\[
\text{Poly}([\beta], \text{transsty}(\sigma_t + \{a \mapsto \text{Var}(\beta), ty)))
\]
\]

ALGORITHM 16.7. Nonrecursive type declarations. Shown here are a few of the translation rules.

uniqueness mark z. The unify function (Algorithm 16.5) tests types for equivalence. Where error is reached, a type-checking error message will need to be printed for the user.

Expansion of Unique types. We do look inside the definition of a Unique type when we need some operation that requires its internal structure. For Array types, this means subscripting; for Record types, this means field selection or record construction. The function expand (Algorithm 16.6) illustrates where TyFun and Unique types must be expanded to expose internal structure.
16.2. TYPE INFERENCE

Translation of types. Algorithm 16.7 shows how the syntax of Poly-Tiger type declarations is translated into the internal representation of the new Types module. The type environments $\sigma_t$ map identifiers to tycons, except that a type-variable identifier is mapped to a ty; type variables are introduced into the environment for explicit type parameters of polymorphic functions, poly types, and parameterized type constructors.

Like the C code on page 119, Algorithm 16.7 does not handle recursive types. The way to handle recursive type declarations is just as described on pages 121–122: process the headers first, then the bodies. For ordinary Tiger, the first pass of processing a recursive declaration creates NAME types whose right-hand sides were not filled in until the second pass. For Poly-Tiger, the “hole” that gets filled in on the second pass must be in the Unique type-constructor, not in the TyFun.

Type-checking. Algorithm 16.8 shows some of the rules for type-checking declarations and expressions. To type-check function $f<z>(x:t_1):t_2=e_1$, we create a new type variable $\beta$ and insert the binding $z \mapsto \beta$ into the type environment for the processing of the function parameters and body, so that uses of $z$ will be correctly recognized. Then we create a Poly type whose formal parameter is $\beta$.

To type-check a function-call $f<int>(e_3)$, we look up $f$ in the variable-environment $\sigma_v$ to get Poly([$\beta$], App(Arrow, [t_1, t_2])), and substitute int for $\beta$ in $t_1$ and $t_2$. Then we check that $e_3$ has type $t_1$, and return type $t_2$ as the type of the entire function-call.

To type-check a record-creation list<int>{head=x, tail=y}, we look up list in the type-environment $\sigma_t$ to get a tycon, translate int in $\sigma_t$ to get $t_1$, and then make the type of the new record, $t_r = \text{App}(\text{tycon}, t_1)$. Then we can get the type of the head field from $t_r$ and make sure that it unifies with the type of $x$ (and similarly for tail).

16.2. TYPE INFERENCE

In order to make polymorphic programming easier, some polymorphic languages – notably ML and Haskell – don’t require the programmer to write down all the types. Instead, the type-checker infers the types. For example, consider the append function from page 353, written without all the $<\text{types}>$ – except that polymorphic record-type declarations must still be written with all type parameters spelled out in full:
\[\sigma_{i0} = \{\text{int} \mapsto \text{App(\text{Int}, [])}, \ldots\}\]  

Initial type environment

**transdec**(\(\sigma_v, \sigma_t\), function \(f <z>(x : t_1) : t_2 = e_1\)) =  

Function declaration

\[
\begin{align*}
\beta & \leftarrow \text{newtyvar}() \\
\sigma' & \leftarrow \sigma_t + \{z \mapsto \text{Var(\(\beta\))}\} \\
t_1' & \leftarrow \text{transsty}(\sigma', t_1); \ t_2' \leftarrow \text{transsty}(\sigma', t_2) \\
\sigma_v' & \leftarrow \sigma_v + \{f \mapsto \text{Poly([\(\beta\)], \text{App(Arrow, [t_1', t_2']})}\} \\
\sigma_v'' & \leftarrow \sigma_v' + \{x \mapsto t_1'\} \\
t_3' & \leftarrow \text{transexp}(\sigma_v'', \sigma_t, e_1) \\
\text{unify}(t_2', t_3') \\
(\sigma, \sigma_v')
\end{align*}
\]

**transdec**(\(\sigma_v, \sigma_t\), var id : ty = exp) =  

Variable declaration

\[
\begin{align*}
t & \leftarrow \text{transsty}(\sigma_t, \text{ty}) \\
\text{unify}(t, \text{transexp}(\sigma_t, \sigma_v, \text{exp})) \\
(\sigma, \sigma_v + \{id \mapsto \text{ty}\})
\end{align*}
\]

**transexp**(\(\sigma_v, \sigma_t\), id) = \(\sigma_v(id)\)  

Identifier expression

\[
\begin{align*}
\text{transexp}(\sigma_v, \sigma_t, e_1 + e_2) = \\
\text{unify}(\text{transexp}(\sigma_v, \sigma_t, e_1), \text{App(\text{Int}, [])}); \\
\text{unify}(\text{transexp}(\sigma_v, \sigma_t, e_2), \text{App(\text{Int}, [])}); \\
\text{App(\text{Int}, [])}
\end{align*}
\]

Integer addition

**transexp**(\(\sigma_v, \sigma_t\), e_1 <t> (e_2)) =  

Function call with instantiation

\[
\begin{align*}
t & \leftarrow \text{transsty}(\sigma_t, \text{ty}) \\
t_f & \leftarrow \text{transexp}(\sigma_v, \sigma_t, e_1) \\
t_e & \leftarrow \text{transexp}(\sigma_v, \sigma_t, e_2) \\
\text{check that expand}(t_f) = \text{Poly([\(\beta\)], \text{App(Arrow, [t_1, t_2])})} \\
\text{unify}(t_e, \text{subst}(t_1, \{\beta \mapsto t\})) \\
\text{subst}(t_2, \{\beta \mapsto t\})
\end{align*}
\]

**transexp**(\(\sigma_v, \sigma_t\), rcrd <ty> {fld_1 = e_1}) =  

Record creation

\[
\begin{align*}
t_r & \leftarrow \text{App}(\sigma_t(rcrd), \text{transsty}(\sigma_t, \text{ty})) \\
\text{check that expand}(t_r) = \text{App(Record([fld_1]), [t_f])} \\
\text{unify}(t_f, \text{transexp}(\sigma_v, \sigma_t, e_1)) \\
t_r
\end{align*}
\]

**Algorithm 16.8.** Type-checking expressions of Poly-Tiger. Shown here are a few of the type-checking rules; not shown are the cases for recursive or multi-argument functions, multiple type arguments, or multiple record fields.
16.2. TYPE INFERENCE

\[
\text{type list<e> = {head: e, tail: list<e>}}
\]

\[
\text{function append(a, b) =}
\]
\[
\quad \text{if a=nil}
\]
\[
\quad \quad \text{then b}
\]
\[
\quad \text{else list\{head= a.head, tail= append(a.tail,b)\}}
\]

This style is more concise to write and perhaps easier to read, but how does a compiler infer the types? First, it inserts place-holders \(\alpha, \beta, \gamma, \delta\) where types will be required:

\[
\text{function append(a: \alpha, b: \beta): \gamma =}
\]
\[
\quad \text{if a=nil}
\]
\[
\quad \quad \text{then b}
\]
\[
\quad \text{else list<\delta>{head= a.head, tail= append(a.tail,b)}}
\]

Now, because of the expressions \(a.\text{head}\) and \(a.\text{tail}\) it knows that \(a\) must be a list,\(^2\) so \(\alpha = \text{list<}\eta>\) for some \(\eta\). Because \(b\) can be returned as the result of \(\text{append}\), it knows that \(\beta = \gamma\). The else clause returns \(\text{list<}\delta>\), so \(\gamma = \text{list<}\delta>\). Finally, because of \(\text{head}=a.\text{head}, \delta = \eta\). Applying these equations to the \(\text{append}\) code, the compiler has:

\[
\text{function append(a: list<\delta>, b: list<\delta>): list<\delta> =}
\]
\[
\quad \text{if a=nil}
\]
\[
\quad \quad \text{then b}
\]
\[
\quad \text{else list<\delta>{head= a.head, tail= append(a.tail,b)}}
\]

It has not relied on any particular property of \(\delta\), so this \(\text{append}\) function should work for any type \(\delta\). We express this by generalizing over \(\delta\), making it an explicit type parameter of the \(\text{append}\) function:

\[
\text{function append<\delta>(a: list<\delta>, b: list<\delta>): list<\delta> =}
\]
\[
\quad \text{if a=nil}
\]
\[
\quad \quad \text{then b}
\]
\[
\quad \text{else list<\delta>{head= a.head, tail= append<\delta>(a.tail,b)}}
\]

and now we have a function identical (modulo renaming of \(\delta\)) to the one shown on page 353. The next few pages will explain this type inference and generalization algorithm in detail.

\(^2\)This follows only if there are no other record types with \text{head} or \text{tail} fields; the issue will be discussed later in this section.
AN IMPLICITLY TYPED POLYMORPHIC LANGUAGE

The Hindley-Milner type inference algorithm takes a polymorphic program written without explicit type annotations, and converts it to an explicitly typed program. To explain the algorithm we can use a language ImplicitPoly-Tiger, which is like Poly-Tiger but without explicit type annotations on function parameters (Grammar 16.9). This language is meant to model some of the important concepts of the ML programming language.

Unlike Poly-Tiger, function declarations in ImplicitPoly-Tiger don’t list the types of their arguments and are not written with a tyargs list. Also, users cannot write explicit poly types in ImplicitPoly-Tiger, although these can be inferred internally by the type inferencing algorithm. Finally, function calls and record creations are written without any type-argument list.

However, type declarations (such as the declaration of list<e>) are written with explicit type parameters and explicitly typed record fields.

Translation of ImplicitPoly-Tiger. Algorithm 16.7 for translating Poly-Tiger types and type declarations also applies to ImplicitPoly-Tiger, although we do not need the last rule (for poly types). But type-checking function declarations and expressions is rather different, so we cannot use Algorithm 16.8 but use Algorithm 16.10 instead.

ALGORITHM FOR TYPE INFERENCE

Type inference uses an internal representation of types similar to the one shown in Figure 16.3b, but with two additional kinds of tys, the first of which is the type metavariable:

\[ ty \rightarrow \text{Meta}(metavar) \]

A metavariable is not like an ordinary Var type variable that is bound by a Poly; it is just a placeholder for an unknown type that we expect to infer. In the append program on page 361, the Greek letters \( \alpha, \beta, \gamma, \delta \) are metavariables; we solve for the values of \( \alpha, \beta, \gamma \), but \( \delta \) is left undetermined. That means we can convert \( \delta \) to an ordinary variable \( d \) that is bound by a Poly in the type of append.

As Algorithm 16.10 shows, when type-checking function \( f(x) = e \) we make up new metavariables \( t_x \) (to stand for the type of \( x \)) and \( t_2 \) (to stand for the return-type of \( f \)). Then we use unify to derive the relationship between the metavariables, in the following way.
16.2. TYPE INFERENCE

<table>
<thead>
<tr>
<th>Syntax</th>

</table>

**Grammar 16.9.** Syntax rules for ImplicitPoly-Tiger.

The type-checker maintains a global environment $\sigma_m$ mapping metavariables to their instantiations. On page 361 when we learn that $\alpha = \text{list}<\eta>$, we add the binding $\alpha \mapsto \text{App}(\text{list}, [\text{Meta}(\eta)])$ into $\sigma_m$.

Most implementations do not implement $\sigma_m$ as a lookup table; instead, each $\text{Meta}(\alpha)$ has an additional field that starts out empty; when an instantiation is done, instead of adding the binding $\alpha \mapsto t$ to a table, a pointer to $t$ is stored into the $\text{Meta}$ record.

The `unify` function of Algorithm 16.5 needs new clauses to handle $\text{Meta}$ types; these clauses access and update the global environment $\sigma_m$:

```plaintext
unify(\text{Meta}(\alpha), t) =
if $\alpha \in \text{domain}(\sigma_m)$
then `unify($\sigma_m(\alpha), t$)
else if $t \equiv \text{App}(\text{TyFun} . . .)$
then `unify(\text{Meta}(\alpha), \text{expand TyFun type as usual})
else if $t \equiv \text{Meta}(\gamma)$ and $\gamma \in \text{domain}(\sigma_m)$
then `unify(\text{Meta}(\alpha), \sigma_m(\gamma))
else if $t \equiv \text{Meta}(\alpha)$
then `OK`
else if $\text{Meta}(\alpha)$ occurs in $t$
then `error`
else $\sigma_m \leftarrow \sigma_m + \{\alpha \mapsto t\}; \ \text{OK}$

`unify(t, \text{Meta}(\alpha)) =` where $t$ is not a Meta
`unify(\text{Meta}(\alpha), t)`
```

If the metavariable $\alpha$ has already been instantiated to some type $u$, then we just unify $u$ with $t$. Otherwise, we instantiate $\alpha$ to $t$, except that we never instantiate $\alpha$ to $\alpha$.  

363
The clause “if \( \text{Meta}(\alpha) \) occurs in \( t \)” is called the occurs check, and it avoids creating circular types: we do not want to instantiate \( \alpha = \text{list}<\alpha> \), because this is not permitted in ImplicitPoly-Tiger’s type system.

Other functions that deal with types – such as subst and expand – need to “see through” instantiated metavariables:

\[
\begin{align*}
\text{subst}(\text{Meta}(\alpha), \sigma) &= \begin{cases} 
\text{subst}(\sigma_m(\alpha), \sigma) & \text{if } \alpha \in \text{domain}(\sigma_m) \\
\text{Meta}(\alpha) & \text{else}
\end{cases} \\
\text{expand}(\text{Meta}(\alpha)) &= \begin{cases} 
\text{expand}(\sigma_m(\alpha)) & \text{if } \alpha \in \text{domain}(\sigma_m) \\
\text{Meta}(\alpha) & \text{else}
\end{cases}
\end{align*}
\]

**Generalization and instantiation.** In the translation of function \( f(x) = e_1 \), we may end up with a type with free metavariables. That is, the type \( t_f \) may be something like \( \text{App} \left( \text{Arrow}, [\text{Meta}(\alpha), \text{Meta}(\alpha)] \right) \) where \( \alpha \) is not instantiated in \( \sigma_m \). In such a case, we would like to generalize this type to

\[
\text{Poly}([a], \text{App}(\text{Arrow}, [\text{Var}(a), \text{Var}(a)]))
\]

so that \( f \) can be applied to any type of argument. But we must be careful. Consider the program

\[
\text{function randomzap}(x) = \\
\quad \text{let function } f(y) = \text{if random()} \text{ then } y \text{ else } x \\
\quad \text{in } f \\
\text{end}
\]

While type-checking randomzap, we recursively call \( \text{transexp} \) on the let expression, which type-checks the declaration of \( f \). At this point, the type of \( x \) in \( \sigma_v \) is \( \text{Meta}(\alpha) \), and the type of \( f \) turns out to be \( \text{App}(\text{Arrow}, [\text{Meta}(\alpha), \text{Meta}(\alpha)]) \). But we cannot generalize – \( f \) cannot take arguments of arbitrary type, only arguments whose type is the same as that of \( x \). The point is that \( \alpha \) appears in the current environment \( \sigma_v \), in the description of \( x \)’s type.

Therefore the algorithm for generalize is:

\[
\text{generalize}(\sigma_v, t) = \\
\quad \text{let } \alpha_1, \ldots, \alpha_k \text{ be the metavariables that appear in } t \\
\quad \text{ but do not appear anywhere in } \sigma_v \\
\quad \text{ (when searching } \sigma_v \text{ we must interpret metavariables} \\
\quad \text{ by looking them up in } \sigma_m \text{ and searching the result) } \\
\quad \text{for } i \leftarrow 1 \text{ to } k \\
\quad \text{let } a_i \leftarrow \text{newtyvar}() \\
\quad \sigma_m \leftarrow \sigma_m + \{a_i \mapsto \text{Var}(a_i)\} \\
\text{return } \text{Poly}([a_1, \ldots, a_k], t)
\]
\[ \sigma_{t_0} = \{ \text{int} \mapsto \text{App(\text{Int, []}), \ldots} \} \]

Initial type environment

\[ \text{transdec}(\sigma_v, \sigma, \text{function } f(x) = e_1) = \]

Function declaration

\[ t_x \leftarrow \text{Meta(newmetavar())} \]
\[ t_2 \leftarrow \text{Meta(newmetavar())} \]
\[ t_f \leftarrow \text{App(\text{Arrow, [} t_x, t_2])} \]
\[ t_3 \leftarrow \text{transexp}(\sigma_v + \{ f \mapsto t_f, x \mapsto t_x \}, \sigma_r, e_1) \]
\[ \text{unify}(t_2, t_3) \]
\[ t'_f \leftarrow \text{generalize}(\sigma_v, t_f) \]
\[ (\sigma_v + \{ f \mapsto t'_f \}, \sigma_r) \]

\[ \text{transdec}(\sigma_v, \sigma_r, \text{var id:=exp}) = \]

Variable declaration with implicit type

\[ t \leftarrow \text{transexp}(\sigma_r, \sigma_v, \text{exp}) \]
check that \( t \) is not \text{Nil}
if \( \text{id} \) is assigned to anywhere in its scope
\[ t' \leftarrow \text{Poly([], t)} \]
else \( t' \leftarrow \text{generalize}(t) \)
\[ (\sigma_r, \sigma_v + \{ \text{id} \mapsto t \}) \]

\[ \text{transexp}(\sigma_v, \sigma_r, \text{id}) = \]

Occurrence of a variable

\[ \text{instantiate}(\sigma_v(\text{id})) \]

\[ \text{transexp}(\sigma_v, \sigma_r, e_1 + e_2) = \]

same as for Poly-Tiger

\[ \text{unify(transexp}(\sigma_v, \sigma_r, e_1), \text{App(\text{Int, []}))) \]
\[ \text{unify(transexp}(\sigma_v, \sigma_r, e_2), \text{App(\text{Int, []}))) \]
\[ \text{App(\text{Int, []})) } \]

\[ \text{transexp}(\sigma_v, \sigma_r, f(e)) = \]

Function call

\[ t_f \leftarrow \text{transexp}(\sigma_v, \sigma_r, f) \]
\[ t_e \leftarrow \text{transexp}(\sigma_v, \sigma_r, e) \]
\[ t_2 \leftarrow \text{Meta(newmetavar())} \]
\[ \text{unify}(t_f, \text{App(\text{Arrow, [} t_e, t_2])}) \]
\[ t_2 \]

Note that \textit{all} functions will be given Poly types – but a monomorphic function will have type Poly([], \ldots) which is polymorphic only in a trivial sense.

The converse of generalization is instantiation. Where a polymorphic variable is used, we replace the bound type variables with metavariables:
CHAPTER SIXTEEN. POLYMORPHIC TYPES

\[
\text{instantiate}(\text{Poly}([a_1, \ldots, a_k], t)) = \\
\text{for } i \leftarrow 1 \text{ to } k \\
\text{let } \alpha_i \leftarrow \text{newmetavar}() \\
\text{return } \text{subst}(t, \{a_1 \mapsto \text{Meta}(\alpha_1), \ldots, a_k \mapsto \text{Meta}(\alpha_k)\})
\]

We perform instantiation at each use of a polymorphic function. At one call site, the bound variable \(a_1\) may be replaced with a metavariable \(\alpha\) that unifies with \text{int}; at another call site, the same \(a_1\) may be replaced with a metavariable \(\beta\) that unifies with \text{string}. But at a particular call site, all the uses of \(\alpha\) must be consistent with each other.

For example, the \text{randomzap} function has type \text{poly}<a> \ a->(a->a). It can be used in the following way:

\[
\text{let var } i0 := \text{randomzap}(0) \\
\text{var s0 := randomzap("zero")} \\
\text{in } i0(3)+\text{size}(s0("three"))
\]

which might return any of the following: 3+5, 0+5, 3+4, or 0+4. The first occurrence of \text{randomzap} is instantiated with the type \(\alpha \rightarrow (\alpha \rightarrow \alpha)\), where \(\alpha\) is a metavariable. But all the \(\alpha\)'s must unify: when type-checking \text{randomzap}(0) we unify \(\alpha\) with \text{int}, which instantiates \(\alpha\); when type-checking \text{i0}(3) we unify \(\alpha\) with \text{int}, but since \(\alpha\) is already instantiated to \text{int} this is just a check that \(\alpha\) is used consistently; then when type-checking \text{i0}(3)+... we again unify \(\alpha\) with \text{int}. Similarly, the second occurrence of \text{randomzap} is instantiated to \(\beta \rightarrow (\beta \rightarrow \beta)\), and the \(\beta\)'s are all unified with \text{string} ("zero", "three", and the argument of \text{size}).

**Updatable variables.** Given a variable declaration \text{var } a := \text{exp}, we generalize the type of \text{exp} in determining the type of \(a\). This is sound as long as there are no assignments to \(a\) other than this initialization. But polymorphic references (i.e., assignable variables of polymorphic type) are a problem. The following program should not be allowed to type-check:

\[
\text{let function identity(x) = x} \\
\text{function increment(i) = i+1} \\
\text{var a := identity} \\
\text{in } a := \text{increment}; \ a("oops")
\]

and one way of assuring this is to avoid generalizing the types of updatable variables; this restriction on polymorphic references is implemented in the \text{Variable declaration with implicit type} clause of Algorithm 16.10.
16.2. TYPE INFERENCE

\[ transdec(\sigma_v, \sigma_t, \text{type id } \langle a \rangle = \{ \text{fld : ty} \} ) = \]

- \( z \leftarrow \text{newunique}() \)
- \( \beta \leftarrow \text{newtyvar}() \)
- \( \sigma'_t \leftarrow \sigma_t + \{ a \mapsto \text{Var}(\beta) \} \)
- \( t \leftarrow \text{transty}(\sigma'_t, ty) \)
- \( t_{id} \leftarrow \text{Unique}((\beta], \text{App}(\text{Record}([\text{fld}]), [t])), z) \)
- \( t_f \leftarrow \text{Poly}([\beta], \text{Field}(t_{id}, t)) \)
- \( (\sigma_v, \sigma_t + \{ \text{id} \mapsto t_{id}, \text{fld} \mapsto t_f \}) \)

\[ \text{transexp}(\sigma_v, \sigma_t, \text{rcrd} \{ \text{fld}_1 = e_1 \} ) = \]

- RECORD CREATION
  - check that \( \sigma_t(\text{rcrd}) = \text{Unique}((\beta], \text{App}(\text{Record}([\text{fld}_1]), [t])), z) \) (perhaps \( k = 0 \))
  - for \( i \leftarrow 1 \) to \( k \) let \( x_i \leftarrow \text{Meta}(\text{newmetavar}()) \)
  - \( t'_r \leftarrow \text{subst}(t_r, \{ \alpha_1 \mapsto x_1, \ldots, \alpha_k \mapsto x_k \}) \)
  - check that \( \text{expand}(t'_r) = \text{App}(\text{Record}([\text{fld}_1]), [t_f]) \)
  - \( \text{unify}(t'_f, \text{transexp}(\sigma_v, \sigma_t, e_1)) \)
  - \( t_r \)

\[ \text{transexp}(\sigma_v, \sigma_t, e.id) = \]

- FIELD SELECTION
  - \( t_e \leftarrow \text{transexp}(\sigma_v, \sigma_t, e) \)
  - \( t_2 \leftarrow \text{Meta}(\text{newmetavar}()) \)
  - \( t_f \leftarrow \text{instantiate}(\sigma_v(\text{id})) \)
  - \( \text{unify}(t_f, \text{Field}(t_e, t_2)) \)
  - \( t_2 \)

ALGORITHM 16.11. Type-checking records and fields in ImplicitPoly-Tiger.

RECURSIVE DATA TYPES

In Tiger and its variants, record types may be recursive; a language must have some form of recursive types in order to build lists and trees. Recursive types pose their own challenges for type inference: we might ask, for example, whether the following parameterized types are equivalent:

\[
\begin{align*}
\text{type list}<a> & = \{ \text{head : } a, \text{tail : } \text{list}<a> \} \\
\text{type sequence}<a> & = \{ \text{head : } a, \text{tail : } \text{sequence}<a> \}
\end{align*}
\]

We have sidestepped this question by the record distinction rule, saying that record types declared at different places are different – a simple and neat solution, overall. The Unique tycons are used to make this distinction, as explained earlier in the chapter.
Global record fields. In the Tiger language, different record types may use the same field names; when compiling \texttt{p.x}, the record type of \texttt{p} is known before looking up field \texttt{x}.

But in ImplicitPoly-Tiger, an expression such as \texttt{p.x} must be type-checked when we don’t yet know the type of \texttt{p} – all we may have is a metavariable for \texttt{p}’s type. Therefore, we require that field names (such as \texttt{x}) have global scope.

The type-checking rules for record declarations, record-creation expressions, and field selection, are shown in Algorithm 16.11. We require a new kind of \texttt{ty} (to be added to Figure 16.3b, along with \texttt{Meta} types):

\[
\text{ty} \rightarrow \text{Field(ty, ty)}
\]

where \texttt{Field(tid, t)} means a field of type \texttt{t} in a record of type \texttt{tid}. The globalization of field names is unpleasant, because it means that the same field name cannot be easily used in two different record types (one will hide the other); but it is the price to be paid for automatic type inference of field selection in Tiger. The ML language solves the problem in a different way, with global data constructors in its datatypes instead of global field names in its record types; so in ML the same data constructor name cannot be used in two different types (or one will hide the other).

A \texttt{Field} such as \texttt{head} is polymorphic: its type is

\[
\text{Poly([\beta], Field(App(list, [\beta]), \beta))}
\]

indicating that it selects a value of type \texttt{\beta} from a record of type \texttt{list<\beta>}. When a field is used in an expression, it must be \textit{instantiated} just like a polymorphic function is.

THE POWER OF HINDLEY-MILNER TYPES

The polymorphic \texttt{append} function can be written in ImplicitPoly-Tiger, a language that uses the Hindley-Milner type system – or it can be written in Poly-Tiger, whose type system is equivalent to second-order lambda calculus. But in fact Poly-Tiger is strictly more expressive than ImplicitPoly-Tiger; the following Poly-Tiger function has no equivalent in ImplicitPoly-Tiger:
function mult(m: poly<a>(a->a)->(a->a)),
n: poly<b>((b->b)->(b->b)))
: poly<c>=(c->c)->(c->c) =
let function g<d>(f: d->d) : d->d =
m<d->d>(n<d>(f))
in g
end

The reason is that the function mult has formal parameters m and n that are explicitly polymorphic. But the only place that the Algorithm 16.10 introduces a poly type is in generalization, which only occurs at function declarations, never at formal parameters.

On the other hand, any ImplicitPoly-Tiger program can be translated directly into Poly-Tiger.³ Algorithm 16.10 can be augmented to perform this translation as it does type-checking; it would then fit in the “Type Inference” box of Figure 16.1.

No Hindley-Milner-style type inference algorithm exists – or can exist – for a Poly-Tiger-like type system (one that can handle functions such as mult). If we wish to use the full power of second-order lambda calculus we will have to write our types out in full. It is not clear whether the extra expressive power of Poly-Tiger is necessary, or whether it outweighs the convenience of type inference available in implicitly typable languages. ML and Haskell, which use implicit polymorphic types, have been quite successful as general-purpose functional programming languages in the research community; no explicitly typed polymorphic language has caught on in the same way. But explicitly typed languages are becoming the state of the art in intermediate representations for polymorphic languages.

³Well, almost any; see Exercise 16.7.
Consider the `append` function, rewritten with variables `x` and `y` to model compiler-generated temporaries:

```plaintext
function append<e>(a: list<e>, b: list<e>) : list<e> = 
  if a=nil 
    then b 
  else let var x : e := a.head 
     var y : list<e> := a.tail 
    in list<e>{head=x, tail=append<e>(y,b)} 
end
```

What is the type of `x`? If it is a pointer (i.e., a record or array type), then it should serve as a root for garbage collection; if is an integer, then it should not. If it is a double-precision floating-point number (in a Poly-Tiger enhanced with floating-point types) then it is eight bytes long; if it is a pointer, it is (typically) four bytes.

It is obvious why the compiler needs to know the size of a value such as `a.head`: it must copy the data from the `a` record to the newly created `list` record, and it needs to know how many bits to copy. But the garbage-collection issue is also important: if the allocation call that creates the new `list` finds that a garbage collection is necessary, then all the local variables and compiler temporaries of `append` are `roots` of garbage collection (see Section 13.7). If `a.head` is an integer `i`, then attempting to trace reachable data from heap-address `i` will lead to disaster.4

But the compile-time type of `a.head` is simply `e`, which is a type variable that will be instantiated differently at different call sites of `append`. How can the machine code deal with different types and sizes of data for `a.head`?

There are several solutions to this problem:

**Expansion:** Don’t generate code for the general-purpose `append<e>` function; instead, for each different type at which `e` is instantiated, generate an `append` function specific to that type.

**Boxing, tagging:** Make sure that every value is the same size (typically one word) and can serve as a root of garbage collection.

**Coercions:** Allow differently typed values to be different sizes, but coerce them into a uniform-size representation when they are passed to polymorphic functions.

**Type-passing:** Allow differently typed values to be different sizes, and pass type information to polymorphic functions along with the values so that the polymorphic functions know how to handle them.

---

4 Only a conservative collector (see page 296) doesn’t need to be told which fields are pointers.
16.3. REPRESENTATION OF POLYMORPHIC VARIABLES

Each of these is a complete solution that can handle every case – some compilers use only expansion, others use only boxing/tagging, and so on. But a compiler can best optimize programs by using tagging for some types, coercions for other types, type-passing to handle other cases, and expansion where convenient.

The next few sections describe these techniques in more detail.

EXPANSION OF POLYMORPHIC FUNCTIONS

A simple approach to polymorphism is to inline-expand all polymorphic functions until everything is monomorphic. This is the way that Ada generics and C++ templates work. The advantage of this approach is a simple and efficient compilation model; the disadvantage is that functions are replicated, which can cause code bloat.

Section 15.4 describes the inline expansion of functions: the body of a function is copied, but with the actual parameters of the call substituted for the formal parameters of the definition. This technique works just as well when the parameters are types instead of values.

Given a function definition

\[ \text{function } f(z_1, \ldots, z_k)(x_1 : t_1, \ldots, x_n : t_n) : t_r = e \]

and a function call \( f(u_1, \ldots, u_k)(a_1, \ldots, a_n) \), we can replace the call by

\[ \text{let function } f(x_1 : t'_1, \ldots, x_n : t'_n) : t'_r = e' \text{ in } f(a_1, \ldots, a_n) \text{ end} \]

where \( t'_i = \text{subst}(t_i, \{z_1 \mapsto u_1, \ldots, z_k \mapsto u_k\}) \) and \( e' \) is formed by replacing any occurrence of a \( z_i \) within \( e \) by \( u_i \).

This works very straightforwardly for nonrecursive functions: we just do it bottom-up, so that in the case of function \( f \) the expression \( e \) would have been processed already, so that it contains no polymorphic function definitions or calls to polymorphic functions. But if \( e \) contains a recursive call to \( f \), then we have two cases to consider:

1. The call to \( f \) within \( e \) is of the form \( f(z_1, \ldots, z_k)(\ldots) \), where the actual type parameters of the call match the formal type parameters of \( f \)'s definition. In this case, we can just delete the parameters as we rewrite \( e \) to use the monomorphic function \( f \) introduced by the \texttt{let} described above. This is, in fact, a very common case; all recursive function-calls introduced by Algorithm 16.10 follow this pattern.

2. The recursive call to \( f \) has different actual type parameters.
The latter situation is called *polymorphic recursion*, and is illustrated by the following program:

```haskell
let function blowup<e>(i:int, x:e) : e =
  if i=0 then x
  else blowup<list<e>>(i-1,list<e>{head=x,tail=nil}).head
in blowup<int>(N, 0)
end
```

The `blowup` function will be called at $N$ different types: `int`, `list<int>`, `list<list<int>>`, and so on. No finite amount of inline expansion of `blowup` can cover all possible values of $N$.

Because ImplicitPoly-Tiger (and languages like ML and Haskell) do not permit polymorphic recursion, this kind of blowup cannot occur, so complete expansion into monomorphic code is possible. But total inline-expansion will not work for Poly-Tiger; and in languages where it does work, there’s still a difficulty with separate compilation: often we’d like to compile a function where it is declared, not recompile it at every place where it’s called.

**FULLY BOXED TRANSLATIONS**

Another way to solve the polymorphic-variable problem is to use *fully boxed* representations, in which all values are the same size, and each value describes itself to the garbage collector. Usually we put each value in one word; when its natural representation is too large to fit, we allocate a record, and use the pointer as the word. This technique is called *boxing*, and the pointer is a *boxed* value. As described in Section 13.7, the record representing the boxed value usually starts with a descriptor indicating how large the record is and whether it contains pointers.

The basic Tiger compiler described in Chapters 2–12 represents everything in one word, but the data objects do not describe themselves to the garbage collector. The garbage-collection descriptor format described at the end of Chapter 13 does better, but still cannot support polymorphism.

**Boxing and tagging.** An integer value fits into a word but doesn’t describe itself to the garbage collector, so it must also be boxed. In this case, we create a one-word record (preceded by a descriptor, as usual) to hold the integer, and the boxed value is the pointer to this record.

To compile arithmetic such as $c \leftarrow a + b$ on boxed values requires that $a$ be fetched from its box (*unboxed*), $b$ be fetched, the addition performed, then a new record be allocated to hold the boxed value $c$. This is quite expensive.
16.3. REPRESENTATION OF POLYMORPHIC VARIABLES

For values (such as characters) whose natural representation is *smaller* than one word, there is an alternative to boxing called *tagging*. Suppose, for example, that all record pointers on a byte-addressed machine are aligned at multiple-of-4 boundaries; then any word ending with a 1 bit will be recognizably not a pointer. So we can represent character values by shifting them left and adding 1:

![c 1]

To compile \( c \leftarrow a + b \) on tagged values requires that \( a \) be shifted right (*untagged*), \( b \) be shifted right, the addition performed, then \( c \) be shifted left and incremented (*tagged*). This is much cheaper than allocating a new (garbage-collectable) record. In fact, many of the shifts cancel out (see Exercise 16.8).

Tagging is so much cheaper than boxing that many implementations of polymorphic languages use tagging for their ordinary integer variables, with the disadvantage that integers cannot use the full word size of the machine because one bit must be reserved for the tag.

COERCION-BASED REPRESENTATION ANALYSIS

The problem with full boxing is that the entire program uses (expensive) boxed representations, even in places where the programmer has not used any polymorphic functions. The idea of *coercion-based representation analysis* is to use unboxed (and untagged) representations for values held in monomorphic variables, and boxed (or tagged) representations for values held in polymorphic variables. That way the monomorphic parts of the program can be very efficient, with a price paid only when polymorphic functions are called.

In Poly-Tiger, or in an ImplicitPoly-Tiger program that the type-checker has converted into Poly-Tiger, the conversion from unboxed to boxed values must occur at the call to a polymorphic function. Consider the definition of \( f \) as

\[
\text{function } f <a>(x : a) : a = \ldots x \ldots x \ldots
\]

with some call-site that calls \( f <\text{int}>(y) \), where \( y \) is an integer variable. The type of \( y \) is \( \text{int} \), and the type of \( x \) is \( a \), which is a polymorphic type variable. In this case we can convert from \( \text{int} \) to “polymorphic” by boxing \( y \).

The type of the formal parameter will always be at least as general as the type of the actual parameter; that is, the actual type can be derived from the formal type by substitution. Based on this substitution, the compiler will always be able to construct a sort of boxing function appropriate for the task.
### Table 16.12. Wrapping and unwrapping of primitive types.

</tr>
</tbody>
</table>

**Table 16.12** shows how to wrap values of primitive types (int, char, string) by boxing or tagging.

**Records by value or by reference?** A Tiger-language record, like a Java object or a C pointer-to-struct, allows several kinds of operations:

1. Is a value there or is it nil?
2. Is it the same record (by pointer-equality) as that one?
3. What are the field values?
4. Let me update one of the fields!

But a C struct or ML record value has no pointer and cannot be “nil.” Therefore, only operation (3) applies. The essential difference is between a *reference* and a *pure value*. The importance of this for representation analysis is that we can take advantage of concept (3) especially when (1), (2), and (4) don’t get in the way: we can copy the record into a different format – we can keep a two-word C struct or ML record in two registers if we want to, and pass the record as a function-parameter in registers. That is, representation analysis can do more on pure values than it can on references.
To give an example of a record-style language construct that is a pure value, I have introduced *tuple* types into Table 16.12. The type \((t_1, t_2)\), for example, is the type of two-element tuples whose first element has type \(t_1\) and whose second has type \(t_2\). Tuples are just like records without field names.

However, I have given these tuples a pure-value semantics: one cannot test a tuple for null, update a field of a tuple value, or test pointer-equality on tuples. This is a design choice; the fact that records have field names and tuples do not is actually irrelevant to the distinction between references and pure values.

**Recursive wrapping.** For structured types such as \((\text{int}, \text{char})\) or \((\text{int} \rightarrow \text{char})\), primitive wrapping (as shown in Table 16.12) can convert the value into a single boxed word. But this is not enough, as shown by this example:

```plaintext
let function get(l) = l.head.1
function dup(x) = list{head=x,tail=list{head=x,tail=nil}}
var tuple = (3,'a')
in extract(dup(tuple))
end
```

If we primitive-wrap `tuple` by making a boxed tuple containing an unboxed integer and an untagged character, then the polymorphic function `get` will be directly handling the unboxed integer – which is not allowed.

To solve this problem we *recursively wrap*: we first wrap the components (bottom-up), then build a tuple of wrapped types. When a function is to be wrapped, we must recursively wrap its argument and result. Recursive wrapping is summarized in Table 16.13. Note that to recursively wrap a function \(f\) of type \((\text{int} \rightarrow \text{char})\), we make a new function \(\overline{f}\) that takes a boxed argument, unwraps the argument, applies \(f\), and wraps the result. Thus, the recursive definition of \(\overline{\text{wrap}}\) relies on \(\overline{\text{unwrap}}\) for function-parameters, and vice versa.

These primitive wrapping functions will suffice when the actual parameter is a polymorphic variable. But when the type of the formal parameter is something like \(a \rightarrow \text{int}\) or \((\text{int}, a)\) where \(a\) is a polymorphic type variable, then we cannot simply box the entire actual parameter. Instead, we must make an unboxed function (or tuple, respectively) whose argument (or component, respectively) is boxed.

Let us use \(\bullet\) as the symbol for a type variable holding a boxed value. We can do this because coercion-based analysis doesn’t care which type variable has been used: they all have the same, boxed, representation.
CHAPTER SIXTEEN. POLYMORPHIC TYPES

<tr>
<td>((t_1, t_2))</td>
<td>(\text{wrap}<em>{(t_1, t_2)}(x)) (\text{unwrap}</em>{(t_1, t_2)}(x)) (\text{wrap}<em>\text{tuple}(\text{wrap}</em>{t_1}(x.1), \text{wrap}<em>{t_1}(x.2))) (\text{unwrap}</em>\text{tuple}(x)); (\text{unwrap}<em>{t_1}(y.1)), (\text{unwrap}</em>{t_2}(y.2))</td>
</tr>
<tr>
<td>(t_1 \rightarrow t_2)</td>
<td>(\text{wrap}<em>{t_1 \rightarrow t_2}(f)) (\text{unwrap}</em>{t_1 \rightarrow t_2}(f)) (\text{wrap}<em>\text{closure}(\text{let function } f\text{w}(a) = \text{wrap}</em>{t_2}(f(\text{unwrap}<em>{t_1}(a))) \text{ in } f\text{w end})) (\text{let function } f\text{u}(a) = \text{unwrap}</em>{t_2} (\text{unwrap}<em>\text{closure}(f)(\text{wrap}</em>{t_1}(a))) \text{ in } f\text{u end})</td>
</tr>
<tr>
<td>({a : t_1, b : t_2})</td>
<td>(\text{wrap}<em>{[a : t_1, b : t_2]}(r)) (\text{unwrap}</em>{[a : t_1, b : t_2]}(r)) (\text{wrap}<em>\text{record}(r)) (\text{unwrap}</em>\text{record}(r))</td>
</tr>
</tbody>
</table>

TABLE 16.13. Recursive wrapping and unwrapping of structured types.

<table>
<thead>
<tr>
<th>Type of actual</th>
<th>Type of formal</th>
<th>Transformation</th>
</tr>
</thead>
<tbody>
<tr>
<td>(y : \bullet)</td>
<td>(\bullet)</td>
<td>(y)</td>
</tr>
<tr>
<td>(y : \text{int})</td>
<td>(\bullet)</td>
<td>(\text{wrap}_\text{int}(y))</td>
</tr>
<tr>
<td>(y : \text{char})</td>
<td>(\bullet)</td>
<td>(\text{wrap}_\text{char}(y))</td>
</tr>
<tr>
<td>(y : (t_1, t_2))</td>
<td>(\bullet)</td>
<td>(\text{wrap}_{(t_1, t_2)}(y))</td>
</tr>
<tr>
<td>(y : (t_1, t_2))</td>
<td>((t_1, \bullet))</td>
<td>((y.1, \text{wrap}_{t_2}(y.2)))</td>
</tr>
<tr>
<td>(y : (t_1, t_2))</td>
<td>((\bullet, \bullet))</td>
<td>((\text{wrap}<em>{t_1}(y.1), \text{wrap}</em>{t_2}(y.2)))</td>
</tr>
<tr>
<td>(f : t_1 \rightarrow t_2)</td>
<td>(\bullet)</td>
<td>(\text{wrap}_{t_1 \rightarrow t_2}(f))</td>
</tr>
<tr>
<td>(f : t_1 \rightarrow t_2)</td>
<td>(\bullet \rightarrow t_2)</td>
<td>(\text{let function } f\text{w}(a) = f(\text{unwrap}_{t_1}(a)) \text{ in } f\text{w end})</td>
</tr>
<tr>
<td>(f : t_1 \rightarrow t_2)</td>
<td>(\bullet \rightarrow \bullet)</td>
<td>(\text{let function } f\text{u}(a) = \text{wrap}<em>{t_2}(f(\text{unwrap}</em>{t_1}(a))) \text{ in } f\text{u end})</td>
</tr>
</tbody>
</table>

To convert variable \(y\) from type \((\text{int}, \text{char})\) to \((\text{int}, \bullet)\) we must create a new record whose first component is copied from the first component of \(y\), and whose second component is \(\text{wrap}_\text{char}\) applied to the second component of \(y\).

To wrap a function \(f : t_1 \rightarrow t_2\) into a boxed \(\bullet\), we recursively wrap \(f\) into a single pointer as shown in Table 16.13. But when the formal parameter is \(x : \bullet \rightarrow t_2\), then that won’t do: the called function expects a function-closure, not a box, and the return-value must be \(t_2\), not a box. The compiler must construct a new function as shown in Table 16.14.

When a polymorphic function returns a result into a monomorphic con-
text, the return value must be unwrapped. If the result is completely polymorphic, then we can use an unwrapper from Table 16.12 or 16.13. But if it is something like \((t_1, t_2 \rightarrow \bullet)\), then we must pick it apart, unwrap some of the components, and rebuild it; the process is complementary to the one shown in Table 16.14.

**Performance advantage.** Coercion-based representation analysis relies on the fact that in typical programs, instantiation of polymorphic variables (which is where the coercions must be inserted) is rarer than ordinary execution. Representation analysis is particularly useful for programs that heavily use floating point numbers (which need lots of boxing/unboxing in the fully boxed translation scheme) or other data types for which tagging or boxing is expensive.

**PASSING TYPES AS RUN-TIME ARGUMENTS**

Another approach to the implementation of polymorphism is to keep data always in its natural representation. A function \(f\) with a polymorphic formal parameter \(x\) will tolerate different representations of \(x\) depending on the type of the actual parameter. To do this, \(f\) must be told the actual type of each instance.

Descriptions of the types of actual parameters can be passed exactly in those places where Poly-Tiger (or, equivalently, second-order lambda calculus) passes a type parameter. Consider the `randomzap` function as an example; its representation in Poly-Tiger is

```plaintext
function randomzap<a>(x:a) : a =
    let function f(y:a) : a = if random() then y else x
        in f
    end
end
```

and a sample use of it is

```plaintext
let var i0 := randomzap<int>(0)
    var s0 := randomzap<string>("zero")
in i0(3)+size(s0("three"))
end
```

So far we have seen three ways to deal with the parameter \(<a>\): substitute for it (expansion of polymorphic functions), ignore it (fully boxed translations), or treat it as a black box (coercion-based representation analysis). But the most explicit thing we could do is to take it at face value: that is, to pass at run time a description of the type \(a\).
The compiler can build run-time descriptions of types, not so different from the data structures summarized in Figure 16.3b. The primitive types can be statically bound to specific labels (such as $L_{\text{int}_\text{type}}$). Then the function $\text{randomzap}<a>(x:a)$ can actually be translated as something like,

```plaintext
function randomzap(a:type,x:a) : a =
  let function f(y:a) : a =
    let var s = sizeof(a)
    in if random()
      then copy s bytes from y to result
      else copy s bytes from x to result
    end
  in f
end
```

The type-description $a$ is a free variable of the inner function $f$, and must be handled using closures as described in Section 15.2. The code in the then-clause inside $f$ that moves a value of type $a$ from its argument $y$ to the return-value register must examine $a$ to see how many words to move, and from what kind of register.

An interesting aspect of type passing is that the descriptions of types can also be used in the garbage-collector interface. The data does not need to describe itself using boxing, because each function knows the type of all its variables – and the polymorphic functions know which variables describe the types of other variables. Type passing also enables the introduction of a typecase facility (see Table 14.6 on page 307).

Type passing has certain implementation challenges. Descriptions of types must be constructed at run time, as in the `append` function (page 353), which receives a type-description $e$ and must construct the description `list<e>`. One must take care that constructing these descriptions does not become too costly. Also, a polymorphic function must treat its variables differently depending on what the type parameters say, and this can become costly.

### 16.4 Resolution of Static Overloading

Some languages permit overloading: different functions of the same name but different argument types. The compiler must choose between function-bodies based on the types of the actual parameters. This is sometimes known as ad hoc polymorphism, as opposed to the parametric polymorphism described in the previous sections.
Static overloading is not difficult to implement. When processing the declaration of an overloaded function $f$, the new binding $b_n$ must not hide the old definitions $b_1, \ldots, b_{n-1}$. Instead, the new binding maps $f$ to a list of different implementations, $f \mapsto [b_1, \ldots, b_n]$. Depending on the language semantics, it may be necessary to give an error message if $b_n$ has identical parameter types to one of the $b_i$.

Then, when looking up $f$ in a place where it is called with actual parameters, the types of the actual parameters will determine which of the bindings $b_i$ should be used.

Some languages allow functions of identical argument types (but different result type) to be overloaded; some languages allow forms of dynamic overloading; see the Further Reading section.

One of the first “polymorphic” languages was Lisp [McCarthy 1960], which has no static (i.e., compile-time checkable) type system at all. Consequently, the fully boxed implementation of data was used, so that the data could describe itself to the run-time type-checker as well as to the garbage collector.

The Hindley-Milner type system was invented for combinatory logic by Hindley [1969] and for the ML programming language by Milner [1978]. Similarly, second-order lambda calculus was invented for logic by Girard [1971] and for programming by Reynolds [1974]. Harper and Mitchell [1993] show how programs using Hindley-Milner types can be translated into second-order lambda calculus (e.g., how ImplicitPoly-Tiger can be automatically translated into Poly-Tiger). Mitchell [1990] explains the theoretical aspects of polymorphic type systems.

The first programming language to use implicit parametric polymorphism was ML, which was originally the MetaLanguage of the Edinburgh theorem prover [Gordon et al. 1978] but was later developed into a general-purpose programming language [Milner et al. 1990]. Cardelli [1984] describes a fully boxed implementation of ML. Leroy [1992] describes coercion-based representation analysis, Shao and Appel [1995] describe a variant that does recursive wrapping only when necessary, and Shao [1997] shows a more general scheme that combines coercion-based and type-passing styles, and also works on explicitly typed languages such as Poly-Tiger. Harper and Morrisett [1995] and Tolmach [1994] describe type-passing style.
CHAPTER SIXTEEN. POLYMORPHIC TYPES

Type inference for ML takes exponential time in the worst case [Mairson 1990], but in practice it runs quickly: the particular arrow-type structures that cause the worst-case behavior have not been observed in real programs. When polymorphic recursion is permitted, then type inference is no longer a computable problem [Henglein 1993; Kfoury et al. 1993].

In the Ada programming language [Ada 1980], the generic mechanism allows a function (in fact, an entire package) to be parameterized over types; but full type-checking is done at each call site after the generic is applied to actual parameters, and the expansion technique of implementation must be used.

Overloading. Ada allows different functions with the same parameter types to be overloaded, as long as the result types are different. When the output of such a function is an argument to another overloaded identifier, then there may be zero, one, or many possible interpretations of the expression; the Ada semantics say that the expression is legal only if there is exactly one interpretation. Aho et al. [1986, section 6.5] discuss this issue and give a resolution algorithm. But Ada-style overloading has not been widely imitated in recent language designs, perhaps because it can confuse the programmer.

Dynamic overloading allows different implementations of a function to be chosen based on the run-time type of an actual parameter; another name for this is overriding, and it is a fundamental concept of object-oriented programming (see Chapter 14). Type classes in the Haskell language allow overloading and parametric polymorphism to interact in a useful and expressive way [Hall et al. 1996].

EXERCISES

16.1 Show the steps in type-checking the declaration of append on page 353 using Algorithm 16.8.

*16.2 Algorithm 16.8 shows how to type-check the declarations and calls of single-argument functions and records. Write a version (in the same notational style) that covers the cases where there are multiple type arguments, multiple value arguments, and multiple record fields; that is, complete these clauses:

\[
\text{transdec}(\sigma_v, \sigma_t, \text{function } f<z_1, \ldots, z_k>(x_1 : t_1, \ldots, x_n : t_n) : t_r = e_{\text{body}}) = \\
\text{transexp}(\sigma_v, \sigma_t, e_f<t_1, \ldots, t_k>(e_1, \ldots, e_n)) = \\
\text{transexp}(\sigma_v, \sigma_t, \text{rcrd}<t_1, \ldots, t_k>{\text{fld}_1 = e_1, \ldots, \text{fld}_n = e_n}) =
\]
16.3 Show the results of calling `unify` on the following pairs of arguments: Is the result `OK` or `error`? What bindings are added to $\sigma_m$? The symbols $\alpha, \beta, \ldots$ stand for Meta types, and in each case $\sigma_m$ is initially empty.

a. $(\alpha, \text{int} \to \gamma)$ and $(\text{int} \to \gamma, \beta)$.

b. $\alpha \to \alpha$ and $\alpha$.

c. $(\text{list}<\beta>, \alpha \to \text{string})$ and $(\text{list}<\alpha>, \beta \to \text{string})$.

d. $\alpha \to \alpha$ and $\text{int} \to \text{string}$.

e. $(\alpha, \alpha, \alpha, \beta, \beta)$ and $(\delta, \text{int}, \gamma, \gamma, \delta)$.

*16.4 Show an algorithm for composing two substitutions. That is, given $\sigma_1$ and $\sigma_2$, construct $\sigma_{12}$ such that $\text{subst}(t, \sigma_{12}) = \text{subst}(\text{subst}(t, \sigma_1), \sigma_2)$ for any type $t$. Then show how Algorithm 16.4 can be written more efficiently.

*16.5 Show the steps in type-inferencing the declaration of `randomzap` (page 364) followed by the expression `randomzap(0)`, using Algorithm 16.10.

16.6 Translate the following declarations from ImplicitPoly-Tiger to Poly-Tiger.

a. type list<e> = {head: e, tail: list<e>}

function map(f,l) =
  if l=nil then nil
  else list{head=f(l.head),tail=map(f,l.tail)}

b. type list<e> = {head: e, tail: list<e>}

function fold(f,z) =
  let function helper(l) =
    if l=nil then z else f(l.head,helper(l.tail))
  in helper
end

function add(i,j) = i+j

var x := fold(add,0)(list{head=3,tail=
  list{head=5,tail=nil}})

*16.7 There is a difficulty in translating the following program from ImplicitPoly-Tiger to Poly-Tiger:

```
let function f(s) = let function g(y) = y
  in print(s); g
end
var f1 := f("beep")
in size(f1("three"))+f1(3)
end
```

a. What integer does this expression return, and what gets printed during the evaluation of the expression?
b. Apply Algorithm 16.10 to this program to demonstrate that it is well typed in ImplicitPoly-Tiger. (Remember that print takes a string argument; it is not polymorphic.) Hint: The type of \( f \) is \( \text{Poly([z], App(String, []) \rightarrow (Var(z) \rightarrow Var(z)))} \).

Show how the declaration function \( f(s) = \ldots \) is translated to Poly-Tiger. Hint: Because the type of \( f \) is \( \text{Poly([z], \ldots)} \), the explicitly typed function should begin function \( f_{<z>}(s: \text{string}) = \ldots \).

d. Translate \( \text{var f1 := f("beep")}. \) Hint: Somewhere in that process you’ll have \( f_{<t>}("beep") \); but where does \( t \) come from? The usual solution is to make up a new function

\[
\text{var f1: ? = let function h_{<t>}(): ? = f_{<t>}("beep") in h end}
\]

but I’ll let you fill the omitted types. The function \( h \) has a type parameter but no value parameter!

e. Translate the expression \( \text{size(f1("three")) + f1(3)}. \)

f. What gets printed during the evaluation of the translated expression? Hint: It’s not the same as what’s printed in part (a).

One way to avoid this problem [Wright 1995] is to restrict the implicitly polymorphic language (such as ML or ImplicitPoly-Tiger) such that expressions containing top-level effects (such the function call \( f("beep") \)) must not be polymorphic.

16.8  On a 32-bit machine, let us represent \textit{pointers} with the last two bits 00 (because they point to word-aligned data), and \textit{integers} with the last bit 1. The 31-bit integer value \( x \) will be represented as \( x' = 2x + 1 \). Show the best sequence of ordinary machine instructions to implement each of the following expressions on tagged values. In each case, compare the length of this instruction sequence with the instructions needed to implement the same expression on 32-bit \textit{untagged} values.

\begin{enumerate}
\item \( c' \leftarrow a' + b' \)
\item \( c' \leftarrow a' + 3 \)
\item \( c' \leftarrow a' \times b' \).
\item A conditional branch on \( a' < b' \).
\item The basic block \( c' \leftarrow a' \times b'; s' \leftarrow s' + c' \) with \( c' \) dead afterwards.
\item Now suppose you wish to have the computer’s \textit{overflow} flags set if any computation computes a value that cannot fit in a 31-bit signed integer. But your computer only calculates this for its 32-bit calculations. Analyze each of the instruction sequences above to see whether it sets the \textit{overflow} appropriately in all cases.
\end{enumerate}
Dataflow Analysis

anal-y-sis: an examination of a complex, its elements, and their relations

Webster’s Dictionary

An optimizing compiler transforms programs to improve their efficiency without changing their output. There are many transformations that improve efficiency:

Register allocation: Keep two nonoverlapping temporaries in the same register.

Common-subexpression elimination: If an expression is computed more than once, eliminate one of the computations.

Dead-code elimination: Delete a computation whose result will never be used.

Constant folding: If the operands of an expression are constants, do the computation at compile time.

This is not a complete list of optimizations. In fact, there can never be a complete list.

NO MAGIC BULLET

Computability theory shows that it will always be possible to invent new optimizing transformations.

Let us say that a fully optimizing compiler is one that transforms each program $P$ to a program $\text{Opt}(P)$ that is the smallest program with the same input/output behavior as $P$. We could also imagine optimizing for speed instead of program size, but let us choose size to simplify the discussion.

For any program $Q$ that produces no output and never halts, $\text{Opt}(Q)$ is short and easily recognizable:

$L_1 : \text{goto } L_1$
Therefore, if we had a fully optimizing compiler we could use it to solve the halting problem; to see if there exists an input on which \( P \) halts, just see if \( \text{Opt}(P) \) is the one-line infinite loop. But we know that no computable algorithm can always tell whether programs halt, so a fully optimizing compiler cannot be written either.

Since we can’t make a fully optimizing compiler, we must build optimizing compilers instead. An optimizing compiler transforms \( P \) into a program \( P' \) that always has the same input/output behavior as \( P \), and might be smaller or faster. We hope that \( P' \) runs faster than the optimized programs produced by our competitors’ compilers.

No matter what optimizing compiler we consider, there must always exist another (usually bigger) optimizing compiler that does a better job. For example, suppose we have an optimizing compiler \( A \). There must be some program \( P_x \) which does not halt, such that \( A(P_x) \neq \text{Opt}(P_x) \). If this were not the case, then \( A \) would be a fully optimizing compiler, which we could not possibly have. Therefore, there exists a better compiler \( B \): 

\[
B(P) = \text{if } P = P_x \text{ then } [L : \text{goto } L] \text{ else } A(P)
\]

Although we don’t know what \( P_x \) is, it is certainly just a string of source code, and given that string we could trivially construct \( B \).

The optimizing compiler \( B \) isn’t very useful – it’s not worth handling special cases like \( P_x \) one at a time. In real life, we improve \( A \) by finding some reasonably general program transformation (such as the ones listed at the beginning of the chapter) that improves the performance of many programs. We add this transformation to the optimizer’s “bag of tricks” and we get a more competent compiler. When our compiler knows enough tricks, we deem it mature.

This theorem, that for any optimizing compiler there exists a better one, is known as the full employment theorem for compiler writers.

17.1 INTERMEDIATE REPRESENTATION FOR FLOW ANALYSIS

In this chapter we will consider intraprocedural global optimization. Intraprocedural means the analysis stays within a single procedure or function (of a language like Tiger); global means that the analysis spans all the statements or basic blocks within that procedure. Interprocedural optimization is more global, operating on several procedures and functions at once.
Each of the optimizing transformations listed at the beginning of the chapter can be applied using the following generic recipe:

**Dataflow analysis:** Traverse the flow graph, gathering information about what may happen at run time (this will necessarily be a conservative approximation).

**Transformation:** Modify the program to make it faster in some way; the information gathered by analysis will guarantee that the program’s result is unchanged.

There are many dataflow analyses that can provide useful information for optimizing transformations. Like the liveness analysis described in Chapter 10, most can be described by *dataflow equations*, a set of simultaneous equations derived from nodes in the flow graph.

**QUADRUPLES**

Chapter 10’s liveness analysis operates on `Assem` instructions, which clearly indicate *uses* and *defs* but whose actual operations are machine-dependent assembly-language strings. Liveness analysis, and register allocation based on it, do not need to know what operations the instructions are performing, just their uses and definitions. But for the analyses and optimizations in this chapter, we need to understand the *operations* as well. Therefore, instead of `Assem` instructions we will use `Tree`-language terms (Section 7.2), simplified even further by ensuring that each `Exp` has only a single `MEM` or `BINOP` node.

We can easily turn ordinary `Tree` expressions into simplified ones. Wherever there is a nested expression of one `BINOP` or `MEM` inside another, or a `BINOP` or `MEM` inside a `JUMP` or `CJUMP`, we introduce a new temporary using `ESEQ`:  

![](image)

and then apply the `Canon` module to remove all the `ESEQ` nodes.

We also introduce new temporaries to ensure that any *store* statement (that
is, a MOVE whose left-hand side is a MEM node) has only a TEMP or a CONST on its right-hand side, and only a TEMP or CONST under the MEM.

The statements that remain are all quite simple; they take one of the forms shown in Table 17.1.

Because the “typical” statement is \( a \leftarrow b \oplus c \) with four components \((a, b, c, \oplus)\), these simple statements are often called quadruples. We use \( \oplus \) to stand for an arbitrary binop.

A more efficient compiler would represent quadruples with their own data type (instead of using Tree data structures), and would translate from trees to quadruples all in one pass.

Intraprocedural optimizations take these quadruples that come out of the Canon phase of the compiler, and transform them into a new set of quadruples. The optimizer may move, insert, delete, and modify the quadruples. The resulting procedure-body must then be fed into the instruction-selection phase.
of the compiler. However, the tree matching will not be very effective on the “atomized” trees where each expression contains only one BINOP or MOVE. After the optimizations are completed, there will be many MOVE statements that define temporaries that are used only once. It will be necessary to find these and turn them back into nested expressions.

We make a control flow graph of the quadruples, with a directed edge from each node (statement) \( n \) to its successors – that is, the nodes that can execute immediately after \( n \).

### 17.2. VARIOUS DATAFLOW ANALYSES

A dataflow analysis of a control flow graph of quadruples collects information about the execution of the program. One dataflow analysis determines how definitions and uses are related to each other, another estimates what values a variable might have at a given point, and so on. The results of these analyses can be used to make optimizing transformations of the program.

#### REACHING DEFINITIONS

For many optimizations we need to see if a particular assignment to a temporary \( t \) can directly affect the value of \( t \) at another point in the program. We say that an unambiguous definition of \( t \) is a particular statement (quadruple) in the program of the form \( t \leftarrow a \oplus b \) or \( t \leftarrow M[a] \). Given such a definition \( d \), we say that \( d \) reaches a statement \( u \) in the program if there is some path of control flow edges from \( d \) to \( u \) that does not contain any unambiguous definition of \( t \).

An ambiguous definition is a statement that might or might not assign a value to \( t \). For example, if \( t \) is a global variable, and the statement \( s \) is a \texttt{CALL} to a function that sometimes modifies \( t \) but sometimes does not, then \( s \) is an ambiguous definition. But our Tiger compiler treats escaping variables as memory locations, not as temporaries subject to dataflow analysis. This means that we never have ambiguous definitions; unfortunately, we also lose the opportunity to perform optimizations on escaping variables. For the remainder of this chapter, we will assume all definitions are unambiguous.

We can express the calculation of reaching definitions as the solution of dataflow equations. We label every \texttt{MOVE} statement with a definition-ID, and we manipulate sets of definition-IDs. We say that the statement \( d_1 : t \leftarrow x \oplus y \) generates the definition \( d_1 \), because no matter what other definitions reach.
Statement  s     gen[s]     kill[s]  
\(\begin{array}{ll}
  d : t \leftarrow b \oplus c & \{d\} \quad \text{def}\{s(t) - \{d\} \\
  d : t \leftarrow M[b] & \{d\} \quad \text{def}\{s(t) - \{d\} \\
  M[a] \leftarrow b & {} \quad {} \\
  \text{if } a \text{ relop } b \text{ goto } L_1 \text{ else goto } L_2 & {} \quad {} \\
  \text{goto } L & {} \quad {} \\
  f(a_1, \ldots, a_n) & {} \quad {} \\
  d : t \leftarrow f(a_1, \ldots, a_n) & \{d\} \quad \text{def}\{s(t) - \{d\}
\end{array}\)  

| TABLE 17.2. | Gen and kill for reaching definitions. |

At the beginning of this statement, we know that \(d_1\) reaches the end of it. And we say that this statement kills any other definition of \(t\), because no matter what other definitions of \(t\) reach the beginning of the statement, they do not reach the end (they cannot directly affect the value of \(t\) after this statement).

Let us define \(\text{def}\{s(t)\}\) as the set of all definitions (or definition-IDs) of the temporary \(t\). Table 17.2 summarizes the generate and kill effects of the different kinds of quadruples.

Using \(\text{gen}\) and \(\text{kill}\), we can compute \(\text{in}[n]\) (and \(\text{out}[n]\)) the set of definitions that reach the beginning (and end) of each node \(n\):

\[
\begin{align*}
  \text{in}[n] &= \bigcup_{p \in \text{pred}[n]} \text{out}[p] \\
  \text{out}[n] &= \text{gen}[n] \cup (\text{in}[n] - \text{kill}[n])
\end{align*}
\]

These equations can be solved by iteration: first \(\text{in}[n]\) and \(\text{out}[n]\) are initialized to the empty set, for all \(n\); then the equations are treated as assignment statements and repeatedly executed until there are no changes.

We will take Program 17.3 as an example; it is annotated with statement numbers that will also serve as definition-IDs. In each iteration, we recalculate \(\text{in}\) and \(\text{out}\) for each statement in turn:
17.2. VARIOUS DATAFLOW ANALYSES

1: \( a \leftarrow 5 \)
2: \( c \leftarrow 1 \)
3: \( L_1: \text{if } c > a \text{ goto } L_2 \)
4: \( c \leftarrow c + c \)
5: \( \text{goto } L_1 \)
6: \( L_2: a \leftarrow c - a \)
7: \( c \leftarrow 0 \)

**PROGRAM 17.3.**

\[
\begin{array}{|c|c|c|c|c|c|c|}
\hline
n & \text{gen}[n] & \text{kill}[n] & \text{in}[n] & \text{out}[n] & \text{in}[n] & \text{out}[n] \\
\hline
1 & 1 & 6 & 1 & 1,2 & 1 & 1,2 \\
2 & 2 & 4,7 & 1,2,4,6 & 1,2,4 & 1,2,4 & 1,2,4,6 \\
3 & 4 & 2,7 & 1,2,4,6 & 1,2,4,6 & 1,2,4 & 1,2,4,6 \\
4 & 6 & 1,4 & 1,2,4,6 & 1,2,4,6 & 1,2,4 & 1,2,4,6 \\
5 & 7 & 2,4 & 2,6,6,7 & 2,4,6,7 & 2,4,6 & 2,4,6,7 \\
\hline
\end{array}
\]

Iteration 3 serves merely to discover that nothing has changed since iteration 2.

Having computed reaching definitions, what can we do with the information? The analysis is useful in several kinds of optimization. As a simple example, we can do constant propagation: only one definition of \( a \) reaches statement 3, so we can replace the test \( c > a \) with \( c > 5 \).

**AVAILABLE EXPRESSIONS**

Suppose we want to do common-subexpression elimination; that is, given a program that computes \( x \oplus y \) more than once, can we eliminate one of the duplicate computations? To find places where such optimizations are possible, the notion of available expressions is helpful.

An expression \( x \oplus y \) is available at a node \( n \) in the flow graph if, on every path from the entry node of the graph to node \( n \), \( x \oplus y \) is computed at least once and there are no definitions of \( x \) or \( y \) since the most recent occurrence of \( x \oplus y \) on that path.

We can express this in dataflow equations using \textit{gen} and \textit{kill} sets, where the sets are now sets of expressions.
Any node that computes \( x \oplus y \) *generates* \( \{ x \oplus y \} \), and any definition of \( x \) or \( y \) *kills* \( \{ x \oplus y \} \); see Table 17.4.

Basically, \( t \leftarrow b + c \) generates the expression \( b + c \). But \( b \leftarrow b + c \) does not generate \( b + c \), because after \( b + c \) there is a subsequent definition of \( b \). The statement \( \text{gen}[s] = \{ b \oplus c \} - \text{kill}[s] \) takes care of this subtlety.

A *store* instruction \((M[a] \leftarrow b)\) might modify any memory location, so it kills any *fetch* expression \((M[x])\). If we were sure that \( a \neq x \), we could be less conservative, and say that \( M[a] \leftarrow b \) does not kill \( M[x] \). This is called *alias analysis*; see Section 17.5.

Given \( \text{gen} \) and \( \text{kill} \), we compute \( \text{in} \) and \( \text{out} \) almost as for reaching definitions, except that we compute the *intersection* of the \( \text{out} \) sets of the predecessors instead of a union. This reflects the fact that an expression is available only if it is computed on *every* path into the node.

\[
\text{in}[n] = \bigcap_{p \in \text{pred}[n]} \text{out}[p] \quad \text{if } n \text{ is not the start node}
\]

\[
\text{out}[n] = \text{gen}[n] \cup (\text{in}[n] - \text{kill}[n])
\]

To compute this by iteration, we define the \( \text{in} \) set of the start node as empty, and initialize all other sets to *full* (the set of all expressions), not empty. This is because the intersection operator makes sets *smaller*, not bigger as the union operator does in the computation of reaching definitions. This algorithm then finds the *greatest* fixed point of the equations.
17.2. VARIOUS DATAFLOW ANALYSES

REACHING EXPRESSIONS
We say that an expression $t \leftarrow x \oplus y$ (in node $s$ of the flow graph) reaches node $n$ if there is a path from $s$ to $n$ that does not go through any assignment to $x$ or $y$, or through any computation of $x \oplus y$. As usual, we can express gen and kill; see Exercise 17.1.

In practice, the reaching expressions analysis is needed by the common-subexpression elimination optimization only for a small subset of all the expressions in a program. Thus, reaching expressions are usually computed ad hoc, by searching backward from node $n$ and stopping whenever a computation $x \oplus y$ is found. Or reaching expressions can be computed during the calculation of available expressions; see Exercise 17.4.

LIVENESS ANALYSIS
Chapter 10 has already covered liveness analysis, but it is useful to note that liveness can also be expressed in terms of gen and kill. Any use of a variable generates liveness, and any definition kills liveness:

<table>
<thead>
<tr>
<th>Statement $s$</th>
<th>gen$[s]$</th>
<th>kill$[s]$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$t \leftarrow b \oplus c$</td>
<td>${b, c}$</td>
<td>${t}$</td>
</tr>
<tr>
<td>$t \leftarrow M[b]$</td>
<td>${b}$</td>
<td>${t}$</td>
</tr>
<tr>
<td>$M[a] \leftarrow b$</td>
<td>${b}$</td>
<td>${}$</td>
</tr>
<tr>
<td>if $a &gt; b$ goto $L_1$ else goto $L_2$</td>
<td>${a, b}$</td>
<td>${}$</td>
</tr>
<tr>
<td>goto $L$</td>
<td>${}$</td>
<td>${}$</td>
</tr>
<tr>
<td>$L :$</td>
<td>${}$</td>
<td>${}$</td>
</tr>
<tr>
<td>$f(a_1, \ldots, a_n)$</td>
<td>${a_1, \ldots, a_n}$</td>
<td>${}$</td>
</tr>
<tr>
<td>$t \leftarrow f(a_1, \ldots, a_n)$</td>
<td>${a_1, \ldots, a_n}$</td>
<td>${t}$</td>
</tr>
</tbody>
</table>

The equations for in and out are similar to the ones for reaching definitions and available expressions, but backward because liveness is a backward dataflow analysis:

$$in[n] = gen[n] \cup (out[n] - kill[n])$$
$$out[n] = \bigcup_{s \in succ[n]} in[s]$$
17.3 TRANSFORMATIONS USING DATAFLOW ANALYSIS

Using the results of dataflow analysis, the optimizing compiler can improve the program in several ways.

COMMON-SUBEXPRESSION ELIMINATION
Given a flow-graph statement \( s : t ← x ⊕ y \), where the expression \( x ⊕ y \) is available at \( s \), the computation within \( s \) can be eliminated.

Algorithm. Compute reaching expressions, that is, find statements of the form \( n : v ← x ⊕ y \), such that the path from \( n \) to \( s \) does not compute \( x ⊕ y \) or define \( x \) or \( y \).

Choose a new temporary \( w \), and for such \( n \), rewrite as

\[
\begin{align*}
  n &: w ← x ⊕ y \\
  n' &: v ← w
\end{align*}
\]

Finally, modify statement \( s \) to be

\( s : t ← w \)

We will rely on copy propagation to remove some or all of the extra assignment quadruples.

CONSTANT PROPAGATION
Suppose we have a statement \( d : t ← c \) where \( c \) is a constant, and another statement \( n \) that uses \( t \), such as \( n : y ← t ⊕ x \).

We know that \( t \) is constant in \( n \) if \( d \) reaches \( n \), and no other definitions of \( t \) reach \( n \).

In this case, we can rewrite \( n \) as \( y ← c ⊕ x \).

COPY PROPAGATION
This is like constant propagation, but instead of a constant \( c \) we have a variable \( z \).

Suppose we have a statement \( d : t ← z \). and another statement \( n \) that uses \( t \), such as \( n : y ← t ⊕ x \).

If \( d \) reaches \( n \), and no other definition of \( t \) reaches \( n \), and there is no definition of \( z \) on any path from \( d \) to \( n \) (including a path that goes through \( n \) one or more times), then we can rewrite \( n \) as \( y ← z ⊕ x \).
A good graph-coloring register allocator will do *coalescing* (see Chapter 11), which is a form of copy propagation. It detects any intervening definitions of *z* in constructing the interference graph – an assignment to *z* while *d* is live makes an interference edge \((z, d)\), rendering *d* and *z* uncoalescable.

If we do copy propagation before register allocation, then we may increase the number of spills. Thus, if our only reason to do copy propagation were to delete redundant MOVE instructions, we should wait until register allocation. However, copy propagation at the quadruple stage may enable the recognition of other optimizations such as common-subexpression elimination. For example, in the program

\[
\begin{align*}
    a & \leftarrow y + z \\
    u & \leftarrow y \\
    c & \leftarrow u + z
\end{align*}
\]

the two \(+\)-expressions are not recognized as common subexpressions until after the copy propagation of \(u \leftarrow y\) is performed.

**DEAD-CODE ELIMINATION**

If there is a quadruple \(s : a \leftarrow b \oplus c\) or \(s : a \leftarrow M[x]\), such that \(a\) is not live-out of \(s\), then the quadruple can be deleted.

Some instructions have implicit side effects. For example, if the computer is configured to raise an exception on an arithmetic overflow or divide by zero, then deletion of an exception-causing instruction will change the result of the computation.

The optimizer should never make a change that changes program behavior, even if the change seems benign (such as the removal of a run-time “error”). The problem with such optimizations is that the programmer cannot predict the behavior of the program – and a program debugged with the optimizer enabled may fail with the optimizer disabled.

**SPEEDING UP DATAFLOW ANALYSIS**

Many dataflow analyses – including the ones described in this chapter – can be expressed using simultaneous equations on finite sets. So also can many of the algorithms used in constructing finite automata (Chapter 2) and parsers (Chapter 3). The equations can usually be set up so that they can be solved by *iteration*: by treating the equations as assignment statements and repeatedly...
executing all the assignments until none of the sets changes any more.

There are several ways to speed up the evaluation of dataflow equations.

**BIT VECTORS**

A set \( S \) over a finite domain (that is, where the elements are integers in the range \( 1 – N \) or can be put in an array indexed by \( 1 – N \)) can be represented by a bit vector. The \( i \)th bit in the vector is a 1 if the element \( i \) is in the set \( S \).

In the bit-vector representation, unioning two sets \( S \) and \( T \) is done by a bitwise-or of the bit vectors. If the word size of the computer is \( W \), and the vectors are \( N \) bits long, then a sequence of \( N/W \) instructions can union two sets. Of course, \( 2N/W \) fetches and \( N/W \) stores will also be necessary, as well as indexing and loop overhead.

Intersection can be done by bitwise-and, set complement can be done by bitwise complement, and so on.

Thus, the bit-vector representation is commonly used for dataflow analysis. It would be inadvisable to use bit vectors for dataflow problems where the sets are expected to be very sparse (so the bit vectors would be almost all zeros), in which case a different implementation of sets would be faster.

**BASIC BLOCKS**

Suppose we have a node \( n \) in the flow graph that has only one predecessor, \( p \), and \( p \) has only one successor, \( n \). Then we can combine the \texttt{gen} and \texttt{kill} effects of \( p \) and \( n \) and replace nodes \( n \) and \( p \) with a single node. We will take \textit{reaching definitions} as an example, but almost any dataflow analysis permits a similar kind of combining.

Consider what definitions reach \texttt{out} of the node \( n \):

\[
\text{out}[n] = \text{gen}[n] \cup \left( \text{in}[n] - \text{kill}[n] \right)
\]

We know \( \text{in}[n] \) is just \( \text{out}[p] \); therefore

\[
\text{out}[n] = \text{gen}[n] \cup \left( \left( \text{gen}[p] \cup \left( \text{in}[p] - \text{kill}[p] \right) \right) - \text{kill}[n] \right)
\]

By using the identity \( (A \cup B) - C = (A - C) \cup (B - C) \) and then \( (A - B) - C = A - (B \cup C) \), we have

\[
\text{out}[n] = \text{gen}[n] \cup \left( \text{gen}[p] - \text{kill}[n] \right) \cup \left( \text{in}[p] - \left( \text{kill}[p] \cup \text{kill}[n] \right) \right)
\]

If we want to say that node \( pn \) combines the effects of \( p \) and \( n \), then this last
equation says that the appropriate \textit{gen} and \textit{kill} sets for \textit{pn} are:

\[
\begin{align*}
\text{gen}[pn] &= \text{gen}[n] \cup (\text{gen}[p] - \text{kill}[n]) \\
\text{kill}[pn] &= \text{kill}[p] \cup \text{kill}[n]
\end{align*}
\]

We can combine all the statements of a basic block in this way, and agglomerate the \textit{gen} and \textit{kill} effects of the whole block. The control-flow graph of basic blocks is much smaller than the graph of individual statements, so the multipass iterative dataflow analysis works much faster on basic blocks.

Once the iterative dataflow analysis algorithm is completed, we may recover the dataflow information of an individual statement (such as \textit{n}) within a block (such \textit{pn} in our example) by starting with the \textit{in} set computed for the entire block and – in one pass – applying the \textit{gen} and \textit{kill} sets of the statements that precede \textit{n} in the block.

\section*{ORDERING THE NODES}

In a \textit{forward} dataflow problem (such as reaching definitions or available expressions), the information coming \textit{out} of a node goes \textit{in} to the successors. If we could arrange that every node was calculated before its successors, the dataflow analysis would terminate in one pass through the nodes.

This would be possible if the control-flow graph had no cycles. We would \textit{topologically sort} the flow graph – this just gives an ordering where each node comes before its successors – and then compute the dataflow equations in sorted order. But often the graph will have cycles, so this simple idea won’t work. Even so, quasi-topologically sorting a cyclic graph by depth-first search helps to reduce the number of iterations required on cyclic graphs; in quasi-sorted order, most nodes come before their successors, so information flows forward quite far through the equations on each iteration.

Depth-first search (Algorithm 17.5) topologically sorts an acyclic graph graph, or quasi-topologically sorts a cyclic graph, quite efficiently. Using \textit{sorted}, the order computed by depth-first search, the iterative solution of dataflow equations should be computed as

\begin{verbatim}
repeat
  for \(i \leftarrow 1\) to \(N\)
  \(n \leftarrow \text{sorted}[i]\)
  \(in \leftarrow \bigcup_{p \in \text{pred}[n]} \text{out}[p]\)
  \(\text{out}[n] \leftarrow \text{gen}[n] \cup (\text{in} - \text{kill}[n])\)
until no \textit{out} set changed in this iteration
\end{verbatim}

There is no need to make \textit{in} a global array, since it is used only locally in
CHAPTER SEVENTEEN. DATAFLOW ANALYSIS

**Topological-sort:**

\[ N \leftarrow \text{number of nodes} \]

for all nodes \( i \)

\[ \text{mark}[i] \leftarrow \text{false} \]

DFS(start-node)

**function** DFS(i)

\[ \text{if mark}[i] = \text{false} \]

\[ \text{mark}[i] \leftarrow \text{true} \]

for each successor \( s \) of node \( i \)

\[ \text{DFS}(s) \]

\[ \text{sorted}[N] \leftarrow i \]

\[ N \leftarrow N - 1 \]

**ALGORITHM 17.5.** Topological sort by depth-first search.

computing **out**.

For **backward** dataflow problems such as liveness analysis, we use a version of **Algorithm 17.5** starting from **exit-node** instead of **start-node**, and traversing **predecessor** instead of **successor** edges.

**USE-DEF AND DEF-USE CHAINS**

Information about reaching definitions can be kept as **use-def chains**, that is, for each use of a variable \( x \), a list of the definitions of \( x \) reaching that use. Use-def chains do not allow faster dataflow analysis per se, but allow efficient implementation of the optimization algorithms that use the results of the analysis.

A generalization of use-def chains is **static single-assignment form**, described in Chapter 19. SSA form not only provides more information than use-def chains, but the dataflow analysis that computes it is very efficient.

One way to represent the results of liveness analysis is via **def-use chains**: a list, for each definition, of all possible uses of that definition. SSA form also contains def-use information.

**WORK-LIST ALGORITHMS**

If any **out** set changes during an iteration of the **repeat-until** loop of an iterative solver, then all the equations are recalculated. This seems a pity, since most of the equations may not be affected by the change.

A **work-list** algorithm keeps track of just which **out** sets must be recalculated. Whenever node \( n \) is recalculated **and its out set is found to change**, all the successors of \( n \) are put onto the work-list (if they’re not on it already). This is illustrated in **Algorithm 17.6**.

The algorithm will converge faster if, whenever a node is removed from
17.4. SPEEDING UP DATAFLOW ANALYSIS

\[ W \leftarrow \text{the set of all nodes} \]

\[ \textbf{while} \ W \text{ is not empty} \]

\[ \quad \text{remove a node } n \text{ from } W \]

\[ \quad \text{old} \leftarrow \text{out}[n] \]

\[ \quad \text{in} \leftarrow \bigcup_{p \in \text{pred}[n]} \text{out}[p] \]

\[ \quad \text{out}[n] \leftarrow \text{gen}[n] \cup (\text{in} \setminus \text{kill}[n]) \]

\[ \textbf{if} \ \text{old} \neq \text{out}[n] \]

\[ \quad \textbf{for} \text{ each successor } s \text{ of } n \]

\[ \quad \quad \textbf{if} \ s \notin W \]

\[ \quad \quad \text{put } s \text{ into } W \]

\begin{algorithm}
\textbf{ALGORITHM 17.6.} A work-list algorithm for reaching definitions.
\end{algorithm}

\[ W \text{ for processing, we choose the node in } W \text{ that occurs earliest in the } \textit{sorted} \]

array produced by Algorithm 17.5.

The coalescing, graph-coloring register allocator described in Chapter 11

is an example of a work-list algorithm with many different work-lists. Section 19.3 describes a work-list algorithm for constant propagation.

INCREMENTAL DATAFLOW ANALYSIS

Using the results of dataflow analysis, the optimizer can perform program

transformations: moving, modifying, or deleting instructions. But optimiza-

tions can cascade:

- Removal of the dead code \[ a \leftarrow b \oplus c \] might cause \[ b \] to become dead in a

  previous instruction \[ b \leftarrow x \oplus y. \]

- One common-subexpression elimination begets another. In the program

\[ x \leftarrow b + c \]

\[ y \leftarrow a + x \]

\[ u \leftarrow b + c \]

\[ v \leftarrow a + u \]

after \[ u \leftarrow b + c \] is replaced by \[ u \leftarrow x \], copy propagation changes \[ a + u \] to

\[ a + x \], which is a common subexpression and can be eliminated.

A simple way to organize a dataflow-based optimizer is to perform a global

flow analysis, then make all possible dataflow-based optimizations, then re-

peat the global flow analysis, then perform optimizations, and so on until no
more optimizations can be found. At best this iterates two or three times, so that on the third round there are no more transformations to perform.

But the worst case is very bad indeed. Consider a program in which the statement \( z \leftarrow a_1 + a_2 + a_3 + \cdots + a_n \) occurs where \( z \) is dead. This translates into the quadruples

\[
\begin{align*}
x_1 & \leftarrow a_1 + a_2 \\
x_2 & \leftarrow x_1 + a_3 \\
& \vdots \\
x_{n-2} & \leftarrow x_{n-3} + a_{n-1} \\
z & \leftarrow x_{n-2} + a_n
\end{align*}
\]

Liveness analysis determines that \( z \) is dead; then dead-code elimination removes the definition of \( z \). Then another round of liveness analysis determines that \( x_{n-2} \) is dead, and then dead-code elimination removes \( x_{n-2} \), and so on. It takes \( n \) rounds of analysis and optimization to remove \( x_1 \) and then determine that there is no more work to do.

A similar situation occurs with common-subexpression elimination, when there are two occurrences of an expression such as \( a_1 + a_2 + a_3 + \cdots + a_n \) in the program.

To avoid the need for repeated, global calculations of dataflow information, there are several strategies:

**Cutoff:** Perform no more than \( k \) rounds of analysis and optimization, for \( k = 3 \) or so. Later rounds of optimization may not be finding many transformations to do anyway. This is a rather unsophisticated approach, but at least the compilation will terminate in a reasonable time.

**Cascading analysis:** Design new dataflow analyses that can predict the cascade effects of the optimizations that will be done.

**Incremental dataflow analysis:** When the optimizer makes a program transformation – which renders the dataflow information invalid – instead of discarding the dataflow information, the optimizer should “patch” it.

**Value numbering.** The value numbering analysis is an example of a cascading analysis that, in one pass, finds all the (cascaded) common subexpressions within a basic block.

The algorithm maintains a table \( T \), mapping variables to value numbers, and also mapping triples of the form \((\text{value number}, \text{operator}, \text{value number})\) to value numbers. For efficiency, \( T \) should be represented as a hash table. There is also a global number \( N \) counting how many distinct values have been seen so far.
17.4. SPEEDING UP DATAFLOW ANALYSIS

\[ T \leftarrow \text{empty} \]
\[ N \leftarrow 0 \]
for each quadruple \( a \leftarrow b \oplus c \) in the block
  if \( (b \mapsto k) \in T \) for some \( k \)
    \( n_b \leftarrow k \)
  else
    \( N \leftarrow N + 1 \)
    \( n_b \leftarrow N \)
    put \( b \mapsto n_b \) into \( T \)
  if \( (c \mapsto k) \in T \) for some \( k \)
    \( n_c \leftarrow k \)
  else
    \( N \leftarrow N + 1 \)
    \( n_c \leftarrow N \)
    put \( c \mapsto n_c \) into \( T \)
  if \( ((n_b, \oplus, n_c) \mapsto m) \in T \) for some \( m \)
    put \( a \mapsto m \) into \( T \)
    mark this quadruple \( a \leftarrow b \oplus c \) as a common subexpression
  else
    \( N \leftarrow N + 1 \)
    put \( (n_b, \oplus, n_c) \mapsto N \) into \( T \)
    put \( a \mapsto N \) into \( T \)

**ALGORITHM 17.7.** Value numbering.

Using \( T \) and \( N \), the value-numbering algorithm (Algorithm 17.7) scans the quadruples of a block from beginning to end. Whenever it sees an expression \( b + c \), it looks up the value number of \( b \) and the value number of \( c \). It then looks up hash\((n_b, n_c, +)\) in \( T \); if found, it means that \( b + c \) repeats the work of an earlier computation; we mark \( b + c \) for deletion, and use the previously computed result. If not found, we leave \( b + c \) in the program and also enter it in the hash table.

Figure 17.8 illustrates value numbering on a basic block: (a) is the list of quadruples, and (b) is the table (after the algorithm is finished). We can view the table as a directed acyclic graph (DAG), if we view an entry \((m, \oplus, n) \mapsto q\) as a node \( q \) with edges to nodes \( m \) and \( n \), as shown in Figure 17.8c.
Value numbering is an example of a single dataflow analysis that calculates the effect of cascaded optimizations: in this case, cascaded common-subexpression elimination. But the optimizer would like to perform a wide variety of transformations – especially when the loop optimizations described in the next chapter are included. It is very hard to design a single dataflow analysis capable of predicting the results of many different optimizations in combination.

Instead, we use a general-purpose dataflow analyzer and a general-purpose optimizer; but when the optimizer changes the program, it must tell the analyzer what information is no longer valid.

**Incremental liveness analysis.** For example, an incremental algorithm for liveness analysis must keep enough information so that if a statement is inserted or deleted, the liveness information can be efficiently updated.

Suppose we delete this statement $s : a ← b ⊕ c$ from a flow graph on which we have live-in and live-out information for every node. The changes to the dataflow information are as follows:

1. $a$ is no longer defined here. Therefore, if $a$ is live-out of this node, it will now be live-in where it was not before.
17.4. SPEEDING UP DATAFLOW ANALYSIS

2. \( b \) is no longer used here. Therefore, if \( b \) is not live-out of this node, it will no longer be live-in. We must propagate this change backwards, and do the same for \( c \).

A work-list algorithm will be useful here, since we can just add the predecessor of \( s \) to the work-list and run until the work-list is empty; this will often terminate quickly.

Propagating change (1) does the same kind of thing that the original (non-incremental) work-list algorithm for liveness does: it makes the live-sets bigger. Thus, our proof (Exercise 10.2) that the algorithm finds a least fixed point of the liveness equations also applies to the propagation of additional liveness caused by the deletion of the definition of \( a \). Even the proof that the liveness analysis terminates was based on the idea that any change makes things bigger, and there was an a priori limit to how big the sets could get.

But change (2) makes live-sets smaller, not bigger, so naively running our original algorithm starting from the previously computed in and out sets may find a fixed point that is not a least fixed point. For example, suppose we have the following program:

```
0    d ← 4
1    a ← 0
2    L_1 : b ← a + 1
3    c ← c + b
3a   a ← d
4    a ← b \cdot 2
5    if a < N goto L_1
6    return c
```

Liveness analysis shows that \( d \) is live-in at statements 1, 2, 3, 3a, 4, 5. But \( a \) is not live-out of statement 3a, so this statement is dead code, and we can delete it. If we then start with the previously computed dataflow information and use Algorithm 10.4 (page 221) until it reaches a fixed point, we will end up with the column \( Y \) of Table 10.7, which is not the best possible approximation of the actual liveness information.

**A more refined liveness analysis.** Therefore, we must use a better algorithm. The solution is that at each point where a variable \( d \) is defined, we must keep track of exactly what uses it might have. Our liveness calculation will be very much like Algorithm 10.4, but it will operate on sets of uses instead of sets of variables. In fact, it is just like the reaching definitions algorithm in
reverse. Let $\text{uses}(v)$ be the set of all uses of variable $v$ in the program. Given a statement $s : a \leftarrow b \oplus c$, the set

$$\text{live-out}[s] \cap \text{uses}(a)$$

contains all the uses of $a$ that could possibly be reached by this definition.

Now, when we delete a quadruple that uses some variable $b$, we can delete that use of $b$ from all the live-in and live-out sets. This gives the least fixed point, as we desire.

**Cascades of dead code** After deleting statement 3a from the program above, the incremental liveness analysis will find that statement 0 is dead code and can be deleted. Thus, incremental liveness analysis cooperates well with dead-code elimination. Other kinds of dataflow analysis can similarly be made incremental; sometimes, as in the case of liveness analysis, we must first refine the analysis.

### 17.5 ALIAS ANALYSIS

The analyses we have described in this chapter consider only the values of Tree-language temporaries. Variables that escape are represented (by the front end of the compiler) in memory locations with explicit fetches and stores, and we have not tried to analyze the definitions, uses, and liveness of these variables. The problem is that a variable or memory location may have several different names, or aliases, so that it is hard to tell which statements affect which variables.

Variables that can be aliases include:

- variables passed as call-by-reference parameters (in Pascal, C++, Fortran);
- variables whose address is taken (in C, C++);
- $l$-value expressions that dereference pointers, such as $p.x$ in Tiger or $*p$ in C;
- $l$-value expressions that explicitly subscript arrays, such as $a[i]$;
- and variables used in inner-nested procedures (in Pascal, Tiger, ML).

A good optimizer should optimize these variables. For example, in the program fragment

$$p.x := 5; \quad q.x := 7; \quad a := p.x$$
we might want our *reaching definitions* analysis to show that only one definition of \( p.x \) (namely, 5) reaches the definition of \( a \). But the problem is that we cannot tell if one name is an alias for another. Could \( q \) point to the same record as \( p \)? If so, there are two definitions (5 and 7) that could reach \( a \).

Similarly, with call-by-reference parameters, in the program

```plaintext
function f(ref i: int, ref j: int) =
    (i := 5; j := 7; return i)
```

a naive computation of reaching definitions would miss the fact that \( i \) might be the same variable as \( j \), if \( f \) is called with \( f(x,x) \).

**The may-alias relation** We use *alias analysis*, a kind of dataflow analysis, to learn about different names that may point to the same memory locations. The result of alias analysis is a *may-alias* relation: \( p \) may-alias \( q \) if, in some run of the program, \( p \) and \( q \) might point to the same data. As with most dataflow analyses, static (compile-time) information cannot be completely accurate, so the may-alias relation is conservative: we say that \( p \) may-alias \( q \) if we cannot prove that \( p \) is never an alias for \( q \).

**ALIAS ANALYSIS BASED ON TYPES**

For languages with *strong typing* (such as Pascal, Java, ML, Tiger) where if two variables have incompatible types they cannot possibly be names for the same memory location, we can use the type information to provide a useful may-alias relation. Also in these languages the programmer cannot explicitly make a pointer point to a local variable, and we will use that fact as well.

We divide all the memory locations used by the program into disjoint sets, called *alias classes*. For Tiger, here are the classes we will use:

- For every frame location created by `F_allocLocal(true)`, we have a new class;
- For every record field of every record type, a new class;
- For every array type \( a \), a new class.

The semantic analysis phase of the compiler must compute these classes, as they involve the concept of *type*, of which the later phases are ignorant. Each class can be represented by a different integer.

The *Translate* functions must label every fetch and store (that is, every MEM node in the Tree language) with its class. We will need to modify the Tree data structure, putting an aliasClass field into the MEM node.
CHAPTER SEVENTEEN. DATAFLOW ANALYSIS

\[
\text{type list = \{head: int, tail: list\}} \quad \text{\{int \ p, \ q; int \ h, \ i;\}}
\]

\[
\text{var p : list := nil} \quad \text{p = &h;}
\]

\[
\text{var q : list := nil} \quad \text{q = &i;}
\]

\[
q := \text{list\{head=0, tail=nil\}; *p = 0;}
\]

\[
p := \text{list\{head=0, tail=q\}; *q = 5;}
\]

\[
q.\text{head := 5; a = *p;}
\]

\[
a := p.\text{head}
\]

(a) Tiger program \hspace{1cm} (b) C program

**PROGRAM 17.9.** \(p\) and \(q\) are not aliases.

Given two MEM nodes \(M_i[x]\) and \(M_j[y]\), where \(i\) and \(j\) are the alias classes of the MEM nodes, we can say that \(M_i[x]\) may-alias \(M_j[y]\) if \(i = j\).

This works for Tiger and Java. But it fails in the presence of call-by-reference or type casting.

**ALIAS ANALYSIS BASED ON FLOW**

Instead of, or in addition to, alias classes based on types, we can also make alias classes based on point of creation.

In Program 17.9a, even though \(p\) and \(q\) are the same type, we know they point to different records. Therefore we know that \(a\) must be assigned 0; the definition \(q.\text{head}:=5\) cannot affect \(a\). Similarly, in Program 17.9b we know \(p\) and \(q\) cannot be aliases, so \(a\) must be 0.

To catch these distinctions automatically, we will make an alias class for each point of creation. That is, for every different statement where a record is allocated (that is, for each call to \texttt{malloc} in C or \texttt{new} in Pascal or Java) we make a new alias class. Also, each different local or global variable whose address is taken is an alias class.

A pointer (or call-by-reference parameter) can point to variables of more than one alias class. In the program

```
1 p := \text{list \{head=0, tail=nil\};
2 q := \text{list \{head=6, tail=p\};
3 \text{if } a=0
4 \quad \text{then } p:=q;
5 \quad p.\text{head} := 4;
```

at line 5, \(q\) can point only to alias class 2, but \(p\) might point to alias class 1 or 2, depending on the value of \(a\).
17.5. ALIAS ANALYSIS

<table>
<thead>
<tr>
<th>Statement $s$</th>

</tbody>
</table>

TABLE 17.10. Transfer function for alias flow analysis.

So we must associate with each MEM node a set of alias classes, not just a single class. After line 2 we have the information $p \mapsto \{1\}, q \mapsto \{2\}$; out of line 4 we have $p \mapsto \{2\}, q \mapsto \{2\}$. But when two branches of control flow merge (in the example, we have the control edges $3 \to 5$ and $4 \to 5$) we must merge the alias class information; at line 5 we have $p \mapsto \{1, 2\}, q \mapsto \{2\}$.

Algorithm. The dataflow algorithm manipulates sets of tuples of the form $(t, d, k)$ where $t$ is a variable and $d, k$ is the alias class of all instances of the $k$th field of a record allocated at location $d$. The set $in[s]$ contains $(t, d, k)$ if $t - k$ might point to a record of alias class $d$ at the beginning of statement $s$. This is an example of a dataflow problem where bit vectors will not work as well as a tree or hash table representation better suited to sparse problems.

Instead of using $gen$ and $kill$ sets, we use a transfer function: we say that if $A$ is the alias information (set of tuples) on entry to a statement $s$, then $trans_s(A)$ is the alias information on exit. The transfer function is defined by Table 17.10 for the different kinds of quadruples.

The initial set $A_0$ includes the binding $(FP, frame, 0)$ where $frame$ is the special alias class of all frame-allocated variables of the current function.

We use the abbreviation $\Sigma_t$ to mean the set of all tuples $(t, d, k)$, where $d, k$ is the alias class of any record field whose type is compatible with variable $t$. Cooperation from the front end in providing a “small” $\Sigma_t$ for each $t$ makes the analysis more accurate. Of course, in a typeless language, or one with type-casts, $\Sigma_t$ might have to be the set of all alias classes.
The set equations for alias flow analysis are:

\[ \text{in}[s_0] = A_0 \quad \text{where } s_0 \text{ is the start node} \]
\[ \text{in}[n] = \bigcup_{p \in \text{pred}_n} \text{out}[p] \]
\[ \text{out}[n] = \text{trans}_n(\text{in}[n]) \]

and we can compute a solution by iteration in the usual way.

**Producing may-alias information.** Finally, we say that

\[ p \text{ may-alias } q \text{ at statement } s \]

if there exists \( d, k \) such that \((p, d, k) \in \text{in}[s]\) and \((q, d, k) \in \text{in}[s]\).

**USING MAY-ALIAS INFORMATION**

Given the may-alias relation, we can treat each alias class as a “variable” in dataflow analyses such as reaching definitions and available expressions.

To take available expressions as an example, we modify one line of Table 17.4, the gen and kill sets:

<table>
<thead>
<tr>
<th>Statement</th>
<th>gen[s]</th>
<th>kill[s]</th>
</tr>
</thead>
<tbody>
<tr>
<td>( M[a] \leftarrow b )</td>
<td>{}</td>
<td>( {M[x]</td>
</tr>
</tbody>
</table>

Now we can analyze the following program fragment:

1: \( u \leftarrow M[t] \)
2: \( M[x] \leftarrow r \)
3: \( w \leftarrow M[t] \)
4: \( b \leftarrow u + w \)

Without alias analysis, the store instruction in line 2 would kill the availability of \( M[t] \), since we would not know whether \( t \) and \( x \) were related. But suppose alias analysis has determined that \( t \) may alias \( x \) at 2 is \textit{false}; then \( M[t] \) is still available at line 3, and we can eliminate the common subexpression; after copy propagation, we obtain:

1: \( z \leftarrow M[r] \)
2: \( M[x] \leftarrow r \)
4: \( b \leftarrow z + z \)
What I have shown here is intraprocedural alias analysis. But an interprocedural analysis would help to analyze the effect of CALL instructions. For example, in the program

1: \( t \leftarrow fp + 12 \)
2: \( u \leftarrow M[t] \)
3: \( f(t) \)
4: \( w \leftarrow M[t] \)
5: \( b \leftarrow u + w \)

does the function \( f \) modify \( M[t] \)? If so, then \( M[t] \) is not available at line 4.

However, interprocedural alias analysis is beyond the scope of this book.

**ALIAS ANALYSIS IN STRICT PURE-FUNCTIONAL LANGUAGES**

Some languages have *immutable* variables that cannot change after their initialization. For example, *const* variables in the C language, most variables in the ML language, and all variables in PureFun-Tiger (see Chapter 15) are immutable.

Alias analysis is not needed for these variables. The purpose of alias analysis is to determine whether different statements in the program interfere, or whether one definition *kills* another. Though it is true that there could be many pointers to the same value, none of the pointers can cause the value to change, i.e. no immutable variable can be killed.

This is a good thing for the optimizer, and also for the programmer. The optimizer can do constant propagation and loop-invariant detection (see Chapter 18) without being bothered by aliases; and the programmer can understand what a segment of the program is doing also without the confusion and complexity introduced by stores through aliased pointers.

**FURTHER READING**

Gödel [1931] proved the *full employment theorem for mathematicians*. Turing [1937] proved that the halting problem is undecidable, and Rice [1953] proved the *full employment theorem for compiler writers*, even before there were any compiler writers.

**EXERCISES**

17.1 Show the dataflow equations for reaching expressions (page 391). Be specific about what happens in the case of quadruples such as \( t \leftarrow t \oplus b \) or \( t \leftarrow M[t] \) where the defined temporary also appears on the right-hand side. The elements of the gen and kill sets will be definition-IDs, as in reaching definitions. **Hint:** If the definition on page 391 is not clear enough to formulate a precise definition, be guided by the role that reaching expressions must play in common-subexpression elimination (page 392).

17.2 Write down the control-flow graph of basic blocks (not just statements) for Program 17.3, and show the gen and kill sets (for reaching definitions) of each block.

*17.3* Show how to combine the gen and kill effects of two adjacent statements in the same basic block for each of:
   a. Available expressions
   b. Liveness analysis

**17.4** Modify the algorithm for computing available expressions to simultaneously compute reaching expressions. To make the algorithm more efficient, you may take advantage of the fact that if an expression is not available at statement \( s \), then we do not need to know if it reaches \( s \) or not (for purposes of common-subexpression elimination). **Hint:** For each available expression \( a + b \) that is propagated through statement \( s \), also propagate a set representing all the statements that define \( a + b \) and reach \( s \).

17.5 Consider the calculation of reaching definitions on the following program:

\[
\begin{align*}
x &:= 1; \\
y &:= 1; \\
\text{if } z <> 0 \\
&\quad \text{then } x := 2 \\
&\quad \text{else } y := 2; \\
w &:= x+y
\end{align*}
\]

a. Draw a control-flow graph for this program.

b. Show the sorted array that results from running Algorithm 17.5 on the program.

c. Calculate reaching definitions, showing the result of each iteration in tabular format as on page 389. How many iterations are required?
*d. Prove that when *reaching definitions* is computed by iteration on an acyclic graph, taking the nodes in the order given by Algorithm 17.5, only one iteration is necessary (the second iteration merely verifies that nothing has changed).

**Hint:** Prove, and make use of, the lemma that each node is visited after all of its predecessors.

e. Suppose we order the nodes according to the order they are *first visited* by depth-first search. Calculate reaching definitions using that order, showing the results in tabular format; how many iterations are required?

*17.6* Write down a work-list algorithm for liveness analysis, in a form similar to that of Algorithm 17.6.
Loop Optimizations

**Loop**: a series of instructions that is repeated until a terminating condition is reached

*Webster’s Dictionary*

Loops are pervasive in computer programs, and a great proportion of the execution time of a typical program is spent in one loop or another. Hence it is worthwhile devising optimizations to make loops go faster. Intuitively, a loop is a sequence of instructions that ends by jumping back to the beginning. But to be able to optimize loops effectively we will use a more precise definition.

A loop in a control-flow graph is a set of nodes \( S \) including a *header* node \( h \) with the following properties:

- From any node in \( S \) there is a path of directed edges leading to \( h \).
- There is a path of directed edges from \( h \) to any node in \( S \).
- There is no edge from any node outside \( S \) to any node in \( S \) other than \( h \).

Thus, the dictionary definition (from *Webster’s*) is not the same as the technical definition.

Figure 18.1 shows some loops. A *loop entry* node is one with some predecessor outside the loop; a *loop exit* node is one with a successor outside the loop. Figures 18.1c, 18.1d, and 18.1e illustrate that a loop may have multiple exits, but may have only one entry. Figures 18.1e and 18.1f contain nested loops.

**REDUCEABLE FLOW GRAPHS**

A *reducible flow graph* is one in which the dictionary definition of *loop* corresponds more closely to the technical definition; but let us develop a more precise definition.
Figure 18.2a does not contain a loop; either node in the strongly connected component \((2, 3)\) can be reached without going through the other.

Figure 18.2c contains the same pattern of nodes \(1, 2, 3\); this becomes more clear if we repeatedly delete edges and collapse together pairs of nodes \((x, y)\), where \(x\) is the only predecessor of \(y\). That is: delete \(6 \rightarrow 9, 5 \rightarrow 4\), collapse \((7, 9), (3, 7), (7, 8), (5, 6), (1, 5), (1, 4)\); and we obtain Figure 18.2a.

An irreducible flow graph is one in which – after collapsing nodes and deleting edges – we can find a subgraph like Figure 18.2a. A reducible flow graph is one that cannot be collapsed to contain such a subgraph. Without such subgraphs, then any cycle of nodes does have a unique header node.

Common control-flow constructs such as if-then, if-then-else, while-do, repeat-until, for, and break (even multilevel break) can only generate reducible flow graphs. Thus, the control-flow graph for a Tiger or Java function, or a C function without goto, will always be reducible.

The following program corresponds to flow graph 18.1e, assuming Tiger were augmented with repeat-until loops:
None of these contains a loop. Dotted lines indicate reduction of graph (c) by deleting edges and collapsing nodes.

In a functional language, loops are generally expressed using tail-recursive function calls. The isPrime program might be written as:

```plaintext
function isPrime(n: int) : int =
    (i := 2;
        repeat j := 2;
            repeat if i*j=n
                then return 0
                else j := j+1
            until j=n;
        i := i+1
    until i=n;
    return 1)
```

```plaintext
function tryI(n: int, i: int) : int =
    tryJ(n,i,2)

function tryJ(n: int, i: int, j: int) : int =
    if i*j=n
        then 0
        else nextJ(n,i,j+1)

function nextJ(n: int, i: int, j: int) : int =
    if j=n
        then nextI(n,i+1)
        else tryJ(n,i,j)

function nextI(n: int, i: int) : int =
    if i=n
        then 1
        else tryI(n,i)
```
where the numbers 1–6 show the correspondence with the flow-graph nodes of Figure 18.1f.

Because the programmer can arrange these functions in arbitrary ways, flow graphs produced by the tail-call structure of functional programs are sometimes irreducible.

**Advantages of reducible flow graphs.** Many dataflow analyses (presented in Chapter 17) can be done very efficiently on reducible flow graphs. Instead of using fixed-point iteration ("keep executing assignments until there are no changes"), we can determine an order for computing the assignments, and calculate in advance how many assignments will be necessary – that is, there will never be a need to check to see if anything changed.

However, for the remainder of this chapter we will assume that our control-flow graphs may be reducible or irreducible.

### 18.1 DOMINATORS

Before we optimize the loops, we must find them in the flow graph. The notion of *dominators* is useful for that purpose.

Each control-flow graph must have a start node \( s_0 \) with no predecessors, where program (or procedure) execution is assumed to begin.

A node \( d \) dominates a node \( n \) if every path of directed edges from \( s_0 \) to \( n \) must go through \( d \). Every node dominates itself.

**Algorithm for finding dominators**

Consider a node \( n \) with predecessors \( p_1, \ldots, p_k \), and a node \( d \) (with \( d \neq n \)). If \( d \) dominates each one of the \( p_i \), then it must dominate \( n \), because every path from \( s_0 \) to \( n \) must go through one of the \( p_i \), but every path from \( s_0 \) to a \( p_i \) must go through \( d \). Conversely, if \( d \) dominates \( n \), it must dominate all the \( p_i \); otherwise there would be a path from \( s_0 \) to \( n \) going through the predecessor not dominated by \( d \).

Let \( D[n] \) be the set of nodes that dominate \( n \). Then

\[
D[s_0] = \{s_0\} \quad D[n] = \{n\} \cup \left( \bigcap_{p \in \text{pred}[n]} D[p] \right) \quad \text{for} \ n \neq s_0
\]

The simultaneous equations can be solved, as usual, by iteration, treating each equation as an assignment statement. However, in this case each set \( D[n] \) (for
\( n \neq s_0 \) must be initialized to hold all the nodes in the graph, because each assignment \( D[n] \leftarrow \{n\} \cup \ldots \) makes \( D[n] \) smaller (or unchanged), not larger.

This algorithm can be made more efficient by ordering the set assignments in quasi-topological order, that is, according to a depth-first search of the graph (Algorithm 17.5). Section 19.2 describes a faster algorithm for computing dominators.

Technically, an unreachable node is dominated by every node in the graph; we will avoid the pathologies this can cause by deleting unreachable nodes from the graph before calculating dominators and doing loop optimizations. See also Exercise 18.4.

**IMMEDIATE DOMINATORS**

**Theorem:** In a connected graph, suppose \( d \) dominates \( n \), and \( e \) dominates \( n \). Then it must be that either \( d \) dominates \( e \), or \( e \) dominates \( d \).

**Proof:** (By contradiction.) Suppose neither \( d \) nor \( e \) dominates the other. Then there is some path from \( s_0 \) to \( e \) that does not go through \( d \). Therefore any path from \( e \) to \( n \) must go through \( d \); otherwise \( d \) would not dominate \( n \).

Conversely, any path from \( d \) to \( n \) must go through \( e \). But this means that to get from \( e \) to \( n \) the path must infinitely loop from \( d \) to \( e \) to \( d \) \ldots and never get to \( n \).

This theorem tells us that every node \( n \) has no more than one *immediate dominator*, \( \text{idom}(n) \), such that

1. \( \text{idom}(n) \) is not the same node as \( n \),
2. \( \text{idom}(n) \) dominates \( n \), and
3. \( \text{idom}(n) \) does not dominate any other dominator of \( n \).

Every node except \( s_0 \) is dominated by at least one node other than itself (since \( s_0 \) dominates every node), so every node except \( s_0 \) has exactly one immediate dominator.

**Dominator tree.** Let us draw a graph containing every node of the flow graph, and for every node \( n \) an edge from \( \text{idom}(n) \) to \( n \). The resulting graph will be a tree, because each node has exactly one immediate dominator. This is called the *dominator tree*.

Figure 18.3 shows a flow graph and its dominator tree. Some edges in the dominator tree correspond single flow-graph edges (such as \( 4 \to 6 \)), but others do not (such as \( 4 \to 7 \)). That is, the immediate dominator of a node is not necessarily its predecessor in the flow graph.
A flow-graph edge from a node \( n \) to a node \( h \) that dominates \( n \) is called a \textit{back edge}. For every back edge there is a corresponding subgraph of the flow graph that is a loop. The back edges in Figure 18.3a are \( 3 \rightarrow 2 \), \( 4 \rightarrow 2 \), \( 10 \rightarrow 5 \), \( 9 \rightarrow 8 \).

**LOOPS**

The \textit{natural loop} of a back edge \( n \rightarrow h \), where \( h \) dominates \( n \), is the set of nodes \( x \) such that \( h \) dominates \( x \) and there is a path from \( x \) to \( n \) not containing \( h \). The \textit{header} of this loop will be \( h \).

The natural loop of the back edge \( 10 \rightarrow 5 \) from Figure 18.3a includes nodes 5, 8, 9, 10 and has the loop 8, 9 nested within it.

A node \( h \) can be the header of more than one natural loop, if there is more than one back edge into \( h \). In Figure 18.3a, the natural loop of \( 3 \rightarrow 2 \) consists of the nodes 3, 2 and the natural loop of \( 4 \rightarrow 2 \) consists of 4, 2.

The loop optimizations described in this chapter can cope with any loop, whether it is a natural loop or not, and whether or not that loop shares its header with some other loop. However, we usually want to optimize an \textit{inner} loop first, because most of the program’s execution time is expected to be in
CHAPTER EIGHTEEN. LOOP OPTIMIZATIONS

the inner loop. If two loops share a header, then it is hard to determine which should be considered the inner loop. A common way of solving this problem is to merge all the natural loops with the same header. The result will not necessarily be a natural loop.

If we merge all the loops with header 2 in Figure 18.3a, we obtain the loop 2, 3, 4 – which is not a natural loop.

Nested loops If A and B are loops with headers a and b respectively, such that \( a \neq b \) and b is in A, then the nodes of B are a proper subset of the nodes of A. We say that loop B is nested within A, or that B is the inner loop.

We can construct a loop-nest tree of loops in a program. The procedure is, for a flow graph G:

1. Compute dominators of G.
2. Construct the dominator tree.
3. Find all the natural loops, and thus all the loop-header nodes.
4. For each loop header h, merge all the natural loops of h into a single loop, \( \text{loop}[h] \).
5. Construct the tree of loop headers (and implicitly loops), such that \( h_1 \) is above \( h_2 \) in the tree if \( h_2 \) is in \( \text{loop}[h_1] \).

The leaves of the loop-nest tree are the innermost loops.

Just to have a place to put nodes not in any loop, we could say that the entire procedure body is a pseudo-loop that sits at the root of the loop-nest tree. The loop-nest tree of Figure 18.3 is shown in Figure 18.4.

LOOP PREHEADER

Many loop optimizations will insert statements immediately before the loop executes. For example, loop-invariant hoisting moves a statement from inside the loop to immediately before the loop. Where should such statements be put? Figure 18.5a illustrates a problem: if we want to insert statement s into a basic block immediately before the loop, we need to put s at the end of blocks 2 and 3. In order to have one place to put such statements, we insert a new, initially empty, preheader node p outside the loop, with an edge \( p \rightarrow h \). All edges \( x \rightarrow h \) from nodes x inside the loop are left unchanged, but all existing edges \( y \rightarrow h \) from nodes y outside the loop are redirected to point to p.
18.1. DOMINATORS

**FIGURE 18.4.** The loop-nest tree for Figure 18.3a. Each loop header is shown in the top half of each oval (nodes 1, 2, 5, 8); a loop comprises a header node (e.g. node 5), all the other nodes shown in the same oval (e.g. node 10), and all the nodes shown in subtrees of the loop-nest-tree node (e.g. 8, 9).

**FIGURE 18.5.** (a) A loop; (b) the same loop with a preheader.
18.2 LOOP-IN Variant COMPUTATIONS

If a loop contains a statement \( t \leftarrow a \oplus b \) such that \( a \) has the same value each time around the loop, and \( b \) has the same value each time, then \( t \) will also have the same value each time. We would like to hoist the computation out of the loop, so it is computed just once instead of every time.

We cannot always tell if \( a \) will have the same value every time, so as usual we will conservatively approximate. The definition \( d : t \leftarrow a_1 \oplus a_2 \) is loop-invariant within loop \( L \) if, for each operand \( a_i \)

1. \( a_i \) is a constant,
2. or all the definitions of \( a_i \) that reach \( d \) are outside the loop,
3. or only one definition of \( a_i \) reaches \( d \), and that definition is loop-invariant.

This leads naturally to an iterative algorithm for finding loop-invariant definitions: first find all the definitions whose operands are constant or from outside the loop, then repeatedly find definitions whose operands are loop-invariant.

HOISTING

Suppose \( t \leftarrow a \oplus b \) is loop-invariant. Can we hoist it out of the loop? In Figure 18.6a, hoisting makes the program compute the same result faster. But in Figure 18.6b, hoisting makes the program faster but incorrect – the original program does not always execute \( t \leftarrow a \oplus b \), but the transformed program does, producing an incorrect value for \( x \) if \( i \geq N \) initially. Hoisting in Figure 18.6c is also incorrect, because the original loop had more than one definition of \( t \), and the transformed program interleaves the assignments to \( t \) in a different way. And hoisting in Figure 18.6d is wrong because there is a use of \( t \) before the loop-invariant definition, so after hoisting, this use will have the wrong value on the first iteration of the loop.

With these pitfalls in mind, we can set the criteria for hoisting \( d : t \leftarrow a \oplus b \) to the end of the loop preheader:

1. \( d \) dominates all loop exits at which \( t \) is live-out;
2. and there is only one definition of \( t \) in the loop,
3. and \( t \) is not live-out of the loop preheader.

Implicit side effects. These rules need modification if \( t \leftarrow a \oplus b \) could raise some sort of arithmetic exception or have other side effects; see Exercise 18.7.

Turning while loops into repeat-until loops. Condition (1) tends to prevent many computations from being hoisted from while loops; from Figure 18.7a
it is clear that none of the statements in the loop body dominates the loop exit node (which is the same as the header node). To solve this problem, we can transform the while loop into a repeat loop preceded by an if statement. This requires duplication of the statements in the header node, as shown in Figure 18.7b. Of course, all the statements in the body of a repeat loop dominate the loop exit (if there are no break or explicit loop-exit statements), so condition (1) will be satisfied.

### 18.3. INDUCTION VARIABLES

Some loops have a variable $i$ that is incremented or decremented, and a variable $j$ that is set (in the loop) to $i \cdot c + d$ where $c$ and $d$ are loop-invariant. Then we can calculate $j$’s value without reference to $i$; whenever $i$ is incremented by $a$ we can increment $j$ by $c \cdot a$.

Consider, for example, Program 18.8a, which sums the elements of an array. Using induction-variable analysis to find that $i$ and $j$ are related induction variables, strength reduction to replace a multiplication by 4 with an addition, then induction-variable elimination to replace $i \geq n$ by $k \geq 4n + a$, followed by miscellaneous copy propagation, we get Program 18.8b. The transformed loop has fewer quadruples; it might even run faster. Let us now take the series of transformations one step at a time.

We say that a variable such as $i$ is a basic induction variable, and $j$ and $k$
FIGURE 18.7. A while loop (a), transformed into a repeat loop (b).

PROGRAM 18.8. A loop before and after induction-variable optimizations.
18.3. INDUCTION VARIABLES

\[ s \leftarrow 0 \]
\[ j' \leftarrow i \cdot 4 \]
\[ b' \leftarrow b \cdot 4 \]

\[ s \leftarrow 0 \]
\[ n' \leftarrow n \cdot 4 \]

\[ L_1 : \text{if } s > 0 \text{ goto } L_2 \]
\[ i \leftarrow i + b \]
\[ j \leftarrow i \cdot 4 \]
\[ x \leftarrow M[j] \]
\[ s \leftarrow s - x \]
\[ \text{goto } L_1 \]
\[ L_2 : i \leftarrow i + 1 \]
\[ s \leftarrow s + j \]
\[ \text{if } i < n \text{ goto } L_1 \]
\[ L_1 : \text{if } s > 0 \text{ goto } L_2 \]
\[ j' \leftarrow j' + b' \]
\[ j \leftarrow j' \]
\[ x \leftarrow M[j] \]
\[ s \leftarrow s - x \]
\[ \text{goto } L_1 \]
\[ L_2 : j' \leftarrow j' + 4 \]
\[ s \leftarrow s + j \]
\[ \text{if } j' < n' \text{ goto } L_1 \]

(a) Before

(b) After

FIGURE 18.9. The basic induction variable \( i \) is incremented by different amounts in different iterations; the derived induction variable \( j \) is not changed in every iteration.

are derived induction variables in the family of \( i \). Right after \( j \) is defined (in the original loop), we have \( j = a_j + i \cdot b_j \), where \( a_j = 0 \) and \( b_j = 4 \). We can completely characterize the value of \( j \) at its definition by \((i, a, b)\), where \( i \) is a basic induction variable and \( a \) and \( b \) are loop-invariant expressions.

If there is another derived induction variable with definition \( k \leftarrow j + c_k \) (where \( c_k \) is loop-invariant), then \( k \) is also in the family of \( i \). We can characterize \( k \) by the triple \((i, c_k, b_j)\), that is, \( k = c_k + i \cdot b_j \).

We can characterize the basic induction variable \( i \) by a triple in the same way, that is \((i, 0, 1)\), meaning that \( i = 0 + i \cdot 1 \). Thus every induction variable can be characterized by such a triple.

If an induction variable changes by the same (constant or loop-invariant) amount in every iteration of the loop, we say it is a linear induction variable. In Figure 18.9a, the induction variable \( i \) is not linear: incremented by \( b \) in some iterations and by 1 in other iterations. Furthermore, in some iterations \( j = i \cdot 4 \) and in other iterations the derived induction variable \( j \) gets (temporarily) left behind as \( i \) is incremented.
DETECTION OF INDUCTION VARIABLES

Basic induction variables. The variable $i$ is a basic induction variable in a loop $L$ with header node $h$ if the only definitions of $i$ within $L$ are of the form $i \leftarrow i + c$ or $i \leftarrow i - c$ where $c$ is loop-invariant.

Derived induction variables. The variable $k$ is a derived induction variable in loop $L$ if:

1. There is only one definition of $k$ within $L$, of the form $k \leftarrow j \cdot c$ or $k \leftarrow j + d$, where $j$ is an induction variable and $c, d$ are loop-invariant;
2. and if $j$ is a derived induction variable in the family of $i$, then:
   (a) the only definition of $j$ that reaches $k$ is the one in the loop,
   (b) and there is no definition of $i$ on any path between the definition of $j$ and the definition of $k$.

Assuming $j$ is characterized by $(i, a, b)$, then $k$ is described by $(i, a \cdot c, b \cdot c)$ or $(i, a + d, b)$, depending on whether $k$’s definition was $j \cdot c$ or $j + d$.

Statements of the form $k \leftarrow j - c$ can be treated as $k \leftarrow j + (-c)$ for purposes of induction-variable analysis (unless $-c$ is not representable, which can sometimes happen with two’s complement arithmetic).

Division. Statements of the form $k \leftarrow j/c$ can be rewritten as $k \leftarrow j \cdot (\frac{1}{c})$, so that $k$ could be considered an induction variable. This fact is useful for floating-point calculations – though we must beware of introducing subtle numerical errors if $1/c$ cannot be represented exactly. If this is an integer division, we cannot represent $1/c$ at all.

STRENGTH REDUCTION

On many machines, multiplication is more expensive than addition. So we would like to take a derived induction variable whose definition is of the form $j \leftarrow i \cdot c$ and replace it with an addition.

For each derived induction variable $j$ whose triple is $(i, a, b)$, make a new variable $j'$ (although different derived induction variables with the same triple can share the same $j'$ variable). After each assignment $i \leftarrow i + c$, make an assignment $j' \leftarrow j' + c \cdot b$ where $c \cdot b$ is a loop-invariant expression that may be computed in the loop preheader. If $c$ and $b$ are both constant, then the multiplication may be done at compile-time. Replace the (unique) assignment to $j$ with $j \leftarrow j'$. Finally, it is necessary to initialize $j'$ at the end of the loop preheader, with $j' \leftarrow a + i \cdot b$. 
We say two induction variables $x, y$ in the family of $i$ are \textit{coordinated} if \((x - a_x)/b_x = (y - a_y)/b_y\) at every time during the execution of the loop, except during a sequence of statements $z_i \leftarrow z_i + c_i$, where $c_i$ is loop-invariant. Clearly, all the new variables in the family of $i$ introduced by strength reduction are coordinated with each other, and with $i$.

When the definition of an induction variable $j \leftarrow \cdots$ is replaced by $j \leftarrow j'$, we know that $j'$ is coordinated but $j$ might not be. However, the standard \textit{copy propagation} algorithm can help here, replacing uses of $j$ by uses of $j'$ where there is no intervening definition of $j'$.

Thus, instead of using some sort of flow analysis to learn whether $j$ is coordinated, we just use $j'$ instead, where copy propagation says it is legal to do so.

After strength reduction there is still a multiplication, but it is outside the loop. If the loop executes more than one iteration, then the program should run faster with additions instead of multiplication, on many machines. The results of strength reduction may be disappointing on processors that can schedule multiplications to hide their latency.

\textbf{Example.} Let us perform strength reduction on Program 18.8a. We find that $j$ is a derived induction variable with triple $(i, 0, 4)$, and $k$ has triple $(i, a, 4)$. After strength reduction on both $j$ and $k$, we have

\begin{verbatim}
  s   \leftarrow 0
  i   \leftarrow 0
  j' \leftarrow 0
  k' \leftarrow a
  L_1 : if i \geq n goto L_2
    j \leftarrow j'
    k \leftarrow k'
    x \leftarrow M[k]
    s \leftarrow s + x
    i \leftarrow i + 1
    j' \leftarrow j' + 4
    k' \leftarrow k' + 4
    goto L_1
L_2
  
We can perform \textit{dead-code elimination} to remove the statement $j \leftarrow j'$. We would also like to remove all the definitions of the \textit{useless variable} $j'$, but
technically it is not dead, since it is used in every iteration of the loop.

**ELIMINATION**

After strength reduction, some of the induction variables are not used at all in the loop, and others are used only in comparisons with loop-invariant variables. These induction variables can be deleted.

A variable is *useless* in a loop $L$ if it is dead at all exits from $L$, and its only use is in a definition of itself. All definitions of a useless variable may be deleted.

In our example, after the removal of $j$, the variable $j'$ is useless. We can delete $j' \leftarrow j' + 4$. This leaves a definition of $j'$ in the preheader that can now be removed by dead-code elimination.

**REWRITING COMPARISONS**

A variable $k$ is *almost useless* if it is used only in comparisons against loop-invariant values and in definitions of itself, and there is some other induction variable in the same family that is not useless. An almost-useless variable may be made useless by modifying the comparison to use the related induction variable.

If we have $k < n$, where $j$ and $k$ are coordinated induction variables in the family of $i$, and $n$ is loop-invariant; then we know that $(j - a_j)/b_j = (k - a_k)/b_k$, so therefore the comparison $k < n$ can be written as

$$a_k + \frac{b_k}{b_j} (j - a_j) < n$$

Now, we can subtract $a_k$ from both sides and multiply both sides by $b_j/b_k$. If $b_j/b_k$ is positive, the resulting comparison is:

$$j - a_j < \frac{b_j}{b_k} (n - a_k)$$

but if $b_j/b_k$ is negative, then the comparison becomes

$$j - a_j > \frac{b_j}{b_k} (n - a_k)$$

instead. Finally, we add $a_j$ to both sides (here we show the positive case):

$$j < \frac{b_j}{b_k} (n - a_k) + a_j$$

The entire right-hand side of this comparison is loop-invariant, so it can be computed just once in the loop preheader.
18.4. ARRAY-BOUNDS CHECKS

Restrictions:

1. If \( b_j(n - a_k) \) is not evenly divisible by \( b_k \), then this transformation cannot be used, because we cannot hold a fractional value in an integer variable.
2. If \( b_j \) or \( b_k \) is not constant, but is a loop-invariant value whose sign is not known, then the transformation cannot be used since we won’t know which comparison (less-than or greater-than) to use.

Example. In our example, the comparison \( i < n \) can be replaced by \( k' < a + 4 \cdot n \). Of course, \( a + 4 \cdot n \) is loop-invariant and should be hoisted. Then \( i \) will be useless and may be deleted. The transformed program is:

\[
\begin{align*}
  s & \leftarrow 0 \\
  k' & \leftarrow a \\
  b & \leftarrow n \cdot 4 \\
  c & \leftarrow a + b \\
  L_1: & \text{if } k' < c \text{ goto } L_2 \\
  & k \leftarrow k' \\
  & x \leftarrow M[k] \\
  & s \leftarrow s + x \\
  & k' \leftarrow k' + 4 \\
  & \text{goto } L_1 \\
  L_2
\end{align*}
\]

Finally, copy propagation can eliminate \( k \leftarrow k' \), and we obtain Program 18.8b.

18.4. ARRAY-BOUNDS CHECKS

Safe programming languages automatically insert array-bounds checks on every subscript operation (see the sermon on page 164). Of course, in well written programs all of these checks are redundant, since well written programs don’t access arrays out of bounds. We would like safe languages to achieve the fast performance of unsafe languages. Instead of turning off the bounds checks (which would not be safe) we ask the compiler to remove any checks that it can prove are redundant.

We cannot hope to remove all the redundant bounds checks, because this problem is not computable (it is as hard as the halting problem). But many array subscripts are of the form \( a[i] \), where \( i \) is an induction variable. These the compiler can often understand well enough to optimize.
The bounds for an array are generally of the form $0 \leq i \land i < N$. When $N$ is nonnegative, as it always is for array sizes, this can be implemented as $i \leq_u N$, where $\leq_u$ is the unsigned comparison operator.

**Conditions for eliminating array-bounds checking.** Although it seems natural and intuitive that an induction variable must stay within a certain range, and we should be able to tell whether that range does not exceed the bounds of the array, the criteria for eliminating a bounds check from a loop $L$ are actually quite complicated:

1. There is an induction variable $j$ and a loop-invariant $u$ used in a statement $s_1$, taking one of the following forms:
   
   - if $j < u$ goto $L_1$ else goto $L_2$
   - if $j \geq u$ goto $L_2$ else goto $L_1$
   - if $u > j$ goto $L_1$ else goto $L_2$
   - if $u \leq j$ goto $L_2$ else goto $L_1$

   where $L_2$ is out of the loop.

2. There is a statement $s_2$ of the form
   
   - if $k <_u n$ goto $L_3$ else goto $L_4$

   where $k$ is an induction variable coordinated with $j$, $n$ is loop-invariant, and $s_1$ dominates $s_2$.

3. There is no loop nested within $L$ containing a definition of $k$.

4. $k$ increases when $j$ does, that is, $b_j/b_k > 0$.

Often, $n$ will be an array length. In a language with static arrays an array length $n$ is a constant. In many languages with dynamic arrays, array lengths are loop-invariant. In Tiger, Java, and ML the length of an array cannot be dynamically modified once the array has been allocated. The array-length $n$ will typically be calculated by fetching the `length` field of some array-pointer $v$. For the sake of illustration, assume the length field is at offset 0 in the array object. To avoid the need for complicated alias analysis, the semantic analysis phase of the compiler should mark the expression $M[v]$ as immutable, meaning that no other store instruction can possibly update the contents of the `length` field of the array $v$. If $v$ is loop-invariant, then $n$ will also be loop-invariant. Even if $n$ is not an array length but is some other loop invariant, we can still optimize the comparison $k <_u n$.

We want to put a test in the loop preheader that expresses the idea that in every iteration, $k \geq 0 \land k < n$. Let $k_0$ be the value of $k$ at the end of the
18.4. ARRAY-BOUNDS CHECKS

preheader, and let \( \Delta k_1, \Delta k_2, \ldots, \Delta k_m \) be all the loop-invariant values that are added to \( k \) inside the loop. Then we can ensure \( k \geq 0 \) by testing

\[
k \geq 0 \land \Delta k_1 \geq 0 \land \cdots \land \Delta k_m \geq 0
\]
at the end of the preheader.

Let \( \Delta k_1, \Delta k_2, \ldots, \Delta k_p \) be the set of loop-invariant values that are added to \( k \) on any path between \( s_1 \) and \( s_2 \) that does not go through \( s_1 \) (again). Then, to ensure \( k < n \) at \( s_2 \), it is sufficient to ensure that

\[
k < n - (\Delta k_1 + \cdots + \Delta k_p) - a_k + a_j
\]

This will always be true if

\[
u < \frac{b_j}{b_k} (n - (\Delta k_1 + \cdots + \Delta k_p) - a_k) + a_j
\]
since the test \( j < u \) dominates the test \( k < n \).

Since everything in this comparison is loop-invariant, we can move it to the preheader as follows. First, ensure that definitions of loop-invariants are hoisted out of the loop. Then, rewrite the loop \( L \) as follows: copy all the statements of \( L \) to make a new loop \( L' \) with header \( L'_h \). Inside \( L' \), replace the statement

\[
\text{if } k < n \text{ goto } L'_3 \text{ else goto } L'_4
\]

by \textbf{goto} \( L'_3 \). At the end of the preheader of \( L \), put statements equivalent to

\[
\begin{align*}
\text{if } k \geq 0 & \land k_1 \geq 0 \land \cdots \land k_m \geq 0 \\
& \land u < \frac{b_j}{b_k} (n - (\Delta k_1 + \cdots + \Delta k_p) - a_k) + a_j \\
goto L'_h \\
\text{else goto } L_h
\end{align*}
\]

The conditional \textbf{goto} tests whether \( k \) will always be between 0 and \( n \).

Sometimes we will have enough information to evaluate this complicated condition at compile time. This will be true in at least two situations:

1. all the loop-invariants mentioned in it are constants, or
2. \( n \) and \( u \) are the same temporary variable, \( a_k = a_j, b_k = b_j \), and there are no \( \Delta k \)'s added to \( k \) between \( s_1 \) and \( s_2 \). In a language like Tiger or Java or ML, this could happen if the programmer writes,
let var u := length(A)
  var i := 0
in while i<u
do (sum := sum + A[i];
  i := i+1)
end

The quadruples for \( \text{length}(A) \) will include \( u \leftarrow M[A] \), assuming that the length of an array is fetched from offset zero from the array pointer; and the quadruples for \( A[i] \) will include \( n \leftarrow M[A] \), to fetch \( n \) for doing the bounds check. Now the expressions defining \( u \) and \( n \) are common subexpressions, assuming the expression \( M[A] \) is marked so that we know that no other STORE instruction is modifying the contents of memory location \( M[A] \).

If we can evaluate the big comparison at compile time, then we can unconditionally use loop \( L \) or loop \( L' \), and delete the loop that we are not using.

**Cleaning up.** After this optimization, the program may have several loose ends. Statements after the label \( L'_4 \) may be unreachable; there may be several useless computations of \( n \) and \( k \) within \( L' \). The former can be cleaned up by unreachable-code elimination, and the latter by dead-code elimination.

**Generalizations.** To be practically useful, the algorithm needs to be generalized in several ways:

1. The loop-exit comparison might take one of the forms

   \[
   \begin{align*}
   &\text{if } j \leq u' \text{ goto } L_1 \text{ else goto } L_2 \\
   &\text{if } j > u' \text{ goto } L_2 \text{ else goto } L_1 \\
   &\text{if } u' \geq j \text{ goto } L_1 \text{ else goto } L_2 \\
   &\text{if } u' < j \text{ goto } L_2 \text{ else goto } L_1
   \end{align*}
   \]

   which compares \( j \leq u' \) instead of \( j < u \).

2. The loop-exit test might occur at the bottom of the loop body, instead of before the array-bounds test. We can describe this situation as follows: There is a test

   \[ s_2 : \text{if } j < u \text{ goto } L_1 \text{ else goto } L_2 \]

   where \( L_2 \) is out of the loop and \( s_2 \) dominates all the loop back edges. Then the \( \Delta K_j \) of interest are the ones between \( s_2 \) and any back edge, and between the loop header and \( s_1 \).

3. We should handle the case where \( b_j/b_k < 0 \).

4. We should handle the case where \( j \) counts downward instead of up, and the loop-exit test is something like \( j \geq l \), for \( l \) a loop-invariant lower bound.

5. The induction-variable increments might be “undisciplined”; for example,
18.5. LOOP UNROLLING

Some loops have such a small body that most of the time is spent incrementing the loop-counter variable and testing the loop-exit condition. We can make these loops more efficient by *unrolling* them, putting two or more copies of the loop body in a row.

Given a loop $L$ with header node $h$ and back edges $s_i \rightarrow h$, we can unroll the loop as follows:

1. Copy the nodes to make a loop $L'$ with header $h'$ and back edges $s'_i \rightarrow h'$.
2. Change all the back edges in $L$ from $s_i \rightarrow h$ to $s_i \rightarrow h'$.
3. Change all the back edges in $L'$ from $s'_i \rightarrow h'$ to $s'_i \rightarrow h$.

For example, Program 18.10a unrolls into Program 18.10b. But nothing useful has been accomplished; each “original” iteration still has an increment and a conditional branch.

Program 18.10. Useless loop unrolling.

```
while i<n-1
  do (if sum<0
      then (i:=i+1; sum:= sum+i; i:=i+1)
      else i := i+2;
      sum := sum + a[i])
```

Here there are three $\Delta i$, (of 1, 1, and 2 respectively). Our analysis will assume that any, all, or none of these increments may be applied; but clearly the effect is $i \leftarrow i + 2$ on either path. In such cases, an analysis that hoists (and merges) the increments above the if will be useful.
CHAPTER EIGHTEEN. LOOP OPTIMIZATIONS

L₁ : \( x \leftarrow M[i] \)
\( s \leftarrow s + x \)
\( x \leftarrow M[i + 4] \)
\( s \leftarrow s + x \)
\( i \leftarrow i + 8 \)
if \( i < n \) goto \( L₁ \) else \( L₂ \)

\( L₂ \) : \( x \leftarrow M[i] \)
\( s \leftarrow s + x \)
\( x \leftarrow M[i + 4] \)
\( s \leftarrow s + x \)
\( i \leftarrow i + 8 \)
if \( i < n \) goto \( L₂ \) else \( L₃ \)

\( L₃ \) : \( x \leftarrow M[i] \)
\( s \leftarrow s + x \)
\( i \leftarrow i + 4 \)
if \( i < n \) goto \( L₂ \) else \( L₃ \)

PROGRAM 18.11. Useful loop unrolling: (a) works correctly only for an even number of iterations of the original loop; (b) works for any number of iterations of the original loop.

By using information about induction variables, we can do better. We need an induction variable \( i \) such that every increment \( i \leftarrow i + \Delta \) dominates every back edge of the loop. Then we know that each iteration increments \( i \) by exactly the sum of all the \( \Delta \), so we can agglomerate the increments and loop-exit tests to get Program 18.11a. But this unrolled loop works correctly only if the original loop iterated an even number of times. We execute “odd” iterations in an epilogue, as shown in Program 18.11b.

Here we have shown only the case of unrolling by a factor of two. When a loop is unrolled by a factor of \( K \), then the epilogue is a loop (much like the original one) that iterates up to \( K - 1 \) times.

FURTHER READING

Splitting control-flow nodes or edges gives a place into which statements
can be moved. The *loop preheader* transformation described on page 416 is an example of such splitting. Other examples are *landing pads* [Cytron et al. 1986] – nodes inserted in each loop-exit edge; *postbody nodes* [Wolfe 1996] – nodes inserted at the end of a loop body (see Exercise 18.6); and edge splitting to ensure a *unique successor or predecessor* property [Rosen et al. 1988] (see Section 19.1).

Chapter 19 describes other loop optimizations and a faster algorithm for computing dominators.

### EXERCISES

**18.1**

a. Calculate the dominators of each node of this flowgraph:

![Flowgraph Diagram]

b. Show the immediate dominator tree.

c. Identify the set of nodes in each natural loop.

**18.2** Calculate the immediate-dominator tree of each of the following graphs:

a. The graph of Figure 2.8.

b. The graph of Exercise 2.3a.

c. The graph of Exercise 2.5a.

d. The graph of Figure 3.27.

**18.3** Let $G$ be a control-flow graph, $h$ be a node in $G$, $A$ be the set of nodes in a loop with header $h$, and $B$ be the set of nodes in a different loop with header $h$. Prove that the subgraph whose nodes are $A \cup B$ is also a loop.

**18.4** The immediate dominator theorem (page 414) is false for graphs that contain unreachable nodes.
CHAPTER EIGHTEEN. LOOP OPTIMIZATIONS

a. Show a graph with nodes d, e, and n such that d dominates n, e dominates n, but neither d dominates e nor e dominates d.

b. Identify which step of the proof is invalid for graphs containing unreachable nodes.

c. In approximately three words, name an algorithm useful in finding unreachable nodes.

*18.5 Show that in a connected flow graph (one without unreachable nodes), a natural loop as defined on page 415 satisfies the definition of loop given on page 410.

18.6 For some purposes it is desirable that each loop header node should have exactly two predecessors, one outside the loop and one inside. We can ensure that there is only one outside predecessor by inserting a preheader node, as described in Section 18.1. Explain how to insert a postbody node to ensure that the loop header has only one predecessor inside the loop.

*18.7 Suppose any arithmetic overflow or divide-by-zero will raise an exception at run time. If we hoist t ← a ⊕ b out of a loop, and the loop might not have executed the statement at all, then the transformed program may raise the exception where the original program did not. Revise the criteria for loop-invariant hoisting to take account of this. Instead of writing something informal like “might not execute the statement,” use the terminology of dataflow analysis and dominators.

18.8 On pages 418–419 the transformation of a while loop to a repeat loop is described. Show how a while loop may be characterized in the control-flow graph of basic blocks (using dominators) so that the optimizer can recognize it. The body of the loop may have explicit break statements that exit the loop.

*18.9 For bounds-check elimination, we required (on page 426) that the loop-exit test dominate the bounds-check comparison. If it is the other way around, then (effectively) we have one extra array subscript at the end of the loop, so the criterion

\[ a_k + i \cdot b_k \geq 0 \land (n - a_k) \cdot b_j < (u - a_j) \cdot b_k \]

is “off by one.” Rewrite this criterion for the case where the bounds-check comparison occurs before the loop-exit test.

*18.10 Write down the rules for unrolling a loop, such that the induction-variable increments are agglomerated and the unrolled loop has only one loop-exit test per iteration, as was shown informally for Program 18.10.
Static Single-Assignment Form

**dominate**: to exert the supreme determining or guiding influence on

*Webster's Dictionary*

Many dataflow analyses need to find the use-sites of each defined variable or the definition-sites of each variable used in an expression. The *def-use chain* is a data structure that makes this efficient: for each statement in the flow graph, the compiler can keep a list of pointers to all the *use* sites of variables defined there, and a list of pointers to all *definition* sites of the variables used there. In this way the compiler can hop quickly from use to definition to use to definition.

An improvement on the idea of def-use chains is *static single-assignment form*, or SSA form, an intermediate representation in which each variable has only one definition in the program text. The one (static) definition-site may be in a loop that is executed many (dynamic) times, thus the name *static* single-assignment form instead of single-assignment form (in which variables are never redefined at all).

The SSA form is useful for several reasons:

1. Dataflow analysis and optimization algorithms can be made simpler when each variable has only one definition.
2. If a variable has \( N \) uses and \( M \) definitions (which occupy about \( N + M \) instructions in a program), it takes space (and time) proportional to \( N \cdot M \) to represent def-use chains – a quadratic blowup (see Exercise 19.8). For almost all realistic programs, the size of the SSA form is linear in the size of the original program (but see Exercise 19.9).
3. Uses and defs of variables in SSA form relate in a useful way to the dominator structure of the control-flow graph, which simplifies algorithms such as interference-graph construction.
4. Unrelated uses of the same variable in the source program become different variables in SSA form, eliminating needless relationships. An example is the program,

```plaintext
for i ← 1 to N do A[i] ← 0
for i ← 1 to M do s ← s + B[i]
```

where there is no reason that both loops need to use the same machine register or intermediate-code temporary variable to hold their respective loop counters, even though both are named \( i \).

In straight-line code, such as within a basic block, it is easy to see that each instruction can define a fresh new variable instead of redefining an old one, as shown in Figure 19.1. Each new definition of a variable (such as \( a \)) is modified to define a fresh new variable (\( a_1, a_2, \ldots \)), and each use of the variable is modified to use the most recently defined version. This is a form of value numbering (see page 398).

But when two control-flow paths merge together, it is not obvious how to have only one assignment for each variable. In Figure 19.2a, if we were to define a new version of \( a \) in block 1 and in block 2, which version should be used in block 4? Where a statement has more than one predecessor, there is no notion of “most recent.”

To solve this problem we introduce a notational fiction, called a \( \phi \)-function. Figure 19.2b shows that we can combine \( a_1 \) (defined in block 1) and \( a_2 \) (defined in block 3) using the function \( a_3 \leftarrow \phi(a_1, a_2) \). But unlike ordinary mathematical functions, \( \phi(a_1, a_2) \) yields \( a_1 \) if control reaches block 4 along the edge 2 → 4, and yields \( a_2 \) if control comes in on edge 3 → 4.

How does the \( \phi \)-function know which edge was taken? That question has two answers:

- If we must execute the program, or translate it to executable form, we can
“implement” the $\phi$-function using a MOVE instruction on each incoming edge, as shown in Section 19.6.

- In many cases, we simply need the connection of uses to definitions, and don’t need to “execute” the $\phi$-functions during optimization. In these cases, we can ignore the question of which value to produce.

Consider Figure 19.3a, which contains a loop. We can convert this to static single-assignment form as shown in Figure 19.3b. Note that variables $a$ and $c$ each need a $\phi$-function to merge their values that arrive on edges $1 \rightarrow 2$ and
2 \rightarrow 2. The $\phi$-function for $b_1$ can later be deleted by dead-code elimination, since $b_1$ is a dead variable. The variable $c$ is live on entry (after conversion to SSA, the implicit definition $c_0$ is live); this might be an uninitialized variable, or perhaps $c$ is a formal parameter of the function whose body this is.

The assignment $c_1 \leftarrow c_2 + b_2$ will be executed many times; thus the variable $c_1$ is updated many times. This illustrates that we do not have a program with dynamic single-assignment (like a pure functional program), but a program in which each variable has only one static site of definition.

### 19.1 CONVERTING TO SSA FORM

The algorithm for converting a program to SSA form first adds $\phi$ functions for the variables, then renames all the definitions and uses of variables using subscripts. The sequence of steps is illustrated in Figure 19.4.

### CRITERIA FOR INSERTING $\phi$-FUNCTIONS

We could add a $\phi$-function for every variable at each join point (that is, each node in the control-flow graph with more than one predecessor). But this is wasteful and unnecessary. For example, block 4 in Figure 19.2b is reached by the same definition of $b$ along each incoming edge, so it does not need a $\phi$-function for $b$. The following criterion characterizes the nodes where a variable’s data-flow paths merge:

**Path-convergence criterion.** There should be a $\phi$-function for variable $a$ at node $z$ of the flow graph exactly when all of the following are true:

1. There is a block $x$ containing a definition of $a$,
2. There is a block $y$ (with $y \neq x$) containing a definition of $a$,
3. There is a nonempty path $P_{xz}$ of edges from $x$ to $z$,
4. There is a nonempty path $P_{yz}$ of edges from $y$ to $z$,
5. Paths $P_{xz}$ and $P_{yz}$ do not have any node in common other than $z$, and
6. The node $z$ does not appear within both $P_{xz}$ and $P_{yz}$ prior to the end, though it may appear in one or the other.

We consider the start node to contain an implicit definition of every variable, either because the variable may be a formal parameter or to represent the notion of $a \leftarrow uninitialized$ without special cases.

Note, however, that a $\phi$-function itself counts as a definition of $a$, so the path-convergence criterion must be considered as a set of equations to be
19.1. CONVERTING TO SSA FORM

\[ i \leftarrow 1 \]
\[ j \leftarrow 1 \]
\[ k \leftarrow 0 \]

while \( k < 100 \)
  
  if \( j < 20 \)
    \[ j \leftarrow i \]
    \[ k \leftarrow k + 1 \]
  
  else
    \[ j \leftarrow k \]
    \[ k \leftarrow k + 2 \]

return \( j \)

Variable \( j \) defined in node 1, but \( DF(1) \) is empty. Variable \( j \) defined in node 5, \( DF(5) \) contains 7, so node 7 needs \( \phi(j,j) \). Now \( j \) is defined in 7 (by a \( \phi \)-function), \( DF(7) \) contains 2, so node 2 needs \( \phi(j,j) \). \( DF(6) \) contains 7, so node 7 needs \( \phi(j,j) \) (but already has it). \( DF(2) \) contains 2, so node 2 needs \( \phi(j,j) \) (but already has it). Similar calculation for \( k \). Variable \( i \) defined in node 1, \( DF(1) \) is empty, so no \( \phi \)-functions necessary for \( i \).

\( n \quad DF(n) \)
\[ 1 \quad \{\} \]
\[ 2 \quad \{2\} \]
\[ 3 \quad \{2\} \]
\[ 4 \quad \{\} \]
\[ 5 \quad \{7\} \]
\[ 6 \quad \{7\} \]
\[ 7 \quad \{2\} \]

Variable \( j \) defined in node 1, but \( DF(1) \) is empty. Variable \( j \) defined in node 5, \( DF(5) \) contains 7, so node 7 needs \( \phi(j,j) \). Now \( j \) is defined in 7 (by a \( \phi \)-function), \( DF(7) \) contains 2, so node 2 needs \( \phi(j,j) \). \( DF(6) \) contains 7, so node 7 needs \( \phi(j,j) \) (but already has it). \( DF(2) \) contains 2, so node 2 needs \( \phi(j,j) \) (but already has it). Similar calculation for \( k \). Variable \( i \) defined in node 1, \( DF(1) \) is empty, so no \( \phi \)-functions necessary for \( i \).

(e) Insertion criteria for \( \phi \)-functions

FIGURE 19.4. Conversion of a program to static single-assignment form. Node 7 is a postbody node, inserted to make sure there is only one loop edge (see Exercise 18.6); such nodes are not strictly necessary but are sometimes helpful.
Iterated path-convergence criterion:

\[
\text{while there are nodes } x, y, z \text{ satisfying conditions } 1-5 \\
\text{and } z \text{ does not contain a } \phi \text{-function for } a \\
\text{do insert } a \leftarrow \phi(a, a, \ldots, a) \text{ at node } Z
\]

where the \( \phi \)-function has as many \( a \) arguments as there are predecessors of node \( z \).

**Dominance property of SSA form.** An essential property of static single-assignment form is that definitions dominate uses; more specifically,

1. If \( x \) is the \( i \)th argument of a \( \phi \)-function in block \( n \), then the definition of \( x \) dominates the \( i \)th predecessor of \( n \).
2. If \( x \) is used in a non-\( \phi \) statement in block \( n \), then the definition of \( x \) dominates \( n \).

Section 18.1 defines the dominance relation: \( d \) dominates \( n \) if every path from the start node to \( n \) goes through \( d \).

**THE DOMINANCE FRONTIER**

The iterated path-convergence algorithm for placing \( \phi \)-functions is not practical, since it would be very costly to examine every triple of nodes \( x, y, z \) and every path leading from \( x \) and \( y \). A much more efficient algorithm uses the dominator tree of the flow graph.

**Definitions.** \( x \) strictly dominates \( w \) if \( x \) dominates \( w \) and \( x \neq w \). In this chapter I use successor and predecessor to refer to graph edges, and parent and child to refer to tree edges. Node \( x \) is an ancestor of \( y \) if there is a path \( x \rightarrow y \) of tree edges, and is a proper ancestor if that path is nonempty.

The dominance frontier of a node \( x \) is the set of all nodes \( w \) such that \( x \) dominates a predecessor of \( w \), but does not strictly dominate \( w \).

Figure 19.5a illustrates the dominance frontier of a node; in essence, it is the “border” between dominated and undominated nodes.

**Dominance frontier criterion.** Whenever node \( x \) contains a definition of some variable \( a \), then any node \( z \) in the dominance frontier of \( x \) needs a \( \phi \)-function for \( a \).
19.1. CONVERTING TO SSA FORM

Iterated dominance frontier. Since a $\phi$-function itself is a kind of definition, we must iterate the dominance-frontier criterion until there are no nodes that need $\phi$-functions.

Theorem. The iterated dominance frontier criterion and the iterated path-convergence criterion specify exactly the same set of nodes at which to put $\phi$-functions.

The end-of-chapter bibliographic notes refer to a proof of this theorem. I will sketch one half of the proof, showing that if $w$ is in the dominance frontier of a definition, then it must be a point of convergence. Suppose there is a definition of variable $a$ at some node $n$ (such as node 5 in Figure 19.5b), and node $w$ (such as node 12 in Figure 19.5b) is in the dominance frontier of $n$. The root node implicitly contains a definition of every variable, including $a$. There is a path $P_{rw}$ from the root node (node 1 in Figure 19.5) to $w$ that does not go through $n$ or through any node that $n$ dominates; and there is a path $P_{nw}$ from $n$ to $w$ that goes only through dominated nodes. These paths have $w$ as their first point of convergence.

Computing the dominance frontier. To insert all the necessary $\phi$-functions, for every node $n$ in the flow graph we need $DF[n]$, its dominance frontier. Given the dominator tree, we can efficiently compute the dominance frontiers of all the nodes of the flow graph in one pass. We define two auxiliary sets

FIGURE 19.5. Node 5 dominates all the nodes in the grey area. (a) Dominance frontier of node 5 includes the nodes (4, 5, 12, 13) that are targets of edges crossing from the region dominated by 5 (grey area including node 5) to the region not strictly dominated by 5 (white area including node 5). (b) Any node in the dominance frontier of $n$ is also a point of convergence of nonintersecting paths, one from $n$ and one from the root node. (c) Another example of converging paths $P_{1,5}$ and $P_{5,5}$.
**CHAPTER NINETEEN. STATIC SINGLE-ASSIGNMENT FORM**

**DF**<sub>local</sub>[n]: The successors of n that are not strictly dominated by n;

**DF**<sub>up</sub>[n]: Nodes in the dominance frontier of n that are not dominated by n’s immediate dominator.

The dominance frontier of n can be computed from **DF**<sub>local</sub> and **DF**<sub>up</sub>:

\[
DF[n] = DF_{local}[n] \cup \bigcup_{c \in \text{children}[n]} DF_{up}[c]
\]

where \text{children}[n] are the nodes whose immediate dominator (idom) is n.

To compute **DF**<sub>local</sub>[n] more easily (using immediate dominators instead of dominators), we use the following theorem: \(DF_{local}[n] = \) the set of those successors of n whose immediate dominator is not n.

The following computeDF function should be called on the root of the dominator tree (the start node of the flow graph). It walks the tree computing **DF**[n] for every node n: it computes **DF**<sub>local</sub>[n] by examining the successors of n, then combines **DF**<sub>local</sub>[n] and (for each child c) **DF**<sub>up</sub>[c].

```plaintext
computeDF[n] =
S ← {}
for each node y in succ[n] This loop computes **DF**<sub>local</sub>[n]
   if idom(y) ≠ n
      S ← S ∪ {y}
   for each child c of n in the dominator tree
      computeDF[c]
      for each element w of **DF**[c] This loop computes **DF**<sub>up</sub>[c]
         if n does not dominate w
            S ← S ∪ {w}
      **DF**[n] ← S
```

This algorithm is quite efficient. It does work proportional to the size (number of edges) of the original graph, plus the size of the dominance frontiers it computes. Although there are pathological graphs in which most of the nodes have very large dominance frontiers, in most cases the total size of all the **DFs** is approximately linear in the size of the graph, so this algorithm runs in “practically” linear time.

**INSERTING φ-FUNCTIONS**

Starting with a program not in SSA form, we need to insert just enough φ-functions to satisfy the iterated dominance frontier criterion. To avoid re-
19.1. CONVERTING TO SSA FORM

Place-\(\phi\)-Functions =

  \(\text{W} \leftarrow \text{defsites}[a]\)
while \(\text{W}\) not empty
  remove some node \(n\) from \(\text{W}\)
  for each \(Y\) in \(DF[n]\)
    if \(Y \notin A_{\phi}[n]\)
      insert the statement \(a \leftarrow \phi(a, a, \ldots, a)\) at the top
      of block \(Y\), where the \(\phi\)-function has as many
      arguments as \(Y\) has predecessors
    \(A_{\phi}[n] \leftarrow A_{\phi}[n] \cup \{Y\}\)
  if \(Y \notin A_{\text{orig}}[n]\)
    \(\text{W} \leftarrow \text{W} \cup \{Y\}\)

ALGORITHM 19.6. Inserting \(\phi\)-functions.

examining nodes where no \(\phi\)-function has been inserted, we use a work-list
algorithm.

Algorithm 19.6 starts with a set \(V\) of variables, a graph \(G\) of control-flow
nodes – each node is a basic block of statements – and for each node \(n\) a set
\(A_{\text{orig}}[n]\) of variables defined in node \(n\). The algorithm computes \(A_{\phi}[n]\), the
set of variables that must have \(\phi\)-functions at node \(n\). Note that a variable
may be in both \(A_{\text{orig}}[n]\) and \(A_{\phi}[n]\); for example, in Figure 19.3b, \(a\) is in both
\(A_{\text{orig}}[2]\) and \(A_{\phi}[2]\).

The outer loop is performed once for each variable \(a\). There is a work-list
\(W\) of nodes that might violate the dominance-frontier criterion.

The representation for \(W\) must allow quick testing of membership and
quick extraction of an element. Work-list algorithms (in general) do not care
which element of the list they remove, so an array or linked list of nodes
suffices. To quickly test membership in \(W\), we can use a mark bit in the
representation of every node \(n\) which is set to true when \(n\) is put into the
list, and false when \(n\) is removed. If it is undesirable to modify the node
representation, a list plus a hash table will also work efficiently.
CHAPTER NINETEEN. STATIC SINGLE-ASSIGNMENT FORM

This algorithm does a constant amount of work \((a)\) for each node and edge in the control-flow graph, \((b)\) for each statement in the program, \((c)\) for each element of every dominance frontier, and \((d)\) for each inserted \(\phi\)-function. For a program of size \(N\), the amounts \(a\) and \(b\) are proportional to \(N\), \(c\) is usually approximately linear in \(N\). The number of inserted \(\phi\)-functions \((d)\) could be \(N^2\) in the worst case, but empirical measurement has shown that it is usually proportional to \(N\). So in practice, Algorithm 19.6 runs in approximately linear time.

RENAMEING THE VARIABLES

After the \(\phi\)-functions are placed, we can walk the dominator tree, renaming the different definitions (including \(\phi\)-functions) of variable \(a\) to \(a_1\), \(a_2\), \(a_3\) and so on.

In a straight-line program, we would rename all the definitions of \(a\), and then each use of \(a\) is renamed to use the most recent definition of \(a\). For a program with control-flow branches and joins whose graph satisfies the dominance-frontier criterion, we rename each use of \(a\) to use the closest definition \(d\) of \(a\) that is above \(a\) in the dominator tree.

Algorithm 19.7 renames all uses and definitions of variables, after the \(\phi\)-functions have been inserted by Algorithm 19.6. In traversing the dominator tree, the algorithm “remembers” for each variable the most recently defined version of each variable, on a separate stack for each variable.

Although the algorithm follows the structure of the dominator tree – not the flow graph – at each node in the tree it examines all outgoing flow edges, to see if there are any \(\phi\)-functions whose operands need to be properly numbered.

This algorithm takes time proportional to the size of the program (after \(\phi\)-functions are inserted), so in practice it should be approximately linear in the size of the original program.

EDGE SPLITTING

Some analyses and transformations are simpler if there is never a control-flow edge that leads from a node with multiple successors to a node with multiple predecessors. To give the graph this \textit{unique successor or predecessor} property, we perform the following transformation: For each control-flow edge \(a \rightarrow b\) such that \(a\) has more than one successor and \(b\) has more than one predecessor, we create a new, empty control-flow node \(z\), and replace the \(a \rightarrow b\) edge with an \(a \rightarrow z\) edge and a \(z \rightarrow b\) edge.
19.1. CONVERTING TO SSA FORM

Initialization:
  
  for each variable $a$
  
  $Count[a] \leftarrow 0$
  
  $Stack[a] \leftarrow \text{empty}$
  
  push 0 onto $Stack[a]$

Rename($n$) =

  for each statement $S$ in block $n$
    
    if $S$ is not a $\phi$-function
    
      for each use of some variable $x$ in $S$
        
        $i \leftarrow \text{top}(Stack[x])$
        
        replace the use of $x$ with $x_i$ in $S$

    for each definition of some variable $a$ in $S$
      
      $Count[a] \leftarrow Count[a] + 1$
      
      $i \leftarrow Count[a]$
      
      push $i$ onto $Stack[a]$
      
      replace definition of $a$ with definition of $a_i$ in $S$

  for each successor $Y$ of block $n$,
    
    Suppose $n$ is the $j$th predecessor of $Y$
    
    for each $\phi$-function in $Y$
      
      suppose the $j$th operand of the $\phi$-function is $a$
      
      $i \leftarrow \text{top}(Stack[a])$
      
      replace the $j$th operand with $a_i$

  for each child $X$ of $n$
    
    Rename($X$)

  for each definition of some variable $a$ in the original $S$
    
    pop $Stack[a]$

ALGORITHM 19.7. Renaming variables.

An SSA graph with this property is in edge-split SSA form. Figure 19.2 illustrates edge splitting. Edge splitting may be done before or after insertion of $\phi$-functions.
EFFICIENT COMPUTATION OF THE DOMINATOR TREE

A major reason for using SSA form is that it makes the optimizing compiler faster. Instead of using costly iterative bit-vector algorithms to link uses to definitions (to compute reaching definitions, for example), the compiler can just look up the (unique) definition, or the list of uses, of each variable.

For SSA to help make a compiler faster, we must be able to compute the SSA form quickly. The algorithms for computing SSA from the dominator tree are quite efficient. But the iterative set-based algorithm for computing dominators, given in Section 18.1, may be slow in the worst case. An industrial-strength compiler that uses dominators should use a more efficient algorithm for computing the dominator tree.

The near-linear-time algorithm of Lengauer and Tarjan relies on properties of the depth-first spanning tree of the control-flow graph. This is just the recursion tree implicitly traversed by the depth-first search (DFS) algorithm, which numbers each node of the graph with a depth-first number (dfnum) as it is first encountered.

The algorithm is rather technical; those readers who feel content just knowing that the dominator tree can be calculated quickly can skip to Section 19.3.

DEPTH-FIRST SPANNING TREES

We can use depth-first search to calculate a depth-first spanning tree of the control-flow graph. Figure 19.8 shows a CFG and a depth-first spanning tree, along with the dfnum of each node.

A given CFG may have many different depth-first spanning trees. From now on I will assume that we have arbitrarily picked one of them – by depth-first search. When I say “a is an ancestor of b” I mean that there is some path from a to b following only spanning-tree edges, or that \( a = b \); “a is a proper ancestor of b” means that a is an ancestor of b and \( a \neq b \).

Properties of depth-first spanning trees. The start node \( r \) of the CFG is the root of the depth-first spanning tree.

If a is a proper ancestor of b, then \( dfnum(a) < dfnum(b) \).

Suppose there is a CFG path from a to b but a is not an ancestor of b. The depth-first recursion (along spanning-tree paths) that found b must have returned all the way up to a and b’s common ancestor before going back down to find b. This means that \( dfnum(a) > dfnum(b) \), and that the path from a to b must include some non-spanning-tree edges.
Therefore, if we know that there is a path from $a$ to $b$, we can test whether $a$ is an ancestor of $b$ just by comparing the $dfnum$'s of $a$ and $b$.

When drawing depth-first spanning trees, we order the children of a node in the order that they are visited by the depth-first search, so that nodes to the right have a higher $dfnum$. This means that if $a$ is an ancestor of $b$, and there is a CFG path from $a$ to $b$ that departs from the spanning tree, it must branch off to the right of the tree path, never to the left.

**Dominator and spanning-tree paths.** Consider a non-root node $n$ in the CFG, and its immediate dominator $d$. The node $d$ must be an ancestor of $n$ in the spanning tree – because any path (including the spanning-tree path) from $r$ to $n$ must include $d$. Therefore $dfnum(d) < dfnum(n)$.

Now we know that $n$'s immediate dominator must be on the spanning-tree path between $r$ and $n$; all that’s left is to see how high up it is.

If some ancestor $x$ does not dominate $n$, then there must be a path that departs from the spanning-tree path above $x$ and rejoins it below $x$. The nodes on the bypassing path are not ancestors of $n$, so their $dfnum$'s are higher than $n$’s. The path might rejoin the spanning-tree path to $n$ either at $n$ or above $n$. 
SEMIDOMINATORS
Paths that bypass ancestors of \( n \) are useful for proving that those ancestors do not dominate \( n \). Let us consider, for now, only those bypassing paths that rejoin the spanning tree at \( n \) (not above \( n \)). Let’s find the path that departs from the tree at the highest possible ancestor \( s \), and rejoins the tree at \( n \). We will call \( s \) the \textit{semidominator} of \( n \).

Another way of saying this is that \( s \) is the node of smallest \( dfnum \) having a path to \( n \) whose nodes (not counting \( s \) and \( n \)) are not ancestors of \( n \). This description of semidominators does not explicitly say that \( s \) must be an ancestor of \( n \), but of course any non-ancestor with a path to \( n \) would have a higher \( dfnum \) than \( n \)’s own parent in the spanning tree, which itself has a path to \( n \) with no non-ancestor internal nodes (actually, no internal nodes at all).

Very often, a node’s semidominator is also its immediate dominator. But as the figure at right shows, to find the dominator of \( n \) it’s not enough just to consider bypassing paths that rejoin the tree at \( n \). Here, a path from \( r \) to \( n \) bypasses \( n \)’s semidominator \( s \), but rejoins the tree at node \( y \), above \( n \). However, finding the semidominator \( s \) is still a useful step toward finding the dominator \( d \).

\textbf{Semidominator Theorem.} To find the semidominator of a node \( n \), consider all predecessors \( v \) of \( n \) in the CFG.

- If \( v \) is a proper ancestor of \( n \) in the spanning tree (so \( dfnum(v) < dfnum(n) \)), then \( v \) is a candidate for \( semi(n) \).
- If \( v \) is a non-ancestor of \( n \) (so \( dfnum(v) > dfnum(n) \)) then for each \( u \) that is an ancestor of \( v \) (or \( u = v \)), let \( semi(u) \) be a candidate for \( semi(n) \).

Of all these candidates, the one with lowest \( dfnum \) is the semidominator of \( n \).

\textbf{Proof.} See the Further Reading section.

\textbf{Calculating dominators from semidominators.} Let \( s \) be the semidominator of \( n \). If there is a path that departs from the spanning tree above \( s \), bypasses \( s \), and rejoins the spanning tree at some node between \( s \) and \( n \), then \( s \) does not dominate \( n \).

However, if we find the node \( y \) between \( s \) and \( n \) with the smallest-numbered semidominator, and \( semi(y) \) is a proper ancestor of \( s \), then \( y \)’s immediate dominator also immediately dominates \( n \).
19.2. EFFICIENT COMPUTATION OF THE DOMINATOR TREE

**Dominator Theorem.** On the spanning-tree path below \( \text{semi}(n) \) and above or including \( n \), let \( y \) be the node with the smallest-numbered semidominator (minimum \( dfnum(\text{semi}(y)) \)). Then,

\[
\text{idom}(n) = \begin{cases} 
\text{semi}(n) & \text{if } \text{semi}(y) = \text{semi}(n) \\
\text{idom}(y) & \text{if } \text{semi}(y) \neq \text{semi}(n)
\end{cases}
\]

**Proof.** See the Further Reading section.

**THE LENGAUER-TARJAN ALGORITHM**

Using these two theorems, Algorithm 19.9 uses depth-first search (DFS) to compute \( dfnum \)'s for every node.

Then it visits the nodes in order, from highest \( dfnum \) to lowest, computing semidominators and dominators. As it visits each node, it puts the node into a spanning forest for the graph. It’s called a forest because there may be multiple disconnected fragments; only at the very end will it be a single spanning tree of all the CFG nodes.

Calculating semidominators requires that, given some edge \( v \rightarrow n \), we look at all ancestors of \( v \) in the spanning tree that have higher \( dfnum \) than \( n \). When Algorithm 19.9 processes node \( n \), only nodes with higher \( dfnum \) than \( n \) will be in the forest. Thus, the algorithm can simply examine all ancestors of \( v \) that are already in the forest.

We use the Dominator Theorem to compute the immediate dominator of \( n \), by finding node \( y \) with lowest semidominator on the path from \( \text{semi}[n] \) to \( n \). When \( s = \text{semi}[n] \) is being computed, it’s not yet possible to determine \( y \); but we will be able to do so later, when \( s \) is being added to the spanning forest. Therefore with each semidominator \( s \) we keep a bucket of all the nodes that \( s \) semidominate; when \( s \) is linked into the spanning forest, we can then calculate the \( \text{idom} \) of each node in \( [s] \).

The forest is represented by an \( \text{ancestor} \) array: for each node \( v \) in the forest, \( \text{ancestor}[v] \) points to \( v \)'s parent. This makes searching upward from \( v \) easy.

Algorithm 19.10a shows a too-slow version of the AncestorWithLowestSemi and Link functions that manage the spanning forest. Link sets the \( \text{ancestor} \) relation, and AncestorWithLowestSemi searches upward for the ancestor whose semidominator has the smallest \( dfnum \).

But each call to AncestorWithLowestSemi could take linear time (in \( N \), the number of nodes in the graph) if the spanning tree is very deep; and AncestorWithLowestSemi is called once for each node and edge. Thus Algorithm 19.9+19.10a has quadratic worst-case time complexity.
DFS(node \( p \), node \( n \)) =
\[
\begin{align*}
\text{if } & d\text{fnum}[n] = 0 \\
& d\text{fnum}[n] \leftarrow N; \quad \text{vertex}[N] \leftarrow n; \quad \text{parent}[n] \leftarrow p \\
& N \leftarrow N + 1 \\
\text{for each successor } & w \text{ of } n \\
& \text{DFS}(n, w)
\end{align*}
\]

Link(node \( p \), node \( n \)) = \text{add edge } p \rightarrow n \text{ to spanning forest implied by ancestor array}

AncestorWithLowestSemi(node \( n \)) = \text{in the forest, find the nonroot ancestor of } n \text{ that has the lowest-numbered semidominator}

Dominator() =
\[
\begin{align*}
N & \leftarrow 0; \quad \forall n. \text{bucket}[n] \leftarrow \{\} \\
\forall n. d\text{fnum}[n] & \leftarrow 0, \quad \text{semi}[n] \leftarrow \text{ancestor}[n] \leftarrow \text{idom}[n] \leftarrow \text{samedom}[n] \leftarrow \text{none} \\
\text{DFS}(\text{none}, r) &
\end{align*}
\]
for \( i \leftarrow N - 1 \) downto 1
\[
\begin{align*}
\text{Skip over node } 0, \text{ the root node.} \\
n & \leftarrow \text{vertex}[i]; \quad p \leftarrow \text{parent}[n]; \quad s \leftarrow p \\
\text{for each predecessor } & v \text{ of } n \\
& \text{if } d\text{fnum}[v] \leq d\text{fnum}[n] \\
& s' \leftarrow v \\
& \text{else } s' \leftarrow \text{semi}[\text{AncestorWithLowestSemi}(v)] \\
& \text{if } d\text{fnum}[s'] < d\text{fnum}[s] \\
& s \leftarrow s' \\
\text{semi}[n] & \leftarrow s \\
\text{bucket}[s] & \leftarrow \text{bucket}[s] \cup \{n\}
\end{align*}
\]

Link(\( p \), \( n \))
\[
\begin{align*}
\text{for each } v \text{ in } \text{bucket}[p] \\
& y \leftarrow \text{AncestorWithLowestSemi}(v) \\
& \text{if } \text{semi}[y] = \text{semi}[v] \\
& \text{idom}[v] \leftarrow p \\
& \text{else } \text{samedom}[v] \leftarrow y \\
\text{bucket}[p] & \leftarrow \{\}
\end{align*}
\]
for \( i \leftarrow 1 \) to \( N - 1 \)
\[
\begin{align*}
n & \leftarrow \text{vertex}[i] \\
\text{if } \text{samedom}[n] & \neq \text{none} \\
& \text{idom}[n] \leftarrow \text{idom}[\text{samedom}[n]]
\end{align*}
\]

19.2. EFFICIENT COMPUTATION OF THE DOMINATOR TREE

AncestorWithLowestSemi(node \( v \)) =
\[
\begin{align*}
  u & \leftarrow v \\
  \textbf{while} \ ancestor[v] \neq \text{none} & \\
  & \quad \textbf{if} \ dfnum[semi[v]] < dfnum[semi[u]] \\
  & \quad \quad u \leftarrow v \\
  & \quad v \leftarrow ancestor[v] \\
  \textbf{return} & u
\end{align*}
\]

Link(node \( p \), node \( n \)) =
\[
\begin{align*}
  ancestor[n] & \leftarrow p \\
  \text{(a) Naive version,} \quad & \quad O(N) \text{ per operation.}
\end{align*}
\]

AncestorWithLowestSemi(node \( v \)) =
\[
\begin{align*}
  a & \leftarrow ancestor[v] \\
  \textbf{if} \ ancestor[a] \neq \text{none} & \\
  & \quad b \leftarrow AncestorWithLowestSemi(a) \\
  & \quad ancestor[v] \leftarrow ancestor[a] \\
  & \quad \textbf{if} \ dfnum[semi[b]] < dfnum[semi[best[v]]] \\
  & \quad \quad best[v] \leftarrow b \\
  \textbf{return} & best[v]
\end{align*}
\]

Link(node \( p \), node \( n \)) =
\[
\begin{align*}
  ancestor[n] & \leftarrow p; \quad best[n] \leftarrow n \\
  \text{(b) With path-compression,} \quad & \quad O(\log N) \text{ per operation.}
\end{align*}
\]

Algorithm 19.10. Two versions of AncestorWithLowestSemi and Link functions for operations on spanning forest. The naive version (a) takes \( O(N) \) per operation (so the algorithm runs in time \( O(N^2) \)) and the efficient version (b) takes \( O(\log N) \) amortized time per operation, for an \( O(N \log N) \) algorithm.

Path compression. The algorithm may call AncestorWithLowestSemi\((v)\) several times for the same node \( v \). The first time, AncestorWithLowestSemi traverses the nodes from \( v \) to \( a_1 \), some ancestor of \( v \), as shown in Figure 19.11a. Then perhaps some new links \( a_3 \to a_2 \to a_1 \) are added to the forest above \( a_1 \), so the second AncestorWithLowestSemi\((v)\) searches up to \( a_3 \). But we would like to avoid the duplicate traversal of the path from \( v \) to \( a_1 \). Furthermore, suppose we later call AncestorWithLowestSemi\((w)\) on some child of \( v \). During that search we would like to be able to skip from \( v \) to \( a_1 \).

The technique of path compression makes AncestorWithLowestSemi faster. For each node \( v \) in the spanning forest, we allow \( ancestor[v] \) to point to some ancestor of \( v \) that may be far above \( v \)’s parent. But then we must remember – in \( best[v] \) – the best node in the skipped-over path between \( ancestor[v] \) and \( v \).

\[
\begin{align*}
  \text{ancestor}[v] & = \text{Any node above } v \text{ in the spanning forest.} \\
  \text{best}[v] & = \text{The node whose semidominator has lowest } dfnum, \text{ in the skipped-over path from } ancestor[v] \text{ down to } v \text{ (including } v \text{ but not } ancestor[v]).
\end{align*}
\]

Now, when AncestorWithLowestSemi searches upwards, it can compress
paths by setting \( \text{ancestor}[v] \leftarrow \text{ancestor}[\text{ancestor}[v]] \), as long as it updates \( \text{best}[v] \) at the same time. This is shown in Algorithm 19.10b.

In a graph of \( K \) nodes and \( E \) edges, there will be \( K - 1 \) calls to Link and \( E + K - 1 \) calls to AncestorWithLowestSemi. With path compression it can be shown that this takes \( O(E \log K) \) time. In terms of the “size” \( N = E + K \) of the control-flow graph, Algorithm 19.9+19.10b takes \( O(N \log N) \) time.

**Balanced path compression.** The most sophisticated version of the Lengauer-Tarjan algorithm is Algorithm 19.9 with Link and AncestorWithLowestSemi functions that rebalance the spanning trees, so that the work of path compression is undertaken only when it do the most good. This algorithm has time complexity \( O(N \cdot \alpha(N)) \), where \( \alpha(N) \) is the slowly growing inverse-Ackermann function that is for all practical purposes constant. In practice it appears that this sophisticated algorithm is about 35% faster than the \( N \log N \) algorithm (when measured on graphs of up to 1000 nodes). See also the Further Reading section of this chapter.
19.3. OPTIMIZATION ALGORITHMS USING SSA

Since we are primarily interested in SSA form because it provides quick access to important dataflow information, we should pay some attention to data-structure representations of the SSA graph.

The objects of interest are statements, basic blocks, and variables:

- **Statement** Fields of interest are containing block, previous statement in block, next statement in block, variables defined, variables used. Each statement may be an ordinary assignment, \( \phi \)-function, fetch, store, or branch.

- **Variable** Has a definition site (statement) and a list of use sites.

- **Block** Has a list of statements, an ordered list of predecessors, a successor (for blocks ending with a conditional branch, more than one successor). The order of predecessors is important for determining the meaning \( \phi(v_1, v_2, v_3) \) inside the block.

**DEAD-CODE ELIMINATION**

The SSA data structure makes dead-code analysis particularly quick and easy. A variable is live at its site of definition if and only if its list of uses is not empty. This is true because there can be no other definition of the same variable (it’s single-assignment form!) and the definition of a variable dominates every use – so there must be a path from definition to use.\(^1\)

This leads to the following iterative algorithm for deleting dead code:

\[
\textbf{while} \hspace{1em} \text{there is some variable } v \text{ with no uses} \\
\hspace{2em} \text{and the statement that defines } v \text{ has no other side-effects} \\
\hspace{3em} \textbf{do} \hspace{1em} \text{delete the statement that defines } v
\]

In deleting a statement \( v \leftarrow x \oplus y \) or the statement \( v \leftarrow \phi(x, y) \), we take care to remove the statement from the list of uses of \( x \) and of \( y \). This may cause \( x \) or \( y \) to become dead, if it was the last use. To keep track of this efficiently, Algorithm 19.12 uses a work-list \( W \) of variables that need to be reconsidered. This takes time proportional to the size of the program plus the number of variables deleted (which itself cannot be larger than the size of the program) – or linear time overall. The only question is how long it takes to delete \( S \) from a (potentially long) list of uses of \( x_i \). By keeping \( x_i \)’s list of uses as a doubly linked list, and having each use of \( x_i \) point back to its own entry in this list, the deletion can be done in constant time.

\(^1\)As usual, we are considering only connected graphs.
CHAPTER NINETEEN. STATIC SINGLE-ASSIGNMENT FORM

\[ W \leftarrow \text{a list of all variables in the SSA program} \]
\[ \textbf{while} \ W \text{ is not empty} \]
\[ \quad \text{remove some variable} \ v \text{ from} \ W \]
\[ \quad \textbf{if} \ v\text{’s list of uses is empty} \]
\[ \quad \quad \text{let} \ S \text{ be} \ v\text{’s statement of definition} \]
\[ \quad \quad \textbf{if} \ S \text{ has no side effects other than the assignment to} \ v \]
\[ \quad \quad \quad \text{delete} \ S \text{ from the program} \]
\[ \quad \quad \textbf{for} \text{ each variable} \ x_i \text{ used by} \ S \]
\[ \quad \quad \quad \text{delete} \ S \text{ from the list of uses of} \ x_i \]
\[ \quad W \leftarrow W \cup \{x_i\} \]

\textbf{ALGORITHM 19.12.} Dead-code elimination in SSA form.

If run on the program of Figure 19.3b, this algorithm would delete the statement \( b_1 \leftarrow \phi(b_0, b_2) \).

A more aggressive dead-code-elimination algorithm, which uses a different definition of \textit{dead}, is shown on page 461.

\textbf{SIMPLE CONSTANT PROPAGATION}

Whenever there is a statement of the form \( v \leftarrow c \) for some constant \( c \), then any use of \( v \) can be replaced by a use of \( c \).

Any \( \phi \)-function of the form \( v \leftarrow \phi(c_1, c_2, \ldots, c_n) \), where all the \( c_i \) are equal, can be replaced by \( v \leftarrow c \).

Each of these conditions is easy to detect and implement using the SSA data structure, and we can use a simple work-list algorithm to propagate constants:

\[ W \leftarrow \text{a list of all statements in the SSA program} \]
\[ \textbf{while} \ W \text{ is not empty} \]
\[ \quad \text{remove some statement} \ S \text{ from} \ W \]
\[ \quad \textbf{if} \ S \text{ is} \ v \leftarrow \phi(c, c, \ldots, c) \text{ for some constant} \ c \]
\[ \quad \quad \text{replace} \ S \text{ by} \ v \leftarrow c \]
\[ \quad \textbf{if} \ S \text{ is} \ v \leftarrow c \text{ for some constant} \ c \]
\[ \quad \quad \text{delete} \ S \text{ from the program} \]
\[ \quad \textbf{for} \text{ each statement} \ T \text{ that uses} \ v \]
\[ \quad \quad \text{substitute} \ c \text{ for} \ v \text{ in} \ T \]
\[ \quad W \leftarrow W \cup \{T\} \]
If we run this algorithm on the SSA program of Figure 19.4g, then the assignment \( j_3 \leftarrow i \) will be replaced with \( j_3 \leftarrow 1 \), and the assignment \( i_1 \leftarrow 1 \) will be deleted. Uses of variables \( j_1 \) and \( k_1 \) will also be replaced by constants.

The following transformations can all be incorporated into this work-list algorithm, so that in linear time all these optimizations can be done at once:

**Copy propagation** A single-argument \( \phi \)-function \( x \leftarrow \phi(y) \) or a copy assignment \( x \leftarrow y \) can be deleted, and \( y \) substituted for every use of \( x \).

**Constant folding** If we have a statement \( x \leftarrow a \oplus b \), where \( a \) and \( b \) are constant, we can evaluate \( c \leftarrow a \oplus b \) at compile time and replace the statement with \( x \leftarrow c \).

**Constant conditions** In block \( L \), a conditional branch \( \text{if } a < b \text{ goto } L_1 \text{ else } L_2 \), where \( a \) and \( b \) are constant, can be replaced by either \( \text{goto } L_1 \) or \( \text{goto } L_2 \), depending on the (compile-time) value of \( a < b \). The control-flow edge from \( L \) to \( L_2 \) (or \( L_1 \), respectively) must be deleted; this reduces the number of predecessors of \( L_2 \) (or \( L_1 \)), and the \( \phi \)-functions in that block must be adjusted accordingly (by removing an argument).

**Unreachable code** Deleting a predecessor may cause block \( L_2 \) to become unreachable. In this case, all the statements in \( L_2 \) can be deleted; use-lists of all the variables that are used in these statements must be adjusted accordingly. Then the block itself should be deleted, reducing the number of predecessors of its successor blocks.

**CONDITIONAL CONSTANT PROPAGATION**

In the program of Figure 19.4b, is \( j \) always equal to 1?

- If \( j = 1 \) always, then block 6 will never execute, so the only assignment to \( j \) is \( j \leftarrow i \), so \( j = 1 \) always.
- If sometimes \( j > 20 \), then block 6 will eventually execute, which assigns \( j \leftarrow k \), so that eventually \( j > 20 \).

Each of these statements is self-consistent; but which is true in practice? In fact, when this program executes, \( j \) is never set to any value other than 1. This is a kind of least fixed point (analogous to what is described in Section 10.1 on page 224).

The “simple” constant-propagation algorithm has the problem of assuming the block 6 might be executed, and therefore that \( j \) might not be constant, and therefore that perhaps \( j \geq 20 \), and therefore that block 6 might be executed. Simple constant propagation finds a fixed point that is not the least fixed point.
Why would programmers put never-executed statements in their programs? Many programs have statements of the form if debug then ... where debug is a constant false value; we would not like to let the statements in the debug-clauses get in the way of useful optimizations.

The SSA conditional constant propagation finds the least fixed point: it does not assume a block can be executed until there is evidence that it can be, and does not assume a variable is non-constant until there is evidence, and so on.

The algorithm tracks the run-time value of each variable as follows:

\[ \forall[v] = \bot \quad \text{We have seen no evidence that any assignment to } v \text{ is ever executed.} \]
\[ \forall[v] = 4 \quad \text{We have seen evidence that an assignment } v \leftarrow 4 \text{ is executed, but no evidence that } v \text{ is ever assigned any other value.} \]
\[ \forall[v] = \top \quad \text{We have seen evidence that } v \text{ will have, at various times, at least two different values, or some value (perhaps read from an input file or from memory) that is not predictable at compile time.} \]

Thus we have a lattice of values, with \( \bot \) meaning never defined, 4 meaning defined as 4, and \( \top \) meaning overdefined:

\[ \ldots 3 4 5 6 7 \ldots \]
\[ \bot \]

New information can only move a variable up in the lattice.²

We also track the executability of each block, as follows:

\[ \mathcal{E}[B] = \text{false} \quad \text{We have seen no evidence that block } B \text{ can ever be executed.} \]
\[ \mathcal{E}[B] = \text{true} \quad \text{We have seen evidence that block } B \text{ can be executed.} \]

Initially we start with \( \forall[ ] = \bot \) for all variables, and \( \mathcal{E}[ ] = \text{false} \) for all blocks. Then we observe the following:

1. Any variable \( v \) with no definition, which is therefore an input to the program, a formal parameter to the procedure, or (horrors!) an uninitialized variable, must have \( \forall[v] \leftarrow \top \).
2. The start block \( B_1 \) is executable: \( \mathcal{E}[B_1] \leftarrow \text{true} \).
3. For any executable block \( B \) with only one successor \( C \), set \( \mathcal{E}[C] \leftarrow \text{true} \).

²Authors in the subfield of dataflow analysis use \( \bot \) to mean overdefined and \( \top \) to mean never defined; authors in semantics and abstract interpretation use \( \bot \) for undefined and \( \top \) for overdefined; I am following the latter practice.
19.3. OPTIMIZATION ALGORITHMS USING SSA

4. For any executable assignment \( v \leftarrow x \oplus y \) where \( v[x] = c_1 \) and \( v[y] = c_2 \), set \( v[v] \leftarrow c_1 \oplus c_2 \).
5. For any executable assignment \( v \leftarrow x \oplus y \) where \( v[x] = \top \) or \( v[y] = \top \), set \( v[v] \leftarrow \top \).
6. For any executable assignment \( v \leftarrow \phi(x_1, \ldots, x_n) \) where \( v[x_i] = c_1 \), \( v[x_j] = c_2 \), \( c_1 \neq c_2 \), the \( i \)th predecessor is executable, and the \( j \)th predecessor is executable, set \( v[v] \leftarrow \top \).
7. For any executable assignment \( v \leftarrow \text{MEM}() \) or \( v \leftarrow \text{CALL}() \), set \( v[v] \leftarrow \top \).
8. For any executable assignment \( v \leftarrow \phi(x_1, \ldots, x_n) \) where \( v[x_i] = \top \) and the \( i \)th predecessor is executable, set \( v[v] \leftarrow \top \).
9. For any assignment \( v \leftarrow \phi(x_1, \ldots, x_n) \) whose \( i \)th predecessor is executable and \( v[x_i] = c_1 \); and for every \( j \) either the \( j \)th predecessor is not executable, or \( v[x_j] = \bot \), or \( v[x_j] = c_1 \), set \( v[v] \leftarrow c_1 \).
10. For any executable branch if \( x < y \) goto \( L_1 \) else \( L_2 \), where \( v[x] = \top \) or \( v[y] = \top \), set \( \mathcal{E}[L_1] \leftarrow \text{true} \) and \( \mathcal{E}[L_2] \leftarrow \text{true} \).
11. For any executable branch if \( x < y \) goto \( L_1 \) else \( L_2 \), where \( v[x] = c_1 \) and \( v[y] = c_2 \), set \( \mathcal{E}[L_1] \leftarrow \text{true} \) or \( \mathcal{E}[L_2] \leftarrow \text{true} \) depending on \( c_1 < c_2 \).

An executable assignment is an assignment statement in a block \( B \) with \( \mathcal{E}[B] = \text{true} \). These conditions “ignore” any expression or statement in an unexecutable block, and the \( \phi \)-functions “ignore” any operand that comes from an unexecutable predecessor.

The algorithm can be made quite efficient using work-lists: there will be one work-list \( W_v \) for variables and and another work-list \( W_b \) for blocks. The algorithm proceeds by picking \( x \) from \( W_v \) and considering conditions 4–9 for any statement in \( x \)’s list of uses; or by picking an block \( B \) from \( W_b \) and considering condition 3, and conditions 4–9 for any statement within \( B \). Whenever a block is newly marked executable, it and its executable successors are added to \( W_v \). Whenever \( v[x] \) is “raised” from \( \bot \) to \( c \) or from \( c \) to \( \top \), then \( x \) is added to \( W_v \). When both \( W_v \) and \( W_b \) are empty, the algorithm is finished. The algorithm runs quickly, because for any \( x \) it raises \( v[x] \) at most twice, and for any \( B \) it changes \( \mathcal{E}[B] \) at most once.

We use this information to optimize the program as follows. After the analysis terminates, wherever \( \mathcal{E}[B] = \text{false} \), delete block \( B \). Wherever \( v[x] = c \), substitute \( c \) for \( x \) and delete the assignment to \( x \).

Figure 19.13 shows the conditional constant propagation algorithm executed on the program of Figure 19.4. The algorithm finds that all the \( j \) variables are constant (with value 1), \( k_1 \) is constant (with value 0), and block 6 is not executed. Deleting unreachable blocks, and replacing uses of constant variables with the constant value – deleting their definitions – leads to some
empty blocks and a \( \phi \)-function that has only one argument; these can be simplified, leaving the program of Figure 19.13d.

The unique successor or predecessor property is important for the proper operation of this algorithm. Suppose we were to do conditional constant propagation on the graph of Figure 19.2b, in a case where \( M[x] \) is known to be 10. Then blocks 1, 2, 3, and 4 will be marked executable, but it will not be clear that edge 2 \( \rightarrow \) 4 cannot be taken. In Figure 19.2c, block 5 would not be executable, making the situation clear. By using the edge-split SSA form, we avoid the need to mark edges (not just blocks) executable.

**Figure 19.13.** Conditional constant propagation.

**Preserving the Dominance Property**

Almost every reasonable optimizing transformation – including the ones described above – preserves the dominance property of the SSA program: the definition of a variable dominates each use (or, when the use is in a \( \phi \)-function, the predecessor of the use).

It is important to preserve this property, since some optimization algorithms (such as Algorithm 19.17) depend on it. Also, the very definition of SSA form – that there is a \( \phi \)-function at the convergence point of any two dataflow paths – implicitly requires it.

But there is one kind of optimization that does not preserve the dominance property. In the program of Figure 19.14a, we can prove that – because the condition \( z > 0 \) evaluates the same way in blocks 1 and 4 – the use of \( x_2 \) in
block 5 always gets the value $x_1$, never $x_0$. Thus it is tempting to substitute $x_1$ for $x_2$ in block 5. But the resulting graph does not have the dominance property: block 5 is not dominated by the definition of $x_1$ in block 2.

Therefore this kind of transformation – based on the knowledge that two conditional branches test the same condition – is not valid for SSA form.

**19.4. ARRAYS, POINTERS, AND MEMORY**

For many purposes in optimization, parallelization, and scheduling, the compiler needs to know, “how does statement $B$ depend on statement $A$?” The transformations of constant propagation and dead-code removal have relied on this dependence information.

There are several kinds of dependence relations:

- **Read-after-write** $A$ defines variable $v$, then $B$ uses $v$.
- **Write-after-write** $A$ defines $v$, then $B$ defines $v$.
- **Write-after-read** $A$ uses $v$, then $B$ defines $v$.
- **Control** $A$ controls whether $B$ executes.

Read-after-write dependences are evident in the SSA graph: $A$ defines $v$, $v$’s list of uses points to $B$; or $B$’s use list contains $v$, and $v$’s def-site is $A$.

Control dependences will be discussed in Section 19.5.
In SSA form, there are no write-after-write or write-after-read dependences. Statements $A$ and $B$ can never write to the same variable, and any use must be “after” (that is, dominated by) the variable’s definition.

**MEMORY DEPENDENCE**

The discussion thus far of assignments and $\phi$-function has been only for scalar non-escaping variables. Real programs must also load and store memory words.

One way to get a single-assignment property for memory is to ensure that each memory word is written only once. Although this seems severe, it is just what a pure functional programming language does (see Chapter 15) – with a garbage collector behind the scenes to allow actual reuse of physical memory locations.

However, in an imperative language we must do something else. Consider a sequence of stores and fetches such as this one:

1. $M[i] \leftarrow 4$
2. $x \leftarrow M[j]$
3. $M[k] \leftarrow j$

We cannot treat each individual memory location as a separate variable for static-single-assignment purposes, because we don’t know whether $i$, $j$, and $k$ are the same address.

We could perhaps treat memory as a “variable,” where the store instruction creates a new value (of the entire memory):

1. $M_1 \leftarrow store(M_0, i, 4)$
2. $x \leftarrow load(M_1, j)$
3. $M_2 \leftarrow store(M_1, k, j)$

This creates the def-use edges $M_1 \rightarrow 2$ and $M_1 \rightarrow 3$. These def-use edges are like any SSA def-use relationship, and we make $\phi$-functions for them at join points in the same way.

But there is no edge from $2 \rightarrow 3$, so what prevents the compiler from reordering the statements as follows?

1. $M_1 \leftarrow store(M_0, i, 4)$
2. $M_2 \leftarrow store(M_1, k, j)$
3. $x \leftarrow load(M_1, j)$
19.5. THE CONTROL-DEPENDENCE GRAPH

The functional dependences are still correct – if $M_1$ is viewed as a snapshot of memory after statement 1, then statement 4 is still correct in loading from address $j$ in that snapshot. But it is inefficient – to say the least! – for the computer to keep more than one copy of the machine’s memory.

We would like to say that there is a write-after-read dependence $2 \rightarrow 3$ to prevent the compiler from creating $M_2$ before all uses of $M_1$ have been computed. But calculation of accurate dependence information for memory locations is beyond the scope of this chapter.

A naive but practical solution. In the absence of write-after-read and write-after-write dependence information, we will just say that a store instruction is always presumed live – we will not do dead-code elimination on stores – and we will not transform the program in such a way as to interchange a load and a store, or two stores. Store instructions can be unreachable, however, and unreachable stores can be deleted.

The optimization algorithms presented in this chapter do not reorder instructions, and do not attempt to propagate dataflow information through memory, so they implicitly use this naive model of loads and stores.

19.5 THE CONTROL-DEPENDENCE GRAPH

Can node $x$ directly control whether node $y$ is executed? The answer to this question can help us with program transformations and optimizations.

Any flow graph must have an exit node. If a control-flow graph represents a single function, then this is the return statement of the function; if there are several return statements, we assume that each one of them is really a control-flow edge to some unique canonical exit node of the CFG.

We say that a node $y$ is control-dependent on $x$ if from $x$ we can branch to $u$ or $v$; from $u$ there is a path to exit that avoids $y$, and from $v$ every path to exit hits $y$: 

![Diagram of the control-dependence graph]

exit

x

u

v
The control-dependence graph (CDG) has an edge from $x$ to $y$ whenever $y$ is control-dependent on $x$.

We say that $y$ postdominates $v$ when $y$ is on every path from $v$ to exit — that is, $y$ dominates $v$ in the reverse control-flow graph.

**Construction of the control-dependence graph.**

To construct the CDG of a control-flow graph $G$,

1. Add a new entry-node $r$ to $G$, with an edge $r \rightarrow s$ to the start node $s$ of $G$ (indicating that the surrounding program might enter $G$) and an edge $r \rightarrow$ exit to the exit node of $G$ (indicating that the surrounding program might not execute $G$ at all).

2. Let $G'$ be the reverse control-flow graph that has an edge $y \rightarrow x$ whenever $G$ has an edge $x \rightarrow y$; the start node of $G'$ corresponds to the exit node of $G$.

3. Construct the dominator tree of $G'$ (its root corresponds to the exit node of $G$).

4. Calculate the dominance frontiers $DF_{G'}$ of the nodes of $G'$.

5. The CDG has edge $x \rightarrow y$ whenever $x \in DF_{G'}(y)$.

That is, $x$ directly controls whether $y$ executes, if and only if $x$ is in the dominance frontier of $y$ in the reverse control-flow graph.

Figure 19.15 shows the CDG for the program of Figure 19.4.

With the SSA graph and the control-dependence graph, we can now answer questions of the form, “must $A$ be executed before $B$?” If there is any path $A \rightarrow B$ composed of SSA use-def edges and CDG edges, then there is a trail of data- and control-dependence requiring $A$ to be performed before $B$. 

**Figure 19.15.** Construction of the control-dependence graph.
AGGRESSIVE DEAD-CODE ELIMINATION

One interesting use of the control-dependence graph is in dead-code elimination. Suppose we have a situation such as the one in Figure 19.13d, where conventional dead-code analysis (as described in Section 17.3 or Algorithm 19.12) determines:

- \( k_2 \) is live because it’s used in the definition of \( k_3 \),
- \( k_3 \) is live because it’s used in the definition of \( k_2 \),

but neither variable contributes anything toward the eventual result of the calculation.

Just as conditional constant propagation assumes a block is unreachable unless there is evidence that execution can be reach it, aggressive dead-code elimination assumes a statement is dead unless it has evidence that it contributes to the eventual result of the program.

Algorithm. Mark live any statement that:

1. Performs input/output, stores into memory, returns from the function, or calls another function that might have side effects;
2. Defines some variable \( v \) that is used by another live statement; or
3. Is a conditional branch, upon which some other live statement is control-dependent.

Then delete all unmarked statements.

This can be solved by iteration (or by a work-list algorithm). Figure 19.16 shows the amusing result of running the this algorithm on the program of Figure 19.13d: the entire loop is deleted, leaving a very efficient program!

Caveat. The aggressive dead-code elimination algorithm will remove output-free infinite loops, which does change the meaning of the program. Instead of producing nothing, the program will execute the statements after the loop, which may produce output. In many environments this is regarded as unacceptable.

But on the other hand, the control-dependence graph is often used in parallelizing compilers: any two statements that are not control-dependent or data-dependent can be executed in parallel. Even if such a compiler did not delete a useless infinite loop, it might choose to execute the loop in parallel with successor statements (that are not control-dependent on it); this would have approximately the same effect as deleting the infinite loop.
CHAPTER NINETEEN. STATIC SINGLE-ASSIGNMENT FORM

19.6 CONVERTING BACK FROM SSA FORM

After program transformations and optimization, a program in static single-assignment form must be translated into some executable representation without \( \phi \)-functions. The definition \( y \leftarrow \phi(x_1, x_2, x_3) \) can be translated as “move \( y \leftarrow x_1 \) if arriving along predecessor edge 1, move \( y \leftarrow x_2 \) if arriving along predecessor edge 2, and move \( y \leftarrow x_3 \) if arriving along predecessor edge 3.” To “implement” this definition in an edge-split SSA form, for each \( i \) we insert the move \( y \leftarrow x_i \) at the end of the \( i \)th predecessor of the block containing the \( \phi \)-function.

The unique successor or predecessor property prevents redundant moves from being inserted; in Figure 19.2b (without the property), block 2 would need a move \( a_3 \leftarrow a_1 \) that is redundant if the then branch is taken; but in Figure 19.2c, the move \( a_3 \leftarrow a_1 \) would be in block 5, and never executed redundantly.

Now we can do register allocation on this program, as described in Chapter 11. Although it is tempting simply to assign \( x_1 \) and \( x_2 \) the same register if they were derived from the same variable \( x \) in the original program, it could be that program transformations on the SSA form have made their live ranges interfere (see Exercise 19.11). Thus, we ignore the original derivation of the
**19.6. CONVERTING BACK FROM SSA FORM**

LivenessAnalysis() =

```plaintext
for each variable \( v \)
    \( M \leftarrow \{ \} \)
    for each site-of-use \( s \) of \( v \)
        if \( s \) is a \( \phi \)-function with \( v \) as its \( i \)th argument
            let \( p \) be the \( i \)th predecessor of the block containing \( s \)
            LiveOutAtBlock\( (p, v) \)
        else LiveInAtStatement\( (s, v) \)
```

LiveOutAtBlock\( (n, v) = \)

```plaintext
v is live-out at \( n \)
if \( n \notin M \)
    \( M \leftarrow M \cup \{ n \} \)
    let \( s \) be the last statement in \( n \)
    LiveOutAtStatement\( (s, v) \)
```

LiveInAtStatement\( (s, v) = \)

```plaintext
v is live-in at \( s \)
if \( s \) is the first statement of some block \( n \)
    \( v \) is live-in at \( n \)
    for each predecessor \( p \) of \( n \)
        LiveOutAtBlock\( (p, v) \)
    else
        let \( s' \) be the statement preceding \( s \)
        LiveOutAtStatement\( (s', v) \)
```

LiveOutAtStatement\( (s, v) = \)

```plaintext
v is live-out at \( s \)
let \( W \) be the set of variables that \( s \) defines
for each variable \( w \in (W - \{ v \}) \)
    add \((v, w)\) to interference graph
if \( v \notin W \)
    LiveInAtStatement\( (s, v) \)
```

**Algorithm 19.17.** Calculation of live ranges in SSA form, and building the interference graph. The graph-walking algorithm is expressed as a mutual recursion between `LiveOutAtBlock`, `LiveInAtStatement`, and `LiveOutAtStatement`. The recursion is bounded whenever `LiveOutAtBlock` finds an already walked block, or whenever `LiveOutAtStatement` reaches the definition of \( v \).

different SSA variables, and we rely on coalescing (copy propagation) in the register allocator to eliminate almost all of the move instructions.

**LIVENESS ANALYSIS FOR SSA**

We can efficiently construct the interference graph of an SSA program, just prior to converting the \( \phi \)-functions to move instructions. For each variable \( v \), Algorithm 19.17 walks backward from each use, stopping when it reaches \( v \)'s definition. The *dominance property of SSA form* ensures that the algorithm will always stay in the region dominated by the definition of \( v \). For many variables this region is small; contrast this with the situation in Figure 19.14 (a non-SSA program), where the algorithm applied to variable \( x_1 \) would walk upwards through the \( 1 \rightarrow 3 \) edge and traverse the entire program. Because this algorithm processes only the blocks where \( v \) is live, its running time
is proportional to the size of the interference graph that it constructs (see Exercise 19.12).

Algorithm 19.17 as shown uses recursion (when \textit{LiveInAtStatement} calls \textit{LiveOutAtBlock}), and also tail recursion (when \textit{LiveInAtStatement} calls \textit{LiveOutAtStatement}, when \textit{LiveOutAtStatement} calls \textit{LiveInAtStatement}, and when \textit{LiveOutAtBlock} calls \textit{LiveOutAtStatement}). Some programming languages or compilers can compile tail recursion very efficiently as a \textit{goto} – see Section 15.6. But when implementing this algorithm in compilers that do not support efficient tail calls, then instead of tail recursion it might be best to use explicit \textit{goto}'s, or use work-lists for \textit{LiveOutAtStatement} and \textit{LiveInAtStatement}.

### 19.7 A FUNCTIONAL INTERMEDIATE FORM

A \textit{functional} programming language is one in which (as discussed in Chapter 15) execution proceeds by binding variables to values, and never modifying a variable once it is initialized. This permits equational reasoning, which is useful to the programmer.

But equational reasoning is even more useful to the compiler – many compiler optimizations involve the rewriting of a slow program into an equivalent faster program. When the compiler doesn’t have to worry about \textit{x}’s value now versus \textit{x}’s value later, then these transformations are easier to express.

This single-assignment property is at the heart of both functional programming and SSA form. There is a close relationship between the functional intermediate representations used by functional-language compilers and the SSA form used by imperative-language compilers.

Figure 19.18 shows the abstract syntax of the kind of intermediate representation used in modern functional-language compilers. It aspires to the best qualities of quadruples, SSA form, and lambda-calculus. As in quadruple notation, expressions are broken down into primitive operations whose order of evaluation is specified, every intermediate result is an explicitly named temporary, and every argument of an operator or function is an \textit{atom} (variable or constant). As in SSA form and lambda-calculus, every variable has a single assignment (or \textit{binding}), and every use of the variable is within the \textit{scope} of the binding. As in lambda-calculus, scope is a simple syntactic notion, not requiring calculation of dominators.

\text{relop} & \rightarrow \text{eq | ne | lt | ...}
\end{align*}
\]

\textbf{FIGURE 19.18.} Functional intermediate representation. Binding occurrences of variables are underlined.

\textbf{Scope.} No variable name can be used in more than one binding. Every binding of a variable has a scope within which all the uses of that variable must occur. For a variable bound by \text{let } v = \ldots \text{ in } \text{exp}, the scope of \textit{v} is just the \textit{exp}. The scope of a function-variable \textit{f}_i bound in

\begin{verbatim}
let function \textit{f}_1(\ldots) = \text{exp}_1 \\
    \ldots \\
function \textit{f}_k(\ldots) = \text{exp}_k \\
\text{in } \text{exp}
\end{verbatim}

includes \textit{all} the \text{exp}_i (to allow for mutually recursive functions) as well as the \text{exp}. For a variable bound as the formal parameter of a function, the scope is the body of that function.
These scope rules make many optimizations easy to reason about; we will take *inline expansion of functions* as an example. As discussed in Section 15.4, when we have a definition \( f(x) = E \) and a use \( f(z) \) we can replace the use by a copy of \( E \) but with all the \( x \)'s replaced by \( z \)'s. In the Tree language of Chapter 7 this is difficult to express because there are no functions; in the functional notation of Chapter 15 the substitution can get complicated if \( z \) is a non-atomic expression (as shown in Algorithm 15.8b). But in the functional intermediate form of Figure 19.18, where all actual parameters are atomic, inline-expansion becomes very simple, as shown in Algorithm 15.8a.

**Translating SSA into functional form.** Any SSA program can be translated into this functional form, as shown in Algorithm 19.20. Each control-flow node with more than one predecessor becomes a function. The arguments of that function are precisely the variables for which there are \( \phi \)-functions at the node. If node \( f \) dominates node \( g \), then the function for \( g \) will be nested inside the body of the function for \( f \). Instead of jumping to a node, a control-flow edge into a \( \phi \)-containing node is represented by a function call. Program 19.19 shows how a translated program looks.
19.7. A FUNCTIONAL INTERMEDIATE FORM

Translate\((node) =\)
let \(C\) be the children of \(node\) in the dominator tree
let \(p_1, \ldots, p_n\) be the nodes of \(C\) that have more than one predecessor
for \(i \leftarrow 1\) to \(n\)
  let \(a_1, \ldots, a_k\) be the targets of \(\phi\) functions in \(p_i\) (possibly \(k = 0\))
  let \(S_i = \text{Translate}(p_i)\)
  let \(F_i = \text{“function } f_{p_i}(a_1, \ldots, a_k) = S_i\text{”}\)
let \(F = F_1 F_2 \cdots F_n\)
return Statements\((node, 1, F)\)

Statements\((node, j, F) =\)
if there are \(< j\) statements in \(node\)
then let \(s\) be the successor of \(node\)
  if \(s\) has only one predecessor
  then return Statements\((s, 1, F)\)
else \(s\) has \(m\) predecessors
  suppose \(node\) is the \(i\)th predecessor of \(s\)
  suppose the \(\phi\)-functions in \(s\) are \(a_1 \leftarrow \phi(a_{11}, \ldots, a_{1m}), \ldots\)
  \(a_k \leftarrow \phi(a_{k1}, \ldots, a_{km})\)
  return “let \(F\) in \(fs(a_{1i}, \ldots, a_{ki})\)”
else if the \(j\)th statement of \(node\) is a \(\phi\)-function
then return Statements\((node, j + 1, F)\)
else if the \(j\)th statement of \(node\) is “return \(a\)”

else if the \(j\)th statement of \(node\) is \(a \leftarrow b \oplus c\)
then let \(S = \text{Statements}(node, j + 1, F)\)
  return “let \(a = b \oplus c\) in \(S\)”
else if the \(j\)th statement of \(node\) is “if \(a < b\) goto \(s_1\) else \(s_2\)”
then (in edge-split SSA form) \(s_1\) has only one predecessor, as does \(s_2\)
  let \(S_1 = \text{Translate}(s_1)\)
  let \(S_2 = \text{Translate}(s_2)\)
  return “let \(F\) in if \(a < b\) then \(S_1\) else \(S_2\)”

ALGORITHM 19.20. Translating SSA to functional intermediate form.
Translating functional programs into functional intermediate form. A functional program in a language such as PureFun-Tiger starts in a form that obeys all the scope rules, but arguments are not atomic and variables are not unique. It is a simple matter to introduce well-scoped intermediate temporaries by a recursive walk of expression trees; dominator and SSA calculations are unnecessary.

All of the SSA-based optimization algorithms work equally well on a functional intermediate form; so will the optimizations and transformations on functional program described in Chapter 15. Functional intermediate forms can also be made explicitly typed, type-checkable, and polymorphic as described in Chapter 16. All in all, this kind of intermediate representation has much to recommend it.

Further Reading

The IBM Fortran H compiler used dominators to identify loops in control-flow graphs of basic blocks of machine instructions [Lowry and Medlock 1969]. Lengauer and Tarjan [1979] developed the near-linear-time algorithm for finding dominators in a directed graph, and prove the related theorems mentioned in this chapter. It is common to use this algorithm while mentioning the existence [Harel 1985] of a more complicated linear-time algorithm. Finding the “best” node above a given spanning-forest node is an example of a union-find problem; analyses of balanced path-compression algorithms for union-find (such as the “sophisticated” version of the Lengauer-Tarjan algorithm) can be found in many algorithms textbooks (e.g. Sections 22.3–22.4 of Cormen et al. [1990]).

Static single-assignment form was developed by Wegman, Zadeck, Alpern, and Rosen [Alpern et al. 1988; Rosen et al. 1988] for efficient computation of dataflow problems such as global value numbering, congruence of variables, aggressive dead-code removal, and constant propagation with conditional branches [Wegman and Zadeck 1991]. Control-dependence was formalized by Ferrante et al. [1987] for use in an optimizing compiler for vector parallel machines. Cytron et al. [1991] describe the efficient computation of SSA and control-dependence graphs using dominance frontiers and prove several of the theorems mentioned in this chapter.

Wolfe [1996] describes several optimization algorithms on SSA (which he
calls factored use-def chains), including induction-variable analysis.

It is useful to perform several transformations on the flow graph before conversion to SSA form. These include the conversion of while-loops to repeat-loops (Section 18.2); and the insertion of loop preheader nodes (see page 416), postbody nodes [Wolfe 1996] (Exercise 18.6), and landing pads for loop-exit edges [Rosen et al. 1988] (edge splitting effectively accomplishes the insertion of landing pads). Such transformations provide locations into which statements (such as loop-invariant computations or common subexpressions) may be placed.

**Varieties of functional intermediate representations.** Functional intermediate forms are all based on lambda-calculus, more or less, but they differ in three important respects:

1. Some are strict and some are lazy (see Chapter 15).
2. Some have arbitrary nesting of subexpressions; some have atomic arguments; and some have atomic arguments $+\lambda$ meaning that all arguments except anonymous functions are atomic.
3. Some permit non-tail calls (direct style) and some support only tail calls (continuation-passing style).

Distinction (1) ceases to matter in continuation-passing style.

The design-space of these options has been well explored, as this table shows:

<table>
<thead>
<tr>
<th></th>
<th>Direct style</th>
<th></th>
<th>Continuation-passing</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Strict</td>
<td>Lazy</td>
<td></td>
</tr>
<tr>
<td>Arbitrarily nested</td>
<td>Cardelli [1984], Cousineau et al. [1985]</td>
<td>Augustsson [1984]</td>
<td></td>
</tr>
<tr>
<td>subexpressions</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Atomic arguments $+\lambda$</td>
<td>Flanagan et al. [1993]</td>
<td></td>
<td>Steele [1978], Kranz et al. [1986]</td>
</tr>
</tbody>
</table>

The functional intermediate form shown in Figure 19.18 fits in the lower left-hand corner, along with Tarditi [1997]. Kelsey [1995] shows how to convert between SSA and continuation-passing style.
EXERCISES

19.1 Write an algorithm, using depth-first search, to number the nodes of a tree in depth-first order and to annotate each node with the number of its highest-numbered descendent. Show how these annotations can be used — once your preprocessing algorithm has been run on a dominator tree — to answer a query of the form “does node i dominate node j?” in constant time.

19.2 Use Algorithm 19.9 to calculate the dominators of the flow graph of Exercise 18.1, showing the semidominators and spanning forest at various stages.

19.3 For each of the graphs of Figure 18.1 and Figure 18.2, calculate the immediate dominator tree (using either Algorithm 19.9 or the algorithm in Section 18.1), and for each node n calculate $DF_{\text{local}}[n]$, $DF_{\text{up}}[n]$, and $DF$.

*19.4 Prove that, for any node v, Algorithm 19.9+19.10 always initializes $\text{best}[v] \leftarrow v$ (in the Link function) before calling $\text{AncestorWithLowestSemi}(v)$.

19.5 Calculate the dominance frontier of each node in each of these graphs:
   a. The graph of Figure 2.8.
   b. The graph of Exercise 2.3a.
   c. The graph of Exercise 2.5a.
   d. The graph of Figure 3.27.

**19.6 Prove that

$$DF[n] = DF_{\text{local}}[n] \cup \bigcup_{Z \in \text{children}[n]} DF_{\text{up}}[Z]$$

as follows:
   a. Show that $DF_{\text{local}}[n] \subseteq DF[n]$;
   b. Show that for each child Z of n, $DF_{\text{up}}[Z] \subseteq DF[n]$;
   c. If there is a node Y in $DF[n]$, then therefore there is an edge $U \rightarrow Y$ such that n dominates U but does not strictly dominate Y. Show that if $Y = n$ then $Y \in DF_{\text{local}}[n]$, and if $Y \neq n$ then $Y \in DF_{\text{up}}[Z]$ for some child Z of N.
   d. Combine these lemmas into a proof of the theorem.

19.7 Convert this program to SSA form:
Show your work after each stage:

a. Add a start node containing initializations of all variables.
b. Draw the dominator tree.
c. Calculate dominance frontiers.
d. Insert $\phi$-functions.
e. Add subscripts to variables.
f. Use Algorithm 19.17 to build the interference graph.
g. Convert back from SSA form by inserting move instructions in place of $\phi$-functions.

19.8 This C (or Java) program illustrates an important difference between def-use chains and SSA form:

```c
int f(int i, int j) {
    int x, y;
    switch(i) {
        case 0: x=3;
        case 1: x=1;
        case 2: x=4;
        case 3: x=1;
        case 4: x=5;
        default: x=9;
    }
    switch(j) {
        case 0: y=x+2;
        case 1: y=x+7;
        case 2: y=x+1;
        case 3: y=x+8;
        case 4: y=x+2;
        default: y=x+8;
        return y;
    }
}
```
a. Draw the control-flow graph of this program.

b. Draw the use-def and def-use data structures of the program: for each definition site, draw a linked-list data structure pointing to each use-site, and vice versa.

c. Starting from the CFG of part (a), convert the program to SSA form. Draw data structures representing the uses, defs, and $\phi$-functions, as described at the beginning of Section 19.3.

d. Count the total number of data-structure nodes in the use-def data, and the total number in the SSA data structure. Compare.

e. Approximate the total sizes of the use-def data structures, and the SSA data structures, if there were $N$ cases in each switch instead of 6.

*19.9* Suppose the graph of Exercise 2.3a is the control-flow graph of a program, and in block 1 there is an assignment to a variable $v$.

a. Convert the graph to SSA form (insert $\phi$-functions for $v$).

b. Show that for any $N$, there is a “ladder” CFG with $O(N)$ blocks, $O(N)$ edges, and $O(N)$ assignment statements (all in the first block!), such that the number of $\phi$-functions in the SSA form is $N^2$.

c. Write a program whose CFG looks like this.

d. Show that a program containing deeply nested repeat-until loops can have the same $N^2$ blowup of $\phi$-functions.

*19.10* Algorithm 19.7 uses a stack for each variable, to remember the current active definition of the variable. This is equivalent to using environments to process nested scopes, as Chapter 5 explained for type-checking.

a. Rewrite Algorithm 19.7, calling upon the imperative environments of the Table module (whose interface is given in Program 5.5) instead of using explicit stacks.

b. Rewrite Algorithm 19.7, using the functional-style symbol tables whose TAB_table interface is described on page 112.

19.11 Show that optimization on an SSA program can cause two SSA variables $a_1$ and $a_2$, derived from the same variable $a$ in the original program, to have overlapping live ranges as described on page 462. **Hint:** Convert this program to SSA, and then do exactly one constant-propagation optimization.

\[
\text{while } c < 0 \text{ do } (b := a; \ a := M[x]; \ c := a + b); \\
\text{return } a;
\]

*19.12* Let $V_c$ and $E_c$ be the nodes and edges of the CFG, and $V_i$ and $E_i$ be the nodes and edges of the interference graph produced by Algorithm 19.17. Let $N = |V_c| + |E_c| + |V_i| + |E_i|$. 

472
EXERCISES

a. Show that the run time of Algorithm 19.17 on the following (weird) program is asymptotically proportional to \( N^{1.5} \):

\[
\begin{align*}
  v_1 &\leftarrow 0 \\
  v_2 &\leftarrow 0 \\
  &\vdots \\
  v_m &\leftarrow 0 \\
  \text{goto } L_1 \\
  L_1 : &\text{ goto } L_2 \\
  L_2 : &\text{ goto } L_3 \\
  &\vdots \\
  L_m^2 : &w_1 \leftarrow v_1 \\
  &w_2 \leftarrow v_2 \\
  &\vdots \\
  &w_m \leftarrow v_m
\end{align*}
\]

*b. Show that if every block defines at least one variable, and has no more than \( c \) statements and no more than \( c \) out-edges (for some constant \( c \)), then the time complexity of Algorithm 19.17 is \( O(N) \). Hint: Whenever \text{LiveOutAtBlock} is called, there will be at most \( c \) calls to \text{LiveOutAtStatement}, and at least one will add an edge to the interference graph.
Pipelining and Scheduling

**schedule**: a procedural plan that indicates the time and sequence of each operation

*Webster's Dictionary*

A simple computer can process one instruction at a time. First it fetches the instruction, then decodes it into opcode and operand specifiers, then reads the operands from the register bank (or memory), then performs the arithmetic denoted by the opcode, then writes the result back to the register bank (or memory); and then fetches the next instruction.

Modern computers can execute parts of many different instructions at the same time. At the same time the processor is writing results of two instructions back to registers, it may be doing arithmetic for three other instructions, reading operands for two more instructions, decoding four others, and fetching yet another four. Meanwhile, there may be five instructions delayed, awaiting the results of memory-fetches.

Such a processor usually fetches instructions from a single flow of control; it's not that several programs are running in parallel, but the adjacent instructions of a single program are decoded and executed simultaneously. This is called *instruction-level parallelism* (ILP), and is the basis for much of the astounding advance in processor speed in the last decade of the twentieth century.

A *pipelined* machine performs the write-back of one instruction in the same cycle as the arithmetic “execute” of the next instruction and the operand-read of the previous one, and so on. A *very-long-instruction-word* (VLIW) issues several instructions in the same processor cycle; the compiler must ensure that they are not data-dependent on each other. A *superscalar* machine
issues two or more instructions in parallel if they are not related by data dependence (which it can check quickly in the instruction-decode hardware); otherwise it issues the instructions sequentially – thus, the program will still operate correctly if data-dependent instructions are adjacent, but it will run faster if the compiler has not scheduled non-data-dependent instructions adjacent to each other. A dynamic-scheduling machine reorders the instructions as they are being executed, so that it can issue several non-data-dependent instructions simultaneously, and may need less help from the compiler. Any of these techniques produce instruction-level parallelism.

The more instructions can be executed simultaneously, the faster the program will run. But why can’t all the instructions of the program be executed in parallel? After all, that would be the fastest possible execution.

There are several kinds of constraints on instruction execution; we can optimize the program for instruction-level parallelism by finding the best schedule that obeys these constraints:

**Data dependence:** If instruction A calculates a result that’s used as an operand of instruction B, then B cannot execute before A is finished.

**Functional unit:** If there are $k_{fu}$ multipliers (adders, etc.) on the chip, then at most $k_{fu}$ multiplication (addition, etc.) instructions can execute at once.

**Instruction issue:** The instruction-issue unit can issue at most $k_{ii}$ instructions at a time.

**Register:** At most $k_r$ registers can be in use at a time; more specifically, any schedule must have some valid register allocation.

The functional-unit, instruction-issue, and register constraints are often lumped together as resource constraints or resource hazards.

On a pipelined machine, even if “B cannot execute before A,” there may be some parts of B’s execution (such as instruction-fetch) that can proceed concurrently with A; Figures 20.2 and 20.3 give details.

There are also pseudo-constraints that can often be made to disappear by renaming variables:

**Write-after-write:** If instruction A writes to a register or memory location, and B writes to the same location, then the order of A and B must not be changed. But often it is possible to modify the program so that A and B write to different locations.

**Write-after-read:** If A must read from a location before B writes to it, then A and B’s order of execution must not be swapped, unless renaming can be done so that they use different locations.

</tbody>
</table>

**FIGURE 20.1.** Functional unit requirements of instructions (on the MIPS R4000 processor). This machine’s floating-point ADD instruction uses the instruction-fetch unit for one cycle; reads registers for one cycle; unpacks exponent and mantissa; then for the next cycle uses a shifter and an adder; then uses both the adder and a rounding unit; then the rounding unit and a shifter; then writes a result back to the register file. The MULT and CONV instructions use functional units in a different order.

**Resource usage of an instruction.** We might describe an instruction in terms of the number of cycles it takes to execute, and the resources it uses at different stages of execution. Figure 20.1 shows such a description for three instructions of a hypothetical machine.

If the \( i \)th cycle of instruction \( A \) uses a particular resource, and the \( j \)th cycle of instruction \( B \) uses the same resource, then \( B \) cannot be scheduled exactly \( i - j \) cycles after \( A \), as illustrated in Figure 20.2.

However, some machines have several functional units of each kind (e.g., more than one adder); on such a machine it does not suffice to consider instructions pairwise, but we must consider all the instructions scheduled for a given time.

**Data-dependence of an instruction.** The same considerations apply to data-dependence constraints. The result of some instruction \( A \) is written back to the register file during the **Write** stage of its execution (see Figure 20.1); if instruction \( B \) uses this register, then the **Read** stage of \( B \) must be after the **Write** stage of \( A \). Some machines have bypass circuitry that may allow the arithmetic stage of \( B \) to follow immediately after the arithmetic stage of \( A \); for example, the **Shift/Add** stage of an ADD instruction might be able to immediately follow the **Round** stage of a MULT. These situations are shown in Figure 20.3.
FIGURE 20.2. If there is only one functional unit of each kind, then an ADD cannot be started at the same time as a MULT (because of numerous resource hazards shown in boldface); nor three cycles after the MULT (because of Add, Round, and Write hazards); nor four cycles later (because of a Round hazard). But if there were two rounding units, then an ADD could be started four cycles after a MULT. Or with dual fetch units, multiple-access register file, and dual unpackers, the MULT and ADD could be started simultaneously.
20.1 LOOP SCHEDULING WITHOUT RESOURCE BOUNDS

Choosing an optimal schedule subject to data-dependence constraints and resource hazards is difficult – it is NP-complete, for example. Although NP-completeness should never scare the compiler writer (graph coloring is NP complete, but the approximation algorithm for graph coloring described in Chapter 11 is very successful), it remains the case that resource-bounded loop scheduling is hard to do in practice.

I will first describe an algorithm that ignores the resource constraints and finds an optimal schedule subject only to the data-dependence constraints. This algorithm is not useful in practice, but it illustrates the kind of opportunities there are in instruction-level parallelism.

The Aiken-Nicolau loop pipelining algorithm has several steps:

1. Unroll the loop;
2. Schedule each instruction from each iteration at the earliest possible time;
3. Plot the instructions in a tableau of iteration-number versus time;
4. Find separated groups of instructions at given slopes;
5. Coalesce the slopes;
6. Reroll the loop.

To explain the notions of tableau, slope, and coalesce, I use Program 20.4a as an example; let us assume that every instruction can be completed in one cycle, and that arbitrarily many instructions can be issued in the same cycle, subject only to data-dependence constraints.
**20.1. LOOP SCHEDULING WITHOUT RESOURCE BOUNDS**

for $i ← 1$ to $N$

\[
\begin{align*}
a &← j \oplus V[i - 1] \\
b &← a \oplus f \\
c &← e \oplus j \\
d &← f \oplus c \\
e &← b \oplus d \\
f &← U[i] \\
g : V[i] &← b \\
h : W[i] &← d \\
j_i &← X[i]
\end{align*}
\]

(a)

for $i ← 1$ to $N$

\[
\begin{align*}
a_i &← j_{i-1} \oplus b_{i-1} \\
b_i &← a_i \oplus f_{i-1} \\
c_i &← e_{i-1} \oplus j_{i-1} \\
d_i &← f_{i-1} \oplus c_i \\
e_i &← b_i \oplus d_i \\
f_i &← U[i] \\
g : V[i] &← b_i \\
h : W[i] &← d_i \\
j_i &← X[i]
\end{align*}
\]

(b)

**PROGRAM 20.4.** (a) A for-loop to be software-pipelined. (b) After a scalar-replacement optimization (in the definition of $a$); and scalar variables labeled with their iteration-number.

**Data dependence through memory.** For optimal scheduling of stores and fetches, we need to trace data dependence as a value is stored into memory and then fetched back. As discussed on page 458, dependence analysis of memory references is not trivial! In order to illustrate loop scheduling for Program 20.4a without full-fledged dependence analysis, we can use scalar replacement to replace the reference to $V[i - 1]$ with the (equivalent) $b$; now we can see that in the resulting Program 20.4b all memory references are independent of each other, assuming that the arrays $U, V, W, X$ do not overlap.

Next we mark each variable in the loop body to indicate whether this iteration’s value is used, or the previous iteration’s value, as shown in Program 20.4b. We can construct a data-dependence graph as a visual aid in scheduling; solid edges are data dependences within an iteration, and dotted edges are loop-carried dependences, as shown in Graph 20.5a.

Now suppose we unroll the loop; the data-dependence graph is a DAG, as shown in Graph 20.5b. Scheduling DAGs is easy if there are no resource constraints; starting from operations with no predecessors, each operation goes...
as soon as its predecessors have all completed:

<table>
<thead>
<tr>
<th>Cycle</th>
<th>Instructions</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$a_1c_1f_1j_1f_2j_2f_3j_3 \ldots$</td>
</tr>
<tr>
<td>2</td>
<td>$b_1d_1$</td>
</tr>
<tr>
<td>3</td>
<td>$e_1g_1h_1a_2$</td>
</tr>
<tr>
<td>4</td>
<td>$b_2c_2$</td>
</tr>
<tr>
<td>5</td>
<td>$d_2g_2a_3$</td>
</tr>
<tr>
<td>\vdots</td>
<td>\vdots</td>
</tr>
</tbody>
</table>

It is convenient to write this schedule in a *tableau* where the rows are successive cycles and the columns are successive iterations of the original loop, as shown in Table 20.6a.

After a few iterations are scheduled, we notice a pattern in the tableau: there is a group of instructions $cdeh$ racing down to the lower-right corner with a slope of three cycles per iteration, another group $abg$ with a more moderate slope of two cycles per iteration, and a third group $fj$ with zero slope. The key observation is that there are gaps in the schedule, separating identical groups, that grow larger at a constant rate. In this case the groups of instructions at iteration $i \geq 4$ are identical to the groups at iteration $i + 1$. In general the groups at iteration $i$ will be identical to the groups at $i + c$, where sometimes $c > 1$; see Exercise 20.1.

**Theorems:**

- If there are $K$ instructions in the loop, the pattern of identical groups separated by gaps will always appear within $K^2$ iterations (and usually much sooner).
- We can increase the slopes of the less steeply sloped groups, either closing the gaps or at least making them small and nonincreasing, without violating data-dependence constraints.
- The resulting tableau has a repeating set of $m$ identical cycles, which can constitute the body of a pipelined loop.
- The resulting loop is optimally scheduled (it runs in the least possible time).

See the Further Reading section for reference to proofs. But to see why the loop is optimal, consider that the data-dependence DAG of the unrolled loop has some path of length $P$ to the last instruction to execute, and the scheduled loop executes that instruction at time $P$.

The result, for our example, is shown in Table 20.6b. Now we can find a repeating pattern of three cycles (since three is the slope of the steepest

(b)
group). In this case, the pattern does not begin until cycle 8; it is shown in a box. This will constitute the *body* of the scheduled loop. Irregularly scheduled instructions before the loop body constitute a *prologue*, and instructions after it constitute the *epilogue*.

Now we can generate the multiple-instruction-issue program for this loop, as shown in Figure 20.7. However, the variables still have subscripts in this “program”: the variable \( j_{i+1} \) is live at the same time as \( j_i \). To encode this program in instructions, we need to put in MOVE instructions between the different variables, as shown in Figure 20.8.

This loop is optimally scheduled – assuming the machine can execute 8 instructions at a time, including four simultaneous loads and stores.

**Multicycle instructions.** Although I have illustrated an example where each instruction takes exactly one cycle, the algorithm is easily extensible to the situation where some instructions take multiple cycles.

## 20.2 RESOURCE-BOUNDED LOOP PIPELINING

A real machine can issue only a limited number of instructions at a time, and has only a limited number of load/store units, adders, and multipliers. To be practically useful, a scheduling algorithm must take account of resource constraints.

The input to the scheduling algorithm must be in three parts:

1. A program to be scheduled;
2. A description of what resources each instruction uses in each of its pipeline stages (similar to Figure 20.1);
3. A description of the resources available on the machine (how many of each kind of functional unit, how many instructions may be issued at once, restrictions on what kinds of instructions may be issued simultaneously, and so on).

Resource-bounded scheduling is NP-complete, meaning that there is unlikely to be an efficient optimal algorithm. As usual in this situation, we use an approximation algorithm that does reasonably well in “typical” cases.

**MODULO SCHEDULING**

*Iterative modulo scheduling* is a practical, though not optimal, algorithm for resource-bounded loop scheduling. The idea is to use iterative backtracking
20.2. RESOURCE-BOUNDED LOOP PIPELINING

![Figure 20.8](image.png)

**FIGURE 20.8.** Pipelined schedule, with move instructions.

![Table](table.png)

**FIGURE 20.7.** Pipelined schedule. Assignments in each row happen simultaneously; each right-hand side refers to the value before the assignment. The loop exit test \( i < N + 1 \) has been "moved past" three increments of \( i \), so appears as \( i < N - 2 \).
to find a good schedule that obeys the functional-unit and data-dependence constraints, and then perform register allocation.

The algorithm tries to place all the instructions of the loop body in a schedule of \( \Delta \) cycles, assuming that there will also be a prologue and epilogue of the kind used by the Aiken-Nicolau algorithm. The algorithm tries increasing values of \( \Delta \) until it reaches a value for which it can make a schedule.

A key idea of modulo scheduling is that if an instruction violates functional-unit constraints at time \( t \), then it will not fit at time \( t + \Delta \), or at any time \( t' \) where \( t \equiv t' \) modulo \( \Delta \).

Suppose, for example, we are trying to schedule Program 20.4b with \( \Delta = 3 \) on a machine that can perform only one load instruction at a time. The following loop-body schedule is illegal, with two different loads at cycle 1:

\[
\begin{array}{c|c|c}
0 & f_i \leftarrow U[i] & j_i \leftarrow X[i] \\
1 & & \\
2 & & \\
\end{array}
\]

We can move \( f_i \) from cycle 1 of the loop to cycle 0, or cycle 2:

\[
\begin{array}{c|c|c}
0 & f_i \leftarrow U[i] & j_i \leftarrow X[i] \\
1 & j_i \leftarrow X[i] & j_i \leftarrow X[i] \\
2 & f_i \leftarrow U[i] & j_i \leftarrow X[i] \\
3 & & \\
\end{array}
\]

Either one avoids the resource conflict. We could move \( f_i \) even earlier, to cycle \(-1\), where (in effect) we are computing \( f_{i+1} \); or even later, to cycle 3, where we are computing \( f_{i-1} \):

\[
\begin{array}{c|c|c}
0 & & \\
1 & j_i \leftarrow X[i] & j_i \leftarrow X[i] \\
2 & f_{i+1} \leftarrow U[i+1] & j_i \leftarrow X[i] \\
3 & f_{i-1} \leftarrow U[i-1] & j_i \leftarrow X[i] \\
\end{array}
\]

But with \( \Delta = 3 \) we can never solve the resource conflict by moving \( f_i \) from cycle 1 to cycle 4 (or to cycle \(-2\)), because \( 1 \equiv 4 \) modulo 3; the calculation of \( f \) would still conflict with the calculation of \( j \):

\[
\begin{array}{c|c|c}
0 & f_{i-1} \leftarrow U[i-1] & j_i \leftarrow X[i] \\
1 & j_i \leftarrow X[i] & j_i \leftarrow X[i] \\
2 & & \\
\end{array}
\]

**Effects on register allocation.** Consider the calculation of \( d \leftarrow f \oplus c \), which occurs at cycle 0 of the schedule in Figure 20.7. If we place the calculation of \( d \) in a later cycle, then the data-dependence edges from the definitions of \( f \) and \( c \) to this instruction would lengthen, and the data-dependence edges
from this instruction to the use of \( d \) in \( W[i] \leftarrow d \) would shrink. If a data-dependence edge shrinks to less than zero cycles, then a data-dependence constraint has been violated; this can be solved by also moving the calculations that use \( d \) to a later cycle.

Conversely, if a data-dependence edge grows many cycles long, then we must carry several “versions” of a value around the loop (as we carry \( f, f', f'' \) around the loop of Figure 20.8), and this means that we are using more temporaries, so that register allocation may fail. In fact, an *optimal* loop-scheduling algorithm should consider register allocation simultaneously with scheduling; but it is not clear whether optimal algorithms are practical, and the *iterated modulo scheduling* algorithm described in this section first schedules, then does register allocation and hopes for the best.

**FINDING THE MINIMUM INITIATION INTERVAL**

Modulo scheduling begins by finding a lower bound for the number of cycles in the pipelined loop body:

**Resource estimator:** For any kind of functional unit, such as a multiplier or a memory-fetch unit, we can see how many cycles such units will be used by the corresponding instructions (e.g. multiply or load, respectively) in the loop body. This, divided by the number of that kind of functional unit provided by the hardware, gives a lower bound for \( \Delta \). For example, if there are 6 multiply instructions that each use a multiplier for 3 cycles, and there are two multipliers, then \( \Delta \geq 6 \cdot 3/2 \).

**Data-dependence estimator:** For any data-dependence cycle in the data-dependence graph, where some value \( x_i \) depends on a chain of other calculations that depends on \( x_{i-1} \), the total latency of the chain gives a lower bound for \( \Delta \).

Let \( \Delta_{\text{min}} \) be the maximum of these estimators.

Let us calculate \( \Delta_{\text{min}} \) for Program 20.4b. For simplicity, we assume that one \( \oplus \)-arithmetic instruction and one load/store can be issued at a time, and every instruction finishes in one cycle; and we will not consider the scheduling of \( i \leftarrow i + 1 \) or the conditional branch.

Then the *arithmetic resource estimator* is 5 \( \oplus \)-instructions in the loop body divided by 1 issuable arithmetic instructions per cycle, or \( \Delta \geq 5 \). The *load/store resource estimator* is 4 load/store instructions in the loop body divided by 1 issuable memory operations per cycle, or \( \Delta \geq 4 \). The data-dependence estimator comes from the cycle \( c_i \rightarrow d_i \rightarrow e_i \rightarrow c_{i+1} \) in Graph 20.5a, whose length gives \( \Delta \geq 3 \).
Next, we prioritize the instructions of the loop body by some heuristic that decides which instructions to consider first. For example, instructions that are in critical data-dependence cycles, or instructions that use a lot of scarce resources, should be placed in the schedule first, and then other instructions can be filled in around them. Let $H_1, \ldots, H_n$ be the instructions of the loop body, in (heuristic) priority order.

In our example, we could use $H = [c, d, e, a, b, f, j, g, h]$, putting early the instructions that are in the critical recurrence cycle or that use the arithmetic functional unit (since the resource estimators for this loop tell us that arithmetic is in more demand than load/stores).

The scheduling algorithm maintains a set $S$ of scheduled instructions, each scheduled for a particular time $t$. The value of $SchedTime[h] = none$ if $h \notin S$, otherwise $SchedTime[h]$ is the currently scheduled time for $h$. The members of $S$ obey all resource and data-dependence constraints.

Each iteration of Algorithm 20.9 places the highest-priority unscheduled instruction $h$ into $S$, as follows:

1. In the earliest time slot (if there is one) that obeys all dependence constraints with respect to already-placed predecessors of $h$, and respects all resource constraints.

2. But if there is no slot in $\Delta$ consecutive cycles that obeys resource constraints, then there can never be such a slot, because the functional units available at time $t$ are the same as those at $t + c \cdot \Delta$. In this case, $h$ is placed without regard to resource constraints, in the earliest time slot that obeys dependence constraints (with respect to already-placed predecessors), and is later than any previous attempt to place $h$.

Once $h$ is placed, other instructions are removed to make the subset schedule $S$ legal again: any successors of $h$ that now don’t obey data-dependence constraints, or any instructions that have resource conflicts with $h$.

This placement-and-removal could iterate forever, but most of the time either it finds a solution quickly or there is no solution, for a given $\Delta$. To cut the algorithm off if it does not find a quick solution, a Budget of $c \cdot n$ schedule placements is allowed (for $c = 3$ or some similar number), after which this value of $\Delta$ is abandoned and the next one is tried.

When a def-use edge associated with variable $j$ becomes longer than $\Delta$ cycles, it becomes necessary to have more than one copy of $j$, with MOVE instructions copying the different-iteration versions in bucket-brigade style. This is illustrated in Figure 20.8 for variables $a, b, f, j$, but I will not show an explicit algorithm for inserting the moves.
for $\Delta \leftarrow \Delta_{\text{min}}$ to $\infty$

Budget $\leftarrow n \cdot 3$

for $i \leftarrow 1$ to $n$

$\text{LastTime}[i] \leftarrow 0$

$\text{SchedTime}[i] \leftarrow \text{none}$

while $\text{Budget} > 0$ and there are any unscheduled instructions

$\text{Budget} \leftarrow \text{Budget} - 1$

let $h$ be the highest-priority unscheduled instruction

$t_{\text{min}} \leftarrow 0$

for each predecessor $p$ of $h$

if $\text{SchedTime}[p] \neq \text{none}$

$t_{\text{min}} \leftarrow \max(t_{\text{min}}, \text{SchedTime}[p] + \text{Delay}(p, h))$

for $t \leftarrow t_{\text{min}}$ to $t_{\text{min}} + \Delta - 1$

if $\text{SchedTime}[h] = \text{none}$

if $h$ can be scheduled without resource conflicts

$\text{SchedTime}[h] \leftarrow t$

if $\text{SchedTime}[h] = \text{none}$

$\text{SchedTime}[h] \leftarrow \max(t_{\text{min}}, 1 + \text{LastTime}[h])$

$\text{LastTime}[h] \leftarrow \text{SchedTime}[h]$

for each successor $s$ of $h$

if $\text{SchedTime}[s] \neq \text{none}$

if $\text{SchedTime}[h] + \text{Delay}(h, s) > \text{SchedTime}[s]$

$\text{SchedTime}[s] \leftarrow \text{none}$

while the current schedule has resource conflicts

let $s$ be some instruction (other than $h$) involved in a resource conflict

$\text{SchedTime}[s] \leftarrow \text{none}$

if all instructions are scheduled

RegisterAllocate()

if register allocation succeeded without spilling

return and report a successfully scheduled loop.

\text{Delay}(h, s) =

\text{Given a dependence edge } h_i \rightarrow s_{i+k}, \text{ so that } h \text{ uses the value of } s \text{ from the } k \text{th previous iteration (where } k = 0 \text{ means that } h \text{ uses the current iteration’s value of } s); \text{ Given that the latency of the instruction that computes } s \text{ is } l \text{ cycles; return } l - k\Delta

\textbf{Algorithm 20.9.} Iterative modulo scheduling.
Checking for resource conflicts is done with a resource reservation table, an array of length $\Delta$. The resources used by an instruction at time $t$ can be entered in the array at position $t \mod \Delta$; adding and removing resource-usage from the table, and checking for conflicts, can be done in constant time.

This algorithm is not guaranteed to find an optimal schedule in any sense. There may be an optimal, register-allocable schedule with initiation-interval $\Delta$, and the algorithm may fail to find any schedule with time $\Delta$, or it may find a schedule for which register-allocation fails. The only consolation is that it is reported to work very well in practice.

The operation of the algorithm on our example is shown in Figure 20.10.

**OTHER CONTROL FLOW**

I have shown scheduling algorithms for simple straight-line loop bodies. What if the loop contains internal control flow, such as a tree of if-then-else statements? One approach is to compute both branches of the loop, and then use a conditional move instruction (provided on many high-performance machines) to produce the right result.

For example, the loop at left can be rewritten into the loop at right, using a conditional move:
for $i \leftarrow 1$ to $N$

\[
x \leftarrow M[i]
\]

if $x > 0$

\[
u \leftarrow z \ast x
\]

else $u \leftarrow A[i]$

\[
s \leftarrow s + u
\]

for $i \leftarrow 1$ to $N$

\[
x \leftarrow M[i]
\]

$u' \leftarrow z \ast x$

if $x > 0$ move $u \leftarrow u'$

\[
s \leftarrow s + u
\]

The resulting loop body is now straight-line code that can be scheduled easily.

But if the two sides of the if differ greatly in size, and the frequently executed branch is the small one, then executing both sides in every iteration will be slower than optimal. Or if one branch of the if has a side effect, it must not be executed unless the condition is true.

To solve this problem we use trace scheduling: we pick some frequently executed straight-line path through the branches of control flow, schedule this path efficiently, and suffer some amount of inefficiency at those times where we must jump into or out of the trace. See Section 8.2 and also the Further Reading section of this chapter.

**SHOULD THE COMPILER SCHEDULE INSTRUCTIONS?**

Many machines have hardware that does dynamic instruction rescheduling at run time. These machines do out-of-order execution, meaning that there may be several decoded instructions in a buffer, and whichever instruction’s operands are available can execute next, even if other instructions that appeared earlier in the program code are still awaiting operands or resources.

Such machines first appeared in 1967 (the IBM 360/91), but did not become common until the mid-1990s. Now it appears that most high-performance processors are being designed with dynamic (run-time) scheduling. These machines have several advantages and disadvantages, and it is not yet clear whether static (compile-time) scheduling or out-of-order execution will become standard.

**Advantages of static scheduling.** Out-of-order execution uses expensive hardware resources and tends to increase the chip’s cycle time and wattage. The static scheduler can schedule earlier the instructions whose future data-dependence path is longest; a real-time scheduler cannot know the length of the data-dependence path leading from an instruction (see Exercise 20.3). The scheduling problem is NP-complete, so compilers – which have no real-time constraint on their scheduling algorithms – should in principle be able to find better schedules.
Advantages of dynamic scheduling. Some aspects of the schedule are unpredictable at compile time, such as cache misses, and can be better scheduled when their actual latency is known (see Figure 21.5). Highly pipelined schedules tend to use many registers; typical machines have only 32 register names in a five-bit instruction-field, but out-of-order execution with run-time register renaming can use hundreds of actual registers with a few static names (see the Further Reading section). Optimal static scheduling depends on knowing the precise pipeline state that will be reached by the hardware, which is sometimes difficult to determine in practice. Finally, dynamic scheduling does not require that the program be recompiled (i.e. rescheduled) for each different implementation of the same instruction set.

### 20.3 BRANCH PREDICTION

In many floating-point programs, such as Program 20.4a, the basic blocks are long, the instructions are long-latency floating-point operations, and the branches are very predictable for-loop exit conditions. In such programs the problem, as described in the previous sections, is to schedule the long-latency instructions.

But in many programs – such as compilers, operating systems, window systems, word processors – the basic blocks are short, the instructions are quick integer operations, and the branches are harder to predict. Here the main problem is fetching the instructions fast enough to be able to decode and execute them.

Figure 20.11 illustrates the pipeline stages of a COMPARE, BRANCH, and ADD instruction. Until the BRANCH has executed, the instruction-fetch of the successor instruction cannot be performed because the address to fetch is unknown.

Suppose a superscalar machine can issue four instructions at once. Then, in waiting three cycles after the BRANCH is fetched before the ADD can be fetched, 11 instruction-issue slots are wasted (3 x 4 minus the slot that the BRANCH occupies).
20.3. BRANCH PREDICTION

Some machines solve this problem by fetching the instructions immediately following the branch; then if the branch is not taken, these fetched-and-decoded instructions can be used immediately. Only if the branch is taken are there stalled instruction slots. Other machines assume the branch will be taken, and begin fetching the instructions at the target address; then if the branch falls through, there is a stall. Some machines even fetch from both addresses simultaneously, though this requires a very complex interface between processor and instruction-cache.

Modern machines rely on branch prediction to make the right guess about which instructions to fetch. The branch prediction can be static – the compiler predicts which way the branch is likely to go and places its prediction in the branch instruction itself; or dynamic – the hardware remembers, for each recently executed branch, which way it went last time, and predicts that it will go the same way.

STATIC BRANCH PREDICTION

The compiler can communicate predictions to the hardware by a 1-bit field of the branch instruction that encodes the predicted direction.

To save this bit, or for compatibility with old instruction sets, some machines use a rule such as “backward branches are assumed to be taken, forward branches are assumed to be not-taken.” The rationale for the first part of this rule is that backward branches are (often) loop branches, and a loop is more likely to continue than to exit. The rationale for the second part of the rule is that it’s often useful to have predicted-not-taken branches for exceptional conditions; if all branches are predicted taken, we could reverse the sense of the condition to make the exceptional case “fall through” and the normal case take the branch, but this leads to worse instruction-cache performance, as discussed in Section 21.2. When generating code for machines that use forward/backward branch direction as the prediction mechanism, the compiler can order the basic blocks of the program in so that the predicted-taken branches go to lower addresses.

Several simple heuristics help predict the direction of a branch. Some of these heuristics make intuitive sense, but all have been validated empirically:

**Pointer:** If a loop performs an equality comparison on pointers (p=null or p=q) then predict the condition as false.

**Call:** A branch is less likely to the successor that dominates a procedure call (many conditional calls are to handle exceptional situations).
Return: A branch is less likely to a successor that dominates a return-fromprocedure.

Loop: A branch is more likely to the successor (if any) that is the header of the loop containing the branch.

Loop: A branch is more likely to the successor (if any) that is a loop preheader, if it does not postdominate the branch. This catches the results of the optimization described in Figure 18.7, where the iteration count is more likely to be > 0 than = 0. (B postdominates A if any path from A to program-exit must go through B; see Section 19.5.)

Guard: If some value r is used as an operand of the branch (as part of the conditional test), then a branch is more likely to a successor in which r is live and which does not postdominate the branch.

There are some branches to which more than one of the heuristics apply. A simple approach in such cases is to give the heuristics a priority order and use the first heuristic in order that applies (the order in which they are listed above is a reasonable prioritization, based on empirical measurements).

Another approach is to index a table by every possible subset of conditions that might apply, and decide (based on empirical measurements) what to do for each subset.

SHOULD THE COMPILER PREDICT BRANCHES?

Perfect static prediction results in a dynamic mispredict rate of about 9% (for C programs) or 6% (for Fortran programs). The “perfect” mispredict rate is not zero because any given branch does not go in the same direction more than 91% of the time, on average. If a branch did go the same direction 100% of the time, there would be little need for it! Fortran programs tend to have more predictable branches because more of the branches are loop branches, and the loops have longer iteration counts.

Profile-based prediction, in which a program is compiled with extra instructions to count the number of times each branch is taken, executed on sample data, and recompiled with prediction based on the counts, approaches the accuracy of perfect static prediction.

Prediction based the heuristics described above results in a dynamic mispredict rate of about 20% (for C programs), or about half as good as perfect (or profile-based) static prediction.

A typical hardware-based branch-prediction scheme uses two bits for every branch in the instruction cache, recording how the branch went the last two times it executed. This leads to misprediction rates of about 11% (for C programs).
A mispredict rate of 10% can result in very many stalled instructions – if each mispredict stalls 11 instruction slots, as described in the example on page 490, and there is one mispredict every 10 branches, and one-sixth of all instructions are branches, then 18% of the processor’s time is spent waiting for mispredicted instruction fetches. Therefore it will be necessary to do better, using some combination of hardware and software techniques. Relying on heuristics that mispredict 20% of the branches is better than no predictions at all, but will not suffice in the long run.

Hennessy and Patterson [1996] explain the design and implementation of high-performance machines, instruction-level parallelism, pipeline structure, functional units, caches, out-of-order execution, register renaming, branch prediction, and many other computer-architecture issues, with comparisons of compiler versus run-time-hardware techniques for optimization. Kane and Heinrich [1992] describe the pipeline constraints of the MIPS R4000 computer, from which Figures 20.1 and 20.2 are adapted.

CISC computers of the 1970s implemented complex instructions sequentially using an internal microcode that could do several operations simultaneously; it was not possible for the compiler to interleave parts of several macroinstructions for increased parallelism. Fisher [1981] developed an automatic scheduling algorithm for microcode, using the idea of trace scheduling to optimize frequently executed paths, and then proposed a very-long-instruction-word (VLIW) architecture [Fisher 1983] that could expose the microoperations directly to user programs, using the compiler to schedule.

Aiken and Nicolau [1988] were among the first to point out that a single loop iteration need not be scheduled in isolation, and presented the algorithm for optimal (ignoring resource constraints) parallelization of loops.

Many variations of the multiprocessor scheduling problem are NP-complete [Garey and Johnson 1979; Ullman 1975]. The iterative modulo scheduling algorithm [Rau 1994] gets good results in practice. In the absence of resource constraints, it is equivalent to the Bellman-Ford shortest-path algorithm [Ford and Fulkerson 1962]. Optimal schedules can be obtained (in principle) by expressing the constraints as an integer linear program [Govindarajan et al.
1996], but integer-linear-program solvers can take exponential time (the
problem is NP-complete), and the register-allocation constraint is still difficult to
express in linear inequalities.

Ball and Larus [1993] describe and measure the static branch-prediction
heuristics shown in Section 20.3. Young and Smith [1994] show a profile-
based static branch-prediction algorithm that does better than optimal static
prediction; the apparent contradiction in this statement is explained by the fact
that their algorithm replicates some basic blocks, so that a branch that’s 80%
taken (with a 20% misprediction rate) might become two different branches,
one almost-always taken and one almost-always not taken.

EXERCISES

20.1 Schedule the following loop using the Aiken-Nicolau algorithm:

\[
\begin{align*}
\text{for } i &\leftarrow 1 \text{ to } N \\
 a &\leftarrow X[i - 2] \\
b &\leftarrow Y[i - 1] \\
c &\leftarrow a \times b \\
d &\leftarrow U[i] \\
e &\leftarrow X[i - 1] \\
f &\leftarrow d + e \\
g &\leftarrow d \times c \\
h &\leftarrow X[i] \\
j &\leftarrow Y[i - 1] \\
\end{align*}
\]

a. Label all the scalar variables with subscripts \(i\) and \(i - 1\). **Hint:** In this
loop there are no loop-carried scalar-variable dependences, so none of
the subscripts will be \(i - 1\).

b. Perform **scalar replacement** on uses of \(X[]\) and \(Y[]\). **Hint:** Now you
will have subscripts of \(i - 1\) and \(i - 2\).

c. Perform **copy propagation** to eliminate variables \(a, b, e\).

d. Draw a data-dependence graph of statements \(c, d, f, g, h, j\); label intra-
iteration edges with 0 and loop-carried edges with 1 or 2, depending on
the number of iterations difference there is in the subscript.

e. Show the Aiken-Nicolau **tableau** (as in Table 20.6a).

f. Find the identical groups separated by increasing gaps. **Hint:** The identical
groups will be \(c\) cycles apart, where in this case \(c\) is greater than
one!

g. Show the steepest-slope group. **Hint:** The slope is not an integer.
h. Unroll the loop $k$ times, where $k$ is the denominator of the slope.

i. Draw the data-dependence graph of the unrolled loop.

j. Draw the tableau for the schedule of the unrolled loop.

k. Find the slope of the steepest-slope group. **Hint:** Now it should be an integer.

l. Move the shallow-slope group(s) down to close the gap.

m. Identify the loop body, the prologue, and the epilogue.

n. Write a schedule showing placement of the prologue, loop body, and epilogue in specific cycles, like Figure 20.7.

o. Eliminate the subscripts on variables in the loop body, inserting move instructions where necessary, as in Figure 20.8.

**20.2** Do parts a–d of Exercise 20.1. Then use iterated modulo scheduling to schedule the loop for a machine that can issue three instructions at a time, of which at most one can be a memory instruction and at most one can be a multiply instruction. Every instruction completes in one cycle.

e. Explicitly represent the increment instruction $i_{i+1} \leftarrow i_{i} + 1$ and the loop branch $k : \text{if } i_{i+1} \leq N \text{ goto loop}$ in the data-dependence graph, with an edge from $i$ to itself (labeled by 1), from $i$ to $k$ (labeled by 0), and from $k$ to every node in the loop body (labeled by 1).

f. Calculate $\Delta_{\min}$ based on data-dependence cycles, the 2-instruction per cycle limit, the 1-load/store-per-cycle limit, and the 1-multiply-per-cycle limit. Remark: the $\Delta$ required for a data-dependence cycle is the length of the cycle divided by the sum of the edge-labels (where edge labels show iteration distance, as described in Exercise 20.1d).

g. Run Algorithm itermod, showing the SchedTime and Resource tables each time a variable has to be removed from the schedule, as in Figure 20.10. Use the priority order $H = [i, k, c, d, g, f, h, j]$.

h. Eliminate the subscripts on variables in the loop body, inserting move instructions where necessary, as in Figure 20.8. If the move instructions don’t fit into the 3-instruction-issue limit, then it’s time to increase $\Delta$ and try again.
20.3 Consider the following program:

```
L :  
  a : a ← U[i]  
  b : b ← a × a  
  c : V[i] ← b  
  i : i ← i + 1  
  d : d ← d × a  
  e : if d < 1.0 goto L
```

Suppose these loops are to be run on an out-of-order execution machine with these characteristics: Each instruction takes exactly one cycle, and may be executed as soon as its operands are ready and all preceding conditional branches have been executed. Several instructions may be executed at once, except that there is only one multiply unit. If two multiply instructions are ready, the instruction from an earlier iteration, or occurring first in the same iteration, is executed.

The program was originally written as shown in loop (I); the compiler has rescheduled it as loop (II). For each of the two loops:

a. Draw the data-dependence graph, showing loop-carried dependences with a dashed line.

b. Add the control dependence as a loop-carried edge from e to each of the other nodes.

c. To simulate how the machine will execute the loop, show the Aiken-Nicolau tableau, with the restriction that b and d must never be put in the same cycle. In a cycle where b and d’s predecessors are both ready, prefer the instruction from the earlier iteration, or from earlier in the same iteration.

d. Compute the steepest slope in the tableau; how many cycles per iteration does the loop take?

e. Can compiler scheduling be useful for dynamically rescheduling (out-of-order execution) machines?

20.4 On many machines, instructions after a conditional branch can be executed even before the branch condition is known (the instructions do not commit until after the branch condition is verified).

Suppose we have an out-of-order execution machine with these characteristics: An add or branch takes one cycle; a multiply takes 4 cycles; each instruction may be executed as soon as its operands are ready. Several instructions may be executed at once, except that there is only one multiply unit. If two multiply
instructions are ready, the instruction from an earlier iteration, or occurring first in the same iteration, is executed.

For a machine with this behavior, do parts a–e of Exercise 20.3 for the following programs:

\[
\begin{align*}
L : & & L : \\
a : & a \leftarrow e \times u & b : & b \leftarrow e \times v \\
b : & b \leftarrow e \times v & a : & a \leftarrow e \times u \\
c : & c \leftarrow a + w & c : & c \leftarrow a + w \\

(1) Unscheduled

(II) Scheduled

20.5 Write a short program that contains an instance of each of the branch-prediction heuristics (pointer, call, return, loop header, loop preheader, guard) described on pages 491–492. Label each instance.

20.6 Use branch-prediction heuristics to predict the direction of each of the conditional branches in the programs of Exercise 8.6 (page 190) and Figure 18.7b (page 420); explain which heuristic applies to each prediction.
21

The Memory Hierarchy

**memory**: a device in which information can be inserted and stored and from which it may be extracted when wanted

**hierarchy**: a graded or ranked series

*Webster's Dictionary*

An idealized *random access memory* (RAM) has *N* words indexed by integers such that any word can be fetched or stored – using its integer address – equally quickly. Hardware designers can make a big slow memory, or a small fast memory, but a big fast memory is prohibitively expensive. Also, one thing that speeds up access to memory is its nearness to the processor, and a big memory must have some parts far from the processor no matter how much money might be thrown at the problem.

Almost as good as a big fast memory is the combination of a small fast *cache memory* and a big slow *main memory*; the program keeps its frequently used data in cache and the rarely used data in main memory, and when it enters a phase in which datum *x* will be frequently used it may move *x* from the slow memory to the fast memory.

It’s inconvenient for the programmer to manage multiple memories, so the hardware does it automatically. Whenever the processor wants the datum at address *x*, it looks first in the cache, and – we hope – usually finds it there. If there is a *cache miss* – *x* is not in the cache – then the processor fetches *x* from main memory and places a copy of *x* in the cache so that the next reference to *x* will be a *cache hit*. Placing *x* in the cache may mean removing some other datum *y* from the cache to make room for it, so that some future access to *y* will be a cache miss.
21.1. CACHE ORGANIZATION

A direct-mapped cache is organized in the following way to do this quickly. There are $2^m$ blocks, each holding $2^l$ words of $2^w$ bytes; thus, the cache holds $2^{w+l+m}$ bytes in all, arranged in an array $Data[block][word][byte]$. Each block is a copy of some main-memory data, and there is a tag array indicating where in memory the current contents come from. Typically, the word size $2^w$ might be 4 bytes, the block size $2^{w+l}$ might be 32 bytes, and the cache size $2^{w+l+m}$ might be as small as 8 kilobytes or as large as 2 megabytes.

<table>
<thead>
<tr>
<th>tag</th>
<th>key</th>
<th>word</th>
<th>byte</th>
</tr>
</thead>
<tbody>
<tr>
<td>$(n - (m + l + w))$ bits</td>
<td>$m$ bits</td>
<td>$l$</td>
<td>$w$</td>
</tr>
</tbody>
</table>

Given an address $x$, the cache unit must be able to find whether $x$ is in the cache. The address $x$ is composed of $n$ bits, $x_{n-1}x_{n-2}\ldots x_2x_1x_0$ (see Figure 21.1). In a direct-mapped cache organization, we take the middle bits as the $key = x_{w+l+m-1}x_{w+l+m-2}\ldots x_{w+l}$, and hold the data for $x$ in $Data[key]$.

**FIGURE 21.1.** Organization of a direct-mapped cache. Key field of the address is used to index the tags array and the data blocks; if $tags[key]$ matches the tag field of the address then the data is valid (cache hit). Word index is used to select a word from the cache block.
The high bits \( x_{n-1}x_{n-2} \ldots x_{w+l+m} \) form the tag, and if \( \text{Tags}[\text{key}] \neq \text{tag} \) then there is a \textit{cache miss} – the word we require is not in cache. In this case contents of \( \text{data}[\text{key}] \) are sent back to main memory, and the contents of memory at address \( x_{n-1} \ldots x_{w+l} \), are fetched into the \( k \)th cache block (and also sent to the CPU). Access time for main memory is much longer than the cache access time, so frequent misses are undesirable.

The next time address \( x \) is fetched, if no intervening instruction has fetched another address with the same key but different tag, there will be a \textit{cache hit}: \( \text{Tags}[\text{key}] = \text{tag} \), and bits \( x_{w+l-1} \ldots x_w \) will address a word within the \( \text{key} \)th block: the contents of \( \text{data}[\text{key}][x_{w+l-1} \ldots x_w] \) are transferred to the processor. This is much faster than going all the way to main memory for the data. If the fetching instruction is a byte-fetch (instead of a word-fetch), then (typically) the processor takes care of selecting the byte \( x_{l-1} \ldots x_0 \) from the word.

Another common organization is the \textit{set-associative} cache, which is quite similar but can hold more than one block with the same \textit{key} value. The compiler optimization strategies presented in this chapter are valid for both direct-mapped caches and set-associative caches, but they are a bit more straightforward to analyze for direct-mapped caches.

**Write-hit policy.** The paragraphs above explain what happens on a \textit{read}, when the CPU asks for data at address \( x \). But what happens when the CPU writes data at address \( x \)? If \( x \) is in the cache, this is a \textit{write hit}, which is easy and efficient to process. On a write hit, main memory may be updated now (write-through), or only when the cache block is about to be flushed from the cache (write-back), but choice of write-hit policy does not much affect the compilation and optimization of sequential programs.

**Write-miss policy.** If the CPU writes data at an address not in the cache, this is a \textit{write miss}. Different machines have different write-miss policies:

- **Fetch-on-write.** Word \( x \) is written to the cache. But now the other data words in the same cache block belonged to some other address (that had the same \textit{key} as \( x \)), so to make a valid cache block the other words are fetched from main memory. Meanwhile, the processor is stalled.

- **Write-validate.** Word \( x \) is written to the cache. The other words in the same cache block are marked \textit{invalid}; nothing is fetched from main memory, so the processor is not stalled.

- **Write-around.** Word \( x \) is written directly to main memory, and not to the cache. The processor is not stalled, as no response is required from the memory sys-
21.1. CACHE ORGANIZATION

The memory hierarchy.

Several layers of cache. A modern machine has a memory hierarchy of several layers, as shown in Figure 21.2: inside the processor are registers, which can typically hold about 200 bytes in all and can be accessed in 1 processor cycle; a bit farther away is the primary cache, which can typically hold 8–64 kilobytes and be accessed in about 2–3 cycles; then the secondary cache can hold about a megabyte and be accessed in 7–10 cycles; main memory can hold 100 megabytes and be accessed in 100 cycles. The primary cache is usually split into an instruction cache – from which the processor fetches instructions to execute, and a data cache, from which the processor fetches and stores operands of instructions. The secondary cache usually holds both instructions and data.

Many processors can issue several instructions per cycle; the number of useful instructions in a cycle varies, depending on data-dependence and resource constraints (see page 475), but let us suppose that two useful instructions can be completed in each cycle, on the average. Then a primary-cache miss is a 15-instruction delay (7–10 cycles, times 2), and a secondary-cache miss is a 200-instruction delay.

This cache organization has several consequences of interest to the programmer (and often to the compiler):

- **Byte fetch:** Fetching a single byte is often more expensive than fetching a whole word, because the memory interface delivers a whole word at a time, so the processor must do extra shifting.
- **Byte store:** Storing a single byte is usually more expensive than storing a whole word, because the other bytes of that word must be fetched from the cache and stored back into it.
Temporal locality: Accessing (fetching or storing) a word that has been recently accessed will usually be a cache hit.

Spatial locality: Accessing a word in the same cache-block as one that has been accessed recently will usually be a cache hit.

Cache conflict: If address $a$ and address $a + i \cdot 2^{w+b+m}$ are both frequently accessed, there will be many cache misses because accessing one will throw the other out of the cache.

The compiler can do optimizing transformations that do not decrease the number of instructions executed, but that decrease the number of cache misses (or other memory stalls) that the program encounters.

21.2 CACHE-BLOCK ALIGNMENT

The typical cache-block size ($B = \text{about 8 words, more or less}$) is similar to the typical data-object size. We may expect that an algorithm that fetches one field of an object will probably fetch other fields as well.

If $x$ straddles a multiple-of-$B$ boundary, then it occupies portions of two different cache blocks, both of which are likely to be active at the same time. On the other hand, if $x$ does not cross a multiple-of-$B$ boundary, then accessing all the fields of $x$ uses up only one cache block.

To improve performance by using the cache effectively, the compiler should arrange that data objects are not unnecessarily split across blocks.

There are simple ways to accomplish this:

1. Allocate objects sequentially; if the next object does not fit in the remaining portion of the current block, skip to the beginning of the next block.
2. Allocate size-2 objects in one area of memory, all aligned on multiple-of-2 boundaries; size-4 objects in another area, aligned on multiple-of-4 boundaries, and so on. This eliminates block-crossing for many common-sized objects, without wasted space between the objects.

Block alignment can waste some space, leaving unused words at the end of some blocks, as shown in Figure 21.3. However, the execution speed may improve; for a given phase of the program, there is a set $S$ of frequently accessed objects, and alignment may reduce the number of cache blocks occupied by $S$ from a number greater than the cache size to a number that fits in the cache.

Alignment can be applied both to global, static data and to heap-allocated data. For global data, the compiler can use assembly-language alignment directives to instruct the linker. For heap-allocated records and objects, it is not
Alignment of data objects (or basic blocks) to avoid crossing cache-block boundaries is often worthwhile, even at the cost of empty space between objects.

ALIGNMENT IN THE INSTRUCTION CACHE

Instruction “objects” (basic blocks) occupy cache blocks just as do data records, and the same considerations of block-crossing and alignment apply to instructions. Aligning the beginning of frequently executed basic blocks on multiple-of-$B$ boundaries increases the number of basic blocks that fit simultaneously in the instruction cache.

Infrequently executed instructions should not be placed on the same cache blocks as frequently executed instructions. Consider the program

$$
\begin{align*}
P; \\
\text{if } x \text{ then } Q; \\
R;
\end{align*}
$$

where $x$ is rarely true. We could generate code for it in either of the ways shown in Figure 21.4; but placing $Q$ out-of-line means that this series of statements (usually) occupies two cache blocks, but placing $Q$ straddling cache blocks between $P$ and $R$ will mean that even in the common case, where $Q$
If $x$ is rarely true, basic-block placement (a) will occupy three in-cache blocks, while (b) will usually occupy only two.

is not executed, this part of the program will occupy three blocks in the cache.

On some machines it is particularly important to align the target of a branch instruction on a power-of-2 boundary. A modern processor fetches an aligned block of $k$ (2 or 4 or more) words. If the program branches to some address that is not on a multiple-of-$k$ boundary, then the instruction-fetch is not fetching $k$ useful instructions.

An optimizing compiler should have a basic-block-ordering phase, after instruction selection and register allocation. Trace scheduling (as described in Section 8.2) can then be used to order a frequently executed path through a contiguous set of cache blocks; in constructing a trace through a conditional branch, it is important to follow the most-likely-taken out-edge, as determined by branch prediction (as described in Section 20.3).

21.3 PREFETCHING

If a load instruction misses the primary (or secondary) cache, there will be a 7–10 cycle delay (or a 70–100 cycle delay, respectively) while the datum is fetched from the next level of the memory hierarchy. In some cases, the need for that datum is predictable many cycles earlier, and the compiler can insert prefetch instructions to start the fetching earlier.

A prefetch instruction is a hint to the hardware to start bringing data at address $x$ from main memory into the cache. A prefetch never stalls the processor – but on the other hand, if the hardware finds that some exceptional condition (such as a page fault) would occur, the prefetch can be ignored. When $\text{prefetch}(x)$ is successful, it means that the next load from $x$ will hit the
cache; an unsuccessful prefetch might cause the next load to miss the cache, but the program will still execute correctly. Many machines now have some form of prefetch instruction.

Of course, one reasonable alternative is – instead of starting the fetch earlier – to just delay the instruction that uses the result of the fetch until later, using the software-pipelining techniques described in Chapter 20. In fact, processors that dynamically reorder instructions (to account for operands not ready) achieve this effect without any special work by the compiler.

The problem with using software pipelining or dynamic rescheduling to hide secondary-cache misses is that it increases the number of live temporaries. Consider the following dot-product loop as an example:

\[
\begin{align*}
L_1 & : x & \leftarrow & M[i] \\
     & y & \leftarrow & M[j] \\
     & z & \leftarrow & x \times y \\
     & s & \leftarrow & s + z \\
     & i & \leftarrow & i + 4 \\
     & j & \leftarrow & j + 4 \\
\text{if} & \ i < N & \text{goto} & L_1
\end{align*}
\]

If the data for the \(i\) and \(j\) arrays are not in the primary cache, or if \(N\) is large (> 8 kilobytes or so) so that the arrays cannot possibly fit in the cache, then each time \(i\) or \(j\) crosses to a new multiple-of-\(B\) boundary (into a new cache block), there will be a cache miss. In effect, the miss rate will be exactly \(W/B\), where \(W\) is the word size and \(B\) is the block size. Typical values for \(W/B\) are \(1/4\) or \(1/8\), and this is a rather high miss rate.

The penalty for a primary cache miss is perhaps 7 cycles, or (on a dual-instruction-issue-per-cycle machine) 14 instructions. This would stall the processor of an early-'90s machine for 14 instructions, but a good late-'90s machine with out-of-order execution will find some other instruction to execute that is not data-dependent on the load.

The effective order of execution, on a dynamic-instruction-reordering machine, is shown in Figure 21.5a. When \(x_1 \leftarrow M[i_0]\) is fetched there is a cache miss, so instructions data-dependent on \(x_1\) cannot be issued for 11 cycles. In the meantime, \(i_1\) and \(j_1\), and even \(i_2\) and \(j_2\) can be computed; and the fetch \(x_2 \leftarrow M[i_1]\) can be issued.

As the number of uncompleted loop-iterations increases, the number of live or reserved registers increases proportionately. The cache-misses for \(x_2, x_3, x_4\) are the same miss as for \(x_1\) because they are all in the same cache.
FIGURE 21.5. Execution of a dot-product loop, with 4-word cache blocks.

(a) Without prefetching

(b) With prefetching

(a) Without prefetching, on a machine with dynamic instruction reordering, the number of outstanding instructions (reserved registers) grows proportionally to the cache-miss latency.

(b) With prefetching, the hardware reservation table never grows large. (Steady-state behavior is shown here, not the initial transient.)
block, so \(x_1, x_2, x_3, x_4\) all become available at about the same time. Iterations 5–8 (which use the next cache block) would be dynamically scheduled like iterations 1–4, and so on.

The primary-cache latency, illustrated here, is usually small enough to handle without prefetching techniques. But with a secondary cache miss latency of 200 instructions (i.e. 29 loop iterations), there will be about 116 outstanding instructions (computations of \(x, y, z, s\) waiting for the cache miss), which may exceed the capacity of the machine’s instruction-issue hardware.

**Prefetch instructions.** Suppose the compiler inserts a *prefetch* instruction for address \(a\), in advance of the time \(a\) will be fetched. This is a hint to the computer that it should start transferring \(a\) from main memory into the cache. Then, when \(a\) is fetched a few cycles later by an ordinary load instruction, it will hit the cache and there will be no delay.

Many machines don’t have a prefetch instruction as such, but many machines do have a non-blocking *load* instruction. That is, when \(r_3 \leftarrow M[r_7]\) is performed, the processor does not stall even on a cache miss, *until* \(r_3\) is used as an operand of some other instruction. If we want to prefetch address \(a\), we can just do \(r_t \leftarrow M[a]\), and then *never use the value of \(r_t\). This will start the load, bringing the value into cache if necessary, but not delay any other instruction. Later, when we fetch \(M[a]\) again, it will hit the cache. Of course, if the computation was already *memory-bound* – fully utilizing the load/store unit while the arithmetic units are often idle – then prefetching using ordinary load instructions may not help.

If the computation accesses every word of an array sequentially, it uses several words from each cache block. Then we don’t need to prefetch every word – just one word per cache block is enough. Assuming a 4-byte word and 16-byte cache block, the dot-product loop with prefetching looks something like this:

\[
L_1 : \text{if } i \mod 16 = 0 \text{ then } \text{prefetch } M[i + K] \\
\quad \text{if } j \mod 16 = 0 \text{ then } \text{prefetch } M[j + K] \\
\quad x \leftarrow M[i] \\
\quad y \leftarrow M[j] \\
\quad z \leftarrow x \times y \\
\quad s \leftarrow s + z \\
\quad i \leftarrow i + 4 \\
\quad j \leftarrow j + 4 \\
\quad \text{if } i < N \text{ goto } L_1
\]
The value $K$ is chosen to match the expected cache-miss latency. For a secondary-cache-miss latency of 200 instructions, when each loop iteration executes 7 instructions and advances $i$ by 4, we would use $K = 200 \cdot 4/7$ rounded up to the nearest multiple of the block size; that is, about 128. Figure 21.5b uses prefetching to “hide” a cache latency of 11 instructions, so $K = 16$, the block size. An additional improvement that may be helpful on some machines, when $K$ is small, is to avoid overlapping the prefetch latencies so the memory hardware needn’t process two misses simultaneously.

In practice, we don’t want to test $i \mod 16 = 0$ in each iteration, so we unroll the loop, or nest a loop within a loop, as shown in Program 21.6. The loop-unrolled version on the left could be further improved – in ways unre-
lated to prefetching – by removing some of the intermediate \textbf{if} statements, as described in Section 18.5.

\textbf{Prefetching for stores.} Sometimes we can predict at compile time that a \textit{store} instruction will miss the cache. Consider the following loop:

\begin{verbatim}
for \( i \leftarrow 0 \) to \( N - 1 \)
    \( A[i] \leftarrow i \)
\end{verbatim}

If the array \( A \) is larger than the cache, or if \( A \) has not recently been accessed, then each time \( i \) crosses into a new cache block there will be a write miss. If the write-miss policy is \textit{write-validate}, then this is no problem, as the processor will not be stalled and all the marked-invalid words will be quickly overwritten with valid data. If the policy is \textit{fetch-on-write}, then the stalls at each new cache block will significantly slow down the program. But prefetching can be used here:

\begin{verbatim}
for \( i \leftarrow 0 \) to \( N - 1 \)
    if \( i \mod \text{blocksize} = 0 \) then \textbf{prefetch} \( A[i + K] \)
    \( A[i] \leftarrow i \)
\end{verbatim}

As usual, unrolling the loop will remove the \textbf{if}-test. The \( A[i + K] \) value that’s prefetched will contain \textit{garbage} – dead data that we know will be overwritten. We perform the prefetch only to avoid the write-miss stall.

If the write-miss policy is \textit{write-around}, then we should prefetch only if we expect the \( A[i] \) values to be fetched soon after they are stored.

\textbf{Summary.} Prefetching is applicable when

\begin{itemize}
    \item The machine has a prefetch instruction, or a non-blocking load instruction that can be used as a prefetch;
    \item The machine does not dynamically reorder instructions, or the dynamic reorder buffer is smaller than the particular cache latency that we desire to hide; \textit{and}
    \item The data in question is larger than the cache, or not expected to be already in cache.
\end{itemize}

I will not describe the algorithm for inserting prefetch instructions in loops, but see the Further Reading section.
21.4 LOOP INTERCHANGE

The most fundamental way of using cache effectively is the reuse of cached data. When nested loops access memory, successive iterations of a loop often reuse the same word, or use adjacent words that occupy the same cache block. If it is the innermost loop whose iterations reuse the same values, then there will be many cache hits. But if one of the outer loops reuses a cache block, it may be that execution of the inner loop stomps through the cache so heavily that by the time the next outer-loop iteration executes, the cache block will have been flushed.

Consider the following nested loops, for example.

```plaintext
for i ← 0 to N − 1
  for j ← 0 to M − 1
    for k ← 0 to P − 1
      A[i, j, k] ← (B[i, j − 1, k] + B[i, j, k] + B[i, j + 1, k])/3
```

The value $B[i, j + 1, k]$ is reused in the next iteration of the $j$ loop (where its “name” is $B[i, j, k]$), and then is reused again in the iteration after that. But in the meantime, the $k$ loop brings $3P$ elements of the $B$ array, and $P$ elements of the $A$ array, through the cache. Some of these words may very well conflict with $B[i, j, k]$, causing a cache miss the next time it is fetched.

The solution in this case is to interchange the $j$ and $k$ loops, putting the $j$ loop innermost:

```plaintext
for i ← 0 to N − 1
  for k ← 0 to P − 1
    for j ← 0 to M − 1
      A[i, j, k] ← (B[i, j − 1, k] + B[i, j, k] + B[i, j + 1, k])/3
```

Now $B[i, j, k]$ will always be a cache hit, and so will $B[i, j − 1, k]$.

To see whether interchange is legal for a given pair of loops, we must examine the data-dependence graph of the calculation. We say that iteration $(j, k)$ depends on iteration $(j’, k’)$ if $(j’, k’)$ computes values that are used by $(j, k)$ (read-after-write), or stores values that are overwritten by $(j, k)$ (write-after-write), or reads values that are overwritten (write-after-read). If the interchanged loops execute $(j’, k’)$ before $(j, k)$, and there is a dependence, then the computation may yield a different result, and the interchange is illegal.
In the example shown above, there is no dependence between any iterations of the nested loops, so interchange is legal.

See the Further Reading section for a discussion of the analysis of dependence relations for array accesses in nested loops.

### 21.5. BLOCKING

The technique of blocking reorders a computation so that all the computations that use one portion of the data are completed before moving on to the next portion. The following nested loop for matrix multiplication, \( C = AB \), illustrates the need for blocking:

```
for i ← 0 to N − 1
  for j ← 0 to N − 1
    for k ← 0 to N − 1
      C[i, j] ← C[i, j] + A[i, k] \cdot B[k, j]
```

If both \( A \) and \( B \) fit into the cache simultaneously, then the \( k \) loop will run without cache misses, and there may be only one cache miss for \( C[i, j] \) on each iteration of the \( j \) loop.

But suppose the cache is large enough to hold only \( 2 \cdot c \cdot N \) matrix elements (floating-point numbers), where \( 1 < c < N \). For example, multiplying 50 \( \times \) 50 matrices of 8-byte floats on a machine with an 8-kilobyte cache, \( c = 10 \). Then every reference to \( B[k, j] \) in the inner loop will be a cache miss, because – since the last time that particular cell of \( B \) was accessed – the entire \( B \) matrix will have been marched through the cache, dumping out the “old” values. Thus, each iteration of the inner loop will have a cache miss.

Loop interchange cannot help here, because if the \( j \) loop is outermost, then \( A \) will suffer cache misses, and if the \( k \) loop is outermost, then \( C \) will suffer misses.

The solution is to reuse rows of the \( A \) matrix and columns of the \( B \) matrix while they are still in cache. A \( c \times c \) block of the matrix \( C \) can be calculated from \( c \) rows of \( A \) and \( c \) columns of \( B \), as follows (see also Figure 21.7):

```
for i ← i_0 to i_0 + c − 1
  for j ← j_0 to j_0 + c − 1
    for k ← 0 to N − 1
      C[i, j] ← C[i, j] + A[i, k] \cdot B[k, j]
```
FIGURE 21.7. Matrix multiplication. Each element of $C$ is computed from a row of $A$ and a column of $B$. With blocking, a $c \times c$ block of the $C$ matrix is computed from a $c \times N$ block of $A$ and a $N \times c$ block of $B$.

Only $c \cdot N$ elements of $A$ and $c \cdot N$ elements of $B$ are used in this loop, and each element is used $c$ times. Thus, at a cost of $2 \cdot c \cdot N$ cache misses to bring this portion of $A$ and $B$ into cache, we are able to compute $c \cdot c \cdot N$ iterations of the inner loop, for a miss rate of $2/c$ misses per iteration.

All that remains is to nest this set of loops inside outer loops that compute each $c \times c$ block of $C$:

for $i_0 \leftarrow 0$ to $N - 1$ by $c$
    for $j_0 \leftarrow 0$ to $N - 1$ by $c$
        for $i \leftarrow i_0$ to min($i_0 + c - 1, N - 1$)
            for $j \leftarrow j_0$ to min($j_0 + c - 1, N - 1$)
                for $k \leftarrow 0$ to $N - 1$
                    $C[i, j] \leftarrow C[i, j] + A[i, k] \cdot B[k, j]$

This optimization is called *blocking* because it computes one block of the iteration space at a time. There are many nested-loop programs on which an optimizing compiler can automatically perform the blocking transformation. Crucial to the situation are loops whose iterations are not data-dependent on each other; in matrix multiplication, the calculation of $C[i, j]$ does not depend on $C[i', j']$, for example.

**Scalar replacement.** Even though the access to $C[i, j]$ in the matrix-multiply program will almost always hit the cache (since the same word is being used repeatedly in the $k$ loop), we can still bring it up one level in the memory hierarchy – from primary cache into registers! – by the *scalar replacement* optimization. That is, when a particular array element is used as a scalar for repeated computations, we can “cache” it in a register:
for $i \leftarrow i_0$ to $i_0 + c - 1$
for $j \leftarrow j_0$ to $j_0 + c - 1$
    $s \leftarrow C[i, j]$
    for $k \leftarrow 0$ to $N - 1$
        $s \leftarrow s + A[i, k] \cdot B[k, j]$
    $C[i, j] \leftarrow s$

This reduces the number of fetches and stores in the innermost loop by a factor of 2.

**Blocking at every level of the memory hierarchy.** To do blocking optimizations, the compiler must know how big the cache is – this determines the best value of $c$, the block size. If there are several levels of the memory hierarchy, then blocking can be done at each level. Even the machine’s registers should be considered as a level of the memory hierarchy.

Taking again the example of matrix multiply, we suppose there are 32 floating-point registers, and we want to use $d$ of them as a kind of cache. We can rewrite the $c \times c$ loop (of the blocked matrix multiply) as follows:

for $i \leftarrow i_0$ to $i_0 + c - 1$
for $k_0 \leftarrow 0$ to $N - 1$ by $d$
    for $k \leftarrow k_0$ to $k_0 + d - 1$
        $T[k - k_0] \leftarrow A[i, k]$
    for $j \leftarrow j_0$ to $j_0 + c - 1$
        $s \leftarrow C[i, j]$
    for $k \leftarrow k_0$ to $k_0 + d - 1$
        $s \leftarrow s + T[k - k_0] \cdot B[k, j]$
    $C[i, j] \leftarrow s$

**Unroll and jam.** *Loop unrolling must be used for register-level blocking,* since registers cannot be indexed by subscripts. So we unroll the $k$-loops $d$ times and keep each $T[k]$ in a separate scalar temporary variable (for illustration, I will use $d = 3$, though $d = 25$ would be more realistic):

for $i \leftarrow i_0$ to $i_0 + c - 1$
for $k_0 \leftarrow 0$ to $N - 1$ by 3
    $t_0 \leftarrow A[i, k_0];$ $t_1 \leftarrow A[i, k_0 + 1];$ $t_2 \leftarrow A[i, k_0 + 2]$
    for $j \leftarrow j_0$ to $j_0 + c - 1$
        $C[i, j] \leftarrow C[i, j] + t_0 \cdot B[k_0, j] + t_1 \cdot B[k_0 + 1, j] + t_2 \cdot B[k_0 + 2, j]$
The register allocator will ensure, of course, that the $t_k$ are kept in registers. Every value of $A[i, k]$ fetched from the cache is used $c$ times; the $B$ values still need to be fetched, so the number of memory accesses in the inner loop goes down by almost a factor of two.

A high-tech compiler would perform – on the same loop! – blocking transformations for the primary cache and for the secondary cache, and scalar replacement and unroll-and-jam for the register level of the memory hierarchy.

21.6 GARBAGE COLLECTION AND THE MEMORY HIERARCHY

Garbage-collected systems have had the reputation as cache-thrashers with bad cache locality: after all, it would appear that a garbage collection touches all of memory in random-access fashion.

But a garbage-collector is really a kind of memory manager, and we can organize it to manage memory for improved locality of reference.

Generations: When generational copying garbage collection is used, the youngest generation (allocation space) should be made to fit inside the secondary cache. Then each memory allocation will be a cache hit, and each youngest-generation garbage collection will operate almost entirely within the cache as well – only the objects promoted to another generation may cause cache-write misses. (Keeping the youngest generation inside the primary cache is impractical, since that cache is usually so small that too-frequent garbage collections would be required.)

Sequential allocation: With copying collection, new objects are allocated from a large contiguous free space, sequentially in order of address. The sequential pattern of stores to initialize these objects is easy for most modern write-buffers to handle.

Few conflicts: The most frequently referenced objects tend to be the newer ones. With sequential allocation of objects in the youngest generations, the keys of these newer objects (in a direct-mapped cache) will be all different. Consequently, garbage-collected programs have significantly lower conflict-miss rates than programs that use explicit freeing.

Prefetching for allocation: The sequential initializing stores cause cache-write misses (in the primary cache, which is much smaller than the allocation space) at the rate of one miss per $B/W$ stores, where $B$ is the cache block size and $W$ is the word size. On most modern machines (those with write-validate cache policies) these misses are not costly, because a write miss does not cause the processor to wait for any data. But on some machines (those with fetch-
on-write or write-around policies) a write miss is costly. One solution is to prefetch the block well in advance of storing into it. This does not require analysis of any loops in the program (like the technique shown in Section 21.3) – instead as the allocator creates a new object at address $a$, it prefetches word $a + K$. The value $K$ is related to the cache-miss latency and also the frequency of allocation versus other computation, but a value of $K = 100$ should work well in almost all circumstances.

**Grouping related objects:** If object $x$ points to object $y$, an algorithm that accesses $x$ will likely access $y$ soon, so it is profitable to put the two objects in the same block. A copying collector using *depth-first* search to traverse the live data will automatically tend to put related objects together; a collector using *breadth-first* search will not. Copying in depth-first order improves cache performance – but only if the cache blocks are larger than the objects.

These cache-locality improvement techniques are all applicable to copying collection. Mark-and-sweep collectors, which cannot move the live objects, are less amenable to cache management; but see the Further Reading section.

---

**Further Reading**

Sites [1992] discusses several kinds of instruction- and data-cache alignment optimizations. Efficient approximation algorithms for the traveling salesman problem (TSP) can be applied to basic-block ordering, to minimize the instruction-fetch penalties for branches [Young et al. 1997].

Mowry et al. [1992] describe an algorithm for inserting prefetch instructions in *for*-loops, taking care not to insert prefetches (which do, after all, have an instruction-issue cost) where the data in question is likely to be in cache already.

The Lisp Machine’s garbage collector used depth-first search to group related objects on the same page to minimize page faults [Moon 1984]. Koopman et al. [1992] describe prefetching for a garbage-collected system. Diwan et al. [1994], Reinhold [1994], and Gonçalves and Appel [1995] analyze the cache locality of programs that use copying garbage collection. For mark-sweep collectors, Boehm et al. [1991] suggest that (to improve page-level locality) new objects should not be allocated into mostly full pages containing old objects, and that the sweep phase should be done incrementally so that pages and cache-blocks are “touched” by the sweep just before they’ll be allocated by the program.
The techniques for optimizing the memory locality of programs with nested loops have much in common with techniques for parallelizing loops. For example, in a parallel implementation of matrix multiplication, having each processor compute one row of the C matrix requires that processor to have $N^2$ elements of A and N elements of B, or $O(N^2)$ words of interprocessor communication. Instead, each processor should compute one block of C (where the block size is $\sqrt{N} \times \sqrt{N}$); then each processor requires $N \cdot \sqrt{N}$ words of A and of B, which is only $O(N^{1.5})$ words of communication. Many of the compilers that use blocking and loop-nest optimizations to generate the most memory-efficient code for uniprocessors are parallelizing compilers – with the parallelization turned off!

To generate good parallel code – or to perform many of the loop optimizations described in this chapter, such as blocking and interchange – it’s necessary to analyze how array accesses are data-dependent on each other. Array dependence analysis is beyond the scope of this book, but is covered well by Wolfe [1996].

Callahan et al. [1990] show how to do scalar replacement; Carr and Kennedy [1994] show how to calculate the right amount of unroll-and-jam for a loop based on the characteristics of the target machine.

Wolf and Lam [1991] describe a compiler optimization algorithm that uses blocking, tiling (like blocking but where the tiles can be skewed instead of rectangular), and loop interchange to achieve locality improvements on many kinds of nested loops.

The textbook by Wolfe [1996] covers almost all the techniques described in this chapter, with particular emphasis on automatic parallelization but also with some treatment of improving memory locality.

**EXERCISES**

**21.1** Write a program in C for multiplying $1000 \times 1000$ double-precision floating-point matrices. Run it on your machine and measure the time it takes.

a. Find out the number of floating-point registers on your machine, the size of the primary cache, and the size of the secondary cache.

b. Write a matrix-multiply program that uses blocking transformations at the secondary cache level only. Measure its run time.
c. Modify your program to optimize on both levels of cache; measure its run time.

d. Modify the program again to optimize over both levels of cache and use registers via unroll-and-jam; view the output of the C compiler to verify that the register allocator is keeping your temporary variables in floating-point registers. Measure the run time.

*21.2 Write a program in C for multiplying $1000 \times 1000$ double-precision floating-point matrices. Use the C compiler to print out assembly language for your loop. If your machine has a prefetch instruction, or a non-stalling load instruction that can serve as a prefetch, insert prefetch instructions to hide secondary-cache misses. Show what calculations you made to take account of the cache-miss latency. How much faster is your program with prefetching?
The Tiger language is a small language with nested functions, record values with implicit pointers, arrays, integer and string variables, and a few simple structured control constructs.

A.1 LEXICAL ISSUES

Identifiers: An identifier is a sequence of letters, digits, and underscores, starting with a letter. Uppercase letters are distinguished from lowercase. In this appendix the symbol id stands for an identifier.

Comments: A comment may appear between any two tokens. Comments start with /* and end with */ and may be nested.

A.2 DECLARATIONS

A declaration-sequence is a sequence of type, value, and function declarations; no punctuation separates or terminates individual declarations.

\[ decs \rightarrow \{dec\} \]

\[ dec \rightarrow tydec \]
\[ \rightarrow vardec \]
\[ \rightarrow fundec \]

In the syntactic notation used here, \( \epsilon \) stands for the empty string and \( \{x\} \) stands for a possibly empty sequence of \( x \)’s.
A.2. DECLARATIONS

DATA TYPES

The syntax of types and type declarations in Tiger is

\[
\begin{align*}
tydec & \rightarrow \text{type type-id} = ty \\
ty & \rightarrow \text{type-id} \\
& \rightarrow \{ \text{tyfields} \} \quad \text{(these braces stand for themselves)} \\
& \rightarrow \text{array of type-id} \\
tyfields & \rightarrow \epsilon \\
& \rightarrow \text{id : type-id} \{, \text{id : type-id}\}
\end{align*}
\]

**Built-in types:** Two named types \texttt{int} and \texttt{string} are predefined. Additional named types may be defined or redefined (including the predefined ones) by type declarations.

**Records:** Record types are defined by a listing of their fields enclosed in braces, with each field described by \texttt{fieldname : type-id}, where \texttt{type-id} is an identifier defined by a type declaration.

**Arrays:** An array of any named type may be made by \texttt{array of type-id}. The length of the array is not specified as part of its type; each array of that type can have a different length, and the length will be decided upon array creation, at run time.

**Record distinction:** Each declaration of a record or array type creates a new type, incompatible with all other record or array types (even if all the fields are similar).

**Mutually recursive types:** A collection of types may be recursive or mutually recursive. Mutually recursive types are declared by a consecutive sequence of type declarations without intervening value or function declarations. Each recursion cycle must pass through a record or array type.

Thus, the type of lists of integers:

\[
\begin{align*}
type \text{intlist} &= \{\text{hd: int, tl: intlist}\} \\
type \text{tree} &= \{\text{key: int, children: treelist}\} \\
type \text{treelist} &= \{\text{hd: tree, tl: treelist}\}
\end{align*}
\]

But the following declaration sequence is illegal:

\[
\begin{align*}
type \ b &= \ c \\
type \ c &= \ b
\end{align*}
\]

**Field name reusability:** Different record types may use the same field names (such as the \texttt{hd} field of \texttt{intlist} and \texttt{treelist} in the example above).
VARIABLES

\[ \text{vardec} \rightarrow \text{var id := exp} \]
\[ \rightarrow \text{var id : type-id := exp} \]

In the short form of variable declaration, the name of the variable is given, followed by an expression representing the initial value of the variable. In this case, the type of the variable is determined from the type of the expression.

In the long form, the type of the variable is also given. The expression must have the same type.

If the initializing expression is \text{nil}, then the long form must be used.

Each variable declaration creates a new variable, which lasts as long as the scope of the declaration.

FUNCTIONS

\[ \text{fundec} \rightarrow \text{function id ( tyfields) = exp} \]
\[ \rightarrow \text{function id ( tyfields) : type-id = exp} \]

The first of these is a procedure declaration; the second is a function declaration. Procedures do not return result values; functions do, and the type is specified after the colon. The \text{exp} is the body of the procedure or function, and the \text{tyfields} specify the names and type of the parameters. All parameters are passed by value.

Functions may be recursive. Mutually recursive functions and procedures are declared by a sequence of consecutive function declarations (with no intervening type or variable declarations):

```plaintext
function treeLeaves(t : tree) : int =
  if t=nil then 1
  else treelistLeaves(t.children)

function treelistLeaves(L : treelist) : int =
  if L=nil then 0
  else treeLeaves(L.hd) + treelistLeaves(L.tl)
```

SCOPE RULES

Local variables: In the expression \text{let \cdots vardec \cdots in exp end}, the scope of the declared variable starts just after its \text{vardec} and lasts until the \text{end}.

Parameters: In function \text{id ( \cdots id_1 : id_2 \cdots ) = exp} the scope of the parameter \text{id_1} lasts throughout the function body \text{exp}. 

A.3. VARIABLES AND EXPRESSIONS

Nested scopes: The scope of a variable or parameter includes the bodies of any function definitions in that scope. That is, access to variables in outer scopes is permitted, as in Pascal and Algol.

Types: In the expression `let · · · tydecs · · · in exps end` the scope of a type identifier starts at the beginning of the consecutive sequence of type declarations defining it and lasts until the `end`. This includes the headers and bodies of any functions within the scope.

Functions: In the expression `let · · · fundecs · · · in exps end` the scope of a function identifier starts at the beginning of the consecutive sequence of function declarations defining it and lasts until the `end`. This includes the headers and bodies of any functions within the scope.

Name spaces: There are two different name spaces: one for types, and one for functions and variables. A type `a` can be “in scope” at the same time as a variable `a` or a function `a`, but variables and functions of the same name cannot both be in scope simultaneously (one will hide the other).

Local redeclarations: A variable or function declaration may be hidden by the redeclaration of the same name (as a variable or function) in a smaller scope; for example, this function prints “6 7 6 8 6” when applied to 5:

```plaintext
function f(v: int) =
let var v := 6 in print(v);
    let var v := 7 in print (v) end;
print(v);
    let var v := 8 in print (v) end;
print(v)
end
```

Functions hide variables of the same name, and vice versa. Similarly, a type declaration may be hidden by the redeclaration of the same name (as a type) in a smaller scope. However, no two functions in a sequence of mutually recursive functions may have the same name; and no two types in a sequence of mutually recursive types may have the same name.

A.3 VARIABLES AND EXPRESSIONS

L-VALUES

An l-value is a location whose value may be read or assigned. Variables, procedure parameters, fields of records, and elements of arrays are all l-values.

\[
\text{l-value} \rightarrow \text{id} \\
\rightarrow \text{lvalue} . \text{id} \\
\rightarrow \text{lvalue} [ \text{exp} ]
\]
Variable: The form \texttt{id} refers to a variable or parameter accessible by scope rules.

Record field: The dot notation allows the selection of the correspondingly named field of a record value.

Array subscript: The bracket notation allows the selection of the correspondingly numbered slot of an array. Arrays are indexed by consecutive integers starting at zero (up to the size of the array minus one).

**EXPRESSIONS**

\textit{l-value}: An \textit{l}-value, when used as an expression, evaluates to the contents of the corresponding location.

Valueless expressions: Certain expressions produce no value: procedure calls, assignment, if-then, while, break, and sometimes if-then-else. Therefore the expression \((a:=b)+c\) is syntactically correct but fails to type-check.

Nil: The expression \texttt{nil} (a reserved word) denotes a value \texttt{nil} belonging to every record type. If a record variable \(v\) contains the value \texttt{nil}, it is a checked runtime error to select a field from \(v\). \texttt{Nil} must be used in a context where its type can be determined, that is:

\begin{verbatim}
var a : my_record := nil          OK
a := nil                           OK
if a <> nil then ...               OK
if nil <> a then ...               OK
if a = nil then ...                OK
function f(p: my_record) = ...    f(nil)     OK
var a := nil                       Illegal
if nil = nil then ...              Illegal
\end{verbatim}

Sequencing: A sequence of two or more expressions, surrounded by parentheses and separated by semicolons \((exp;exp;\ldots;exp)\) evaluates all the expressions in order. The result of a sequence is the result (if any) yielded by the last of the expressions.

No value: An open parenthesis followed by a close parenthesis (two separate tokens) is an expression that yields no value. Similarly, a \texttt{let} expression with nothing between the \texttt{in} and \texttt{end} yields no value.

Integer literal: A sequence of decimal digits is an integer constant that denotes the corresponding integer value.

String literal: A string constant is a sequence, between quotes ("), of zero or more printable characters, spaces, or escape sequences. Each escape sequence is introduced by the escape character \textbackslash, and stands for a character sequence. The allowed escape sequences are as follows (all other uses of \textbackslash being illegal):
A.3. VARIABLES AND EXPRESSIONS

\n A character interpreted by the system as end-of-line.
\t Tab.
ˆc The control character c, for any appropriate c.
ddd The single character with ASCII code ddd (3 decimal digits).
" The double-quote character (").
\ The backslash character (\).
f\ This sequence is ignored, where f\ stands for a sequence of one or more formatting characters (a subset of the non-printable characters including at least space, tab, newline, formfeed). This allows one to write long strings on more than one line, by writing \ at the end of one line and at the start of the next.

Negation: An integer-valued expression may be prefixed by a minus sign.

Function call: A function application \( id() \) or \( id(exp[, exp]) \) indicates the application of function \( id \) to a list of actual parameter values obtained by evaluating the expressions left to right. The actual parameters are bound to the corresponding formal parameters of the function definition and the function body is bound using conventional static scoping rules to obtain a result. If \( id \) actually stands for a procedure (a function returning no result), then the function body must produce no value, and the function application also produces no value.

Arithmetic: Expressions of the form \( exp op exp \), where \( op \) is \(+, -, *, /\), require integer arguments and produce an integer result.

Comparison: Expressions of the form \( exp op exp \), where \( op \) is \(=, <, >, <=, >=\), compare their operands for equality or inequality and produce the integer 1 for true, 0 for false. All these operators can be applied to integer operands. The equals and not-equals operators can also be applied to two record or array operands of the same type, and compare for “reference” or “pointer” equality (they test whether two records are the same instance, not whether they have the same contents).

String comparison: The comparison operators may also be applied to strings. Two strings are equal if their contents are equal; there is no way to distinguish strings whose component characters are the same. Inequality is according to lexicographic order.

Boolean operators: Expressions of the form \( exp op exp \), where \( op \) is \& or |, are short-circuit boolean conjunctions and disjunctions: they do not evaluate the right-hand operand if the result is determined by the left-hand one. Any nonzero integer value is considered true, and an integer value of zero is false.

Precedence of operators: Unary minus (negation) has the highest precedence. Then operators \(*, /\) have the next highest (tightest binding) precedence, fol-

... followed by +, -, then by =,<,>,<,>,>=,<=, then by &,
then by |.

**Associativity of operators:** The operators *, /, +, - are all left-associative. The comparison operators do not associate, so a=b=c is not a legal expression, although a=(b=c) is legal.

**Record creation:** The expression `type-id {id=exp, id=exp}` or (for an empty record type) `type-id {}` creates a new record instance of type `type-id`. The field names and types of the record expression must match those of the named type, in the order given. The braces `{ }` stand for themselves.

**Array creation:** The expression `type-id [exp1] of exp2` evaluates `exp1` and `exp2` (in that order) to find `n`, the number of elements, and `v` the initial value. The type `type-id` must be declared as an array type. The result of the expression is a new array of type `type-id`, indexed from 0 to `n − 1`, in which each slot is initialized to the value `v`.

**Array and record assignment:** When an array or record variable `a` is assigned a value `b`, then `a` references the same array or record as `b`. Future updates of elements of `a` will affect `b`, and vice versa, until `a` is reassigned. Parameter passing of arrays and records is similarly by reference, not by copying.

**Extent:** Records and arrays have infinite extent: each record or array value lasts forever, even after control exits from the scope in which it was created.

**Assignment:** The assignment statement `lvalue := exp` evaluates the `lvalue`, then evaluates the `exp`, then sets the contents of the `lvalue` to the result of the expression. Syntactically, `:=` binds weaker than the boolean operators `&` and `|`. The assignment expression produces no value, so that `(a := b) + c` is illegal.

**If-then-else:** The if-expression `if exp1 then exp2 else exp3` evaluates the integer expression `exp1`. If the result is nonzero it yields the result of evaluating `exp2`; otherwise it yields the result of `exp3`. The expressions `exp2` and `exp3` must have the same type, which is also the type of the entire if-expression (or both expressions must produce no value).

**If-then:** The if-expression `if exp1 then exp2` evaluates the integer expression `exp1`. If the result is nonzero, then `exp2` (which must produce no value) is evaluated. The entire if-expression produces no value.

**While:** The expression `while exp1 do exp2` evaluates the integer expression `exp1`. If the result is nonzero, then `exp2` (which must produce no value) is executed, and then the entire while-expression is reevaluated.

**For:** The expression `for id := exp1 to exp2 do exp3` iterates `exp3` over each integer value of `id` between `exp1` and `exp2`. The variable `id` is a new variable implicitly declared by the `for` statement, whose scope covers only `exp3`, and may not be assigned to. The body `exp3` must produce no value. The upper and lower bounds are evaluated only once, prior to entering the body of the loop. If the upper bound is less than the lower, the body is not executed.
A.4. STANDARD LIBRARY

Break: The break expression terminates evaluation of the nearest enclosing while-expression or for-expression. A break in procedure p cannot terminate a loop in procedure q, even if p is nested within q. A break that is not within a while or for is illegal.

Let: The expression let decs in expseq end evaluates the declarations decs, binding types, variables, and procedures whose scope then extends over the expseq. The expseq is a sequence of zero or more expressions, separated by semicolons. The result (if any) of the last exp in the sequence is then the result of the entire let-expression.

Parentheses: Parentheses around any expression enforce syntactic grouping, as in most programming languages.

PROGRAMS
Tiger programs do not have arguments: a program is just an expression exp.

#### A.4 STANDARD LIBRARY

Several functions are predefined:

function print(s : string)  
    Print s on standard output.
function flush()  
    Flush the standard output buffer.
function getchar() : string  
    Read a character from standard input; return empty string on end of file.
function ord(s: string) : int  
    Give ASCII value of first character of s; yields -1 if s is empty string.
function chr(i: int) : string  
    Single-character string from ASCII value i; halt program if i out of range.
function size(s: string) : int  
    Number of characters in s.
function substring(s:string, first:int, n:int) : string  
    Substring of string s, starting with character first, n characters long. Characters are numbered starting at 0.
function concat (s1: string, s2: string) : string  
    Concatenation of s1 and s2.
function not(i : integer) : integer  
    Return (i=0).
function exit(i: int)  
    Terminate execution with code i.
A.5

SAMPLE Tiger PROGRAMS

On this page and the next are two complete Tiger programs; Program 6.3 (page 134) is a fragment (one function) of a Tiger program.

**QUEENS.TIG**

/* A program to solve the 8-queens problem */
let
  var N := 8

type intArray = array of int

var row := intArray [ N ] of 0
var col := intArray [ N ] of 0
var diag1 := intArray [N+N-1] of 0
var diag2 := intArray [N+N-1] of 0

function printboard() =
  (for i := 0 to N-1
   do (for j := 0 to N-1
       do print(if col[i]=j then " O" else " .");
       print("\n"));
   print("\n"))

function try(c:int) =
  if c=N
    then printboard()
  else for r := 0 to N-1
    do if row[r]=0 & diag1[r+c]=0 & diag2[r+7-c]=0
      then (row[r]:=1; diag1[r+c]:=1; diag2[r+7-c]:=1;
          col[c]:=r;
          try(c+1);
          row[r]:=0; diag1[r+c]:=0; diag2[r+7-c]:=0)
    in try(0)
  end

This program prints out all the ways to put eight queens on a chessboard so that no two are in the same row, column, or diagonal. It illustrates arrays and recursion. Suppose we have successfully placed queens on columns 0 to \( c - 1 \). Then \( \text{row}[r] \) will be 1 if the \( r \)th row is occupied, \( \text{diag1}[d] \) will be 1 if the \( d \)th lower-left-to-upper-right diagonal is occupied, and \( \text{diag2}[d] \) will be 1 if the \( d \)th upper-left-to-lower-right diagonal is occupied. Now, \( \text{try}(c) \) attempts to place the queens in rows \( c \) to \( N - 1 \).
**MERGE.TIG**

This program reads two lists of integers from the standard input; the numbers in each list should be sorted in increasing order, separated by blanks or newlines; each list should be terminated by a semicolon.

The output is the merge of the two lists: a single list of integers in increasing order.

The any record is used to simulate call by reference in Tiger. Although readint cannot update its argument (to signify whether any more numbers remain on the input), it can update a field of its argument.

The assignment any:=any{any=0} illustrates that a name can mean a variable, a type, and a field, depending on context.

```tiger
let type any = {any : int}
  var buffer := getchar()

function readint(any: any) : int =
  let var i := 0
  function isdigit(s : string) : int =
    ord(buffer)>=ord("0") & ord(buffer)<=ord("9")
  in while buffer=" " | buffer="\n" do buffer := getchar()
    any.any := isdigit(buffer);
  while isdigit(buffer)
    do (i := i*10+ord(buffer)-ord("0");
        buffer := getchar());
  i

end

type list = {first: int, rest: list}

function readlist() : list =
  let var any := any{any=0}
  var i := readint(any)
  in if any.any
    then list{first=i,rest=readlist()}
  else (buffer := getchar(); nil)
end

function merge(a: list, b: list) : list =
  if a=nil then b
  else if b=nil then a
  else if a.first < b.first
    then list{first=a.first,rest=merge(a.rest,b)}
  else list{first=b.first,rest=merge(a,b.rest)}

function printint(i: int) =
  let function f(i:int) = if i>0
    then (f(i/10); print(chr(i-i/10*10+ord("0"))))
  in if i<0 then (print("-"); f(-i))
  else if i>0 then f(i)
  else print("0")
end

function printlist(l: list) =
  if l=nil then print("\n")
  else (printint(l.first); print(" "); printlist(l.rest))

/* BODY OF MAIN PROGRAM */
in printlist(merge(readlist(), readlist()))
end
```

template, 350
temporary variable, 141
terminal symbol, 41
thunk, 338–341, 344, 348
Tiger
  abstract syntax, 97–101
  instruction selection, 205–214
  language, 518–525
tile, 191–206, 212, 257–259
  cost, 197
  optimum vs. optimal, 194
tools, compiler generation, 5, 201
trace, 186–188
trace scheduling, 489, 493
Translate module, 142, 154
tree
  canonical, see intermediate representa-
    tion, canonical
data structures, 7
  intermediate representation, 6
parse, see parse tree
pattern, see tile
pattern matching, 201
red-black, 108
register allocation for, 257–260
search, see search tree
Tree intermediate representation, 151–154, 266
Tree module, 152
type
  checking, 115–122, 354–359
  constructor, 352
  equivalence, 114, 355, 357
  generalization, 364
  hierarchy analysis, 311
  Hindley-Milner, 362, 368, 379
  inference, 359–369
  instantiation, 365
  metavariable, 362
  passing, 377, 379
  polymorphic, 352
  propagation, 311
  recursive, 114, 359
  substitution, 355, 373
  unification, 357, 362–364
Types module, 113

unification, see type unification
union-find, 468
unique successor or predecessor property, 462
unreachable code, 428, 453
unroll and jam, 513, 516
unrolling, see loop unrolling
use (of variable), 220
use-def chain, 472
  factored, 469
useless variable, 424
value numbering, 398, 407, 434, 468
varargs, 131
variable
  escaping, see escape
  free, 332
  in frame, 132
  live, see liveness
  local, 125
  useless, 424
view shift, 137, 139, 266
VLIW, 493

WAR, see dependence, write-after-read
WAW, see dependence, write-after-write
work-list algorithms, 249, 396, 441, 452, 455

Yacc, 5, 69–90, 92, 96
