REMARKS: The concept of a nondeterministic automaton, and especially the notion of acceptance, can be nonintuitive and confusing at first. We can, however, explain them in terms that should be familiar, namely those of a *solitaire* game such as "Klondike." The game starts with a certain arrangement of cards, which we can regard as the input, and has a desired "final" position—in Klondike, when all the cards have been built up by suit from ace to king. At each step, the rules of the game dictate how a new arrangement of cards can be reached from the current one—and the element of nondeterminism is that there is often more than one choice of move (otherwise the game would be little fun!). Some positions have no possible move, and lose the game. Most crucially, some positions have moves that unavoidably lead to a loss, and other moves that keep open the possibility of winning. Now for a given position, the important analytical question is, "Is there a way to win?" The answer is "yes" so long as there is at least one sequence of moves that ends in a (or the) desired final position. For the starting position, this condition is much the same as for an input to be accepted by an NFA. (Practically speaking, some winnable starting positions may give so many chances to go wrong along the way that a player may have little chance to find a winning sequence of moves. That, however, is beside the point in defining which positions are *winnable.* If one can always (efficiently!) answer the yes/no question of whether a given position is winnable, then one can always avoid losing moves—and win—so long as the start position is winnable to begin with.)

In any event, the set of strings accepted by a (deterministic or nondeterministic) finite automaton M is denoted by $L(M)$. When we say that M *accepts a language* L, we mean that M accepts all strings in L *and nothing else,* i.e., $L = L(M)$. Two machines are **equivalent** if they accept the same language.

Nondeterminism is capable of modeling many important situations other than solitaire games. Concurrent computing offers some examples. Suppose a device or resource (such as a printer or a network interface) is controllable by more than one process. Each process could change the state of the device in a different way. Since there may be no way to predict the order in which processes may be given control in any step, the evolution of the device may best be regarded as nondeterministic.

Sometimes a state change can occur without input stimulus. This can be modeled by allowing an NFA to make ϵ*-transitions,* which change state without advancing the read head. Then the second argument of δ can be ϵ instead of a character in Σ, and these transitions can even be nondeterministic, for instance if $\delta(q_0, \epsilon) = \{q_1, q_2\}$. It is not hard to see that by suitable "lookahead" on states reachable by ϵ*-transitions,* one can always convert such a machine into an equivalent NFA that does not use them.

EXAMPLE 24.1:

We design an NFA to accept the language $0(0 + 1)^*1$. Recall that this regular expression defines those strings in $\{0, 1\}^*$ that begin with a 0 and end with a 1. A standard way to draw finite automata is exemplified by Fig. 24.2. As a convention, each circle represents a state, and an unlabeled arrow points to the start state (here, state "a"). Final states such as "c" have darker (or double) circles. The transition function δ is represented by the labeled edges. For example, $\delta(\mathrm{a}, 0) = \{\mathrm{b}\}$, and $\delta(\mathrm{b}, 1) = \{\mathrm{b}, \mathrm{c}\}$. When a transition is missing, such as on input 1 from state "a" and on both inputs from state "c," the transition is assumed to lead to an implicit nonaccepting "dead" state, which has transitions to itself on all inputs. In a DFA such a dead state must be included when counting the number of states, while in an NFA it can be left out.

The machine in Fig. 24.2 is nondeterministic since from "b" on input 1 the machine has two choices: stay at "b" or go to "c." Figure 24.3 gives a DFA that accepts the same language. The DFA has four, not three, states, since a dead state reached by an initial '1' is not shown.

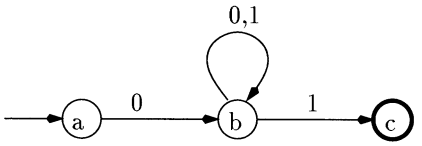

FIGURE 24.2 An NFA accepting $0(0+1)^*1$.

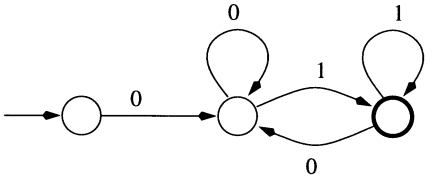

FIGURE 24.3 A DFA accepting $0(0+1)^*1$.

EXAMPLE 24.2:

The DFA in Fig. 24.4 accepts the language of all strings in $\{0, 1\}^*$ with an even number of 1's, which has the regular expression $(0^*10^*1)^*0^*$.

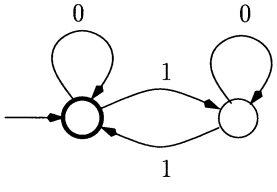

FIGURE 24.4 A DFA accepting $(0^*10^*1)^*0^*$.

EXAMPLE 24.3:

For a final example of a regular language, we introduce a general "tiling problem" to be discussed further in Chapter 26, and then strip it down to a simpler problem. A *tile* is a unit-sized square divided into four quarters by joining two diagonals. Each quarter has a color chosen from a finite set C of colors. Suppose you are given a set T of different types of tiles, and have an unlimited supply of each type. A $k \times n$ rectangle is said to be *tiled* using the tiles in T if the rectangle can be filled with exactly kn unit tiles (with no overlaps) such that at every edge between two tiles, the quarters of the two tiles sharing that edge have the same color. The tile set T is said to *tile* an entire plane if the plane can be covered with tiles subject to the color compatibility stated above. As a standard application of König's infinity lemma (for which see [19, Chapter 2, p. 381]), it can be shown that the entire plane can be tiled with a tile set T if and only if all finite integer sided rectangles can be tiled with T. We will see in Chapter 26 that the problem of whether a given tile set T can tile the entire plane is *unsolvable.* Chapter 26 will also say more about the meaning and implications of this tiling problem.

Here we will consider a simpler problem: Let k be a fixed positive integer. Given a set T of unit tiles, we want to know whether T can tile an infinite *strip* of width k. The answer is yes if T can tile any $k \times n$ rectangle for all n. It turns out that this problem is solvable by an efficient algorithm. One way to design such an algorithm is based on finite automata. We present the solution for $k = 1$ and leave the generalization for other values of k as an exercise. Number the quarters of each tile as in Fig. 24.5. Given a tile set T, we want to know whether for all n, the $1 \times n$ rectangle can be tiled using T.

FIGURE 24.5 Numbering the quarters of a tile.

To use finite automata, we define a language that corresponds to valid tilings. Define Σ, the input alphabet, to be T, the tile set. Each tile in T can be described by a 4-tuple $[A, B, P, Q]$ where A, B, P, and Q are (possibly equal) members of the color set C. Next we define a language L over Σ to be the set of strings $T_1T_2...T_n$ such that (i) each T_i is in Σ, and (ii) for each i, $1 \leq i \leq n-1$, T_i's third-quadrant color is the same as T_{i+1}'s first-quadrant color. These two conditions say that $T_1T_2...T_n$ is a valid $1 \times n$ tiling.

We will now informally describe a DFA M_L that recognizes the language L. Basically, M_L "remembers" (using the current state as the memory) the relevant information—for this problem, it need only remember the third-quadrant color Q of the *most recently seen* tile. Suppose the DFA's current state is Q. If the next (input) tile is $[X, Y, W, Z]$, it is consistent with the last tile if and only if $Q = X$. In this case, the next state will be W. Otherwise, the tile sequence is inconsistent, so M_L enters a "dead state" from which it can never leave and rejects. All other states of M_L are accepting states. Then the infinite strip of width 1 can be tiled if and only if the language L accepted by M_L contains strings of all lengths. There are standard algorithms to determine this property for a given DFA.

The next three theorems show the satisfying result that all the following language classes are identical:

- The class of languages accepted by DFAs;
- The class of languages accepted by NFAs;
- The class of languages generated by regular expressions;
- The class of languages generated by the right-linear, or Type-3, grammars, which are formally defined in Chapter 25 and informally used here.

This class of languages is called the **regular languages.**

THEOREM 24.1 *For every NFA, there is an equivalent DFA.*

PROOF An NFA might look more powerful since it can carry out its computation in parallel with its nondeterministic branches. But since we are working with a *finite number* of states, we can simulate an NFA $M = (Q, \Sigma, \delta, q_0, F)$ by a DFA $M' = (Q', \Sigma, \delta', q_0', F')$, where

- $Q' = \{[S] : S \subseteq Q\}$;
- $q_0' = [\{q_0\}]$;
- $\delta'([S], a) = [S'] = [\cup_{q_l \in S} \delta(q_l, a)]$;
- F' is the set of all subsets of Q containing a state in F.

Here square brackets have been placed around sets of states to help one view these sets as being states of the DFA M'. The idea is that whenever M' has read some initial segment y of its input x, its current state equals the set of states q such that M has a computation path reading y that leads to state q. When all of x is read, this means that M' is in an accepting state if and only if M has an accepting computation path. Hence $L(M) = L(M')$.

EXAMPLE 24.4:

Example 24.1 contains an NFA and an equivalent DFA accepting the same language. In fact the above proof provides an effective procedure for converting an NFA to a DFA. Although each NFA can be converted

to an equivalent DFA, the resulting DFA may require exponentially many more states, since the above procedure may assign a state for every eligible subset of the states of the NFA. For any $k > 0$, consider the language $L_k = \{x \mid x \in \{0, 1\}^*$ and the kth letter from the right of x is a 1$\}$. An NFA of $k + 1$ states (for $k = 3$) accepting L_k is given in Fig. 24.6. Now we claim that any DFA M accepting L_k needs a separate state for every possible value $y \in \{0, 1\}^k$ of the last k bits read. Take any distinct $y_1, y_2 \in \{0, 1\}^k$ and let i be a position in which they differ. Let $z = 0^{k-i}$. Then M must accept one of the strings y_1z, y_2z and reject the other. This is possible only if the state M is in after processing y_1 (with z to come) is different from that after y_2, and thus M needs a different state for each string in $\{0, 1\}^k$. The 2^k required states are also sufficient, as the reader may verify.

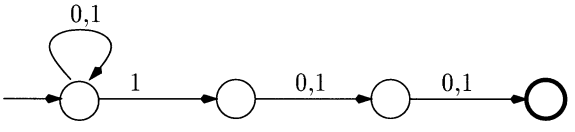

FIGURE 24.6 An NFA accepting L_3.

The remaining results of this section point forward to the **formal-language** models defined in Chapter 25. The point of including them here is to show the power of the finite automaton model. Regular expressions have been defined above, while a *regular grammar* over Σ consists of a set V of variable symbols, a starting variable $S \in V$, and a set P of substring-rewrite rules of the forms $A \to cB$, $A \to \epsilon$, or $A \to c$, where $A, B \in V$ and $c \in \Sigma$.

THEOREM 24.2 *A language L is generated by a regular grammar if and only if L is accepted by an NFA.*

PROOF Let L be accepted by an NFA $M = (Q, \Sigma, \delta, q_0, F)$. We define an equivalent regular grammar $G = (\Sigma, V, S, P)$ by taking $V = Q$ with $S = q_0$, adding a rule $q_i \to cq_j$ whenever $q_j \in \delta(q_i, c)$, and adding rules $q_j \to \epsilon$ for all $q_j \in F$. Then the grammar simulates computations by the NFA in a direct manner, giving $L(G) = L(M)$.

Conversely, suppose L is the language of a regular grammar $G = (\Sigma, V, S, P)$. We design an NFA $M = (Q, \Sigma, \delta, q_0, F)$ by taking $Q = V \cup \{f\}$, $q_0 = S$, and $F = \{f\}$. To define the δ function, we have $B \in \delta(A, c)$ iff $A \to cB$. For rules $A \to c$, $\delta(A, c) = \{f\}$. Then $L(M) = L(G)$—if this is not clear already, the treatment of grammars in Chapter 25 will make it so.

THEOREM 24.3 *A language L is specified by a regular expression if and only if L is accepted by an NFA.*

PROOF PROOF SKETCH. *Part 1.* We inductively convert a regular expression to an NFA that accepts the same language as follows.

- The pattern ϵ converts to the NFA $M_\epsilon = (\{q\}, \Sigma, \emptyset, q, \{q\})$, which accepts only the empty string.
- The pattern $\emptyset$ converts to the NFA $M_\emptyset = (\{q\}, \Sigma, \emptyset, q, \emptyset)$, which accepts no strings at all.
- For each $c \in \Sigma$, the pattern c converts to the NFA $M_c = (\{q, f\}, \Sigma, \delta(q, c) = \{f\}, q, \{f\})$, which accepts only the string c.
- A pattern of the form $\alpha + \beta$, where α and β are regular expressions that (by induction hypothesis) have corresponding NFAs M_α and M_β, converts to an NFA M that connects M_α and M_β in parallel: M includes all the states and transitions of M_α and M_β and has an extra start state q_0, which is connected by ϵ-transitions to the start states of M_α and M_β.

- A pattern of the form $\alpha \cdot \beta$, where α and β have the corresponding NFAs M_α and M_β, converts to an NFA M that connects M_α and M_β in series: M includes all the states and transitions of M_α and M_β and has extra ϵ-transitions from the final states of M_α to the start state of M_β. The start state of M is that of M_α, while the final states of M are those of M_β.
- A pattern of the form α^*, where α has the corresponding NFA M_α, converts to an NFA M that figuratively feeds M_α back into itself. M includes the states and transitions of M_α, plus ϵ-transitions from the final states of M_α back to its start state. This state is not only the start state of M but the only final state of M as well.

Part 2. We now show how to convert an NFA to an equivalent regular expression. The idea used here is based on [2]; see also [3] and [41].

Given an NFA M, add a new final state t, and add ϵ-transitions from each old final state of M to t. Also add a new start state s with an ϵ-transition to the old start state of M. The idea is to eliminate all states p other than s and t as follows. To eliminate a state p, we eliminate each arc coming in to p from some other state q as follows: For each triple of states q, p, q' as shown in Fig. 24.7(a), add the transition(s) shown in Fig. 24.7(b). (Note that if p does not have a transition leading back to p, then $\beta = \beta^* = \epsilon$.) After we have considered all such triples, we can delete state p and transitions related to p. Finally, we obtain Fig. 24.8, and the final α is a regular expression for $L(M)$.

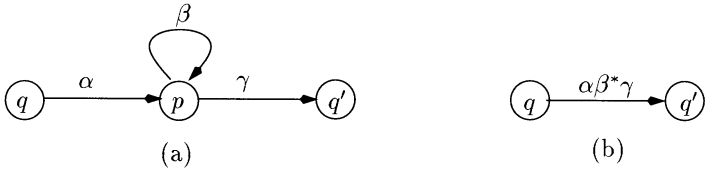

FIGURE 24.7 Converting an NFA to a regular expression.

FIGURE 24.8 The reduced NFA.

The last three theorems underline the importance of the class of regular languages, since it connects to notions of automata, grammars, patterns, and much else. However, regular languages and finite automata are not powerful enough to serve as our model for a modern computer. Many extremely simple languages cannot be accepted by DFAs. For example, $L = \{xx \mid x \in \{0, 1\}^*\}$ cannot be accepted by a DFA. To show this, we can argue similarly to the "L_k" languages in Example 24.4 that for any two strings $y_1 = 0^m1$ and $y_2 = 0^n1$ with $n \neq m$, a hypothetical DFA M would need to be in a different state after processing y_1 from that after y_2, because with $z = 0^m1$ it would need to accept y_1z and reject y_2z. However, in this case we would conclude that M needs *infinitely* many states, contradicting the definition of a *finite* automaton. Hence the language L is not regular. Other ways to prove assertions of this kind include so-called "pumping lemmas" or a direct argument that some strings y contain more information than a *finite* state machine can *remember* [26]. We refer the interested readers to Chapter 25 and textbooks such as [10, 11, 15, 41].

One can also try to generalize the DFA to allow the input head to move backwards as well as forwards, in order to review earlier parts of the input string, while keeping it read-only. However, such "two-way DFAs" are not more powerful—they can be simulated by normal DFAs. The point of departure for a

more-powerful model is to allow the machine to *write* on its tape and later review what it has written. Then the tape becomes a *storage* medium, not just a sequence of events to react to. This ability to write down intermediate results for future reference makes DFAs into full-blown general-purpose computers.

Turing Machines

A **Turing machine** (TM), pictured in Fig. 24.9, consists of a *finite control,* an infinite *tape* divided into cells, and a read/write *head* on the tape. The finite control can be in any one of a finite set Q of states. Each cell can contain one symbol from the *tape alphabet* Γ, which contains the *input alphabet* Σ and a special character B called the *blank.* Γ may contain other characters besides B and those in Σ, but most often $\Sigma = \{0, 1\}$ and $\Gamma = \{0, 1, B\}$. We refer to the two directions on the tape as *left* and *right,* and abbreviate them by L and R. At any time, the head is positioned over a particular cell that it is said to *scan.* Initially, the head scans a distinguished cell on the tape called the *start cell,* the finite control is in the start state q_0, and all cells contain B except for a contiguous finite sequence of cells, extending from the start cell to the right, that contain characters in Σ. These cells hold the *input string* x; in case $x = \epsilon$ the whole tape is blank. The machine is said to begin its computation on input x at time 0, and computation unfolds in discrete time steps numbered $1, 2, \ldots$.

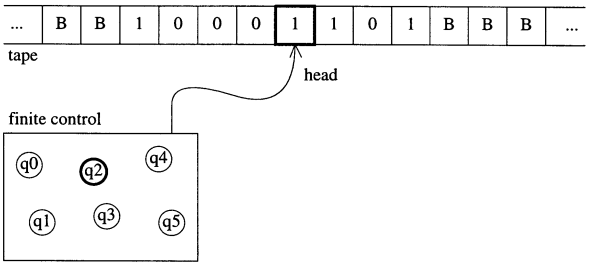

FIGURE 24.9 A Turing machine.

In any step, contingent on its current state and the character being scanned, the device is allowed to perform one the following two basic operations:

1. Write a symbol from the tape alphabet Γ into the scanned cell, or
2. Shift the head one cell left or right.

Then it may change its internal state in the same step. The allowed actions of a particular machine are specified by a finite set δ of *instructions.* Each instruction has the form (q, c, d, r) with $q, r \in Q, c \in \Gamma$, and either $d \in \Gamma$ or $d \in \{L, R\}$. This means that if the machine is in state q scanning character c on the tape, it may either change c to d (if $d \in \Gamma$) or move its head (if $d \in \{L, R\}$), and it enters state r. Either $c = d$ or $q = r$ is allowed. (Many texts use an alternate formalism in which *both* basic operations may be performed in the same step, so that instructions have the form (q, c, d, D, r) with $q, r \in Q, c, d \in \Gamma$, and $D \in \{L, R\}$, sometimes adding the option $D = S$ of keeping the head stationary. The differences do not matter for our purposes.)

If for every combination of q and c there is at most one instruction (q, c, d, r) that the machine can execute, then the machine is *deterministic.* Otherwise, the machine is *nondeterministic.* In order for computations to possibly halt, there must be some combinations q, c for which δ has *no* instruction (q, c, d, r). If a computation reaches such a state q while scanning c, the device is said to *halt.* Then if q is designated as a final state, we say the machine *accepts* its input string x; if q is not a final state, we say that the machine *rejects* the input. We adopt the convention that there is only one final state labeled q_f, and that q_f is also a halting state, meaning that there is no instruction (q, c, d, r) with source state $q = q_f$ at all.

DEFINITION 24.2 A **Turing machine** is a 7-tuple $M = (Q, \Sigma, \Gamma, \delta, B, q_0, q_f)$, where each of the components has been described above.

Given an input x, a deterministic Turing machine M carries out a uniquely determined succession of operations, which may or may not terminate in a finite number of steps. If it terminates, then the *output* $M(x)$ is determined to be the longest string of characters over Σ beginning in the cell in which the head halted and extending to the right. (If the scanned cell holds B or some other character in $\Gamma \setminus \Sigma$, then the output is ϵ.) A function $f : \Sigma^* \to \Sigma^*$ is **computable** if there is a Turing machine M such that for all inputs $x \in \Sigma^*$, $M(x) = f(x)$.

A nondeterministic Turing machine is analogous to an NFA. One may imagine that it carries out its computation in parallel. The computation may be viewed as a (possibly infinite) tree, each of whose nodes is labeled by a configuration of the machine. A *configuration* specifies the current state q, the position of the tape head, and the contents of the tape, including the character c currently being scanned. Each node has as many children as there are different instructions $(q, c, \cdot, \cdot)$ to execute, and each child is the configuration that results from executing the corresponding instruction. The root of the tree is the starting configuration of the machine. If any of the branches terminates in the final state q_f, we say the machine accepts the input. Note that this is the same "benefit of all doubt" criterion for acceptance that we discussed above for NFAs. Note also that a deterministic Turing machine always defines a "tree" with a single branch that forms a simple (possibly infinite) path.

A language L is said to be **recursively enumerable** (**r.e.**) if there is a Turing machine M such that $L = \{x : M \text{ accepts } x\}$. Furthermore, if M is *total,* i.e., if every computation of M on every input x halts, then $L(M)$ is **recursive.** These terms reflect an important correspondence between languages and functions. For any language $L \subseteq \Sigma^*$, define the *characteristic function* f_L by $f_L(x) = 1$ of $x \in L$, $f(x) = 0$ otherwise. Then a language L is recursive if and only if f_L is computable—and **computable functions** were originally defined with regard to formalisms that used *recursion.* Note that having L be acceptable by a Turing machine M is *not* enough for f_L to be computable, because there may be inputs $x \notin L$ for which the computation of M on x never halts.

Conversely, given a function $f : \Sigma^* \to \Sigma^*$, and letting # be a new input symbol not in Σ, one can define the language $L_f = \{x\#y : y \text{ is an initial segment of } f(x)\}$. Recognizing L_f allows one to find successive bits of the value $f(x)$. Hence it is common in the field to identify function problems with language problems and concentrate on the latter. A language can also be identified with a property of strings and with the associated **decision problem** "given a string x, does x have the property?" For instance, the problem of deciding whether a given number is prime is identifiable with the language of (binary string encodings of) prime numbers. The problem is **decidable** if the associated language is recursive, and a total Turing machine accepting the language is said to *decide* the problem. The term "decidable language" is a synonym for "**recursive language,**" and "recursive function" is a synonym for "computable function." A Turing machine M that does not halt on all inputs computes a **partial recursive function** (whose domain is a proper subset of Σ^*), and $L(M)$ is a **partially decidable** language (or problem, or property). Any problem or language that is not decidable by a Turing machine is called **undecidable,** and any (partial or total) function that is not computable by a Turing machine is called **uncomputable.**

Now when we say that a Turing machine M' *simulates* another Turing machine M, we usually mean more than saying they accept the same language or compute the same (partial) function. Usually there is some overt correspondence between computations of M and those of M'. This is so in the simulations claimed by the following theorem, which says that many variations in the basic machine model do not alter the notion of computability.

THEOREM 24.4 *All the following generalizations of Turing machines can be simulated by the one-tape deterministic Turing machine model defined in Definition 24.2, with tape alphabet* $\{0, 1, B\}$.

- *Enlarging the tape alphabet* Γ*;*

- *Adding more tapes;*
- *Adding more read/write heads or other access points on each tape;*
- *Having two- or higher-dimensional grids in place of tapes, where the head may move to any adjacent grid cell;*
- *Allowing nondeterminism.*

Extra tapes after the input tape are called *worktapes* provided they allow read-write access. A two-tape Turing machine, or alternately a one-tape machine with two heads, has instructions with six components: current state, two characters read by the heads, two head actions, next state. Although these generalizations do not make a Turing machine compute more, they do make Turing machines more efficient and easier to **program.** Many more variants of Turing machines have been studied and used in the literature.

Of all the simulations in Theorem 24.4, the last one needs special comment. A nondeterministic computation branches like a tree. The easiest way for a deterministic Turing machine to simulate it is by traversing the tree in a breadth-first manner, which is the same as trying all possibilities at any step with nondeterministic choices. However, even if there are at most two choices at any step, simulating n steps of the NTM could take on the order of 2^n steps by the DTM. Whether a more-efficient simulation is possible is bound up with the famous "P vs. NP" problem, to be discussed below and in Chapter 27.

EXAMPLE 24.5:

A DFA can be regarded as the special case of a Turing machine in which every instruction moves the head right. Turing machines naturally accept more languages than DFAs can. For example, a Turing machine can accept the non-regular language $L = \{xx \mid x \in \{0, 1\}^*\}$ as follows. Given an input string $w \in \{0, 1\}^*$:

- First find the middle point. A TM with two tape heads can do this efficiently by moving one head twice for every move of the other, until the further-advanced head sees the blank that marks the end of w. This stage can also tell whether w has even or odd length and immediately *reject* in the latter case.
- Then check whether the scanned characters match while moving both heads one cell left until the leftmost head sees the blank to the left of the beginning of w. If all pairs match, *accept,* else *reject.*

For a TM with only one head the strategy is more cumbersome. One way is to use "alias" characters a for 0 and b for 1, aliasing first the leftmost 0/1 character on the tape, then the rightmost, then the next-leftmost,... until finding the character just left of middle (if w has even length). Then "un-alias" it and check that the rightmost aliased character matches it, un-aliasing the latter as well. By looking for cases of an a or b immediately to the left of an un-aliased 0 or 1, the TM can repeat this check until all of the left half is compared with the right half. Whereas the two-head TM needs only $3n/2$ steps to decide whether a string w of length n belongs to L, the one-head TM takes about n^2 steps. It is known that n^2 steps are necessary (asymptotically) for any one-head TM to accept the language L (see, for instance, [15] or [26]).

Three restrictions of the notion of a Turing machine tape merit special mention.

- A *pushdown store* (or *stack*) is a semi-infinite worktape with one head such that each time the head moves to the left, it erases the symbol scanned previously. This is a last-in first-out storage.
- A *queue* is a semi-infinite work tape with two heads that only move to the right, the leading head is write-only and the trailing head is read-only. This is a first-in first-out storage.
- A *counter* is a pushdown store with a single-letter alphabet, except for a special bottom-of-stack marker that allows testing the counter for zero. Then a push increments the counter by one, and a pop decrements it by one.

EXAMPLE 24.6:

A **pushdown automaton** (PDA) has one read-only input tape and one pushdown store. A PDA can be identified with a two-tape Turing machine whose tape-1 head can never move left and whose tape-2 head can move left only while scanning a blank (combined with a previous step that writes a blank, this simulates popping the stack).

Pushdown automata have been thoroughly studied because nondeterministic PDAs accept precisely the class of context-free languages, to be defined in Chapter 25. Various types of PDAs have fundamental applications in compiler design.

The PDA has less power than a Turing machine. For example, $L = \{xx \mid x \in \{0, 1\}^*\}$ cannot be accepted by a PDA, but it can be accepted by a Turing machine as in Example 24.5. However, a PDA is more powerful than a DFA. For example, a PDA can accept the nonregular language $L' = \{0^n 1^n \mid n \geq 0\}$ easily: For each initial 0 read, push a 0 onto the stack; then pop a 0 for each 1 read, and accept if and only if a blank is read after the block of 1s exactly when the stack is empty. Indeed, this PDA is a counter machine with a single counter.

Two pushdown stores can easily be used to simulate a tape—let one stack represent the part of the tape currently to the left of the input head, and let the other stack represent the rightward portion. Much more subtle is the fact that two *counters* can simulate a tape; unlike the two-pushdown case this takes exponentially more time. Finally, a single queue can simulate a tape: send the lead head to the right end so that it can write the next-step update of the configuration that the trailing head is reading. This involves encoding the current state of the TM being simulated onto the tape of the queue machine that is simulating it. Hence a single-queue machine, with the input initially resting in the queue, is as powerful as a Turing machine, although it may require the square of the running time. For comparisons of powers of pushdown stores, queues, counters, and tapes, see [40, 26].

Much more important is the fact that there are single Turing machines that are capable of simulating *any* Turing machine. Formally, a **universal Turing machine** U takes an encoding $\langle M, w\rangle$ of a (deterministic) Turing machine M and a string w as input, and simulates M on input w. U accepts $\langle M, w\rangle$ if and only if M accepts w. Intuitively, U models a general-purpose computer that takes a "program" M and "data" w, and executes M on input w. Universal Turing machines have many applications. For example, the definition of Kolmogorov complexity (see [26]) fundamentally relies on them.

EXAMPLE 24.7:

Let $L_u = \{\langle M, w\rangle | M \text{accepts} w\}$. Then L_u is *the* language accepted by a universal Turing machine, so it is recursively enumerable. We shall see in Chapter 26, however, that L_u is not recursive. The same properties hold for the language $L_h = \{\langle M, w\rangle : M \text{ on input } w \text{ halts}\}$, which is the language of the so-called **Halting Problem.**

Oracle Turing Machines

In order to study the comparative hardness of computational problems, we often need to extend the power of Turing machines by adding oracles to them.

Informally, a Turing machine T with an *oracle* A operates similarly to a normal Turing machine, with the exception that it can write down a string z and ask whether z is in the language A. The machine gets the correct yes/no answer from the oracle in one step, and can branch its computation accordingly. This feature can be used as often as desired. We now give the definition precisely.

DEFINITION 24.3 An **oracle Turing machine** is a normal Turing machine T with an extra *oracle query tape,* a special state $q_?$, and two distinguished states labeled q_y and q_n. Let A be any language over an

alphabet Σ. Whenever T enters state $q_?$ with some string $z \in \Sigma^*$ on the query tape, control passes to state q_y if $z \in A$, or to q_n if $z \notin A$. The computation continues normally until the next time the machine enters $q_?$. The machine T with a given choice of oracle A is denoted by T^A.

EXAMPLE 24.8:

In Example 24.7, we know that the universal language $L_u = \{\langle M, w\rangle | M \text{accepts } w\}$ is not Turing decidable. But if we can use L_u as the oracle set, there is a trivial oracle TM T such that T with oracle L_u decides L_u. T simply copies its input x onto the query tape and enters $q_?$. If control passes to q_y, T accepts; otherwise from q_n it rejects.

For something less trivial, suppose we have $L_h = \{\langle M, w\rangle : M \text{ on input } w \text{ halts}\}$ as the oracle set. Given a (non-oracle) Turing machine M, there is a standard way to modify M to the code of an equivalent Turing machine M' in which the accepting state q_f is the only place where M' can halt. This is done by making every other combination q, c where M might halt send control to an extra state that causes an infinite loop. Thus M' halts on w if and only if M accepts w. Now design an oracle Turing machine T' that on any input x of the form $\langle M, w\rangle$ (rejecting if x does not have the form) writes $x' = \langle M', w\rangle$ on the query tape and enters $q_?$, accepting if control goes to q_y and rejecting from q_n. Then T' with oracle set L_h decides whether $x \in L_u$, since $x \in L_u \iff x' \in L_h$. This is a simple case where an oracle for one problem helps one decide a different problem.

A language A is **Turing-reducible** to a language B, written $A \leq_T B$, if there is an oracle Turing machine that with oracle B decides A. For example, we have just shown that $L_u \leq_T L_h$. The important special case in which the oracle TM T makes exactly one query, accepting from q_y and rejecting from q_n, gets its own notation: $A \leq_m B$. Equivalently, $A \leq_m B$ if there is a computable function f such that for all $x \in \Sigma^*, x \in A \iff f(x) \in B$. The function f represents the computation done by T prior to making the sole query. This case is called a **many-one reduction** (hence the subscript "m") for the arcane historical reason that f need not be a one-to-one function. The term "many-one reduction" is standard now. The above example actually shows that $L_u \leq_m L_h$. It is not hard to show that also $L_h \leq_m L_u$, so that the Halting Problem and the membership problem for a universal Turing machine are *many-one equivalent.*

Alternating Turing Machines

Turing machines can be naturally generalized to model parallel computation. A nondeterministic Turing machine accepts an input if there exists a move sequence leading to acceptance. We can call any nondeterministic state entered along this sequence an *existential state.* We can naturally add another type of state, a *universal state.* When a machine enters a universal state, the machine will accept if and only if *all* moves from this state lead to acceptance. These machines are called **alternating Turing machines.**

Let us describe the computation of alternating Turing machines formally and precisely. An alternating Turing machine is simply a nondeterministic Turing machine with the extra power that some states can be universal. A *configuration* of an alternating Turing machine A has the same form as was described for a deterministic Turing machine, namely,

```
(current state, tape contents, head positions).
```

We write

$$\alpha \vdash \beta$$

if, in one step, A can move from configuration α to configuration β. A configuration with current state q is *accepting* if

- q is an accepting state (i.e., $q = q_f$); or
- q is existential, and there exists an accepting configuration β such that $\alpha \vdash \beta$; or

- q is universal, and or each configuration β such that $\alpha \vdash \beta$, β is an accepting configuration.

This definition may seem circular, but by working backwards from configurations with q_f in the current-state field, one may verify that it inductively defines the set of accepting configurations in a natural manner. Then A accepts an input x if its initial configuration (with current state q_0, x on the input tape, heads at initial positions) is accepting.

Alternating Turing machines were first proposed by [4] for the purpose of modeling parallel computation. In order to allow sublinear computation times, a random-access model is used to read the input. When in a special "read" state, the alternating Turing machine is allowed to write a number in binary which is then interpreted as the address of a location on the input tape, whose symbol is then read in unit time. By using universal states to relate different branches of the computation, one can effectively read the whole input in as little as logarithmic time.

Just as a nondeterministic Turing machine is a model for solitaire games, an alternating Turing machine is a model for general two-person games. Alternating Turing machines have been successfully used to provide a theoretical foundation of parallel computation as well as to establish the complexity of various two person games. For example, a chess position with White to move can be modeled from White's point of view as a configuration α whose first component is an existential state. The position is winning if there exists a move for White such that the resulting position β is winning. Here β with Black to move has a universal state q, and is a winning position (for White) if and only if either Black is checkmated (this is the base case $q = q_f$) or for all moves by Black to a position γ, γ is a winning position for White. Chapter 28, Sections 28.5 and 28.6, will demonstrate the significance of games for time and space complexity, to which we now turn.

24.3 Time and Space Complexity

With Turing machines, we can now formally define what we mean by time and space complexity. The formal investigation by [1, 14] in the 1960s marked the beginning of the field of *computational complexity.*

An important point with space complexity is that a machine should be charged only for those cells it uses for calculation, and not for read-only input, which might be provided on cheaper non-writable media such as CD-ROM or accessed piecemeal over a network. Hence we modify the Turing machine of Fig. 24.9 by making the tape containing the input read-only, and giving it one or more worktapes.

DEFINITION 24.4 Let M be a Turing machine. If for all n, every sequence of legal moves on an input x of length n halts within $t(n)$ steps, we say that M is of **time complexity** $t(n)$. Similarly, if every such sequence uses at most $s(n)$ *worktape* cells, then M is of **space complexity** $s(n)$.

THEOREM 24.5 *Fix a number $c > 0$, a space bound $s(n)$, and a time bound $t(n)$.*

(a) Any Turing machine of $s(n)$ space complexity, using any number of tapes or grids of any dimension, can be simulated by a Turing machine with a single (one-dimensional) worktape that has space complexity $s(n)/c$.

(b) Any Turing machine of $t(n)$ time complexity can be simulated by a Turing machine, with the same number and kinds of worktapes, that has time complexity $n + t(n)/c$.

The proof of these so-called *linear speed-up theorems* involves enlarging the original TM's worktape alphabet Γ to an alphabet Γ' large enough that one character in Γ' can encode a block of c consecutive characters on a tape of the original machine (see [15]). The extra "$n+$" in the time for part (b) is needed to read and translate the input into the "compressed" alphabet Γ'. If we think of memory in units of bits the idea that this saves space and time is illusory, but if we regard the machine with Γ' as having a larger

word size, the savings make sense. Definition 24.4 is phrased in a way that applies also to nondeterministic and alternating TMs, and the two statements in Theorem 24.5 hold for them as well.

In Theorem 24.5, if $s(n) \geq n$, then we do not need to separate the input tape from the worktape(s). For any Turing machine M of linear space complexity, part (a) implies that we can simulate M by a one-tape TM M' that on any input x uses only the cells initially occupied by x (except for one visit to the blank cell to the right of x to tell where x ends). Then M' is called a *linear bounded automaton.*

The main import and convenience of Theorem 24.5 is that one does not need to use "$O()$-notation" to define complexity classes: space complexity $O(s(n))$ is no different from space complexity $s(n)$, and similarly for time. As we shall see, it is not always possible to reduce the number of tapes and run in the same time complexity, so researchers have settled on Turing machines with any finite number of tapes as the bench model for time complexity.

DEFINITION 24.5

- DTIME$[t(n)]$ is the class of languages accepted by multitape deterministic TMs in time $t(n)$;
- NTIME$[t(n)]$ is the class of languages accepted by multitape nondeterministic TMs in time $t(n)$;
- DSPACE$[s(n)]$ is the class of languages accepted by deterministic TMs in space $s(n)$;
- NSPACE$[s(n)]$ is the class of languages accepted by multitape nondeterministic TMs in space $O(s(n))$;
- P is the complexity class $\bigcup_{c\in\mathcal{N}}$ DTIME$[n^c]$;
- NP is the complexity class $\bigcup_{c\in\mathcal{N}}$ NTIME$[n^c]$;
- PSPACE is the complexity class $\bigcup_{c\in\mathcal{N}}$ DSPACE$[n^c]$;
- ATIME$[s(n), t(n)]$ is the class of languages accepted by alternating Turing machines operating simultaneously in time $t(n)$ and space $s(n)$.

EXAMPLE 24.9:

In Example 24.5 we demonstrated how the language $L = \{xx | x \in \{0, 1\}^*\}$ can be decided by a Turing machine. We gave a two-head, one-tape TM running in time $3n/2$, and it is easy to design a two-tape, one-head-per-tape TM that executes the same strategy in time $2n$. Theorem 24.5 says that by using a larger tape alphabet, one can push the time down to $(1 + \epsilon)n$ for any fixed $\epsilon > 0$. However, our basic one-tape, one-head Turing machine model can do no better than time on the order of n^2.

EXAMPLE 24.10:

Any multitape, multihead Turing machine, not just the one accepting L in the last example, can be simulated by our basic one-tape, one-head model in at most the square of the original's running time. For example, a two-tape machine M with tape alphabet Γ can be simulated by a one-tape machine M' with a Γ' large enough to encode all pairs of characters over Γ. Then M' can regard its single tape as having two "tracks," one for each tape of M. M' also needs to mark the locations of the two heads of M, one on each track—this can be facilitated by adding more characters to Γ'. Now to simulate one step of M, the one-tape machine M' must use its single head to update the computation at the two locations with the two head markers. If M runs in time $t(n)$, then the two head markers cannot be more than $t(n)$ cells apart. Thus to simulate each step by M, M' moves its head for at most $t(n)$ distance. Hence M' runs in time at most $t(n)^2$.

The simulation idea in Example 24.10 does not work if M uses two- or higher-dimensional tapes, or a more-general "random-access" storage (see the next section). However, a one-tape M' can be built to simulate it whose running time is still no worse than a polynomial in the time of M. It is important to note that our basic one-tape deterministic Turing machine is known to simulate all of the extended models we offer above and below—except nondeterministic and alternating TMs—with at most polynomial slowdown. This is a key point in taking the class P, defined as above in terms of Turing machine time, as the benchmark for which languages and functions are considered *feasibly computable* for general computation. (See Chapter 27 for more discussion of this point.) Polynomial time for nondeterministic Turing machines defines the class NP. Interestingly, polynomial space for nondeterministic TMs does equal polynomial space for deterministic TMs [34], and polynomial *time* for *alternating* TMs equals the same class, namely PSPACE.

EXAMPLE 24.11:

All of the basic arithmetical operations—plus, minus, times, and division—belong to P. Given two n-digit integers x and y, we can easily add or subtract them in $O(n)$ steps. We can multiply or divide them in $O(n^2)$ steps using the standard algorithms learned in school. Actually, by grouping blocks of digits in x and y and using some clever tricks one can bring the time down to $O(n^{1+\epsilon})$ bit-operations for any desired fixed $\epsilon > 0$, and the asymptotically fastest method known takes time $O(n \log n \operatorname{loglog} n)$ [37]. Computing x^y is technically not in P because the sheer length of the output may be exponential in n, but if we measure time as a function of output length as well as input length, it is in P. However, the operation of *factoring* a number into primes, which is a kind of inverse of multiplication, is commonly believed *not* to belong to P. The language associated to the factoring function (refer to "L_f" before Theorem 24.4 above) does belong to NP.

EXAMPLE 24.12:

There are many other important problems in NP that are not known to be in P. For example, consider the following "King Arthur" problem, which is equivalent to the problem called HAMILTONIAN CIRCUIT in Chapter 28. King Arthur plans to have a round table meeting. By one historical account he had 150 knights, so let $n = 150$. It is known that some pairs of knights hate each other, and some do not. King Arthur's problem is to arrange the knights around a round table so that no pair of knights who sit side by side hate each other. King Arthur can solve this problem by enumerating all possible permutations of n knights. But even at $n = 150$, there are 150! permutations. All the computers in the whole world, even if they started a thousand years ago and worked non-stop, would still be going on today, having examined only a tiny fraction of the 150! permutations. However, this problem is in NP because a nondeterministic Turing machine can just guess an arrangement and verify the correctness of the solution—by checking if any two neighboring knights are enemies—in polynomial time. It is currently unknown if every problem in NP is also in P. This problem has a special property—namely, if it is in P then every problem in NP is also in P.

The following relationships are true:

$$\mathrm{P} \subseteq \mathrm{NP} \subseteq \mathrm{PSPACE}\ .$$

Whether or not either of the above inclusions is proper is one of the most fundamental open questions in computer science and mathematics. Research in computational complexity theory centers around these questions. The first step in working on these questions is to identify the hardest problems in NP or PSPACE.

DEFINITION 24.6 Given two languages A and B over an alphabet Σ, a function $f : \Sigma^* \to \Sigma^*$ is

called a **polynomial-time many-one reduction** from A to B if

(a) f is polynomial-time computable, and
(b) for all $x \in \Sigma^*$, $x \in A$ if and only if $f(x) \in B$.

One also writes $A \leq_m^p B$.

The only change from the definition of "many-one reduction" at the end of "Oracle Turing Machines" is that we have inserted "polynomial-time" before "computable." There is also a polynomial-time version of Turing reducibility as defined there, which gets the notation $A \leq_T^p B$.

DEFINITION 24.7 A language B is called **NP-complete** if

1. B is in NP;
2. for every language $A \in$ NP, $A \leq_m^p B$.

In this definition, if only the second item holds, then we say the language B is *NP-hard.* (Curiously, while "NP-complete" is always taken to refer by default to polynomial-time many-one **reductions,** "NP-hard" is usually extended to refer to polynomial-time **Turing reductions.**) The upshot is that if a language B is NP-complete and B is in P, then NP = P. An **NP-complete language** is in this sense a hardest language in the class NP. Working independently, Cook [7] and Levin [24] introduced NP-completeness, and Karp [16] further demonstrated its importance. PSPACE and other classes also have complete languages.

Chapters 27 and 28 of this *Handbook* develop the topics of this section in much greater detail. We also refer the interested reader to the textbooks [10, 15, 25, 41, 42].

24.4 Other Computing Models

Over the years, many alternative computing models have been proposed. Under reasonable definitions of running time for these models, they can all be simulated by Turing machines with at most a polynomial slow-down. The reference [40] provides a nice survey of various computing models other than Turing machines. We will discuss a few such alternatives very briefly and refer our readers to Chapter 45 and [40] for more information.

Random Access Machines

The *random access machine* [8] consists of a finite control where a program is stored, several arithmetic registers, and an infinite collection of memory registers $R[1], R[2], \ldots$. All registers have an unbounded word length. The basic instructions for the program are LOAD, STORE, ADD, MUL, GOTO, and conditional-branch instructions. The LOAD and STORE commands can use indirect addressing. Compared to Turing machines, this appears to be a closer but more complicated approximation of modern computers. There are two standard ways for measuring time complexity of the model:

- The *Unit-cost RAM:* Here each instruction takes one unit of time, no matter how big the operands are. This measure is convenient for analyzing many algorithms.
- The *Log-cost RAM:* Here each instruction is charged for the sum of the lengths of all data manipulated by the instruction. Equivalently, each use of an integer i is charged $\log i$ time units, since $\log i$ is approximately the length of i. This is a more realistic model, but sometimes less convenient to use.

Log-cost RAMs and Turing machines can simulate each other with polynomial overheads. The unit-cost assumption becomes unrealistic when the MUL instruction is used repeatedly to form exponentially large

numbers. Taking MUL out, however, makes the unit-cost RAM polynomially equivalent to the Turing machine as well.

Pointer Machines

Pointer machines were introduced by [22] in 1958 and in modified form by Schönhage in the 1970s. Schönhage called his form the "storage modification machine" [36], and both forms are sometimes named for their authors. We informally describe Schönhage's form here. A pointer machine is similar to a RAM, but instead of having an unbounded array of registers for its memory structure, it has modifiable pointer links that form a Δ-*structure.* A Δ-structure S, for a finite alphabet Δ of size k, is a finite directed graph in which each node has k out-edges labeled by the k symbols in Δ. Every node also has a cell holding an integer, as with a RAM. At every step of the computation, one node of S is distinguished as the *center,* which acts as a starting point for addressing. A word $w \in \Delta^*$ addresses the cell of the node formed by following the path of pointer links selected by the successive characters in w. Besides having all the RAM instructions, the pointer machine has various instructions and rules for moving its center and redirecting pointer links, thus modifying the storage structure. Under the log-cost criterion, pointer machines are polynomially equivalent to RAMs and Turing machines. There are many interesting studies on the precise efficiency of the simulations among these models, and we refer to the reader to the survey [40] as a center for further pointers on them.

Circuits and Nonuniform Models

A *Boolean circuit* is a finite, labeled, directed acyclic graph. Input nodes are nodes without ancestors; they are labeled with input variables $x_1, \ldots, x_n$. The internal nodes are labeled with functions from a finite set of Boolean operations such as {AND, OR, NOT} or {NAND}. The number of ancestors of an internal node is precisely the number of arguments of the Boolean function that the node is labeled with. A node without successors is an output node. The circuit is naturally evaluated from input to output: at each node the function labeling the node is evaluated using the results of its ancestors as arguments. Two cost measures for the circuit model are

- *depth:* the length of a longest path from an input node to an output node.
- *size:* the number of nodes in the circuit.

These measures are applied to a family $\{C_n \mid n \geq 1\}$ of circuits for a particular problem, where C_n solves the problem of size n. Subject to the *uniformity condition* that the layout of C_n be computable given n (in time polynomial in n), circuits are (polynomially) equivalent to Turing machines. Chapters 27 and 45 give full presentations of circuit complexity, while [40, 17] have more details and pointers to the literature.

24.5 Defining Terms

Alternating turing machine: A generalization of a nondeterministic Turing machine. In the latter, every state can be called an existential state since the machine accepts if one of the possible moves leads to acceptance. In an alternating Turing machine there are also universal states, from which the machine accepts only if all possible moves out of that state lead to acceptance.

Algorithm: A finite sequence of instructions that is supposed to solve a particular problem.

Complexity class NP: The class of languages that can be accepted by a nondeterministic Turing machine in polynomial time.

Complexity class P: The class of languages that can be accepted by a deterministic Turing machine in polynomial time.

Complexity class PSPACE: The class of languages that can be accepted by a Turing machine in polynomial space.

Computable function: A function that can be computed by an algorithm—equivalently, by a Turing machine.

Decidable problem/language: A problem that can be decided by an algorithm—equivalently, whose associated language is accepted by a Turing machine that halts for all inputs.

Deterministic: Permitting at most one next move at any step in a computation.

Finite automaton or finite-state machine: A restricted Turing machine where the head is read-only and shifts only from left to right.

(Formal) language: A set of strings over some fixed alphabet.

Halting Problem: The problem of deciding whether a given program (or Turing machine) halts on a given input.

Many-one reduction: A reduction that maps an instance of one problem into an equivalent instance of another problem.

Nondeterministic: Permitting more than one choice of next move at some step in a computation.

NP-complete language: A language in NP such that every language in NP can be reduced to it in polynomial time.

Oracle Turing machine: A Turing machine with an extra oracle tape and three extra states $q_?$, q_y, q_n. When the machine enters $q_?$, control goes to state q_y if the oracle tape content is in the oracle set; otherwise control goes to state q_n.

Partial recursive function: A partial function computed by a Turing machine that need not halt for all inputs.

Partially decidable problem: One whose associated language is recursively enumerable. Equivalently, there exists a program that halts and outputs 1 for every instance having a yes answer, but is allowed not to halt or to halt and output 0 for every instance with a no answer.

Polynomial time reduction: A reduction computable in polynomial time.

Program: A sequence of instructions that can be executed, such as the code of a Turing machine or a sequence of RAM instructions.

Pushdown automaton: A restricted Turing machine where the tape acts as a pushdown store (or a stack), with an extra one-way read-only input tape.

Recursive language: A language accepted by a Turing machine that halts for all inputs.

Recursively enumerable (r.e.) language: A language accepted by a Turing machine.

Reduction: A computable transformation of one problem into another.

Regular language: A language which can be described by some right-linear/regular grammar (or equivalently by some regular expression).

Time/space complexity: A function describing the maximum time/space required by the machine on any input of length n.

Turing machine: A simplest formal model of computation consisting a finite-state control and a semi-infinite sequential tape with a read-write head. Depending on the current state and symbol read on the tape, the machine can change its state and move the head to the left or right. Unless otherwise specified, a Turing machine is deterministic.

Turing reduction: A reduction computed by an oracle Turing machine that halts for all inputs with the oracle used in the reduction.

Uncomputable function: A function that cannot be computed by any algorithm—equivalently, not by any Turing machine.

Undecidable problem/language: A problem that cannot be decided by any algorithm—equivalently, whose associated language cannot be recognized by a Turing machine that halts for all inputs.

Universal Turing machine: A Turing machine that is capable of simulating any other Turing machine if the latter is properly encoded.

Further Information

The fundamentals of the theory of computation, automata theory, and formal languages can be found in Chapters 25 through 27 and in many text books including [10, 11, 12, 15, 25, 38, 41, 42]. One central focus of research in this area is to understand the relationships between different resource complexity classes. This work is motivated in part by some major open questions about the relationships between resources (such as time and space) and the role of control mechanisms (such as nondeterminism or randomness). At the same time, new computational models are being introduced and studied. One recent model that has led to the resolution of a number of interesting problems is the *interactive proofs* (IP) model. IP is defined in terms of two Turing machines that communicate with each other. One of them has unlimited power and the other (called the *verifier*) is a probabilistic Turing machine whose time complexity is bounded by a polynomial. The study of IP has led to new ways to encrypt information as well as to the proof of some unexpected results about the difficulty of solving NP-hard problems (such as coloring, clique etc.) even approximately. See Chapter 29, Sections 3 and 5. Another new model is the *quantum Turing machine,* which can solve in polynomial time some problems such as factoring that are believed to require

exponential time on any hardware that follows the laws of "classical" (pre-quantum) physics. There are also attempts to use molecular or cell-level interactions as the basic operations of a computer.

The following annual conferences present the leading research work in computation theory: ACM Annual Symposium on Theory of Computing (STOC), IEEE Symposium on the Foundations of Computer Science (FOCS), IEEE Conference on Computational Complexity (CCC, formerly Structure in Complexity Theory), International Colloquium on Automata, Languages and Programming (ICALP), Symposium on Theoretical Aspects of Computer Science (STACS), Mathematical Foundations of Computer Science (MFCS), and Fundamentals of Computation Theory (FCT). There are many related conferences in the following areas: computational learning theory, computational geometry, algorithms, principles of distributed computing, computational biology, and database theory. In each case, specialized computational models and concrete algorithms are studied for a specific application area. There are also conferences in both pure and applied mathematics that admit topics in computation theory and complexity. We conclude with a partial list of major journals whose primary focus is in theory of computation: *Journal of the ACM, SIAM Journal on Computing, Journal of Computer and System Sciences, Information and Computation, Theory of Computing Systems* (formerly *Mathematical Systems Theory*), *Theoretical Computer Science, Computational Complexity, Journal of Complexity, Information Processing Letters, International Journal of Foundations of Computer Science,* and *Acta Informatica.*

25.1 Introduction

Formal language theory as a discipline is generally regarded as growing from the work of linguist Noam Chomsky in the 1950s, when he attempted to give a precise characterization of the structure of natural languages. His goal was to define the syntax of languages using simple and precise mathematical rules. Later it was found that the syntax of programming languages can be described using one of Chomsky's grammatical models called **context-free grammars.** Much earlier, the Norwegian mathematician Axel Thue studied sequences of binary symbols subject to interesting mathematical properties, such as not having the same substring three times in a row. His work influenced Emil Post, Stephen Kleene, and others to study the mathematical properties of strings and collections of strings.

Soon after the advent of modern electronic computers, people realized that all forms of information—whether numbers, names, pictures, or sound waves—can be represented as strings. Then collections of strings known as *languages* became central to computer science. This chapter is concerned with fundamental mathematical properties of languages and language generating systems, such as grammars. Every programming language from Fortran to Java can be precisely described by a grammar. Moreover, the grammar allows us to write a computer program (called the *syntax analyzer* in a compiler) to determine whether a string of statements is syntactically correct in the programming language. Many people would wish that natural languages such as English could be analyzed as precisely, that we could write computer programs to tell which English sentences are grammatically correct. Despite recent advances in *natural language processing*, many of which have been spurred by formal grammars and other theoretical tools, today's commercial products for grammar and style fall well short of that ideal. The main problem is that *there is no common agreement* on what are grammatically correct (English) sentences; nor has anyone yet been able to offer a grammar precise enough to propose as definitive. And style is a matter of taste(!) such as not beginning sentences with "and" or using interior exclamations. Formal languages and grammars

have many applications in other fields, including molecular biology (see [17]) and symbolic dynamics (see [14]).

In this chapter, we will present some formal systems that define families of formal languages arising in many computer science applications. Our primary focus will be on **context-free languages,** since they are most widely used to describe the syntax of programming languages. In the rest of this section, we present some basic definitions and terminology.

DEFINITION 25.1 An **alphabet** is a finite nonempty set of *symbols.* Symbols are assumed to be indivisible.

For example, an alphabet for English can consist of as few as the 26 lower-case letters $a, b, \ldots, z$, adding some punctuation symbols if sentences rather than single words will be considered. Or it may include all of the symbols on a standard North American typewriter, which together with terminal control codes yields the 128-symbol ASCII alphabet, in which much of the world's communication takes place. The new world standard is an alphabet called *UNICODE,* which is intended to provide symbols for all the world's languages—as of this writing, over 38,000 symbols have been assigned. But most important aspects of formal languages can be modeled using the simple two-letter alphabet $\{0, 1\}$, over which ASCII and UNICODE are encoded to begin with. We usually use the symbol Σ to denote an alphabet.

DEFINITION 25.2 A **string** over an alphabet Σ is a finite sequence of symbols of Σ.

The number of symbols in a string x is called its *length,* denoted by $|x|$. It is convenient to introduce a notation ϵ for the empty string, which contains no symbols at all. The length of ϵ is 0.

DEFINITION 25.3 Let $x = a_1 a_2 \cdots a_n$ and $y = b_1 b_2 \cdots b_m$ be two strings. The *concatenation* of x and y, denoted by xy, is the string $a_1 a_2 \cdots a_n b_1 b_2 \cdots b_m$.

Then for any string x, $\epsilon x = x\epsilon = x$. For any string x and integer $n \geq 0$, we use x^n to denote the string formed by sequentially concatenating n copies of x.

DEFINITION 25.4 The set of all strings over an alphabet Σ is denoted by Σ^*, and the set of all nonempty strings over Σ is denoted by Σ^+. The empty set of strings is denoted by $\emptyset$.

DEFINITION 25.5 For any alphabet Σ, a **language** over Σ is a set of strings over Σ. The members of a language are also called the *words* of the language.

EXAMPLE 25.1:

The sets $L_1 = \{01, 11, 0110\}$ and $L_2 = \{0^n 1^n | n \geq 0\}$ are two languages over the binary alphabet $\{0, 1\}$. L_1 has three words, while L_2 is infinite. The string 01 is in both languages while 11 is in L_1 but not in L_2.

Since languages are just sets, standard set operations such as union, intersection, and complementation apply to languages. It is useful to introduce two more operations for languages: *concatenation* and *Kleene closure.*

DEFINITION 25.6 Let L_1 and L_2 be two languages over Σ. The concatenation of L_1 and L_2, denoted by $L_1 L_2$, is the language $\{xy | x \in L_1, y \in L_2\}$.

DEFINITION 25.7 Let L be a language over Σ. Define $L^0 = \{\epsilon\}$ and $L^i = LL^{i-1}$ for $i \geq 1$. The *Kleene closure* of L, denoted by L^*, is the language

$$L^* = \bigcup_{i \geq 0} L^i .$$

The *positive closure* of L, denoted by L^+, is the language

$$L^+ = \bigcup_{i \geq 1} L^i .$$

In other words, the Kleene closure of a language L consists of all strings that can be formed by concatenating zero or more words from L. For example, if $L = \{0, 01\}$, then $LL = \{00, 001, 010, 0101\}$, and L^* comprises all binary strings in which every 1 is preceded by a 0. Note that concatenating zero words always gives the empty string, and that a string with no 1s in it still makes the condition on "every 1" true. L^+ has the meaning "concatenate *one* or more words from L," and satisfies the properties $L^* = L^+ \cup \{\epsilon\}$ and $L^+ = LL^*$. Furthermore, for any language L, L^* always contains ϵ, and L^+ contains ϵ if and only if L does. Also note that Σ^* is in fact the Kleene closure of the alphabet Σ when Σ is viewed as a language of words of length 1, and Σ^+ is just the positive closure of Σ.

25.2 Representation of Languages

In general a language over an alphabet Σ is a subset of Σ^*. How can we describe a language rigorously so that we know whether a given string belongs to the language or not? As shown in Example 25.1, a finite language such as L_1 can be explicitly defined by enumerating its elements. An infinite language such as L_2 cannot be exhaustively enumerated, but in the case of L_2 we were able to give a simple rule characterizing all of its members. In English, the rule is, "some number of 0s followed by an equal number of 1s." Can we find systematic methods for defining rules that characterize a wide class of languages? In the following we will introduce three such methods: **regular expressions, pattern systems,** and **grammars.** Interestingly, only the last is capable of specifying the simple rule for L_2, although the first two work for many intricate languages. The term **formal languages** refers to languages that can be described by a body of systematic rules.

Regular Expressions and Languages

Let Σ be an alphabet.

DEFINITION 25.8 The **regular expressions** over Σ and the languages they represent are defined inductively as follows.

1. The symbol $\emptyset$ is a regular expression, and represents the empty language.
2. The symbol ϵ is a regular expression, and represents the language whose only member is the empty string, namely $\{\epsilon\}$.
3. For each $c \in \Sigma$, c is a regular expression, and represents the language $\{c\}$, whose only member is the string consisting of the single character c.
4. If r and s are regular expressions representing the languages R and S, then $(r + s)$, (rs) and (r^*) are regular expressions that represent the languages $R \cup S$, RS, and R^*, respectively.

For example, $((0(0+1)^*) + ((0+1)^*0))$ is a regular expression over $\{0, 1\}$ that represents the language consisting of all binary strings that begin or end with a 0. Since the set operations union and concatenation

are both associative, and since we can stipulate that Kleene closure takes precedence over concatenation and concatenation over union, many parentheses can be omitted from regular expressions. For example, the above regular expression can be written as $0(0+1)^* + (0+1)^*0$. We will also abbreviate the expression rr^* as r^+. Let us look at a few more examples of regular expressions and the languages they represent.

EXAMPLE 25.2:

The expression $0(0 + 1)^*1$ represents the set of all strings that begin with a 0 and end with a 1.

EXAMPLE 25.3:

The expression $0 + 1 + 0(0 + 1)^*0 + 1(0 + 1)^*1$ represents the set of all nonempty binary strings that begin and end with the same bit. Note the inclusion of the strings 0 and 1 as special cases.

EXAMPLE 25.4:

The expressions 0^*, 0^*10^*, and $0^*10^*10^*$ represent the languages consisting of strings that contain no 1, exactly one 1, and exactly two 1's, respectively.

EXAMPLE 25.5:

The expressions $(0+1)^*1(0+1)^*1(0+1)^*$, $(0+1)^*10^*1(0+1)^*$, $0^*10^*1(0+1)^*$, and $(0+1)^*10^*10^*$ all represent the same set of strings that contain at least two 1's.

Two or more regular expressions that represent the same language, as in Example 25.5, are called *equivalent.* It is possible to introduce algebraic identities for regular expressions in order to construct equivalent expressions. Two such identities are $r(s + t) = rs + rt$, which says that concatenation distributes over union the same way "times" distributes over "plus" in ordinary algebra (but taking care that concatenation isn't commutative), and $r^* = (r^*)^*$. These two identities are easy to prove; the reader seeking more detail may consult [16].

EXAMPLE 25.6:

Let us construct a regular expression for the set of all strings that contain no consecutive 0s. A string in this set may begin and end with a sequence of 1s. Since there are no consecutive 0s, every 0 that is not the last symbol of the string must be followed by a 1. This gives us the expression $1^*(01^+)^*1^*(\epsilon + 0)$. It is not hard to see that the second 1^* is redundant and thus the expression can in fact be simplified to $1^*(01^+)^*(\epsilon + 0)$.

Regular expressions were first introduced by [13] for studying the properties of neural nets. The above examples illustrate that regular expressions often give very clear and concise representations of languages. The languages represented by regular expressions are called the **regular languages.** Fortunately or unfortunately, not every language is regular. For example, there are no regular expressions that represent the languages $\{0^n1^n | n \geq 1\}$ or $\{xx \mid x \in \{0, 1\}^*\}$; the latter case is proved in Section 24.2 in Chapter 24.

Pattern Languages

Another way of representing languages is to use *pattern systems* [2] (see also [12]).

DEFINITION 25.9 A **pattern system** is a triple (Σ, V, p), where Σ is the alphabet, V is the set of *variables* with $\Sigma \cap V = \emptyset$, and p is a string over $\Sigma \cup V$ called the *pattern.*

DEFINITION 25.10 The language generated by a pattern system (Σ, V, p) consists of all strings over Σ that can be obtained from p by replacing each variable in p with a string over Σ.

An example pattern system is $(\{0, 1\}, \{v_1, v_2\}, v_1 v_1 0 v_2)$. The language it generates contains all words that begin with a 0 (since v_1 can be chosen as the empty string, and v_2 as an arbitrary string), and contains some words that begin with a 1, such as 110 (by taking $v_1 = 1$, $v_2 = \epsilon$) and 101001 (by taking $v_1 = 10$, $v_2 = 1$). However, it does not contain the strings ϵ, 1, 10, 11, 100, 101, etc. The pattern system $(\{0, 1\}, \{v_1\}, v_1 v_1)$ generates the set of all strings that are the concatenation of two equal substrings, namely the set $\{xx | x \in \{0, 1\}^*\}$. The languages generated by pattern systems are called *pattern languages.*

Regular languages and pattern languages are really different. We have noted that the pattern language $\{xx | x \in \{0, 1\}^*\}$ is not a regular language, and one can prove that the set represented by the regular expression 0^*1^* is not a pattern language. Although it is easy to write an algorithm to decide whether a given string is in the language generated by a given pattern system, such an algorithm would most likely have to be very inefficient [2].

General Grammars

Perhaps the most useful and general system for representing languages is based on the formal notion of a *grammar.*

DEFINITION 25.11 A **grammar** is a quadruple (Σ, V, S, P), where

1. Σ is a finite nonempty set called the **terminal alphabet.** The elements of Σ are called the **terminals.**
2. V is a finite nonempty set disjoint from Σ. The elements of V are called the **nonterminals** or **variables.**
3. $S \in V$ is a distinguished nonterminal called the **start symbol.**
4. P is a finite set of **productions** (or **rules**) of the form

$$\alpha \rightarrow \beta$$

where $\alpha \in (\Sigma \cup V)^* V (\Sigma \cup V)^*$ and $\beta \in (\Sigma \cup V)^*$, i.e., α is a string of terminals and nonterminals containing at least one nonterminal and β is a string of terminals and nonterminals.

EXAMPLE 25.7:

Let $G_1 = (\{0, 1\}, \{S, T, O, I\}, S, P)$, where P contains the following productions

$$\begin{aligned} S &\rightarrow TO \\ S &\rightarrow OI \\ T &\rightarrow SI \\ O &\rightarrow 0 \\ I &\rightarrow 1 \end{aligned}$$

As we shall see, the grammar G_1 can be used to describe the set $\{0^n 1^n | n \geq 1\}$.

EXAMPLE 25.8:

Let $G_2 = (\{0, 1, 2\}, \{S, A\}, S, P)$, where P contains the following productions

$$\begin{aligned} S &\rightarrow 0SA2 \\ S &\rightarrow \epsilon \\ 2A &\rightarrow A2 \\ 0A &\rightarrow 01 \\ 1A &\rightarrow 11 \end{aligned}$$

This grammar G_2 can be used to describe the set $\{0^n 1^n 2^n \geq n \geq 0\}$.

EXAMPLE 25.9:

To construct a grammar G_3 to describe English sentences, one might let the alphabet Σ comprise all English *words* rather than letters. V would contain nonterminals that correspond to the structural components in an English sentence, such as <sentence>, <subject>, <predicate>, <noun>, <verb>, <article>, and so on. The start symbol would be <sentence>. Some typical productions are as follows:

$$\begin{aligned} \text{<sentence>} &\rightarrow \text{<subject><predicate>} \\ \text{<subject>} &\rightarrow \text{<noun>} \\ \text{<predicate>} &\rightarrow \text{<verb><article><noun>} \\ \text{<noun>} &\rightarrow \text{mary} \\ \text{<noun>} &\rightarrow \text{algorithm} \\ \text{<verb>} &\rightarrow \text{wrote} \\ \text{<article>} &\rightarrow \text{an} \end{aligned}$$

The rule <sentence> $\rightarrow$ <subject><predicate> models the fact that a sentence can consist of a subject phrase and a predicate phrase. The rules <noun> $\rightarrow$ mary and <noun> $\rightarrow$ algorithm mean that both "mary" and "algorithm" are possible nouns. This approach to grammar, stemming from Chomsky's work, has influenced even elementary-school teaching.

To explain how a grammar represents a language, we need the following concepts.

DEFINITION 25.12 Let (Σ, V, S, P) be a grammar. A **sentential form** of G is any string of terminals and nonterminals, i.e., a string over $\Sigma \cup V$.

DEFINITION 25.13 Let (Σ, V, S, P) be a grammar, and let γ_1, γ_2 be two sentential forms of G. We say that γ_1 **directly derives** γ_2, written $\gamma_1 \Rightarrow \gamma_2$, if $\gamma_1 = \sigma\alpha\tau$, $\gamma_2 = \sigma\beta\tau$, and $\alpha \rightarrow \beta$ is a production in P.

For example, the sentential form $00S11$ directly derives the sentential form $00OT11$ in grammar G_1, and $A2A2$ directly derives $AA22$ in grammar G_2.

DEFINITION 25.14 Let γ_1 and γ_2 be two sentential forms of a grammar G. We say that γ_1 **derives** γ_2, written $\gamma_1 \Rightarrow^* \gamma_2$, if there exists a sequence of (zero or more) sentential forms $\sigma_1, \ldots, \sigma_n$ such that

$$\gamma_1 \Rightarrow \sigma_1 \Rightarrow \cdots \Rightarrow \sigma_n \Rightarrow \gamma_2 \, .$$

The sequence $\gamma_1 \Rightarrow \sigma_1 \Rightarrow \cdots \Rightarrow \sigma_n \Rightarrow \gamma_2$ is called a **derivation** of γ_2 from γ_1.

For example, in grammar G_1, $S \Rightarrow^* 0011$ because

$$S \Rightarrow \underline{O}T \Rightarrow 0\underline{T} \Rightarrow 0S\underline{I} \Rightarrow 0\underline{S}1 \Rightarrow 0\underline{O}I1 \Rightarrow 00\underline{I}1 \Rightarrow 0011$$

and in grammar G_2, $S \Rightarrow^* 001122$ because

$$S \Rightarrow 0\underline{S}A2 \Rightarrow 00\underline{S}A2A2 \Rightarrow 00\underline{A}2A2 \Rightarrow 0012\underline{A}2 \Rightarrow 0011\underline{A}22 \Rightarrow 001122\,.$$

Here the left-hand side of the relevant production in each derivation step is underlined for clarity.

DEFINITION 25.15 Let (Σ, V, S, P) be a grammar. The language generated by G, denoted by $L(G)$, is defined as

$$L(G) = \left\{ x \,|\, x \in \Sigma^*, S \Rightarrow^* x \right\}\,.$$

The words in $L(G)$ are also called the *sentences* of $L(G)$.

Clearly, $L(G_1)$ contains all strings of the form $0^n 1^n$, $n \geq 1$, and $L(G_2)$ contains all strings of the form $0^n 1^n 2^n$, $n \geq 0$. Although only a partial definition of G_3 is given, we know that $L(G_3)$ contains sentences like "mary wrote an algorithm" and "algorithm wrote an algorithm," but does not contain strings like "an wrote algorithm."

Formal grammars were introduced as such by [15], and had antecedents in work by Thue and others. However, the study of their rigorous use in describing formal (and natural) languages did not begin until the mid-1950s [3]. In the next section, we consider various restrictions on the form of productions in a grammar, and see how these restrictions can affect its power to represent languages. In particular, we will show that regular languages and pattern languages can all be generated by grammars under different restrictions.

25.3 Hierarchy of Grammars

Grammars can be divided into four classes by gradually increasing the restrictions on the form of the productions. Such a classification is due to Chomsky [3, 4] and is called the *Chomsky hierarchy.*

DEFINITION 25.16 Let $G = (\Sigma, V, S, P)$ be a grammar.

1. G is also called a **Type**-0 grammar or an **unrestricted** grammar.
2. G is a **Type-1** or **context-sensitive grammar** if each production $\alpha \rightarrow \beta$ in P satisfies $|\alpha| \leq |\beta|$. By "special dispensation," we also allow a Type-1 grammar to have the production $S \rightarrow \epsilon$, provided S does not appear on the right-hand side of any production.
3. G is a **Type-2** or **context-free** grammar if each production $\alpha \rightarrow \beta$ in P satisfies $|\alpha| = 1$; i.e., α is a single nonterminal.
4. G is a **Type**-3 or **right-linear** or **regular** grammar if each production has one of the following three forms:
$$A \rightarrow cB, \quad A \rightarrow c, \quad A \rightarrow \epsilon\,,$$
where A, B are nonterminals (with $B = A$ allowed) and c is a terminal.

The language generated by a Type-i grammar is called a Type-i language, $i = 0, 1, 2, 3$. A Type-1 language is also called a **context-sensitive language** (CSL), and a Type-2 language is also called a **context-free language** (CFL). The "special dispensation" allows a CSL to contain ϵ, and thus allows one to say that

every CFL is also a CSL. Many sources allow "right-linear" grammars to have productions of the form $A \to xB$, where x is any string of terminals, and/or exclude one of the forms $A \to c$, $A \to \epsilon$ from their definition of "regular" grammar (perhaps allowing $S \to \epsilon$ in the latter case). Regardless of the choice of definitions, every Type-3 grammar generates a regular language, and every regular language has a Type-3 grammar; we have proved this using finite automata in Chapter 24. Stated in other words:

THEOREM 25.1 *The class of Type-3 languages and the class of regular languages are equal.*

The grammars G_1 and G_3 given in the last section are context-free and the grammar G_2 is context-sensitive. Now we give some examples of unrestricted and right-linear grammars.

EXAMPLE 25.10:

Let $G_4 = (\{0, 1\}, \{S, A, O, I, T\}, S, P)$, where P contains

$$\begin{array}{rcl@{\qquad}rcl} S & \to & AT & & & \\ A & \to & 0AO & A & \to & 1AI \\ O0 & \to & 0O & O1 & \to & 1O \\ I0 & \to & 0I & I1 & \to & 1I \\ OT & \to & 0T & IT & \to & 1T \\ A & \to & \epsilon & T & \to & \epsilon \end{array}$$

Then G_4 generates the set $\{xx | x \in \{0, 1\}^*\}$. To understand how this grammar works, think of the nonterminal O as saying, "I must ensure that the right half gets a terminal 0 in the same place as the terminal 0 in the production $A \to 0AO$ that introduced me." The nonterminal I eventually forces the precise placement of a terminal 1 in the right-hand side in the same way. The nonterminal T makes sure that O and I place their 0 and 1 on the right-hand side rather than prematurely. Only after every O and I has moved right past any earlier-formed terminals 0 and 1 and been eliminated "in the context of" T, and the production $A \to \epsilon$ is used to signal that no additional O or I will be introduced, can the endmarker T be dispensed with via $T \to \epsilon$. For example, we can derive the word 0101 from S as follows:

$$S \Rightarrow \underline{A}T \Rightarrow 0\underline{A}OT \Rightarrow 01\underline{A}IOT \Rightarrow 01I\underline{OT} \Rightarrow 01\underline{I0}T \Rightarrow 010\underline{IT} \Rightarrow 0101\underline{T} \Rightarrow 0101 .$$

Only the productions $A \to \epsilon$ and $T \to \epsilon$ prevent this grammar from being Type-1. The interested reader is challenged to write a Type-1 grammar for this language.

EXAMPLE 25.11:

We give a right-linear grammar G_5 to generate the language represented by the regular expression in Example 25.3, i.e., the set of all nonempty binary strings beginning and ending with the same bit. Let $G_5 = (\{0, 1\}, \{S, O, I\}, S, P)$, where P contains

$$\begin{array}{rcl@{\qquad}rcl} S & \to & 0O & S & \to & 1I \\ S & \to & 0 & S & \to & 1 \\ O & \to & 0O & O & \to & 1O \\ I & \to & 0I & I & \to & 1I \\ O & \to & 0 & I & \to & 1 \end{array}$$

Here O means to remember that the last bit must be a 0, and 1 similarly forces the last bit to be a 1. Note again how the grammar treats the words 0 and 1 as special cases.

Every regular grammar is a context-free grammar, but not every context-free grammar is context-sensitive. However, every context-free grammar G can be transformed into an equivalent one in which every production has the form $A \to BC$ or $A \to c$, where A, B, and C are (possibly identical) variables, and c is a terminal. If the empty string is in $L(G)$, then we can arrange to include $S \to \epsilon$ under the same "special dispensation" as for CSLs. This form is called **Chomsky normal form** [4], where it was used to prove the case $i = 1$ of the next theorem. The grammar G_1 in the last section is an example of a context-free grammar in Chomsky normal form.

THEOREM 25.2 *For each $i = 0, 1, 2$, the class of Type-i languages properly contains the class of Type-$(i+1)$ languages.*

The containments are clear from the above remarks. For the proper containments, we have already seen that $\{0^n 1^n | n \geq 0\}$ is a Type-2 language that is not regular, and Chapter 26 will show that the language of the Halting Problem is Type-0 but not Type-1. One can prove by a technique called "pumping" that the Type-1 languages $\{0^n 1^n 2^n | n \geq 0\}$ and $\{xx | x \in \{0, 1\}^*\}$ are not Type-2. See [11] for this, and for a presentation of the algorithm for converting a context-free grammar into Chomsky normal form.

The four classes of languages in the Chomsky hierarchy have also been completely characterized in terms of Turing machines (see Chapter 24) and natural restrictions on them. We mention this here to make the point that these characterizations show that these classes capture fundamental properties of computation, not just of formal languages. A *linear bounded automaton* is a possibly nondeterministic Turing machine that on any input x uses only the cells initially occupied by x, except for one visit to the blank cell immediately to the right of x (which is the initially scanned cell if $x = \epsilon$). Pushdown automata may also be nondeterministic and were likewise introduced in Chapter 24.

THEOREM 25.3

(a) The class of Type-0 languages equals the class of languages accepted by Turing machines.
(b) The class of Type-1 languages equals the class of languages accepted by linear bounded automata.
(c) The class of Type-2 languages equals the class of languages accepted by pushdown automata.
(d) The class of Type-3 languages equals the class of languages accepted by finite automata.

PROOF (a) Given a Type-0 grammar G, one can build a nondeterministic Turing machine M that accepts $L(G)$ by having M first write the start symbol S of G on a second tape. M always nondeterministically chooses a production and chooses a place (if any) on its second tape where it can be applied. If and when the second tape becomes an all-terminal string, M compares it to its input, and if they match, M accepts. Then $L(M) = L(G)$, and by Theorem 24.4 of Chapter 24, M can be converted into an equivalent deterministic single-tape Turing machine.

For the reverse simulation of a TM by a grammar we give full details. Given any TM M_0, we may modify M_0 into an equivalent TM $M = (Q, \Sigma, \Gamma, \delta, B, q_0, q_f)$ that has the following five properties: (i) M never writes a blank; (ii) M when reading a blank always converts it to a nonblank symbol on the current step; (iii) M begins with a transition from q_0 that overwrites the first input cell (remembering what it was) by a special symbol $\wedge$ that is never altered; (iv) M never reenters state q_0 or moves left of $\wedge$; and (v) whenever M is about to accept, M moves left to the $\wedge$, where it executes an instruction that moves right and enters a distinguished state q_e. In state q_e it overwrites any nonblank character by a special new symbol # and moves right; when it hits the blank after having #-ed out the rightmost nonblank symbol on its tape, M finally goes to q_f and accepts.

Given M with these properties, take $V = \{S, A, \} \cup (Q \times \Gamma) \cup (\Gamma \setminus \Sigma)$. A single symbol in $Q \times \Gamma$ is written using square brackets; e.g., $[q, c]$ means that M is in state q scanning character c. The grammar

G has the following productions, which intuitively can simulate any accepting computation by M in reverse:

(1) $S \to \wedge S_0$; $\quad S_0 \to \#S_0 \mid [q_e, \#]$;
(2) $[r, d] \to [q, c]$, for all instructions $(q, c, d, r) \in \delta$ with $q, r \in Q$ and $c, d \in \Gamma$;
(3) $c[r, B] \to [q, c]A$, for all $(q, c, R, r) \in \delta$;
(4) $c[r, d] \to [q, c]d$, for all $(q, c, R, r) \in \delta$ and $d \in \Gamma, d \neq B$;
(5) $[r, d]c \to d[q, c]$, for all $(q, c, L, r) \in \delta$ and $d \in \Gamma, d \neq B$;
(6) $[q_0, c] \to c$ for all $c \in \Sigma$, and
(7) $A \to \epsilon$.

For all $x \in L(M)$, G can generate x by first using the productions in (1) to lay down a # for every cell *used* during the computation, using the productions (2)–(5) to simulate the computation in reverse, using (6) to restore the first bit of x (blank if $x = \epsilon$) one step after having eliminated the nonterminal $\wedge$, and using (7) to erase each A marking an initially-blank cell that M used. Conversely, the only way G can eliminate $\wedge$ and reach an all-terminal string is by winding back an accepting computation of M all the way to state q_0 scanning the first cell. Hence $L(G) = L(M)$.

(b) If the given TM M_0 is a linear bounded automaton, then we can patch the last construction to eliminate the productions in (3) and (7), yielding a context-sensitive grammar G. To do this, we need to make M postpone its one allowed visit to the blank cell after the input until the last step of an accepting computation. To do this, we make M nondeterministically guess which bit of its input x is the last one, and overwrite it by an immutable right endmarker \$ the same way it did with $\wedge$ on the left. Then we arrange that from state q_e, M will accept only if it sees a blank immediately to the right of the \$, meaning that its initial guess delimited exactly the true input x. (Technically this needs another state q'_e.) Now M never even scans a blank in the middle of an accepting computation, and we can delete the productions in (3) as well as (7). Moreover, if M_0 accepts ϵ, we can add the production $S \to \epsilon$ allowed by the "special dispensation" for context-sensitive grammars above.

Going the other way, if the grammar G in the first paragraph of this proof is context-sensitive, then the resulting TM M uses only $O(n)$ space, and can be converted to an equivalent linear bounded automaton by Theorem 24.5 of Chapter 24.

(c) Given a context-free grammar G, we may assume that G is in Chomsky normal form. We can build a nondeterministic PDA M whose initial moves lay down a bottom-of-stack marker $\wedge$ and the start symbol S of G, and go to a "central" state q. For every production of the form $A \to BC$ in G, M has moves that pop the stack if A is uppermost and push C and then B, returning to state q. For every production of the form $A \to c$, M can pop an uppermost A from its stack if the currently-scanned input symbol is c; then it moves its input head right. If G has the production $S \to \epsilon$ as a special case, then M can pop the initial S. A computation path accepts if and only if the stack gets down to $\wedge$ precisely when M reaches the blank at the end of its input x. Then accepting paths of M on an input x are in 1–1 correspondence with **leftmost derivations** (see below) of x in G, so $L(M) = L(G)$.

Going from a PDA M to an equivalent CFG G is much trickier, and is covered well in [11].

(d) This has been proved in Chapter 24, Theorem 24.2.

Since $\{xx | x \in \{0, 1\}^*\}$ is a pattern language, we know from discussions above that the class of pattern languages is not contained in the class of context-free languages. It is contained in the class of context-sensitive languages, however.

THEOREM 25.4 *Every pattern language is context-sensitive.*

This was proved by showing that every pattern language is accepted by a linear bounded automaton [2], whereupon it is a corollary of Theorem 25.3(b).

Given a class of languages, we are often interested in the so-called *closure properties* of the class.

DEFINITION 25.17 A class of languages is said to be *closed under* a particular operation (such as union, intersection, complementation, concatenation, or Kleene closure) if every application of the operation on language(s) of the class yields a language of the class.

Closure properties are often useful in constructing new languages from existing languages, and for proving many theoretical properties of languages and grammars. The closure properties of the four types of languages in the Chomsky hierarchy are summarized below. Proofs may be found in [8, 10, 11], the closure of the CSLs under complementation is the famous Immerman–Szelepcsényi Theorem, which is given as Theorem 27.4(c) in Chapter 27.

THEOREM 25.5

1. *The class of Type-0 languages is closed under union, intersection, concatenation, and Kleene closure, but not under complementation.*
2. *The class of context-free languages is closed under union, concatenation and Kleene closure, but not under intersection or complementation.*
3. *The classes of context-sensitive and regular languages are closed under all of the five operations.*

For example, let $L_1 = \{0^m 1^n 2^p | m = n\}$, $L_2 = \{0^m 1^n 2^p | n = p\}$, and $L_3 = \{0^m 1^n 2^p | m = n \text{ or } n = p\}$. Now L_1 is the concatenation of the context-free languages $\{0^n 1^n | n \geq 0\}$ and 2^*, so L_1 is context-free. Similarly L_2 is context-free. Since $L_3 = L_1 \cup L_2$, L_3 is context-free. However, intersecting L_1 with L_2 gives the language $\{0^m 1^n 2^p | m = n = p\}$, which is not context-free.

We will look at context-free grammars more closely in the next section and introduce the concepts of parsing and ambiguity.

25.4 Context-Free Grammars and Parsing

From a practical point of view, for each grammar $G = (\Sigma, V, S, P)$ representing some language, the following two problems are important:

1. **Membership problem:** Given a string over Σ, does it belong to $L(G)$?
2. **Parsing problem:** Given a string in $L(G)$, how can it be derived from S?

The importance of the membership problem is quite obvious—given an English sentence or computer program, we wish to know if it is grammatically correct or has the right format. Solving the membership problem for context-free grammars is an integral step in the *lexical analysis* of computer programs, namely the stage of decomposing each statement into *tokens,* prior to fully parsing the program. For this reason, the membership problem is also often referred to as lexical analysis (cf. [6]). Parsing is important because a derivation usually brings out the "meaning" of the string. For example, in the case of a Pascal program, a derivation of the program in the Pascal grammar tells the compiler how the program should be executed. The following theorem qualifies the decidability of the membership problem for the four classes of grammars in the Chomsky hierarchy. Proofs of the first assertion can be found in [4, 10, 11], while the second assertion is treated below. Decidability and time complexity were defined in Chapter 24.

THEOREM 25.6 *The membership problem for Type-0 grammars is undecidable in general, but it is decidable given any context-sensitive grammar. For context-free grammars the problem is decidable in polynomial time, and for regular grammars, linear time.*

Since context-free grammars play a very important role in describing computer programming languages, we discuss the membership and parsing problems for context-free grammars in more detail in this and the next section. First, let us look at another example of a context-free grammar. For convenience, let us abbreviate a set of productions

$$A \to \alpha_1, \ldots, A \to \alpha_n$$

with the same left-hand side nonterminal as

$$A \to \alpha_1 | \ldots | \alpha_n \ .$$

EXAMPLE 25.12:

We construct a context-free grammar G_6 for the set of all valid real-number literals in Pascal. In general, a real constant in Pascal has one of the following forms:

$$m.n, \quad m\mathbf{e}q, \quad m.n\mathbf{e}q \ ,$$

where m, q are signed or unsigned integers and n is an unsigned integer. Let Σ comprise the digits 0–9, the decimal point '.', the $+$ and $-$ signs, and the **e** for scientific notation. Let the set V of variables be $\{S, M, N, D\}$ and let the set P of the productions be

$$\begin{aligned} S &\to M.N | M\mathbf{e}M | M.N\mathbf{e}M \\ M &\to N | +N | -N \\ N &\to DN | D \\ D &\to 0|1|2|3|4|5|7|8|9 \end{aligned}$$

Then the grammar generates all valid Pascal real values (allowing redundant leading 0s). For instance, the value 12.3**e**-4 can be derived via

$$\begin{aligned} &S \Rightarrow \underline{M}.N\mathbf{e}M \Rightarrow \underline{N}.N\mathbf{e}M \Rightarrow \underline{D}N.N\mathbf{e}M \Rightarrow 1\underline{N}.N\mathbf{e}M \Rightarrow 1\underline{D}.N\mathbf{e}M \Rightarrow \\ &12.\underline{N}\mathbf{e}M \Rightarrow 12.\underline{D}\mathbf{e}M \Rightarrow 12.3\mathbf{e}\underline{M} \Rightarrow 12.3\mathbf{e} - \underline{N} \Rightarrow 12.3\mathbf{e}\text{-}\underline{D} \Rightarrow 12.3\mathbf{e}\text{-}4 \end{aligned}$$

Perhaps the most natural representation of derivations in a context-free grammar is a **derivation tree** or a **parse tree.** Every leaf of such a tree corresponds to a terminal (or to ϵ), and every internal node corresponds to a nonterminal. If A is an internal node with children $B_1, \ldots, B_n$, ordered from left to right, then $A \to B_1 \cdots B_n$ must be a production. The concatenation of all leaves from left to right yields the string being derived. For example, the derivation tree corresponding to the above derivation of 12.3**e**-4 is given in Fig. 25.1. Such a tree also makes possible the extraction of the parts 12, 3 and -4, which are useful in the storage of the real value in a computer memory.

DEFINITION 25.18 A context-free grammar G is **ambiguous** if there is a string $x \in L(G)$ that has two distinct derivation trees. Otherwise G is **unambiguous.**

Unambiguity is a very desirable property because it promises a unique interpretation of each sentence in the language. It is not hard to see that the grammar G_6 for Pascal real values and the grammar G_1 defined in Example 25.7 are both unambiguous. The following example shows an ambiguous grammar.

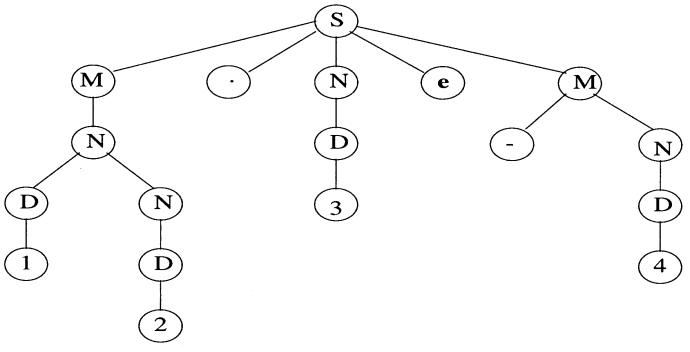

FIGURE 25.1 The derivation tree for $12.3\mathbf{e} - 4$.

EXAMPLE 25.13:

Consider a grammar G_7 for all valid arithmetic expressions that are composed of unsigned positive integers and symbols $+, *, (,)$. For convenience, let us use the symbol **n** to denote any unsigned positive integer—it is treated as a terminal. This grammar has the productions

$$\begin{aligned} S &\rightarrow T + S | S + T | T \\ T &\rightarrow F * T | T * F | F \\ F &\rightarrow \mathbf{n} | (S) \end{aligned}$$

Two possible different derivation trees for the expression $1 + 2 * 3 + 4$ are shown in Fig. 25.2. Thus G_7 is ambiguous. The left tree means that the first addition should be done before the second addition, while the right tree says the opposite.

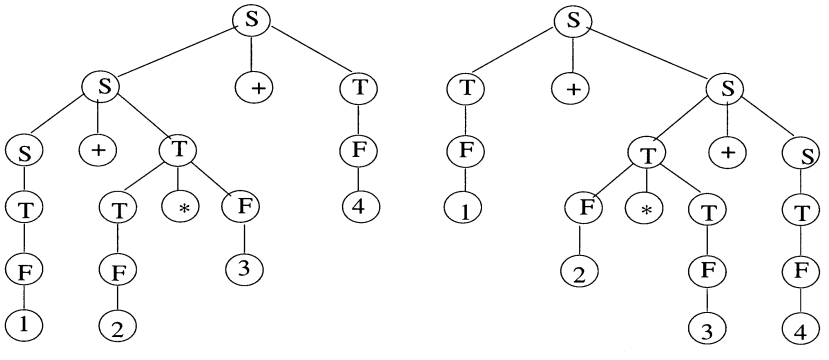

FIGURE 25.2 Different derivation trees for the expression $1 + 2 * 3 + 4$.

Although in the above example different derivations/interpretations of any expression always result in the same value because the operations addition and multiplication are associative, there are situations where the difference in the derivation can affect the final outcome. Actually, the grammar G_7 can be made unambiguous by removing the redundant productions $S \rightarrow T + S$ and $T \rightarrow F * T$. This corresponds to the convention that a sequence of consecutive additions or multiplications is always evaluated from left to right. Deleting the two productions does not change the language of strings generated by G_7, but it does fix unique interpretations of those strings.

It is worth noting that there are context-free languages that cannot be generated by any unambiguous context-free grammar. Such languages are said to be *inherently ambiguous.* An example taken from [11]

(where this fact is proved) is

$$\left\{ 0^m 1^m 2^n 3^n \,\middle|\, m, n > 0 \right\} \cup \left\{ 0^m 1^n 2^n 3^m \,\middle|\, m, n > 0 \right\} .$$

The reason is that every context-free grammar G must yield two parse trees for some strings of the form $x = 0^n 1^n 2^n 3^n$, where one tree intuitively expresses that x is a member of the first set of the union, and the other tree expresses that x is in the second set.

We end this section by presenting an efficient algorithm for the membership problem for context-free grammars, following the treatment in [11]. The algorithm is due to Cocke, Younger, and Kasami, and is often called the CYK algorithm. Let $G = (\Sigma, V, S, P)$ be a context-free grammar in Chomsky normal form.

EXAMPLE 25.14:

If we use the algorithm in [11] to convert the grammar G_7 from Example 25.13 into Chomsky normal form, we are led to introduce new "alias variables" A, B, C, D for the operators and parentheses, and "helper variables" S_1, T_1, T_2, F_1, F_2 to break up the productions in G_7 with right-hand sides of length > 2 into length-2 pieces. The resulting grammar is:

$$\begin{array}{rcl}
S & \rightarrow & T_1 S | S T_2 | F_1 T | T F_2 | C S_1 | \mathbf{n} \\
T_1 & \rightarrow & T A \\
T_2 & \rightarrow & A T \\
T & \rightarrow & F_1 T | T F_2 | C S_1 | \mathbf{n} \\
F_1 & \rightarrow & F B \\
F_2 & \rightarrow & B F \\
F & \rightarrow & \mathbf{n} | C S_1 \\
S_1 & \rightarrow & S D \\
A & \rightarrow & + \\
B & \rightarrow & * \\
C & \rightarrow & (\\
D & \rightarrow &)
\end{array}$$

While this grammar is much less intuitive to read than G_7, having it in Chomsky normal form facilitates the description and operation of the CYK algorithm.

Now suppose that $x = a_1 \cdots a_n$ is a string of n terminals that we want to test for membership in $L(G)$. The basic idea of the CYK algorithm is a form of *dynamic programming.* For each pair i, j, where $1 \leq i \leq j \leq n$, define a set $X_{i,j} \subseteq V$ by

$$X_{i,j} = \left\{ A \,|\, A \Rightarrow^* a_i \cdots a_j \right\} .$$

Then $x \in L(G)$ if and only if $S \in X_{1,n}$. The sets $X_{i,j}$ can be computed inductively in ascending order of $j - i$. It is easy to figure out $X_{i,i}$ for each i since $X_{i,i} = \{A | A \rightarrow a_i \in P\}$. Suppose that we have computed all $X_{i,j}$ where $j - i < d$ for some $d > 0$. To compute a set $X_{i,j}$, where $j - i = d$, we just have to find all the nonterminals A such that there exist some nonterminals B and C satisfying $A \rightarrow BC \in P$ and for some k, $i \leq k < j$, $B \in X_{i,k}$ and $C \in X_{k+1,j}$. A rigorous description of the algorithm in a Pascal-style pseudocode is given below.

Algorithm CYK($x = a_1 \cdots a_n$)
1 **for** $i \leftarrow 1$ **to** n **do**
2 $\quad X_{i,i} \leftarrow \{A | A \rightarrow a_i \in P\}$;
3 **for** $d \leftarrow 1$ **to** $n-1$ **do**
4 $\quad$ **for** $i \leftarrow 1$ **to** $n-d$ **do**
5 $\quad\quad X_{i,i+d} \leftarrow \emptyset$;
6 $\quad$ **for** $t \leftarrow 0$ **to** $d-1$ **do**
7 $\quad\quad X_{i,i+d} \leftarrow X_{i,i+d} \cup \{A | A \rightarrow BC \in P$ for some $B \in X_{i,i+t}$ and $C \in X_{i+t+1,i+d}\}$;

Table 25.1 shows the sets $X_{i,j}$ for the grammar G_1 and the string $x = 000111$. In this run it happens that every $X_{i,j}$ is either empty or a singleton. The computation proceeds from the main diagonal toward the upper-right corner.

TABLE 25.1 An Example Execution of the CYK Algorithm

		0	0	0	1	1	1
				$j \rightarrow$			
		1	2	3	4	5	6
	1	O					S
	2		O			S	T
i	3			O	S	T	
$\downarrow$	4				I		
	5					I	
	6						I

We now analyze the asymptotic time complexity of the CYK algorithm. Step 2 is executed n times. Step 5 is executed $\Sigma_{d=1}^{n-1} n-d = (n-1)(n-1+n-(n-1))/2 = n(n-1)/2 = O(n^2)$ times. Step 7 is repeated for $\Sigma_{d=1}^{n-1} d(n-d) = O(n^3)$ times. Therefore, the algorithm requires asymptotically $O(n^3)$ time to decide the membership of a string length n in $L(G)$, for any grammar G in Chomsky normal form.

25.5 More Efficient Parsing for Context-Free Grammars

The CYK algorithm presented in the last section can be easily extended to solve the parsing problem for context-free grammars: In step 7, we also record a production $A \rightarrow BC$ and the corresponding value of t for any nonterminal A that gets added to $X_{i,i+d}$. Thus a derivation tree for x can be constructed by starting from the nonterminal S in $X_{1,n}$ and repeatedly applying the productions recorded for appropriate nonterminals in appropriate sets $X_{i,j}$. However, the cubic running time of this algorithm is generally too high for parsing applications. In practice, with compilation modules thousands of lines long, people seek grammars in other forms besides Chomsky's that permit parsing in linear or nearly linear time.

Before we present some of these forms, we discuss parsing strategies in general. Parsing algorithms fall into two basic types, called **top-down parsers** and **bottom-up parsers.** As indicated by their names, a top-down parser builds derivation trees from the top (root) to the bottom (leaves), while a bottom-up parser starts from the leaves and works up to the root. Although neither method is good for handling all context-free grammars, each provides efficient parsing for many important subclasses of the context-free grammars, including those used in most programming languages.

We will only consider unambiguous grammars. To simplify the description of the parsers, we will assume that each string to be parsed ends with a special delimiter \$ that does not appear anywhere else in the string. This assumption makes the detection of the end of the string easy in a left-to-right scan. The assumption does not put any serious restriction on the range of languages that can be parsed—the \$ is just like the end-of-file marker in a real input file. The following definition will be useful.

DEFINITION 25.19 A derivation from a sentential form to another is said to be **leftmost** (or **rightmost**) if at each step the leftmost (or rightmost, respectively) nonterminal is replaced.

For example, Example 25.14 gave a leftmost derivation of the word 12.3**e**-4 in the grammar G_6. For a given word x, leftmost derivations are in 1–1 correspondence with derivation trees, since we can find the leftmost derivation specified by a derivation tree by tracing the tree down from the root going from left to right. Rightmost derivations are likewise in 1–1 correspondence with derivation trees. Hence, in an unambiguous context-free grammar, every derivable string has a unique leftmost derivation and a unique rightmost derivation. The parsing methods considered next find one or the other.

Top-Down Parsing

An important member of the top-down parsers is the **LL parser** (see [1, 6]). Here, the first "L" means scanning the input from left to right, and the second means leftmost derivation. In other words, for any input string x, the parser intends to find the sequence of productions used in the leftmost derivation of x.

Let $G = (\Sigma, V, S, P)$ be a context-free grammar. A *parsing table* T for G has rows indexed by members of V and columns indexed by members of Σ and \$. Each entry $T[A, c]$ is either blank or contains one or more productions of the form $A \to \alpha$. Here we will suppose that G allows the construction of a parsing table T such that every non-blank entry $T[A, c]$ contains only *one* production. Then the LL parser for G is a device very similar to a pushdown automaton as described in Chapter 24. The parser has an input buffer, a pushdown stack, a parsing table, and an output stream. The input buffer contains the string to be parsed followed by the delimiter \$. The stack contains a sequence of terminals or nonterminals, with another delimiter # that marks the bottom of the stack. Initially, the input pointer points to the first symbol of the input string, and the stack contains the start nonterminal S on top of #. Figure 25.3 illustrates schematically the components of the parser. As usual, the input pointer will only move to the right, while the stack pointer is allowed to move up and down.

The parser is controlled by an algorithm that behaves as follows. At any instant of time, the algorithm considers the symbol X on top of the stack and the current input symbol c pointed by the input pointer, and makes one of the following moves.

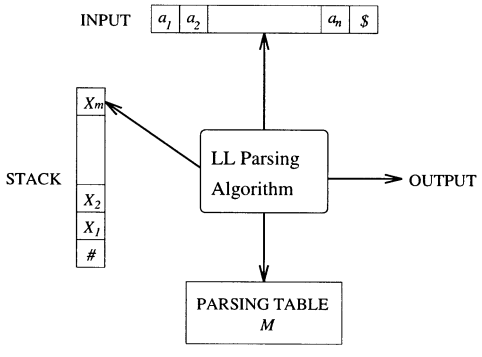

FIGURE 25.3 A schematic illustration of the LL parser.

1. If X is a nonterminal, the algorithm consults the entry $T[X, a]$ of the parsing table T. If the entry is blank, the parser halts and states that the input string x is not in the language $L(G)$. If not, the entry is a production of the form $X \rightarrow Y_1 \cdots Y_k$. Then the algorithm replaces the top stack symbol X with the string $Y_1 \cdots Y_k$ (with Y_1 on top), and outputs the production.
2. If X is a terminal, X is compared with c. If $X = c$, the algorithm pops X off the stack and shifts the input pointer to the next input symbol. Otherwise, the algorithm halts and states that $x \notin L(G)$.
3. If $X = \#$, then provided $c = \$$, the algorithm halts and declares the successful completion of parsing. Otherwise the algorithm halts and states that $x \notin L(G)$.

Intuitively, the parser reconstructs the derivation of a string $x = a_1 \cdots a_n$ as follows. Suppose that the leftmost derivation of x is

$$S = \gamma_0 \Rightarrow \gamma_1 \Rightarrow \cdots \Rightarrow \gamma_i \Rightarrow \gamma_{i+1} \Rightarrow \cdots \Rightarrow \gamma_m = x \ ,$$

where each γ_j is a sentential form. Suppose, moreover, that the derivation step $\gamma_i \Rightarrow \gamma_{i+1}$ is the result of applying a production $X \rightarrow Y_1 \cdots Y_k$. This means that $\gamma_i = \alpha X \beta$ for some string α of terminals and sentential form β. Since no subsequent derivation will change α, this string must match a leading substring $a_1 \cdots a_j$ of x for some j. In other words, $\gamma_i = a_1 \cdots a_j X \beta$ and $\gamma_{i+1} = a_1 \cdots a_j Y_1 \cdots Y_k \beta$. Suppose that the parser has successfully reconstructed the derivation steps up to γ_i. To complete the derivation, the parser must transform the tail end of γ_i into $a_{j+1} \cdots a_n$. Thus, it keeps the string $X\beta$ on the stack and repeatedly replaces the top stack symbol (i.e., replaces the leftmost nonterminal) until a_{j+1} appears on top. At this point, a_{j+1} is removed from the stack, and the remainder of the stack must be transformed to match $a_{j+2} \cdots a_n$. The procedure is repeated until all the input symbols are matched.

The following example illustrates the parsing table for a simple context-free grammar, and how the parser operates.

EXAMPLE 25.15:

Consider again the language of valid arithmetic expressions from Example 25.13, where an ambiguous grammar G_7 was given that could be made unambiguous by removing two productions. Let us remove the ambiguity in a different way. The new grammar is called G_8 and has the following productions

$$\begin{aligned} S &\rightarrow TS' \\ S' &\rightarrow +S|\epsilon \\ T &\rightarrow FT' \\ T' &\rightarrow *T|\epsilon \\ F &\rightarrow \mathbf{n}|(S) \end{aligned}$$

It is easy to see that grammar G_8 is unambiguous. A parsing table for this grammar is shown in Table 25.2. We will discuss how such a table can be constructed shortly.

To demonstrate how the parser operates, consider the input string $(\mathbf{n} + \mathbf{n}) * \mathbf{n}$. Table 25.3 shows the content of the stack, the remaining input symbols, and the output after each step. If we trace the actions of the parser carefully, we see that the sequence of productions it outputs constitutes the leftmost derivation of $(\mathbf{n} + \mathbf{n}) * \mathbf{n}$.

Now we turn to the question of how to construct an LL parser for a given grammar $G = (\Sigma, V, S, P)$. It suffices to show how to compute the entries $T[A, c]$, where $A \in V$ and $c \in \Sigma \cup \{\$\}$. We first need to introduce two functions $FIRST(\alpha)$ and $FOLLOW(A)$. The former maps a sentential form to a terminal or ϵ, and the latter maps a nonterminal to a terminal or \$.

TABLE 25.2 An LL Parsing Table for Grammar G_8

NONTER-MINAL	INPUT SYMBOL					
	n	+	*	(	)	$

DEFINITION 25.20 For each sentential form $\alpha \in \{\Sigma \cup V\}^*$, and for each nonterminal $A \in V$,

$$\begin{aligned} FIRST(\alpha) &= \left\{ c \in \Sigma \,|\, \text{for some } \beta \in \{\Sigma \cup V\}^*, \alpha \Rightarrow^* c\beta \right\} \cup \left\{ \epsilon \,|\, \alpha \Rightarrow^* \epsilon \right\} \\ FOLLOW(A) &= \left\{ c \in \Sigma \,|\, \text{for some } \alpha, \beta \in \{\Sigma \cup V\}^*, S \Rightarrow^* \alpha A c \beta \right\} \\ &\cup \left\{ \$ \,|\, \text{for some } \alpha \in \{\Sigma \cup V\}^*,\ S \Rightarrow^* \alpha A \right\} . \end{aligned}$$

Intuitively, for any sentential form α, $FIRST(\alpha)$ consists of all the terminals that appear as the first symbol of some sentential form derivable from α. The empty string ϵ is included in $FIRST(\alpha)$ as a special case if α derives ϵ. On the other hand, for any nonterminal A, $FOLLOW(A)$ consists of all the terminals that immediately follow an occurrence of A in some sentential form derivable from the start symbol S.

The end delimiter \$ is included in $FOLLOW(A)$ as a special case if A appears at the end of some sentential form derivable from S.

Algorithms for computing the $FIRST()$ and $FOLLOW()$ functions are fairly straightforward and can be found in [1, 6]. It turns out that to construct the parsing table for a grammar G, we only need to know the values of $FIRST(\alpha)$ for those sentential forms α appearing on the right-hand sides of the productions in G.

EXAMPLE 25.16:

The following illustrate the functions $FIRST(\alpha)$ and $FOLLOW(A)$ for the grammar G_8 described in the above example. For the former, only those sentential forms appearing on the right-hand sides of the productions in G_8 are considered.

$$\begin{aligned}
FIRST(TS') &= \{(, \mathbf{n}\} \\
FIRST(+S) &= \{+\} \\
FIRST(FT') &= \{(, \mathbf{n}\} \\
FIRST(*T) &= \{*\} \\
FIRST((S)) &= \{(\} \\
FIRST(\mathbf{n}) &= \{\mathbf{n}\} \\
FIRST(\epsilon &= \{\epsilon\} \\
FIRST(S) &= \{), \$\} \\
FIRST(S') &= \{), \$\} \\
FIRST(T) &= \{+,), \$\} \\
FIRST(T') &= \{+,), \$\} \\
FIRST(F') &= \{*, +,), \$\}
\end{aligned}$$

Given the functions $FIRST(\alpha)$ and $FOLLOW(A)$ for a grammar G, we can easily construct the **LL parsing** table $T[A, c]$ for G. The basic idea is as follows. Suppose that $A \rightarrow \alpha$ is a production and $c \in FIRST(\alpha)$. Then, the parser will replace A with α when A is on top of the stack and c is the current input symbol. The only complication occurs when α may derive ϵ. In this case, the parser should still replace A with α if the current input symbol is a member of $FOLLOW(A)$. The detailed algorithm is given below.

Algorithm LL-Parsing-Table($G = (\Sigma, V, S, P)$)
1 Initialize each entry of the table to blank.
2 **for** each production $A \rightarrow \alpha$ in P **do**
3 **for** each terminal $a \in FIRST(\alpha)$ **do**
4 add $A \rightarrow \alpha$ to $T[A, a]$;
5 **if** $\epsilon \in FIRST(\alpha)$ **then**
6 **for** each terminal or delimiter $a \in FOLLOW(A)$ **do**
7 add $A \rightarrow \alpha$ to $T[A, a]$;

The above algorithm can be applied to any context-free grammar to produce a parsing table. However, for some grammars the table may have entries containing multiple productions. Multiply defined entries

in a parsing table, however, would present our parsing algorithm with an unwelcome choice. It would be possible for it to make a wrong choice and incorrectly report a string as not being derivable, and backtracking to the last choice to try another would blow up the running time unacceptably.

EXAMPLE 25.17:

Recall that we could make the grammar G_7 of Example 25.13 unambiguous by deleting two unnecessary productions. The resulting grammar, which we call G_9, has the following productions:

$$\begin{aligned} S &\rightarrow S + T | T \\ T &\rightarrow T * F | F \\ F &\rightarrow \mathbf{n} | (S) \end{aligned}$$

It is easy to see that both $FIRST(S + T)$ and $FIRST(T)$ contain the terminal **n**. Hence, the entry $T[S, \mathbf{n}]$ of the parsing table is multiply defined, so this table is not well-conditioned for LL parsing.

A context-free grammar whose parsing table has no multiply defined entries is called an **LL(1) grammar.** Here, the "1" signifies the fact that the LL parser uses one input symbol of lookahead to decide its next move. For example, G_8 is an LL(1) grammar, while G_9 is not. It is easy to show that our LL parser runs in linear time for any LL(1) grammar.

What can we do for grammars that are not LL(1), such as G_9? The first idea is to extend the LL parser to use more input symbols of lookahead. In other words, we will allow the parser to see the next several input symbols before it makes a decision. For one more symbol of lookahead, this requires expanding the parsing table to have a column for every *pair* of symbols in Σ (plus \$ as a possible second symbol), but so doing may separate and/or eliminate multiply defined entries in the original parsing table. The *FIRST*() and *FOLLOW*() functions have to be modified to take two (or more) lookahead symbols into consideration. For any constant $k > 1$, a grammar is said to be an **LL(k) grammar** if its parsing table using k lookahead symbols has no multiply defined entries. For example, the grammar G_1 given in Example 25.7 is not LL(1), but it is LL(2).

Although LL(k) grammars form a larger class than LL(1) grammars, there are still grammars that are not LL(k) for any constant k. The grammar G_7 and G_9 are examples. The texts [1, 6] provide several techniques for dealing with non-LL(k) grammars, such as grammar transformations and backtracking. When backtracking is used, the parsing process is often called *recursive-descent parsing,* and can be very time consuming due to the use of many recursive calls.

Bottom-Up Parsing

The most popular **bottom-up parsing** technique is **LR parsing.** Here, the "L" again means scanning the input from left to right, while the "R" means constructing the rightmost derivation. For any input string x, the LR parser scans x from left to right and tries to find the *reverse* of the sequence of productions used in the rightmost derivation of x. It turns out that in bottom-up parsing rightmost derivations are easier to deal with than leftmost derivations. LR parsing is especially attractive in practice for many reasons summarized in [1]: (i) it can handle virtually all programming language constructs; (ii) it has very efficient implementations; (iii) it is more powerful than LL parsing; and (iv) it detects syntactic errors quickly. The principal drawback of the method is that constructing an LR parser is very involved. Fortunately, there exist efficient algorithms that can automatically generate LR parsers from certain context-free grammars. Because of space limitations, we describe only the operation of an LR parser here, and refer the reader to [1] for the construction of such a parser.

Similar to an LL parser, an LR parser has an input buffer, a pushdown stack, a parsing table, and an output stream, and is controlled by an algorithm that is the same for all LR parsers. The input string is

again assumed to have an end delimiter \$. At any time during parsing, the stack stores a string of the form $q_m X_m q_{m-1} \cdots X_1 q_0$ (with q_0 at bottom), where each X_i is a grammar symbol (i.e., a terminal or nonterminal of the grammar involved) and q_i is a *state* symbol. The number of distinct states is finite, and each state symbol intends to summarize the information contained in the stack below it. The combination of the state on top of the stack and the current input symbol are used to index the parsing table and determine the move of the parser. It will be seen that the state symbols subsume all information in the grammar symbols, and a real parser omits the latter. However, we retain the grammar symbols $X_1, \ldots, X_m$ to make our illustration easier to follow, and for consistency with previous examples.

The parsing table consists of two parts: a parsing action function $ACTION(q, c)$, which maps a state and an input symbol to a move, and a function $GOTO(q, X)$, which maps a state and a grammar symbol to a state. For each state q and each input symbol c, the value of the function $ACTION(q, c)$ can be one of the following:

1. *shift,*
2. *reduce by* $A \to \alpha$, where $A \to \alpha$ is a production in the grammar,
3. *accept,* and
4. *blank.*

The algorithm controlling the LR parser operates as follows. Suppose that the state on top of the stack is q and the current input symbol is c. It consults $ACTION(q, c)$ and makes one of the four types of moves as below.

1. If $ACTION(q, c) =$ *shift,* the parser pushes the string $GOTO(q, c)c$ on the stack and shifts its input pointer to the next input symbol.
2. If $ACTION(q, c) =$ *reduce by* $A \to \alpha$, the parser applies the production $A \to \alpha$ as follows. Let $k = |\alpha|$, and let the current stack content be $q_m X_m q_{m-1} \cdots X_1 q_0$. The parser first pops the top $2k$ symbols $q_m, X_m, \ldots, q_{m-k+1}, X_{m-k+1}$ off the stack. It then consults $GOTO(q_{m-k}, A)$ and pushes the string $GOTO(q_{m-k}, A)A$ onto the stack, resulting in a stack with content $GOTO(q_{m-k}, A)Aq_{m-k}X_{m-k} \cdots X_1 q_0$. The parser also outputs the production $A \to \alpha$. It is always guaranteed in the above that $X_{m-k+1} \cdots X_m = \alpha$.
3. If $ACTION(q, a) =$ *accept,* the parser successfully terminates.
4. If $ACTION(q, a) =$ *blank,* the parser terminates and declares that the input string is not a member of the language.

Intuitively, the LR parser reconstructs the rightmost derivation of a string $x = a_1 \cdots a_n$ as follows. Suppose that the rightmost derivation of x is

$$S = \gamma_0 \Rightarrow \gamma_1 \Rightarrow \cdots \Rightarrow \gamma_i \Rightarrow \gamma_{i+1} \Rightarrow \cdots \Rightarrow \gamma_m = x \ ,$$

where each γ_j is a sentential form. Furthermore, suppose that the derivation step $\gamma_i \Rightarrow \gamma_{i+1}$ is the result of applying a production $A \to Y_1 \cdots Y_k$. This means that $\gamma_i = \alpha Az$ for some sentential form $\alpha = X_1 \cdots X_t$ and string z of terminals, and $\gamma_{i+1} = \alpha Y_1 \cdots Y_k z = X_1 \cdots X_t Y_1 \cdots Y_k z$. Since no subsequent derivation will change z, this string must match a trailing substring $a_j \cdots a_n$ of x for some j. In other words, $\gamma_i = X_1 \cdots X_t A a_j \cdots a_n$ and $\gamma_{i+1} = X_1 \cdots X_t Y_1 \cdots Y_k a_j \cdots a_n$.

Suppose that the parser has successfully reconstructed the derivation steps in reverse from γ_m back to γ_{i+1}. At this point, the stack must be holding a string of the form

$$q_{t+h} Y_h \cdots q_{t+1} Y_1 q_t X_t \cdots q_1 X_1 q_0 \ ,$$

where $h \leq k$ and $q_0, q_1, \ldots q_{t+h}$ are some states, and the input pointer is pointing at a_{j+h-k}. Moreover, it must be that $Y_{h+1} = a_{j+h-k}, \ldots, Y_k = a_{j-1}$. To recover γ_i, the parser consults the state q_{t+h} on top

of stack and the current input symbol a_{j+h-k}. It then shifts the $h-k$ input symbols $a_{j+h-k}, \ldots, a_{j-1}$ and $h-k$ appropriate state symbols onto the stack. It also advances the input pointer to a_j. Then, the parser *reduces* the string $Y_1 \cdots Y_k$ to the nonterminal A by replacing the top $2k$ stack symbols with A and an appropriate state symbol.

The above shift-and-reduce process is repeated until the sentential form $\gamma_0 = S$ is obtained. For this reason, the LR parser is sometimes called a *shift-reduce parser.*

Clearly, the state symbols stored on the stack play a key role in dictating the actions of the parser. Below we first give an example of LR parsing tables and show exactly how the parser operates on a specific input. Then we will briefly sketch how the states are chosen for a grammar and what they represent.

EXAMPLE 25.18:

Consider again the unambiguous grammar G_9 given in Example 25.17. For convenience, let us number the productions as follows.

$$
\begin{array}{lllll}
(1) & S & \rightarrow & S + T \\
(2) & S & \rightarrow & T \\
(3) & T & \rightarrow & T * F \\
(4) & T & \rightarrow & F \\
(5) & F & \rightarrow & \mathbf{n} \\
(6) & F & \rightarrow & (S)
\end{array}
$$

Tables 25.4 and 25.5 illustrate the functions $ACTION(q, c)$ and $GOTO(q, X)$ for the grammar. In the first table, shf means shift, pi means reduce by production i, acc means accept, and blank means reject. The states are numbered $0, 1, \ldots, 11$.

TABLE 25.4 The Function $ACTION(q, c)$ for the Unambiguous Grammar G_9

STATE	**n**	+	*	(	)	$
0	shf			shf		
1		shf				acc
2		p2	shf		p2	p2
3		p4	p4		p4	p4

5		p6	p6		p6	p6
6	shf			shf		
7	shf			shf		
8		shf			shf	
9		p1	shf		p1	p1
10		p3	p3		p3	p3
11		p5	p5		p5	p5

Now we demonstrate how the parser operates on the string $(\mathbf{n} + \mathbf{n}) * \mathbf{n}$. Table 25.6 shows the content of the stack, the remaining input symbols, and the output after each step. It is easy to see that the reverse sequence of the productions in the reduce steps constitute the rightmost derivation of $(\mathbf{n} + \mathbf{n}) * \mathbf{n}$.

There are several techniques for constructing an LR parsing table, such as simple-LR (SLR), canonical-LR, and lookahead-LR (LALR), as described by [1]. In general, these techniques all use states that are sets

$1S0$	$\$$	accept

of *items* of the form $A \to \alpha \cdot \beta$, where $A \to \alpha\beta$ is a production and the $\cdot$ marks a place in the right-hand side. Such items are commonly known as the *LR items.* Each item expresses the assertion that the part α has already been obtained by previous shift/reduce steps and pushed on the stack, and the part β is expected to be obtainable from the next few input symbols by some shift/reduce steps. Since at any given time the parser may not be able to predict what input symbols should follow, it has to maintain a set of LR items to deal with all possibilities.

Again, not all context-free grammars have effective LR parsers. For example, the grammar with productions

$$S \rightarrow 0S0|1S1|0|1|\epsilon$$

cannot be handled by LR parsing. This grammar generates the set of all palindromes. The grammars that have effective LR parsers are called *LR grammars.* In fact, there are context-free languages that cannot be represented by any LR grammars. The set of palindromes is one such language.

25.6 Defining Terms

Ambiguous context-free grammar: A context-free grammar in which some derivable terminal strings have two distinct derivation trees.

Bottom-up parsing: A process of building a derivation tree from the leaves up to the root.

Chomsky normal form: A form of context-free grammar in which every rule has the form $A \rightarrow BC$ or $A \rightarrow a$, where A, B, C are nonterminals and a is a terminal.

Context-free grammar: A grammar whose rules have the form $A \rightarrow \beta$, where A is a nonterminal and β is a string of nonterminals and terminals.

Context-free language: A language that can be described by some context-free grammar.

Context-sensitive grammar: A grammar whose rules have the form $\alpha \rightarrow \beta$, where α, β are strings of nonterminals and terminals, and $|\alpha| \leq |\beta|$.

Context-sensitive language: A language that can be described by some context-sensitive grammar.

Derivation or parsing: A sequence of applications of rules of a grammar that transforms the start symbol into a given terminal string or sentential form.

Derivation tree or parse tree: A rooted, ordered tree that describes a particular derivation of a string with respect to some context-free grammar.

(Formal) language: A set of strings over some fixed alphabet.

(Formal) grammar: A description of some language, typically consisting of a set of terminals, a set of nonterminals, a distinguished nonterminal called the start symbol, and a set of rules (or productions) of the form $\alpha \rightarrow \beta$, which determine which substrings α of a sentential form can be replaced by some another string β.

Leftmost (or rightmost) derivation: A derivation in which at each step, the leftmost (respectively, rightmost) nonterminal is rewritten.

LL parsing: A type of top-down parsing in which one reads the input from left to right in order to reconstruct a leftmost derivation.

LL(k) grammar: A context-free grammar whose LL(k) parsing table has no multiply defined entries.

LL(k) parsing: An LL parsing that uses k symbols of lookahead.

LR parsing: A type of bottom-up parsing in which one reads the input from left to right in order to reconstruct a rightmost derivation in reverse order of steps.

LR grammar: A context-free grammar that has an effective LR parser.

Membership problem (or lexical analysis): The problem or process of deciding whether a given string is generated by a given grammar.

Parsing problem: The problem of reconstructing a derivation of a given input string in a given grammar.

Regular expression: A description of some language using the operators union, concatenation, and Kleene closure.

Regular language: A language that can be described by some regular expression, or equivalently, by some right-linear/regular grammar.

Right-linear or regular grammar: A grammar whose rules have the form $A \to cB$, $A \to c$, or $A \to \epsilon$, where A, B are nonterminals, c is a terminal, and ϵ is the empty string.

Sentential form: A string of terminals and nonterminals obtained at some step of a derivation in a grammar.

Top-down parsing: A process of building derivation trees from the top (root) down to the bottom (leaves).

Further Information

The fundamentals of formal languages and grammars can be found in many text books including [6, 7, 8, 9, 10, 11, 18]. The central focus of research in this area has been to find formal grammatical representations of languages that are very expressive and are yet easy to parse. The research results have

greatly benefited many fields of computer science, including programming languages, compiler design, and natural language processing. Chapter 24 presents the machine model counterparts of regular grammars, context-free grammars, context-sensitive grammars, and unrestricted grammars, and Chapter 26 introduces the concepts of decidability and undecidability, which has a close relation to formal grammars. The following annual conferences present the leading research work in formal languages and grammars: International Colloquium on Automata, Languages and Programming (ICALP), ACM Annual Symposium on Theory of Computing (STOC), IEEE Symposium on the Foundations of Computer Science (FOCS), ACM Symposium on Principles of Programming Languages (POPL), Symposium on Theoretical Aspects of Computer Science (STACS), Mathematical Foundations of Computer Science (MFCS), Fundamentals of Computation Theory (FCT), Foundation of Software Technology and Theoretical Computer Science (FSTTCS), and Conference on Developments in Language Theory (DLT). There are many related conferences, including Computational Learning Theory (COLT), Colloquium on Trees in Algebra and Programming (CAAP), and International Conference on Concurrency Theory (CONCUR), where either specific issues concerning formal grammars are considered or specialized grammatical systems are studied for a specific application area. We conclude with a list of major journals that publish papers in formal language theory: *Journal of the ACM, SIAM Journal on Computing, Journal of Computer and System Sciences, Information and Computation, Theory of Computing Systems* (formerly *Mathematical Systems Theory*), *Theoretical Computer Science, Information Processing Letters, International Journal of Foundations of Computer Science,* and *Acta Informatica.*

26.1 Introduction

In the last two chapters, we have introduced several important computational models, including Turing machines and Chomsky's hierarchy of formal grammars. In this chapter, we will explore the limits of mechanical computation as defined by these models. We begin with a list of fundamental problems for which automatic computational solution would be very useful. One of these is the *universal simulation problem:* can one design a single algorithm that is capable of simulating *any* algorithm? Turing's demonstration that the answer is *yes* [28] supplied the proof for Babbage's dream of a single machine that could be programmed to carry out any computational task. We introduce a simple Turing machine programming language called "GOTO" in order to facilitate our own design of a universal machine. Next, we describe the schemes of *primitive recursion* and μ*-recursion,* which enable a concise, mathematical description of computable functions that is independent of any machine model. We show that the μ-recursive functions are the same as those computable on a Turing machine, and describe some computable functions, including one that solves a second problem on our list.

The success in solving ends there, however. We show in the last section of this chapter that all of the remaining problems on our list are *unsolvable* by Turing machines, and subject to the *Church–Turing thesis,* have no mechanical or human solver at all. That is to say, there is no Turing machine or physical device, no stand-alone product of human invention, that is capable of giving the correct answer to all—or even most—instances of these problems. The implication we draw is that in order to solve *some* important instances of these problems, human ingenuity is needed to guide powerful computers down the paths felt most likely to yield the answers. To cite Raymond Smullyan quoting P. Rosenbloom, the results on unsolvability imply that "man can never eliminate the necessity of using his own cleverness, no matter how cleverly he tries."

Almost the first consequence of formalizing computation was that we can formally establish its limits. Kurt Gödel showed that the process of proof in any formal axiomatic system of logic can be simulated by the basic arithmetical functions that computation is made of. Then he proved that any sound formal system that is capable of stating the grade-school rules of arithmetic can make statements that are neither provable nor disprovable in the system. Put another way, every sound formal system is *incomplete* in the sense that there are mathematical truths that cannot be proved in the system. Turing realized that Gödel's basic method could be applied to computational models themselves, and thus proved the first computational unsolvability results. Since then problems from many areas, including group theory, number theory, combinatorics, set theory, logic, cellular automata, dynamical systems, topology, and knot theory, have been shown to be unsolvable. In fact, proving unsolvability is now an accepted "solution" to a problem. It is just a way of saying that the problem is too general for a computer to handle—that supplementary information is needed to enable a mechanical solution.

Since Turing machines capture the power of mechanical computability, our study will be based on Turing's model. In the next section, we describe a Turing machine as a computer that can run programs written in a very simple language we call the "GOTO Language." This formalism is equivalent to Chapter 24's description of Turing machines using the standard 7-tuple notation. Our language provides an alternate way to write programs and makes proofs about Turing machines more intuitive.

26.2 Computability and a Universal Program

Turing's notion of mechanical computation was based on identifying the *basic steps* in any mechanical computation. He reasoned that an operation such as numerical multiplication is not primitive, because it can be divided into simpler steps such as using the times-table on individual pairs of digits, shifting, and adding. Addition itself can be broken down into simpler steps such as adding the lowest digits, computing the carry, and moving to the next digit. Turing concluded that the most basic features of mechanical computation are the ability to read and write on a storage medium, the ability to move about on that medium, and the ability to make simple logical decisions. Turing chose the storage medium to be a single linear *tape* divided into cells. He showed that such a tape could model spatial memory in three (or any number of) dimensions through the use of indexed co-ordinates. With much care he argued that human sensory input could be encoded by strings over a finite alphabet of cell symbols called the *tape alphabet.* (This bold discretization of sensory experience now seems a harbinger of the digital revolution that was to follow.) A decision step enables the computer to exert local control over the sequence of actions. Turing restricted the next action performed to be in a cell neighboring the one on which the current action occurred, and showed how nonlocal actions can be simulated by successions of steps of this kind. He also introduced an instruction to tell the computer to stop.

In summary, Turing proposed a model to characterize mechanical computation as being carried out as a sequence of instructions. Our "GOTO" formalism provides the following five kinds of instructions. Here i stands for a tape symbol and j stands for a line number.

PRINT i
MOVE RIGHT
MOVE LEFT
IF i IS SCANNED GOTO LINE j
STOP

When we speak about programs recognizing languages rather than computing functions, we replace STOP by statements ACCEPT and REJECT, each of which need occur only once in a program.

A program in this language is a sequence of instructions or "lines" numbered 1 to k. The input to the program is a string over a designated *input alphabet* Σ, which we take to be $\{0, 1\}$ throughout this chapter. The tape alphabet includes Σ and a special *blank* character B representing an empty cell, and may (but

need not) contain other symbols. The input is stored on the tape, with the read head scanning the first symbol (or B if the input is empty), before the computation begins.

How much memory should we allow the computer to use? Rather than postulate that the tape is actually infinite—an unrealistic assumption—we prefer here to say that the tape has expandable boundaries. Initially the input defines the two boundaries of the tape. Whenever the machine moves left of the left boundary or right of the right boundary, a new memory cell containing the blank is attached. This convention clarifies what we mean by saying that if and when the machine halts by reaching the STOP instruction, the "result" of the computation is the entire content of the tape.

We present an example program written in the GOTO language. This program accomplishes the simple task of doubling the number of initial 1s in the input string. Informally, the program achieves its goal as follows: When it reads a 1, it changes the 1 to a 0, moves left looking for a new cell, and writes a 1 in that cell. Then it returns rightward to the 0 that marks where it had been, rewrites it as a 1, and moves right to look for more 1s. If it immediately finds another 1 it repeats the process from line 1, while if it doesn't, it halts right there. This program even has a "bug"—it "should" leave strings that do not begin with a 1 unchanged, but instead it alters them.

```
1 PRINT 0
2 MOVE LEFT
3 IF 1 IS SCANNED GOTO LINE 2
4 PRINT 1
5 MOVE RIGHT
6 IF 1 IS SCANNED GOTO LINE 5
7 PRINT 1
8 MOVE RIGHT
9 IF 1 IS SCANNED GOTO LINE 1
10 STOP
```

FIGURE 26.1 The doubling program in the GOTO language.

The main change from the traditional Turing machine formalism of Chapter 24 is that we have replaced "states" by line numbers. A Turing machine of the former kind can always be simulated in our GOTO language by making blocks of successive lines, themselves divided into sub-blocks (for each character) that are headed by "IF" statements, carry out the instructions for each state. Our formalism makes many programs more succinct and closer to programmers' experience, and highlights the role of (conditional) GOTO instructions in setting up loops and enabling statements to be repeated. Despite the popular scorn of `goto` statements, this feature is ultimately the most important aspect of programming and can be found in every imperative-style programming language—at least in the code produced by the compiler if the language has no `goto` instruction itself. Indeed, the above example could be rendered into a structured programming language such as C as follows,

```
do {
   do { PRINT 0; MOVE LEFT; } while (1 is scanned);
   PRINT 1;
   do MOVE RIGHT; while (1 is scanned);
   PRINT 1; MOVE RIGHT; }
while (1 is scanned);
```

and a C compiler (using a character array `tape[i]` and `++i`, `--i` for the moves) might plausibly convert this into something exactly like our GOTO program!

The simplicity of the GOTO language is rather deceptive. As the above example hints, any program in any known high-level programming language can be converted into an equivalent GOTO program, under suitable conventions on how inputs and outputs are represented on the tape. (If the program only reads from the standard input stream and writes to the standard output stream, then no such conventions are necessary.) There is strong reason to believe that any mechanical computation of any future kind can be expressed by a suitable GOTO program. Note, however, that a program written in the GOTO language need not always halt; i.e., on certain inputs the program may never reach a STOP instruction. On such inputs we say that the output of the program is *undefined.*

Now we can give a precise definition of what we mean by an *algorithm,* attempting to rule out this last situation. An algorithm is *any program written in the* GOTO *language that has the additional property of halting on all inputs.* Such programs will be called *halting programs,* and correspond to "total" deterministic Turing machines in Chapter 24. When we consider **decision problems,** which have yes/no answers, halting programs are required to end their computation with either an ACCEPT or a REJECT statement, on any input.

Some Computational Problems

We begin by listing a collection of computational problems for which a mechanical solution can be very helpful. By a mechanical solution, we mean a step-by-step process that takes into account all possible inputs, and that can be executed without any human assistance once a certain input is provided. An algorithm is required to work correctly on all instances.

We now list some problems that are fundamental either because they are inherently important or because they played a historical role in the development of computation theory. For the first four, P stands for a program in our GOTO language, and x is a string over the input alphabet, which we fix to be $\{0, 1\}$.

1. *Universal simulation.* Given a program P and an input x to P, determine the output (if any) that P would produce on input x.
2. *Halting problem.* Given P and x, output 1 (for yes) if P would halt when given input x, and 0 (for no) if P would not halt.
3. *Type-0 grammar membership.* Given a type-0 grammar G and a string x, determine whether x can be derived from the start symbol of G.
4. *String compression.* Given a string x, find the shortest program P such that when P is started with empty tape, P eventually halts with x as its output. Here "shortest" means that the total number of symbols in the program's instructions is as small as possible.
5. *Tiling.* Given a finite set T of tile types, where all tiles of a type are unit squares with the same four colors on their four edges, determine whether every finite rectangle can be *tiled* by T. If k and n are the integer sides of the rectangle, being tiled means that kn tiles drawn from T can be arranged so that every two tiles that share an edge have the same color at that edge.
6. *Linear programming.* Given some number k of linear inequalities in n unknowns, determine whether there is an assignment of n values to the unknowns that satisfies all the inequalities.
7. *Integer equations.* Given k-many polynomial equations in n unknowns, determine whether there is an assignment of n integers to the unknowns that satisfies all the equations.

SOME REMARKS ABOUT THE ABOVE PROBLEMS: A solution to Problem 1 realizes Babbage's objective of a single program or machine capable of simulating all programs P. For cases where P run on x would never halt and produce output, we have left open whether we require the solution itself to halt and detect this fact—i.e., to be an algorithm. For any such algorithm to exist, there must be an

algorithm to solve Problem 2, which is a yes/no *decision problem.* An algorithm for Problem 2 would be a boon to reliable software design, since it could be used to test whether a given block of code can cause infinite loops. Problem 3 is another decision problem; its solution would be useful for natural-language processing and much more. Problem 4 is a function-computation problem of central importance in information theory. For illustration, think of x as a large amount of scientific data for which we seek a concise theory P that can generate and hence explain it. A famous example is Kepler's laws, which explained Tycho Brahe's voluminous and meticulous observational data. Problem 4 thus asks whether the heart of science (to paraphrase Occam's Razor, "finding the simplest explanation that fits the facts") can be done automatically on a computer.

The tiles in Problem 5, which we introduced in detail in Chapter 24, are sometimes named after Hao Wang who wrote the first research paper about them [30]. Figure 26.2(a) shows an example of a set T of tile types, and Fig. 26.2(b) shows how tiles drawn from T can be used to tile a 5×5 square area. The tiling

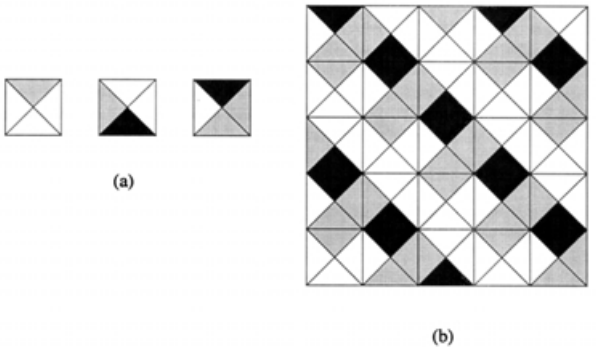

FIGURE 26.2 An example of tiling.

problem is not merely an interesting puzzle. It has been an art form pursued by artists from many cultures for centuries. Tiling problems have deep significance in combinatorics, algebra, and formal languages. Note that our decision problem does not ask simply whether a given $k \times n$ rectangle can be tiled, but whether—given T—*all* $k \times n$ rectangles can be tiled via T. The full problem of linear programming adds to Problem 6 a clause saying: if there exist *feasible solutions,* i.e., assignments that satisfy all the so-called linear *constraints,* find one that maximizes (or minimizes) a given *objective function* (or *cost function*). This problem has central importance in economics, game theory, and operations research. Problem 7 is called *Hilbert's tenth problem,* and was one of twenty-four that David Hilbert posed as challenges for the new century at the International Congress of Mathematicians in 1900. It goes back two thousand years to the mathematician Diophantus' study of these so-called *Diophantine equations.* Actually, Hilbert posed the "meta-problem" of finding an algorithm that can solve any Diophantine equation, or at least tell whether it has a solution.

Recall from Chapter 24 that a decision problem is *decidable* if it has an algorithm, and *undecidable* otherwise. If our program correctly evaluates all instances for which the answer is "yes," but may fail to halt on some instances for which the answer is "no," then the program is a *partial decision procedure,* and the problem is *partially decidable.* A partially **decidable problem,** however, is undecidable—unless you can find an algorithm that removes the word "partially." Likewise, if our program correctly outputs $f(x)$ whenever $f(x)$ is defined, but may fail to halt when $f(x)$ is undefined, then the partial function f is *partial computable.*

In the remainder of the subsection, we present some simple algorithm design techniques and sketch how they make progress on solving some of these problems and special cases of them. These techniques may seem too obvious to warrant explicit description. However, we feel that such a description will help new readers to appreciate the limits on information processing that make certain problems undecidable.

Table Look-Up

For certain functions g it can be advantageous to create a table with one column for inputs x and one for values $g(x)$, looking up the value in the table whenever an evaluation $g(x)$ is needed. A function f that is defined on an infinite set such as Σ^* cannot have its values enumerated in a finite table in this manner, but sometimes the infinite table for f can be described in a finite way that constitutes an algorithm for f. Moreover, tables for other functions g may help the task of computing f, such as the digit-by-digit times-table used in multiplying integers of arbitrary size. These ideas come into play next.

Bounding the Search Domain

Many solutions to decision problems involve finding a *witness* that proves a "yes" or "no" answer for a given instance. The term reflects an analogy to a criminal trial where a key witness may determine the guilt or innocence of the defendant. Thus the first step in solving many decision problems is to identify the right kind of witness to look for. For example, consider the problem of determining whether a given number N is prime. Here a (counter-) witness would be a factor of N (other than 1 and N itself). If N is composite, it is easy to prove by simple division that the witness' claim is correct.

In cases where the given number is prime, a witness of a different kind needs to be searched for. This search may involve integers larger than N, and trying to summon every integer sequentially as a witness would violate the requirement of an algorithm to terminate in finite number of steps. *This is often the main challenge in establishing decidability*. The difficulty can be surmounted if, based on the structure of the problem, we can establish ahead of time an upper bound such that if any witness exists at all, one exists that meets the bound. Then a sufficient body of potential witnesses can be examined in a finite number of steps. In the case of composite N, the bound is N itself. For prime N, there is a known polynomial p such that a witness exists in the numbers between 1 and $2^{p(n)}$, where n is the number of digits in N, according to a certain witnessing scheme whose test for correct claims is easy to compute. This kind of "polynomial size-bounded witnessing scheme" characterizes the important complexity class NP, and is discussed much further in Chapter 27.

For another example, let us consider the special case of Problem 3 where the given G is a Type-1 grammar, and we wish to determine whether a given string x can be generated from the start symbol S of G. A witness in this case can be a sequence of sentential forms starting from S and ending with x that forms a valid derivation in G. The length of x imposes a limit on the size of such sentential forms because G has no length-decreasing productions, and this in turn defines a (much larger) limit on the number of sequences that need be considered before all possibilities are exhausted. Readers may find the details in a standard text such as [12].

For one more example, consider the full version of the linear programming problem where one wishes to maximize a linear objective function f over the set of feasible solutions s. This set may be infinite, and so a table-lookup through all values $f(s)$ cannot be used. However, it is possible to reduce the search domain to a finite set as follows. The feasible solutions form a collection in n-dimensional space (where n is the number of variables plus the number of constraints), known as a *convex polytope.* Unless the polytope is empty or unbounded—cases that can be detected and resolved—the polytope has a finite number of "corner" points, which are similar to the vertices of a polygon, and which are easily computed. In this case, it is known that a linear objective function attains its maximum value at one (or more) of these corner points. Thus we know the problem is decidable via table-lookup of values at the corner points. In practice, there are intelligent algorithms that find a maximum-giving corner point after searching (usually) only a small part of this table.

Use of Subroutines

This is more a programming technique than an algorithm design tool. The idea is to use one program P as a single step in another program Q. Building programs from simpler programs is a natural way to deal with the complexity of the programmer's task. A simple example is using a lookup to the times

table as a subroutine in multiplying two integers i and j. Let us examine this in the context of designing Turing machines, where i and j are represented on the tape by the string 1^i01^j (namely, i 1s followed by a 0 and then by j 1s). The basic idea of our GOTO program is to duplicate the string of i 1s $j-1$ times, meanwhile erasing the string 1^j bit-by-bit to count the iterations. A little thought reveals that our earlier GOTO program in Fig. 26.1 can *almost* be used verbatim as a subroutine to call $j-1$ times. The only hitch is that the first call would run $2i$-many 1s together so that further calls would duplicate too many 1s. To fix the problem, we introduce a new tape symbol 2, using two initial steps to convert the tape to 21^i01^j, and "patch" the subroutine so that it will not overwrite this 2. The new subroutine can be called by a line "k: IF 2 IS SCANNED GOTO m," where m is the number of the first line in the subroutine, and can return control to the point of call by replacing its STOP instruction by "IF 0 IS SCANNED GOTO $k+1$." Careful writing will ensure that this latter 0 is the one initially separating 1^i from 1^j. The remaining details are left to the interested reader, while performing a similar patch without using a new symbol "2" is left to the obsessive reader. This subroutine mechanism is in fact no different from the one programmers in BASIC have used for decades.

A Universal Program

We will now solve Problem 1 by arguing the existence of a program U written in the GOTO language that takes as input a program P (also written in the GOTO language) and data x for P, and that produces the same output as P does on input x, *if* $P(x)$ halts and produces output at all. The last caveat hints that we shall only achieve a partial solution, formally showing only that the function $U(P,x) = P(x)$ is partial computable.

For convenience, we assume that all programs written in the GOTO language use the fixed alphabet $\{0, 1, B\}$. Since we have thus far used the full English alphabet for the notation of our GOTO programs, we must first address the issue of what the formal input to the program U will look like. This problem can be circumvented by *encoding* each instruction using only 0 and 1. The idea of such an encoding should not be mysterious—we could refer to the 0-1 encoding defined by the ASCII standard, which the terminal used to type this chapter has already carried out for these example programs. However, we prefer the more-succinct encoding defined by Table 26.1.

TABLE 26.1 Encoding GOTO Instructions

Instruction	Code
PRINT i	0001^{i+1}
MOVE LEFT	001
MOVE RIGHT	010
IF i IS SCANNED GOTO j	0111^j01^{i+1}
STOP	100

To encode an entire program, we simply write down in order (without the line numbers) the code for each instruction as given in the table. For example, here is the code for the doubling program shown in Fig. 26.1:

$$000100101111011000110100111111101100011010011101 1100 .$$

Note that the encoded string preserves all the information about the program, so that one can easily reverse the process to decode the string into a GOTO program. From now on, if P is a program in the GOTO language, *code* (P) will denote its binary encoding. When there is no confusion, we will identify P and

code (P). We may also assume that all programs P have a unique STOP instruction that comes last. This convention ensures that a input string to U of the form $w = code\,(P)x$ can be parsed into its P and x components. (When we consider decision problems we will use the code 100 for a unique final ACCEPT instruction, and assign some other code to REJECT.) Before proceeding further, readers may test their understanding of the encoding/decoding process by decoding the following string: 0100111011001001.

The basic idea behind the construction of a universal program is simple, although the details involved in actually constructing one are substantial. Turing in his original paper [28] exhibited a universal program in glorious gory detail, while simpler constructions may be found in more-recent sources such as [22]. Here we will content ourselves with a sketch that conveys the central ideas.

U has as its input a string w of the form *code* $(P)x$. (If U is given an input string not of this form, it can detect the flaw and immediately stop.) To simulate the computational steps of P on input x, U divides its tape into two segments, one containing the program P, and one modeling the contents of the tape of P as it changes with successive moves. The computation by U consists of a sequence of *cycles,* each of which simulates one step by P and is analogous to an *REW cycle* (for "read-evaluate-write") in many real computer systems.

To execute a cycle, U first needs to know the cell that the "virtual" tape head of P is currently scanning, and the instruction P is currently executing. We can assist U by extending its own work alphabet to include new "alias" symbols $0'$, $1'$, B' for the characters of P. U maintains the condition that there is exactly one aliased symbol in the "P" segment of its tape that marks the encoding of the current instruction, and exactly one in the other segment that marks the cell currently scanned by P. For example, suppose that after thirty-nine steps, P is reading the fourth symbol from the left on its tape containing 01001001. Then the second tape segment of U after thirty-nine cycles consists of the string $0100'1001$. We can further assist U by adding a symbol $\wedge$ to divide the two segments, although the unique STOP instruction itself could serve as the divider. The computation by U on an input $w = code\,(P)x$ can begin with some steps that prime the first symbol of *code* (P), insert a $\wedge$ before the first symbol of x (caterpillaring x one cell to the right), and prime the first symbol of x. We may suppose that each cycle by U begins with its own head scanning the $\wedge$.

At the beginning of a new cycle, U moves its head left to find the current instruction, and begins decoding it. The only information U needs to retain is which type of instruction it is, and in the case of a PRINT i or IF $i\ldots$ instruction, which character i is involved. To execute a PRINT i, MOVE RIGHT, or MOVE LEFT instruction, P unprimes the instruction, primes the next one, and marches down its tape to find the primed cell on its copy of P's tape and execute the action. It is possible that a MOVE LEFT instruction may bump into the $\wedge$, in which case U makes another call to its "caterpillar" subroutine to move P's tape over, and inserts a B' for the blank P would scan after that move. The only case that requires cumbersome action by U is an instruction IF i IS SCANNED GOTO j, when U finds that P really is scanning character i. Then U needs to find the jth instruction in the "P" part of its tape. Because we have used a unary encoding 1^j of the required line number j, it is not too difficult to write a subroutine that counts off the 1s in 1^j and advances an instruction marker each time beginning from line 1, knowing to stop when the jth instruction has been located. Finally, if the current instruction is STOP, U gleefully *erases* P, erases the $\wedge$, and unprimes the scanned symbol, leaving exactly the final output $P(x)$.

One last refinement is needed to answer the objection that U is using extra tape symbols $0'$, $1'$, B', $\wedge$ that we have expressly forbidden to GOTO programs. This use can be eliminated by one more level of encoding. Give each of the seven tape symbols its own three-bit code, and make U treat blocks of three cells as single cells in the simulation that was described above. U itself can be programmed to convert its input *code* $(P)x$ to this encoding before the first cycle, and to invert it when restoring the final output $P(x)$. Then U is a bona-fide GOTO program that meets all our requirements. It is even possible to run U on input *code* $(U)w$ where $w = code\,(P)x$, producing (more slowly) the same output $P(x)$. It is important to note that the code of U itself is completely independent of any program P that might be simulated. The code of U itself is not long—a reader with good programming skill can make it shorter than the prose description we have just given.

Besides solving what was asked for in Problem 1, we have also shown that Problem 2 is partially decidable. Namely, for any "yes"-instance $w = code(P)x$ where P on input x halts, U on input w will eventually detect that fact—and the slight edit of changing U's own STOP instruction to ACCEPT will make U halt and accept w. However, on a "no"-instance where $P(x)$ does not halt, our U will blindly follow P and not halt either. The question is whether we can improve U so that it will *detect* every case in which $P(x)$ does not halt, and signal this by executing a REJECT instruction. We will see in Section 26.5 that all the programming skill in the world cannot produce such a U—the halting problem is *un*decidable.

Before presenting undecidability, however, we develop a fundamentally different way to formalize the notion of mechanical computability in the next section.

26.3 Recursive Function Theory

The main advantage of using the class of *μ-recursive* functions to define computation is their mathematical elegance. Proofs about this class can be presented in a rigorous and concise way, without long prose descriptions or complicated programs that are hard to verify. These functions need and make no reference to any computational machine model, so it is remarkable that they characterize "mechanical" computability.

An analogy to the two broad families of programming languages is in order. We have already discussed how Turing machines and our particular "GOTO" formalism abstract the essence of *imperative* programming languages, in which a program is a sequence of operational commands and the major program structures are subroutines and loops and other forms of *iteration.* By contrast, specifications in recursive function theory are *declarative,* and the major structures are forms of *recursion.* "Declarative" means that a function f is specified by a direct description of the value $f(x)$ on a general argument x, as opposed to giving steps to compute $f(x)$ on input x. Often this description is *recursive,* meaning that $f(x)$ is defined in terms of values $f(y)$ on other (usually smaller) arguments y. Programming languages built on declarative principles include Lisp, ML, and Haskell, which are known as *functional languages.* These languages have recursion syntax that is not greatly different from the recursion schemes presented here. They also draw upon Church's *lambda calculus,* which can be called the world's first general programming language. A formal proof of equivalence between lambda calculus and the Turing machine model (via a programming language called I) can be found in [13], which presents computability theory from a programming perspective.[1]

In this section, we will describe this functional approach to computation and code some simple functions using recursion. Owing to space limitation, we will not present a complete proof that the class of *μ-recursive* functions is the same as the class of (partial) computable functions on a Turing machine. The full proof can be found in standard texts such as [27]. All the functions we consider have one or more nonnegative integers as arguments, and produce a single nonnegative integer value.

Before presenting formal definitions, we qualify the above ideas with a few examples. Consider first the simple definition of a two-variable linear function by

$$h(y, z) = z + 2 * y + 1 \,. \tag{26.1}$$

Here $h(y, z)$ is defined with the aid of other functions (here, plus and times) and quantities (here, 2 and 1) that presumably have already been defined or given. This is an example of an *explicit definition* because all entities on the right-hand side are known—in particular, this definition does not involve recursion. If we

[1] Turing created an addendum to his seminal paper [28] showing that his definition of a (partial) computable function was equivalent to the one proposed by Church. The lambda calculus uses essentially a single execution scheme called *reduction* to govern its computations, and by suitable conditioning one can make this scheme carry out recursion. Another declarative language, Prolog, also fixes a single execution scheme that tries to limit the operational decisions the programmer needs to make, and also relies upon recursion.

rewrite the infix functions + and ∗ in prefix-function style as "*plus* " and "*times* ," the expression becomes

$$h(y, z) = plus\ (z, plus\ (times\ (2, y), 1))\ , \tag{26.2}$$

and we can glimpse another hallmark of functional languages: function names can be regarded as parameters the same way that variable names can. Now consider the somewhat-similar definition of a one-variable function by

$$f(x) = f(x - 1) + 2 * (x - 1) + 1\ , \tag{26.3}$$

together with a base case such as $f(0) = 0$. Here not every quantity on the right-hand side is known—one must first know $f(x - 1)$ to compute $f(x)$. However, this is still "declarative" insofar as $f(x)$ is defined in terms of known quantities and values $f(y)$ for other (smaller) arguments y. The reader may check that this is a recursive definition of the squaring function.

Why use recursion? One reason is that explicit definition by itself is known not to be powerful enough to capture the essence of mechanical computation. The next two sections define the two principal schemes of recursion in recursive function theory.

Primitive Recursive Functions

The class of *primitive recursive functions* is built up from the following set of *basic functions,* which are the only ones we need to presuppose are "known:"

1. The *successor function* S is defined for all x by $S(x) = x + 1$.
2. The *zero function* Z is defined for all x by $Z(x) = 0$. The constant 0 is also provided here.
3. For all fixed numbers i and n with $1 \leq i \leq n$, the *projection function* p_i^n is defined for all n-tuples $(x_1, x_2, \ldots, x_n)$ by $p_i^n(x_1, x_2, \ldots, x_n) = x_i$.

The primitive recursive functions are constructed from the basic functions by applications of the following two operations. The case $n = 0$ is allowed in them; a 0-variable function is the same as a constant, and a 0-tuple is the empty list.

1. *Functional composition:* Given k-many functions $g_1, \ldots, g_k$ that each take n variables, and a function h that takes k variables, one can define a function f of n variables by

$$f\ (x_1, \ldots, x_n) = h\ (g_1\ (x_1, \ldots, x_n)\ , g_2\ (x_1, \ldots, x_n)\ , \ldots, g_k\ (x_1, \ldots, x_n))\ . \tag{26.4}$$

   If $g_1, \ldots, g_k$ and h are primitive recursive, then f is defined to be primitive recursive.
2. *Primitive recursion:* Given a function g that takes n variables, and a function h that takes $n + 2$ variables, one can define a function f of $n + 1$ variables by

$$f\ (x_1, \ldots, x_n, 0) = g\ (x_1, \ldots, x_n)\ ; \tag{26.5}$$

$$f\ (x_1, \ldots, x_n, S(y)) = h\ (x_1, \ldots, x_n, y, f\ (x_1, \ldots, x_n, y))\ . \tag{26.6}$$

   If g and h are primitive recursive, then f is defined to be primitive recursive.

Here (26.5) is the *basis* and (26.6) is the *recursion step.* It is conventional to call $x_1, \ldots, x_n$ the *parameters* and y the *recursion variable.* From a computational viewpoint, the scheme is easy to interpret. Given integer values for variables $x_1, \ldots, x_n$ and z, how can we evaluate $f(x_1, \ldots, x_n, z)$? We start building a table T in which each row y contains the value of $f(x_1, \ldots, x_n, y)$. The basis step gives us the top row via $T[0] = f(x_1, \ldots, x_n, 0) = g(x_1, \ldots, x_n)$. Whenever we have filled a row y, we can fill the next row via the recursion step, via $T[y + 1] = f(x_1, \ldots, x_n, S(y)) = h(x_1, \ldots, x_n, y, T[y])$. As soon as row z is

filled, using y such that $z = S(y)$, we are done. The point is that provided g and h are computable, the function f is also computable. Functional composition likewise preserves computability. Moreover, since the basic functions are all total and produce nonnegative values, every function that we can build up in this manner is also total and produces nonnegative values.

DEFINITION 26.1 A function is said to be **primitive recursive** if it can be built up from the successor, zero and projection functions by a finite number of applications of composition and primitive recursion.

EXAMPLE 26.1:

To show how the scheme of primitive recursion models the informal recursion defining the function f of one variable (so we have $n = 0$) in Eq. (26.3), take "$g()$" to be the constant 0, and take h to be the two-variable function $h(y, z) = z + 2y + 1$, which happens to be our example of "explicit definition" in (26.1). Then we have $f(0) = 0$ and

$$f(S(y)) = h(y, f(y)) = f(y) + 2 * y + 1 .$$

With "$x - 1$" in place of "y" and "x" in place of "$S(y)$," this is the same as (26.3). We will return to this notational difference later.

As the prefix form (26.2) indicates, h itself can be built up via functional composition from the *plus* and *times* functions. It is interesting to see how the usual functions of arithmetic can themselves be constructed from the rather Spartan basis we have been given. To begin with, the constants $1, 2, \ldots$ are formally introduced by functional composition, with "$g_1()$" as the constant 0 and "h" as the successor function, via $1 = S(0)$, $2 = S(1) = S(S(0))$, $3 = S(2)$, and so on.

EXAMPLE 26.2:

Addition. Take $g(x) = x$ and $h(x, y, z) = S(z)$. Formally, g is the basis function p_1^1, and h is the functional composition of the successor function with p_3^3. Then primitive recursion gives us $plus\,(x, 0) = g(x) = x$ and

$$plus\,(x, S(y)) = h(x, y, plus\,(x, y)) = S(plus\,(x, y)) = S(x + y) = x + y + 1 ,$$

as we would demand. Hence this formal definition of *plus* correctly computes addition, and we may use the standard "+" notation in the formal examples that follow.

EXAMPLE 26.3:

Multiplication. Take $g(x) = 0$ and $h(x, y, z) = x + z$. Formally, g is the zero function (of one variable rather than the constant zero), and h is the functional composition of *plus* with the two functions p_1^3 and p_3^3 (so $k = 2$ here). Then primitive recursion gives us $times\,(x, 0) = g(x) = 0$ and

$$times\,(x, S(y)) = h(x, y, times\,(x, y)) = x + times\,(x, y) = x * (y + 1) ,$$

again as we would demand. Hence this formal definition of *times* correctly computes multiplication. Note that we had to go to some length (of making h a function of 3 variables) so that our definition exactly agrees with the formal requirements in Eq. (26.6).

EXAMPLE 26.4:

Exponentiation. Take $g(x) = 1$ and $h(x, y, z) = x * z$. Formally, g is the one-variable function that always outputs 1 and is defined by composing S and the zero function Z, while h is the same as in Example 26.3 but with *times* in place of *plus*. Then primitive recursion gives us $exp\,(x, 0) = g(x) = 1$ (note that even 0^0 equals 1) and

$$exp\,(x, S(y)) = h(x, y, exp\,(x, y)) = x * exp\,(x, y) = x^{y+1}\ .$$

Once again the correctness of this definition for all values of x and y is easy to verify, via a simple proof by induction that follows the recursion.

It is now straightforward to omit some of the formal apparatus and write the definitions more succinctly. For instance, the last example becomes

$$\begin{aligned} exp\,(x, 0) &= 1 \\ exp\,(x, y+1) &= x * exp\,(x, y)\ . \end{aligned}$$

This resembles a program one would actually write, especially in a language like C that does not provide exponentiation as a built-in operator.

At this point the alert reader, noting the way our schemes all involve nonnegative numbers, will first wonder how on earth we can ever define *subtraction* this way. The key is that the syntax of primitive recursion allows us to define a function $P(y)$ that computes "proper subtraction by 1," and then use P to define *proper subtraction* itself. The word "proper" here means that any negative value is replaced by 0, in order to maintain our restriction to the nonnegative numbers. The definitions are

$$\begin{aligned} P(0) &= 0 \\ P(S(y)) &= y \\ sub\,(x, 0) &= x \\ sub\,(x, S(y)) &= P(sub\,(x, y)) \end{aligned}$$

For P we took $h(y, z) = y$, i.e., $h = p_1^2$, and for *sub* we took $h(y, z) = P(z)$. To trace this out, $sub\,(3, 2) = P(sub\,(3, 1)) = P(P(sub\,(3, 0)) = P(P(3)) = P(2) = 1$, and $sub\,(2, 3) = P(P(P(2))) = P(0) = 0$, which is the "proper" value.

Second, the reader may have felt uncomfortable defining functions in terms of "$S(y)$" rather than "y." For example, the primitive recursion for the factorial function, with 0! standardly defined to be 1, gives us

```
fact(0) = 1 | fact(y+1) = (y+1)*fact(y);
```

here "`|`" separates the base and recursion cases. This would actually be valid syntax in the programming language ML *except* that "`fact(y+1)`" is an illegal function header. The syntax of ML forces one to write it this way:

```
fact(0) = 1 | fact(y) = y*fact(y-1);
```

this is literally the example used in many texts. To make the formal Eq. (26.6) for primitive recursion reflect the syntax of programming languages, we can use P in place of S to change it to

$$f\,(x_1, \ldots, x_n, y) = h\,(x_1, \ldots, x_n, y, f\,(x_1, \ldots, x_n P(y)))\ , \tag{26.7}$$

and alternately make the middle argument of h be $P(y)$ instead of y. Either way, one might then expect to be able to recover the function S by defining it in terms of P and the other two basis functions, just as we defined P in terms of S above. However, this is impossible—one could never define any increasing functions at all. This curious asymmetry partly explains why primitive recursion was defined the way

it is. Nevertheless, if S as well as P is provided in the basis, then one can use the modified definition and obtain exactly the same class of primitive recursive functions. For instance, addition is definable by $plus\,(x, 0) = x \mid plus\,(x, y) = S(plus\,(x, P(y)))$, and so on. Hence primitive recursion is for the most part exactly what ML and other functional languages *do*.[2]

Finally, the reader may wonder what has become of functions defined on *strings.* A string over an alphabet Σ can always be identified with its number in the standard lexicographic enumeration of Σ^*, with ϵ corresponding to 0. Then a string function $f : \Sigma^* \to \Sigma^*$ can be called primitive recursive if the corresponding numerical function (of one variable) is primitive recursive. For instance, the function that appends a '1' to a binary string x corresponds to $2x + 2$. Cutting the other way, under some transparent encoding of negative and rational and complex numbers (etc.) by strings, one can extend the concept of primitive recursion to define addition and multiplication and nearly all familiar mathematical functions in their full generality. The meaning and proof of the following statement should now be clear; full detail can be found in [27].

THEOREM 26.1 *Every primitive recursive function is computable by a Turing machine.*

The converse is false, however. A famous example of a computable total function that is not primitive recursive is *Ackermann's function;* this and other examples may be found in [19]. To obtain all computable functions we need to introduce one more scheme of recursion—at the inevitable cost, however, of opening a Pandora's box of functions that are no longer total.

μ-Recursive Functions

We will add a new operation called *minimalization* that does not preserve totality. Again we restrict numerical arguments to be non-negative integers.

DEFINITION 26.2 A possibly-partial function f of n variables is defined by **μ-recursion** from a function g of $n + 1$ variables, written

$$f\,(x_1, \ldots, x_n) = \mu y.g\,(x_1, \ldots, x_n, y)\ ,$$

if whenever $f(x_1, \ldots, x_n)$ is defined, it equals the least number y such that $g(x_1, \ldots, x_n, y) = 1$. If $f(x_1, \ldots, x_n)$ is undefined, there must be no y such that $g(x_1, \ldots, x_n, y) = 1$. The class of **$\mu$-recursive functions** is the class of all functions that can be built up from the successor, zero, and projection functions by the operations of composition, primitive recursion, and μ-recursion.

The computation of $f(x_1, \ldots, x_n)$ that is implicit in Definition 26.2 can be described by building a table as before. First fill in the row $T[0] = g(x_1, \ldots, x_n, 0)$, then $T[1] = g(x_1, \ldots, x_n, 1)$, and so on. If and when one finds a y whose value $T[y]$ equals 1, halt and output y. The "if" is the big difference from the algorithm for primitive recursion, because if $g(x_1, \ldots, x_n, y)$ never takes the value 1, this procedure will never halt. This procedure is called an *unbounded search.* Compared another way to primitive recursion, μ-recursion increments its recursion variable rather than decrement it.

[2] Primitive recursion has its counterpart in imperative languages as well, aside from the fact that most of them support recursion directly. The "table $T[y]$" computation above shows how primitive recursion can be simulated by a simple for-loop **for** $y = 0$ **to** z **do**. . . **end** that fixes its bounds and never alters y in the loop body. A theorem [18] in programming languages states that the primitive recursive functions are exactly the total functions computable by programs that use only if-then-else and simple nested for-loops.

There is nothing special about "= 1" here: zero or any other constant could be used instead. Our use of 1 suggests the special case in which g is a total function that takes on only the values 0 and 1. Then we can regard its output as a Boolean truth value, with 1 = true and 0 = false, and call g a *predicate.* The class of μ-recursive functions is not changed under the restriction that g be a predicate. Then we can read the syntax "$\mu y.g(x_1, \ldots, x_n, y)$" in English as "the least y such that $g(x_1, \ldots, x_n, y)$ is true." From all this we can see that whereas primitive recursion corresponds to a **for** loop, μ-recursion corresponds to a **while** loop, with $g(\ldots)$ as the test condition.

EXAMPLE 26.5:

Partial square-root function. Define the predicate $g(x, y)$ to hold if and only if $x = y^2$. Then the function f defined for all x by $f(x) = \mu y.g(x, y)$ computes the square root of x when x is a perfect square. When x is not a perfect square, however, the recursion is undefined, so f is a partial recursive function.

EXAMPLE 26.6:

Linear programming. The standard *simplex algorithm* uses a **while** loop that executes a basic *pivot step* until a predicate expressing optimality holds. Hence the function that embodies the solution to a linear programming problem is μ-recursive. In point of fact, because a bound on the number of polytope corner points is explicitly definable from the problem instance, the same function can be computed via a simple **for** loop, so it is primitive recursive. However, the former method is usually much faster.

Part (a) of the next theorem expresses the fact that **while** loops, together with **if-then-else,** suffice to make a general-purpose programming language. Part (b) is the gist of the famous theorem, credited in various forms to various sources, that *at most one* **while** *loop is needed in any program.*

THEOREM 26.2

(a) A (partial) function is μ-recursive if and only if it is a Turing-computable (partial) function.

(b) Moreover, given any Turing machine T, we can find a primitive recursive function u and a primitive recursive predicate t such that for all x, $T(x) = u(\mu y.t(x, y))$.

In the standard proof of part (b), the predicate $t(x, y)$ is designed to hold if and only if y encodes the sequence of configurations of a halting computation of T on input x, and the function u picks off the output from the final configuration. To complete the proof of (a), all one needs to show is that given a Turing machine that computes g in Definition 26.2, one can build a Turing machine that computes f. This is done by following the unbounded-search procedure sketched above.

The corresponding theorem for formal languages also merits mention here. In Chapter 24 we defined the *characteristic function* of a language L to be the function f_L defined for all x by $f_L(x) = 1$ if $x \in L$, $f_L(x) = 0$ if $x \notin L$. This is simply the predicate corresponding to membership in L. The *partial characteristic function* still takes the value 1 when $x \in L$, but is undefined when $x \notin L$.

THEOREM 26.3

(a) A language is recursive if and only if its characteristic function is μ-recursive.

(b) A language is r.e. if and only if its partial characteristic function is μ-recursive.

Part (a) explains how the term "recursive" became applied to languages and predicates as a synonym for

"decidable." It is important to recall that not all languages L accepted by Turing machines have computable characteristic functions (i.e., are decidable); unless we find a Turing machine accepting L that halts for all inputs, all we know is that the *partial* characteristic function of L is (partial-) computable. Before proceeding to *un*decidable languages, we take time to interpret these two theorems and others presented in Chapters 24 and 25.

26.4 Equivalence of Computational Models and the Church–Turing Thesis

In Chapter 24 we introduced various machine models, the most important of which is the Turing machine. In Chapter 25 we introduced the grammar hierarchy of Chomsky, of which the most powerful was the Type-0 grammar. Here we have presented the purely mathematical model of μ-recursive functions. Although these models were defined over different domains for different purposes, they are all equivalent in a precise technical sense—they all define the same class of computable functions and decidable languages, and the same class of partial computable functions and partially decidable languages. We can summarize all this by saying that Turing machines, type-0 grammars, and μ-recursive functions have the same problem-solving power.

This equivalence extends to vastly many other computational models, of which we mention a few:

(1) *Cellular Automata.* Cellular automata are intended to model the evolution of a colony of microorganisms. Each cell is a deterministic finite automaton that receives its input in discrete time steps from neighboring cells, so that its current state is defined by its own previous state and the previous states of its neighbors. All the cells execute the same DFA. There are different schemes for specifying the representation of the input to a cellular automaton and its output. But under any reasonable scheme, the largest class of problems that can be solved on cellular automata coincides with the class of **solvable problems** on a Turing machine.

(2) *String-Rewriting Systems.* A string-rewriting system is similar to a grammar. The main difference is that there are no nonterminals. Let the input alphabet be Σ. The production rules of a rewriting system T will be of the form $\alpha \rightarrow \beta$ where α and β are strings over Σ. One can apply such a rule by replacing any occurrence of α in a string by β. T is defined as a finite set of rewrite rules, along with a finite set of initial strings. The language generated by T is defined as the set of strings that can be obtained from an initial string by applying the rewrite rules a finite number of times. The systems proposed before 1930 by Thue and Post fall roughly into this category. It turns out that the class of string-rewriting languages is the same as the r.e. languages (see [1]).

(3) *Tree-Rewriting Systems.* These are similar to string-rewriting systems except that the local edits are done on subtrees of a tree, and rules may have more than one argument. The subtrees typically represent *terms* in algebraic or logical expressions that are being operated on. Under reasonable schemes for encoding numbers or strings by trees, all known tree-rewriting systems generate r.e. languages or compute partial recursive functions. Church's λ-*calculus* and most formal systems of logic fall into this category.

(4) *Extensions of Turing's Model.* As mentioned in Chapter 24, one can also create numerous modifications to the basic Turing machine model, such as having multi-dimensional tapes or binary trees with MOVE UP, MOVE DOWN LEFT, and MOVE DOWN RIGHT instructions (the latter are tantamount to having random-access to stored values), allowing nondeterminism or alternation, making computation probabilistic (see Chapter 29, Section 29.2), and so on. All of these machines compute the same functions as the simple one-tape Turing machine.

(5) *Random-Access Machines and High-Level Programming Languages.* These can be mentioned in tandem because a RAM, as described in Chapter 24, is just an idealization of assembly or

machine language. Every high-level language yet devised can be compiled into some machine language. Even the standard *Java Virtual Machine* is little more than a RAM, with some added handling of class objects via pointers that is not unlike the workings of a pointer machine, and some hooks to enable the host system to control physical devices and network communications. Without excessive effort one can extend the construction of a **universal Turing machine** in Section 26.2 to handle the case where P is a RAM program rather than a GOTO program. The registers of P can be simulated on the tape by adding one more tape symbol # and using strings of the form $\#i\#j\#$, where i is the register's number and j is its contents. As stated in Chapter 24, Section 24.4, this simulation is even fairly efficient. Hence all these high-level languages have the same problem-solving power as the lowly one-tape Turing machine.

The convergence of so many disparate formal models on the same class of languages or functions is the main evidence for the assertion that they all exactly capture the informal notion of what is mechanically or humanly computable. This assertion is called the **Church–Turing thesis.** In one form, it asserts that every problem that is humanly solvable is solvable by a Turing machine. Put more precisely, any cognitive process that a human being could or will ever use to distinguish certain numbers or strings as "good" defines an r.e. language—and if it also would determine that any other given number or string is "bad," it defines a **recursive language.** An extension of the thesis claims that no one will ever design a physical device to compute functions that are not μ-recursive. The Church–Turing thesis is not a mathematical conjecture and is not subject to mathematical proof; it is not even clear whether the extension is resolvable scientifically.

26.5 Undecidability

The Church–Turing thesis implies that if a language is undecidable in the formal sense defined above, then the problem it represents is really, humanly, physically undecidable. The existence of languages that are not even partially decidable can be established by a counting argument: Turing machines can be counted 1, 2, 3, . . ., but the mathematician Georg Cantor proved that the totality of all sets of integers cannot be so counted. Hence there are sets left over that are not accepted, let alone decided, by any program. This argument, however, does not apply to languages or problems *that one can state,* since these are also countable. The remarkable fact is that many easily-stated problems of high practical relevance are undecidable. This section shows that the five remaining problems on our list in Section 26.2, namely 2 through 5 and 7, are all unsolvable.

Diagonalization and Self-Reference

Undecidability is inextricably tied to the concept of *self-reference,* and so we begin by looking at this perplexing and sometimes paradoxical concept. The simplest examples of self-referential paradox are statements such as "This statement is false" and "Right now I am lying." If the former statement is true, then by what it says, it is false; and if false, it is true. . . . The idea and effects of self-reference go back to antiquity; a version of the latter "liar" paradox ascribed to the Cretan poet Epimenides even found its way into the New Testament, Titus 1:12–13. For a more colorful example, picture a barber of Seville hanging out an advertisement reading, "I shave those who do not shave themselves." When the statement is applied to the barber himself, we need to ask: Does he shave himself? If *yes,* then he is one of those who do shave themselves, which are not the people his statement says he shaves. The contrary answer *no* is equally untenable. Hence the statement can be neither true nor false (it may be good ad copy), and this is the essence of the paradox. Such paradoxes have made entry into modern mathematics in various forms. We will present some more examples in the next few paragraphs. Many variations on the theme of self-reference can be found in the books of the logician and puzzlist Raymond Smullyan, including [25] and [26].

Berry's paradox concerns English descriptions of natural numbers. For example, the number 24 can be described by many different phrases: "twenty-four," "six times four," "four factorial," etc. We are interested in the *shortest* of such descriptions, namely one(s) having the fewest letters. Here, "two dozen" beats all of the above. Clearly there are (infinitely) many positive integers whose shortest descriptions require one hundred letters or more. (A simple counting argument can be used to show this. The set of positive integers is infinite, but the set of positive integers with English descriptions of fewer than one hundred letters is finite.) Let D denote the set of positive integers that do not have English descriptions of fewer than one hundred letters. Thus D is not empty. It is a well-known fact in set theory that any nonempty subset of positive integers has a smallest integer. Let x be the smallest integer in D. Does x have an English description of fewer than one hundred letters? By the definition of the set D and x, the answer is *yes:* such a description of x is, "the smallest positive integer that cannot be described in English in fewer than one hundred letters." This is an absurdity, because the quoted part of the last sentence is clearly a description of x, and it contains fewer than one hundred letters.

Russell's paradox similarly turns on issues in defining sets. In formal mathematics, we can perfectly easily describe "the set of all sets that do not include themselves as elements" by the definition $S = \{x | x \notin x\}$. The question "Is $S \in S$?" leads to a real conundrum. This also resembles the barber paradox, with "$\notin$" read as "does not shave." This paradox forced the realization that the formal notion of a *set,* and importantly the formal rules that apply to sets, do not and cannot apply to everything that we informally regard as being a "set."

Our last example is a charming paradox named for the mathematician William Zwicker. Consider the collection of all two-person games that are *normal* in the sense that every play of the game must end after a finite number of moves. Tic-tac-toe is normal since it always ends within nine moves, while chess is normal because the official "fifty move rule" prevents games from going on forever. Now here is *hypergame.* In the first move of hypergame, the first player calls out a normal game—and then the two players go on to play that game, with the second player making the first move. Now we need to ask, "Is hypergame normal?" If *yes,* then it is legal for the first player to call out "hypergame!"—since it is a normal game. By the rules, the second player must then play the first move of hypergame—and this move can be calling out "hypergame!" Thus the players can keep saying "hypergame" without end, but this contradicts the definition of a normal game. On the other hand, suppose hypergame is not normal. Then in the first move, player 1 cannot call out hypergame and must call a normal game instead—so that the infinite move sequence given above is not possible and hypergame is normal after all!

Let us try to implement Zwicker's paradox. To play hypergame, we need a way of formalizing and encoding the rules of a game as a string x, and we need a decision procedure `isNormal(x)` to tell if the game is normal. Then the rules of hypergame are easily formalized: pick a string x, verify `isNormal(`x`)`, and play game x. Let h be the string encoding of these rules. Now we get a real contradiction when `isNormal(`h`)` is run. We must conclude that either (i) our formalization of games is inadequate or inconsistent, or (ii) a decision procedure `isNormal` simply cannot exist. Now (i) is the way out for Russell's paradox with "sets" in place of "games." For *computation,* however, we know that our formalization is adequate and consistent—and hence we will be faced with conclusions of (ii), namely that our corresponding computational problems are unsolvable.

Before showing how the above paradoxes can be modified and ingrained into our problems, we need to review the 0-1 encoding of GOTO programs from Section "A Universal Program," including the conventions that ACCEPT has the same code 100 as STOP for programs that accept languages, and that such an ACCEPT statement be last and unique. We may assign the code 101 to REJECT, which may appear anywhere. If a binary string x encodes a program P, it is easy to decode x into P, and we may identify x with P. If x does not encode a legal GOTO program, this fact is easy to detect. Then we may choose to treat x as an alternate code for the trivial GOTO program that consists of a single REJECT statement.

Now we can define the so-called "diagonal language" L_d as follows:

$$L_d = \{x \mid x \text{ is a GOTO program that does not accept the string } x\} \tag{26.8}$$

This language consists of all programs in the GOTO language that do not halt in the ACCEPT statement when given their own encoding as input—they may either REJECT or not halt at all on that input. For example, consider $x = 01111101101100$, which encodes a program that accepts any string beginning with 1 and rejects any string beginning with 0. Then $x \in L_d$ since the program does not accept 01111101101100. Note the self-reference in (26.8). Although the definition of L_d seems artificial, its importance will become clear when we use it to show the undecidability of other problems. First we prove that L_d is not even accepted by any Turing machine, let alone decided by one.

THEOREM 26.4 *L_d is not recursively enumerable.*

PROOF Suppose for the sake of contradiction that L_d is r.e. Then there is a GOTO program that accepts L_d—call it P. Now what does P do on input $x = code\,(P)$? If P accepts x, then x is not in L_d, but this contradicts $L(P) = L_d$. But if P does not accept x, then x *is* in L_d, and this also contradicts $L(P) = L_d$. Hence a program P such that $L(P) = L_d$ cannot exist, and so L_d is not r.e.

The definition of L_d is motivated by Russell's paradox, reading "$\notin$" as "does not accept." Whereas in Russell's paradox we had to conclude that S is not a *set,* here we conclude that L_d is not a *Turing-acceptable* set.

We can similarly carry over Zwicker's paradox by treating a given string x as formally defining "Game-x" as follows: The first player decodes x into a GOTO program P, and then tries to choose some string x' in the language $L(P)$. If $L(P)$ is empty, in particular if x decodes to the trivial program "1. REJECT" as stipulated above, then the game ends then and there. But if the first player finds such an x', then the second player must play the same way with x'. Then we can say that x is *normal* if every play of Game-x must terminate (by reaching a GOTO program that accepts the empty language) in a finite number of steps. Finally define L_Z to be the set of normal strings. By applying the reasoning from Zwicker's paradox, one can imitate the above proof to show that L_Z is not recursively enumerable.

Reductions and More Undecidable Problems

Recall from Chapter 24 (Section 24.3) the notion of Turing reducibility. Basically, a language L_1 is Turing reducible to L_2 if there is a halting Turing machine for language L_1 using an oracle for language L_2. If L_1 is reducible to L_2 and L_2 is decidable, then so is L_1. This is because one can replace queries to oracles by executing a halting computation for L_2. The contrapositive of this statement can be used to show undecidability. If L_1 is undecidable, then so is L_2. We will first express Problem (2) as a language:

$$L_U = \{code(P)111x \,|\, P \text{accepts the string } x\}.$$

Thus L_U takes as input a program in GOTO, and a binary string x, and accepts the encoded pair (P, x) if and only if P accepts x. (Note 111 is used as a separator between P and x.) The universal program presented in "A Universal Program" accepts the language L_U hence it is recursively enumerable. We will show that L_U is not recursive. First, we will show a simple fact about recursive languages.

THEOREM 26.5 *Recursive languages are closed under complement.*

PROOF Let P be a GOTO program for language L. The program P' obtained by interchanging the ACCEPT and REJECT instructions is easily seen to accept the language $\overline{L}$. This standard trick works to complement the computations of most of the deterministic devices (such as DFA).

Now we show that L_U is not recursive.

THEOREM 26.6 *L_U is not recursive.*

PROOF Consider the language $L'_U = \{x|\ x$ when interpreted as a GOTO program accepts its own encoding$\}$. Obviously, $L'_U = \overline{L}_d$. Since L_d is not recursively enumerable, it is not recursive. (Recall that the set of recursive languages is a subset of **recursively enumerable languages.**) By the above theorem, L'_U is not recursive. Finally, note that L'_U can be reduced to L_U as follows. Given an algorithm for L_U, we can construct an algorithm for L'_U as follows: Let P be an algorithm for L_U. To construct an algorithm for L'_U simply note the connection between the two problems. An input string x belongs to L'_U if and only if $x111x$ belongs to L_U. Thus, a simple copy program (similar to one presented in Section 26.2) can be first used to convert the input x into $x111x$. Move the scanning head back to the leftmost character of the first copy of x. Now simply run the program P. Note that the program P' described above is being constructed using only P, not x. This reduction shows that L_U is not recursive.

Next we consider problem (3) in our list. Earlier we showed that a special case of this problem (when the input is restricted to type-1 grammar) is totally solvable. It is not hard to see that the general problem is partially solvable. (To see this, suppose there is a derivation for a string x starting from S, the start symbol of the grammar. Suppose the length of one such derivation is k. A program can try all possible derivations of length 1, 2, etc., until it succeeds. Such a program will always halt on strings x generated by the grammar G. Thus the language

$$L_0 = \{G\#x|G \text{is a type-0 grammar and } x \text{ can be generated by } G\}$$

is recursively enumerable. A standard result from formal language theory [12] is that for every Turing machine M, there is a type-0 grammar G such that $L(M) = T(G)$. This conversion from M to G is the reduction that shows that the language is not recursive.

The string compression problem, numbered 4 on our list, is not a decision problem, but reduction techniques can still be used to show that it is unsolvable. We refer the reader to [17] for details.

By a fairly elaborate reduction (from L_d), it can be shown that the tiling problem (5) in our list is also not partially decidable. We will not do it here and refer the interested reader to [8]. But we would like to point out how the undecidability result can be used to infer a result about *aperiodic tilings.* This deduction is interesting because the result appears to have some deep implications and is hard to deduce directly. We need the following discussion before we can state the result. A different way to pose the tiling problem is whether a given set of tiles can tile *an entire plane* in such a way that all the adjacent tiles have the same color on the meeting quarter. (Note that this question is different from the way we originally posed it: Can a given set of tiles tile any *finite* rectangular region? Interestingly, the two problems are identical in the sense that the answer to one version is "yes" if and only if it is "yes" for the other version.) Call a tiling of the plane *periodic* if one can identify a $k \times k$ square such that the entire tiling is made by repeating this $k \times k$ square tile. Otherwise, call it *aperiodic.* Consider the question: Is there a (finite) set of unit tiles that can tile the plane, but only aperiodically? The answer is "yes" and it can be shown from the total undecidability of the tiling problem. Suppose the answer is "no." Then, for any given set of tiles, the entire plane can be tiled if and only if the plane can be tiled periodically. But such a periodic tiling can be found, if one exists, by trying to tile a $k \times k$ region for successively increasing values of k. This process will eventually succeed (in a finite number of steps) if the tiling exists. This would make the tiling problem partially decidable, which contradicts the total undecidability of the problem. This means that the assumption that the entire plane can be tiled if and only if some $k \times k$ region can be tiled is wrong. Thus there must exist a finite set of tiles that can tile the entire plane, but only aperiodically.

We conclude with a brief remark about problem 7 in our list. After many years of effort by several mathematicians and computer scientists (including Davis and Robinson), Matiyasevich found an effective way to transform a given Turing machine T into a set of equations in variables $x, y_1, \ldots, y_m$ such that for any x, T on input x halts if and only if the other m variables can be set to solve the equations. This reduction shows that Hilbert's tenth problem is undecidable. Details behind this reduction can be found in [6].

26.6 Defining Terms

Decision problem: A computational problem with a yes/no answer. Equivalently, a function whose range consists of two values {0, 1}.

Decidable problem: A decision problem that can be solved by a GOTO program that halts on all inputs in a finite number of steps. For emphasis, the equivalent term *totally decidable* problem is used. The associated language is called *recursive.*

Partially decidable problem: A decision problem that can be solved by a GOTO program that halts (and outputs ACCEPT) on all yes-instances. The program may or may not halt on no-instances. Equivalently, the collection of yes-instance strings forms a type-0 language. (See Chapter 25.)

Recursively enumerable language: Same as partially decidable language.

μ-recursive function: A function that is a basic function (Zero, Successor or Projection), or one that can be obtained from other μ-recursive functions using composition and μ-recursion.

Recursive language: A language that can be accepted by a GOTO program that halts on all inputs. The associated problem is called *decidable.*

Solvable problem: A computational problem that can be solved by a halting GOTO program. The problem may have a nonbinary output.

Totally undecidable problem: A problem that cannot be solved by a GOTO program. Equivalently, one for which the set of yes-instance strings is not a type-0 language.

Undecidable problem: A decision problem that is not (totally) decidable. It could be partially decidable or totally undecidable.

Universal Turing machine: A Turing machine that can simulate any other Turing machine.

Unsolvable problem: A computational problem that is not solvable. The associated function is called an uncomputable function.

Further Information

The fundamentals of computability can be found in many books including the classic texts [4, 20, 23]. More-recent books on automata and formal languages have also devoted at least a few chapters to computability [6, 7, 8, 9, 12, 24, 29]. Early work on computability was motivated by a quest to address profound questions about the basis of logical reasoning, mathematical proofs and automatic computation. Various formalisms discussed in this chapter were proposed at around the same time, and soon thereafter, their equivalence was tested. Thus, in a short time, the Church-Turing thesis took deep roots. Subsequent work has focused on whether specific problems are decidable or not. Another direction of research has been

to make finer distinctions among unsolvable problems by introducing degrees of unsolvability. Recursive function theory and lambda calculus also led to the development of functional programming languages such as Lisp, Scheme, Haskell, and ML. Computability theory is also closely related to logic, formal deductive systems, and complexity theory. Logic and deductive systems are of interest to philosophers and researchers in artificial intelligence, as well as to computation theorists. Although there are no journals devoted exclusively to computability, many theory journals (such as those listed at the end of Chapters 24 and 25) publish papers on this topic. In addition, *Annals of Pure and Applied Logic* publishes papers on logic and computability.

27.1 Introduction

The purposes of complexity theory are to ascertain the amount of computational resources required to solve important computational problems, and to classify problems according to their difficulty. The resource most often discussed is computational time, although memory (space) and circuitry (or hardware) have also been studied. The main challenge of the theory is to prove lower bounds, i.e., that certain problems cannot be solved without expending large amounts of resources. Although it is easy to prove that inherently difficult problems exist, it has turned out to be much more difficult to prove that any *interesting* problems are hard to solve. There has been much more success in providing strong evidence of intractability, based on plausible, widely held conjectures. In both cases, the mathematical arguments of intractability rely on the notions of *reducibility* and *completeness*—which are the topics of Chapter 28. Before one can understand reducibility and completeness, however, one must grasp the notion of a *complexity class*—and that is the topic of this chapter.

First, however, we want to demonstrate that complexity theory really can prove—to even the most skeptical practitioner—that it is hopeless to try to build programs or **circuits** that solve certain problems.

[1]Eric Allender — Supported by the National Science Foundation under Grant CCR-9509603. Portions of this work were performed while a visiting scholar at the Institute of Mathematical Sciences, Madras, India.

As our example, we consider the manufacture and testing of logic circuits and communication protocols. Many problems in these domains are solved by building a logical formula over a certain vocabulary, and then determining whether the formula is logically valid, or whether counterexamples (that is, bugs) exist. The choice of vocabulary for the logic is important here, as the next paragraph illustrates.

One particular logic that was studied by Stockmeyer [42] is called WS1S. (We need not be concerned with any details of this logic.) Stockmeyer showed that any circuit that takes as input a formula with up to 616 symbols and produces as output a correct answer saying whether the formula is valid, requires at least 10^{123} gates. According to Stockmeyer [43], "Even if gates were the size of a proton and were connected by infinitely thin wires, the network would densely fill the known universe."

Of course, Stockmeyer's theorem holds for one particular sort of circuitry, but the awesome size of the lower bound makes it evident that, no matter how innovative the architecture, no matter how clever the software, no computational machinery will enable us to solve the validity problem in this logic. For the practitioner testing validity of logical formulas, the lessons are (1) be careful with the choice of the logic, (2) use small formulas, and often (3) be satisfied with something less than full validity testing.

In contrast to this result of Stockmeyer, most lower bounds in complexity theory are stated asymptotically. For example, one might show that a particular problem requires time $\Omega(t(n))$ to solve on a Turing machine, for some rapidly growing function t. For the Turing machine model, no other type of lower bound is possible, because Turing machines have the linear-speed-up property (see Chapter 24, Theorem 24.5). This property makes Turing machines mathematically convenient to work with, since constant factors become irrelevant, but it has the by-product—which some find disturbing—that for any n there is a Turing machine that handles inputs of length n in just n steps by looking up answers in a big table. Nonetheless, these asymptotic lower bounds essentially always can be translated into concrete lower bounds on, say, the number of components of a particular technology, or the number of clock cycles on a particular vendor's machine, that are required to compute a given function on a certain input size.[2]

Sadly, to date, few general complexity–theoretic lower bounds are known that are interesting enough to translate into concrete lower bounds in this sense. Even worse, for the vast majority of important problems that are believed to be difficult, no nontrivial lower bound on complexity is known today. Instead, complexity theory has contributed (1) a way of dividing the computational world up into *complexity classes,* and (2) evidence suggesting that these complexity classes are probably distinct. If this evidence can be replaced by mathematical proof, then we will have an abundance of interesting lower bounds.

What is a Complexity Class?

Typically, a complexity class is defined by (1) a model of computation, (2) a resource (or collection of resources), and (3) a function known as the *complexity bound* for each resource.

The models used to define complexity classes fall into two main categories: (1) machine-based models, and (2) circuit-based models. Turing machines (TMs) and random-access machines (RAMs) are the two principal families of machine models; they were described in Chapter 24. We describe circuit-based models later, in Section 27.3. Other kinds of (Turing) machines were also introduced in Chapter 24, including deterministic, nondeterministic, alternating, and oracle machines.

When we wish to model real computations, deterministic machines and circuits are our closest links to reality. Then why consider the other kinds of machines? There are two main reasons.

---

[2]The skeptical practitioner can still argue that these lower bounds hold only for the worst-case behavior of an algorithm, and that these bounds are irrelevant if the worst case arises very rarely in practice. There is a complexity theory of problems that are hard on average (as a counterpoint to the average case analysis of algorithms considered in Chapter 14), but to date only a small number of natural problems have been shown to be hard in this sense, and this theory is beyond the scope of this volume. See **Further Information** at the end of this chapter.

The most potent reason comes from the computational problems whose complexity we are trying to understand. The most notorious examples are the hundreds of natural NP-complete problems [15]. To the extent that we understand anything about the complexity of these problems, it is because of the model of *nondeterministic* Turing machines. Nondeterministic machines do not model physical computation devices, but they do model real computational problems. There are many other examples where a particular model of computation has been introduced in order to capture some well-known computational problem in a complexity class. This phenomenon is discussed at greater length in Chapter 29.

The second reason is related to the first. Our desire to understand real computational problems has forced upon us a repertoire of models of computation and resource bounds. In order to understand the relationships between these models and bounds, we combine and mix them and attempt to discover their relative power. Consider, for example, nondeterminism. By considering the complements of languages accepted by nondeterministic machines, researchers were naturally led to the notion of alternating machines. When alternating machines and deterministic machines were compared, a surprising virtual identity of deterministic space and alternating time emerged. Subsequently, alternation was found to be a useful way to model efficient parallel computation. (See "Alternating Complexity Classes" and "Circuits and Parallel Classes" below.) This phenomenon, whereby models of computation are generalized and modified in order to clarify their relative complexity, has occurred often through the brief history of complexity theory, and has generated some of the most important new insights.

Other underlying principles in complexity theory emerge from the major theorems showing *relationships* between complexity classes. These theorems fall into two broad categories. **Simulation theorems** show that computations in one class can be simulated by computations that meet the defining resource bounds of another class. The containment of nondeterministic logarithmic space (NL) in polynomial time (P), and the equality of the class P with alternating logarithmic space, are simulation theorems. **Separation theorems** show that certain complexity classes are distinct. Complexity theory currently has precious few of these. The main tool used in those separation theorems we have is called **diagonalization.** We illustrate this tool by giving proofs of some separation theorems in this chapter. In the next chapter, however, we show some apparently severe limitations of this tool. This ties in to the general feeling in computer science that *lower bounds are hard to prove.* Our current inability to separate many complexity classes from each other is perhaps the greatest challange posed by complexity theory.

27.2 Time and Space Complexity Classes

We begin by emphasizing the fundamental resources of time and space for deterministic and nondeterministic Turing machines. We concentrate on resource bounds between logarithmic and exponential, because those bounds have proved to be the most useful for understanding problems that arise in practice.

Time complexity and **space complexity** were defined in Chapter 24, Definition 24.4. We repeat Definition 24.5 of that chapter to define the following **fundamental time classes** and **fundamental space classes**, given functions $t(n)$ and $s(n)$:

- $\mathsf{DTIME}[t(n)]$ is the class of languages decided by deterministic Turing machines of time complexity $t(n)$.
- $\mathsf{NTIME}[t(n)]$ is the class of languages decided by nondeterministic Turing machines of time complexity $t(n)$.
- $\mathsf{DSPACE}[s(n)]$ is the class of languages decided by deterministic Turing machines of space complexity $s(n)$.
- $\mathsf{NSPACE}[s(n)]$ is the class of languages decided by nondeterministic Turing machines of space complexity $s(n)$.

We sometimes abbreviate $\mathsf{DTIME}[t(n)]$ to $\mathsf{DTIME}[t]$ (and so on) when t is understood to be a function, and when no reference is made to the input length n.

Canonical Complexity Classes

The following are the **canonical complexity classes:**

- $\mathsf{L} = \mathsf{DSPACE}[\log n]$ (deterministic log space)
- $\mathsf{NL} = \mathsf{NSPACE}[\log n]$ (nondeterministic log space)
- $\mathsf{P} = \mathsf{DTIME}[n^{O(1)}] = \bigcup_{k\geq 1} \mathsf{DTIME}[n^k]$ (polynomial time)
- $\mathsf{NP} = \mathsf{NTIME}[n^{O(1)}] = \bigcup_{k\geq 1} \mathsf{NTIME}[n^k]$ (nondeterministic polynomial time)
- $\mathsf{PSPACE} = \mathsf{DSPACE}[n^{O(1)}] = \bigcup_{k\geq 1} \mathsf{DSPACE}[n^k]$ (polynomial space)
- $\mathsf{E} = \mathsf{DTIME}[2^{O(n)}] = \bigcup_{k\geq 1} \mathsf{DTIME}[k^n]$
- $\mathsf{NE} = \mathsf{NTIME}[2^{O(n)}] = \bigcup_{k\geq 1} \mathsf{NTIME}[k^n]$
- $\mathsf{EXP} = \mathsf{DTIME}[2^{n^{O(1)}}] = \bigcup_{k\geq 1} \mathsf{DTIME}[2^{n^k}]$ (deterministic exponential time)
- $\mathsf{NEXP} = \mathsf{NTIME}[2^{n^{O(1)}}] = \bigcup_{k\geq 1} \mathsf{NTIME}[2^{n^k}]$ (nondeterministic exponential time)
- $\mathsf{EXPSPACE} = \mathsf{DSPACE}[2^{n^{O(1)}}] = \bigcup_{k\geq 1} \mathsf{DSPACE}[2^{n^k}]$ (exponential space)

The space classes PSPACE and EXPSPACE are defined in terms of the DSPACE complexity measure. By Savitch's Theorem (see Theorem 27.3 below) the NSPACE measure with polynomial bounds also yields PSPACE, and with $2^{n^{O(1)}}$ bounds yields EXPSPACE.

Why Focus on These Classes?

The class P contains many familiar problems that can be solved efficiently, such as finding shortest paths in networks, parsing context-free grammars, sorting, matrix multiplication, and linear programming. By definition, in fact, P contains all problems that can be solved by (deterministic) programs of reasonable worst-case time complexity.

But P also contains problems whose best algorithms have time complexity $n^{10^{500}}$. It seems ridiculous to say that such problems are computationally feasible. Nevertheless, there are four important reasons to include these problems:

1. For the main goal of proving lower bounds, it is sensible to have an overly generous notion of the class of feasible problems. That is, if we show that a problem is *not* in P, then we have shown in a very strong way that solution via deterministic algorithms is impractical.
2. The theory of complexity-bounded reducibility (Chapter 28) is predicated on the simple notion that if functions f and g are both easy to compute, then the composition of f and g should also be easy to compute. If we want to allow algorithms of time complexity n^2 to be considered feasible (and certainly many algorithms of this complexity are used daily), then we are immediately led to regard running times n^4, n^8, ... as also being feasible. Put another way, the choice is either to lay down an arbitrary and artificial limit on feasibility (and to forgo the desired property that the composition of easy functions be easy), or to go with the natural and overly generous notion given by P.
3. Polynomial time has served well as the intellectual boundary between feasible and infeasible problems. Empirically, problems of time complexity $n^{10^{500}}$ do not arise in practice, while problems of time complexity $O(n^4)$, and those proved or believed to be $\Omega(2^n)$, occur often. Moreover, once a polynomial-time algorithm for a problem is found, the foot is in the door, and an armada of mathematical and algorithmic techniques can be used to improve the algorithm. Linear programming may be the best known example. The breakthrough $O(n^8)$ time algorithm of Khachiyan [29], for $n \times n$ instances, was impractical in itself, but it prompted an innovation by Karmarkar [27] that produced an algorithm whose running time of about

$O(n^3)$ on all cases competes well commercially with the simplex method, which runs in $O(n^3)$ time in most cases but takes 2^n time in some. Of course, if it should turn out that the Hamiltonian circuit problem (or some other NP-complete problem) has complexity $n^{10^{500}}$, then the theory would need to be overhauled. For the time being, this seems unlikely.

4. We would like our fundamental notions to be independent of arbitrary choices we have made in formalizing our definitions. There is much that is arbitrary and historically accidental in the prevalent choice of the Turing machine as the standard model of computation. This choice does not affect the class P itself, however, because the natural notions of polynomial time for essentially all models of sequential computation that have been devised yield the same class. The random-access and pointer machine models described in Section 4 of Chapter 30 can be simulated by Turing machines with at most a cubic increase in time. Many feel that our "true" experience of running time on real sequential computers falls midway between Turing machines and these more-powerful models, but this only bolsters our conviction that the class P gives the "true" notion of polynomial time.

By analogy to the famous *Church–Turing thesis* (see Chapter 26, Section 26.4), which states that the definition of a (partial) recursive function captures the intuitive notion of a computable process, several authorities have proposed the following

Polynomial-Time Church-Turing Thesis

The class P captures the true notion of those problems that are computable in polynomial time by sequential machines, and is the same for any physically relevant model and minimally reasonable time measure of sequential computation that will ever be devised.

This thesis extends also to parallel models if "time" is replaced by the technologically important notion of parallel *work* (see Chapter 45, on parallel computation).

Another way in which the concept of P is robust is that P is characterized by many concepts from logic and mathematics that do not mention machines or time. Some of these characterizations are surveyed in Chapter 29.

The class NP can also be defined by means other than nondeterministic Turing machines. NP equals the class of problems whose solutions can be *verified* quickly, by deterministic machines in polynomial time. Equivalently, NP comprises those languages whose membership proofs can be checked quickly.

For example, one language in NP is the set of composite numbers, written in binary. A proof that a number z is composite can consist of two factors $z_1 \geq 2$ and $z_2 \geq 2$ whose product $z_1 z_2$ equals z. This proof is quick to check if z_1 and z_2 are given, or guessed. Correspondingly, one can design a nondeterministic Turing machine N that on input z branches to write down "guesses" for z_1 and z_2, and then deterministically multiplies them to test whether $z_1 z_2 = z$. Then $L(N)$, the language accepted by N, equals the set of composite numbers, since there exists an accepting computation path if and only if z really is composite. Note that N does not really solve the problem—it just checks the candidate solution proposed by each branch of the computation.

Another important language in NP is the set of satisfiable Boolean formulas, called SAT. A Boolean formula ϕ is satisfiable if there exists a way of assigning `true` or `false` to each variable such that under this truth assignment, the value of ϕ is `true`. For example, the formula $x \wedge (\overline{x} \vee y)$ is satisfiable, but $x \wedge \overline{y} \wedge (\overline{x} \vee y)$ is not satisfiable. A nondeterministic Turing machine N, after checking the syntax of ϕ and counting the number n of variables, can nondeterministically write down an n-bit 0-1 string a on its tape, and then deterministically (and easily) evaluate ϕ for the truth assignment denoted by a. The computation path corresponding to each individual a accepts if and only if $\phi(a) =$ `true`, and so N itself accepts ϕ if and only if ϕ is satisfiable; i.e., $L(N) =$ SAT. Again, this checking of given assignments differs significantly from trying to find an accepting assignment.

The above characterization of NP as the set of problems with easily verified solutions is formalized as follows: $A \in \mathsf{NP}$ if and only if there exist a language $A' \in \mathsf{P}$ and a polynomial p such that for every x, $x \in A$ if and only if there exists a y such that $|y| \leq p(|x|)$ and $(x, y) \in A'$. Here, whenever x belongs to A, y is interpreted as a positive solution to the problem represented by x, or equivalently, as a proof that x belongs to A. The difference between P and NP is that between solving and checking, or between finding a proof of a mathematical theorem and testing whether a candidate proof is correct. In essence, NP represents all sets of theorems with proofs that are short (i.e., of polynomial length), while P represents those statements that can proved or refuted quickly from scratch.

The theory of NP-completeness, together with the many known NP-complete problems, is perhaps the best justification for interest in the classes P and NP. All of the other canonical complexity classes listed above have natural and important problems that are complete for them (under various reducibility relations, the subject of the next chapter). Further motivation for studying L, NL, and PSPACE, comes from their relationships to P and NP. Namely, L and NL are the largest space-bounded classes known to be contained in P, and PSPACE is the smallest space-bounded class known to contain NP. (It is worth mentioning here that NP does not stand for "nonpolynomial time"; the class P is a subclass of NP.)

Similarly, EXP is of interest primarily because it is the smallest deterministic time class known to contain NP. The closely-related class E is not known to contain NP; we will see in "Padding Arguments" the main reason for interest in E.

Constructibility

Before we go further, we need to introduce the notion of *constructibility.* Without it, no meaningful theory of complexity is possible.

The most basic theorem that one should expect from complexity theory would say, "If you have more resources, you can do more." Unfortunately, if we aren't careful with our definitions, then this claim is false:

THEOREM 27.1 **(Gap Theorem)** *There is a computable time bound $t(n)$ such that* $\mathsf{DTIME}[t(n)] = \mathsf{DTIME}[2^{2^{t(n)}}]$.

That is, there is an empty gap between time $t(n)$ and time doubly exponentially greater than $t(n)$, in the sense that anything that can be computed in the larger time bound can already be computed in the smaller time bound. That is, even with much more time, you can't compute more. This gap can be made much larger than doubly exponential; for any computable r, there is a computable time bound t such that $\mathsf{DTIME}[t(n)] = \mathsf{DTIME}[r(t(n))]$. Exactly analogous statements hold for the NTIME, DSPACE, and NSPACE measures.

Fortunately, the gap phenomenon cannot happen for time bounds t that anyone would ever be interested in. Indeed, the proof of the Gap Theorem proceeds by showing that one can define a time bound t such that no machine has a running time that is between $t(n)$ and $2^{2^{t(n)}}$. This theorem indicates the need for formulating only those time bounds that actually describe the complexity of some machine.

A function $t(n)$ is **time-constructible** if there exists a deterministic Turing machine that halts after exactly $t(n)$ steps for every input of length n. A function $s(n)$ is **space-constructible** if there exists a deterministic Turing machine that uses exactly $s(n)$ worktape cells for every input of length n. (Most authors consider only functions $t(n) \geq n + 1$ to be time-constructible, and many limit attention to $s(n) \geq \log n$ for space bounds. There do exist sublogarithmic space-constructible functions, but we prefer to avoid the tricky theory of $o(\log n)$ space bounds.)

For example, $t(n) = n+1$ is time-constructible. Furthermore, if $t_1(n)$ and $t_2(n)$ are time-constructible, then so are the functions $t_1 + t_2$, $t_1 t_2$, $t_1^{t_2}$, and c^{t_1} for every integer $c > 1$. Consequently, if $p(n)$ is a polynomial, then $p(n) = \Theta(t(n))$ for some time-constructible polynomial function $t(n)$. Similarly, $s(n) = \log n$ is space-constructible, and if $s_1(n)$ and $s_2(n)$ are space-constructible, then so are the functions

$s_1 + s_2$, $s_1 s_2$, $s_1^{s_2}$, and c^{s_1} for every integer $c > 1$. Many common functions are space-constructible: e.g., $n \log n$, n^3, 2^n, $n!$.

Constructibility helps eliminate an arbitrary choice in the definition of the basic time and space classes. For general time functions t, the classes $\mathsf{DTIME}[t]$ and $\mathsf{NTIME}[t]$ may vary depending on whether machines are required to halt within t steps on all computation paths, or just on those paths that accept. If t is time-constructible and s is space-constructible, however, then $\mathsf{DTIME}[t]$, $\mathsf{NTIME}[t]$, $\mathsf{DSPACE}[s]$, and $\mathsf{NSPACE}[s]$ can be defined without loss of generality in terms of Turing machines that always halt.

As a general rule, any function $t(n) \geq n + 1$ and any function $s(n) \geq \log n$ that one is interested in as a time or space bound, is time- or space-constructible, respectively. As we have seen, little of interest can be proved without restricting attention to constructible functions. This restriction still leaves a rich class of resource bounds.

The Gap Theorem is not the only case where intuitions about complexity are false. Most people also expect that a goal of algorithm design should be to arrive at an optimal algorithm for a given problem. In some cases, however, no algorithm is remotely close to optimal.

THEOREM 27.2 **(Speed-Up Theorem)** *There is a decidable language A such that for every machine M that decides A, with running time $u(n)$, there is another machine M' that decides A much faster: its running time $t(n)$ satisfies $2^{2^{t(n)}} \leq u(n)$ for all but finitely many n.*

This statement, too, holds with any computable function $r(t)$ in place of 2^{2^t}. Put intuitively, the program M' running on an old IBM PC is better than the program M running on the fastest hardware to date. Hence A has no best algorithm, and no well-defined time-complexity function. Unlike the case of the Gap Theorem, the speed-up phenomenon may hold for languages and time bounds of interest. For instance, a problem of time complexity bounded by $t(n) = n^{\log n}$, which is just above polynomial time, may have arbitrary polynomial speed-up—i.e., may have algorithms of time complexity $t(n)^{1/k}$ for all $k > 0$.

One implication of the Speed-Up Theorem is that the complexities of some problems need to be sandwiched between upper and lower bounds. Actually, there is a sense in which every problem has a well defined lower bound on time. For every language A there is a computable function t_0 such that for every time-constructible function t, there is some machine that accepts A within time t if and only if $t = \Omega(t_0)$ [31]. A catch, however, is that t_0 itself may not be time-constructible.

Basic Relationships

Clearly, for all time functions $t(n)$ and space functions $s(n)$, $\mathsf{DTIME}[t(n)] \subseteq \mathsf{NTIME}[t(n)]$ and $\mathsf{DSPACE}[s(n)] \subseteq \mathsf{NSPACE}[s(n)]$, because a deterministic machine is a special case of a nondeterministic machine. Furthermore, $\mathsf{DTIME}[t(n)] \subseteq \mathsf{DSPACE}[t(n)]$ and $\mathsf{NTIME}[t(n)] \subseteq \mathsf{NSPACE}[t(n)]$, because at each step, a k-tape Turing machine can write on at most $k = O(1)$ previously unwritten cells. The next theorem presents additional important relationships between classes.

THEOREM 27.3 *Let $t(n)$ be a* **time-constructible function,** *and let $s(n)$ be a* **space-constructible function,** *$s(n) \geq \log n$.*

(a) $\mathsf{NTIME}[t(n)] \subseteq \mathsf{DTIME}[2^{O(t(n))}]$.

(b) $\mathsf{NSPACE}[s(n)] \subseteq \mathsf{DTIME}[2^{O(s(n))}]$.

(c) $\mathsf{NTIME}[t(n)] \subseteq \mathsf{DSPACE}[t(n)]$.

(d) **(Savitch's Theorem)** $\mathsf{NSPACE}[s(n)] \subseteq \mathsf{DSPACE}[s(n)^2]$.

As a consequence of the first part of this theorem, $\mathsf{NP} \subseteq \mathsf{EXP}$. No better general upper bound on deter-

ministic time is known for languages in NP, however. See Fig. 27.1 for other known inclusion relationships between canonical complexity classes. (Classes AC^0, TC^0, and NC^1 are defined in Section 27.3.)

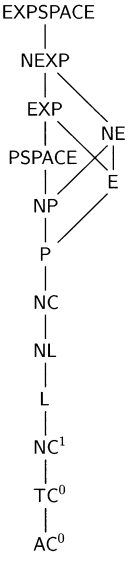

FIGURE 27.1 Inclusion relationships between the canonical complexity classes.

Although we do not know whether allowing nondeterminism strictly increases the class of languages decided in polynomial time, Savitch's Theorem says that for space classes, nondeterminism does not help by more than a polynomial amount.

Complementation

For a language A over an alphabet Σ, define $\overline{A}$ to be the complement of A in the set of words over Σ: $\overline{A} = \Sigma^* - A$. For a class of languages $\mathcal{C}$, define co-$\mathcal{C} = \{\overline{A} : A \in \mathcal{C}\}$. If $\mathcal{C} =$ co-$\mathcal{C}$, then $\mathcal{C}$ is **closed under complementation.**

In particular, co-NP is the class of languages that are complements of languages in NP. For the language SAT of satisfiable Boolean formulas, $\overline{\text{SAT}}$ is the set of unsatisfiable formulas, whose value is `false` for every truth assignment, together with the syntactically incorrect formulas. A closely related language in co-NP is the set of Boolean tautologies, namely, those formulas whose value is `true` for every truth assignment. The question of whether NP equals co-NP comes down to whether every tautology has a short (i.e., polynomial-sized) proof. The only obvious general way to prove a tautology ϕ in m variables is to verify all 2^m rows of the truth table for ϕ, taking exponential time. Most complexity theorists believe that there is no general way to reduce this time to polynomial, hence that NP $\neq$ co-NP.

Questions about complementation bear directly on the P vs. NP question. It is easy to show that P is closed under complementation (see the next theorem). Consequently, if NP $\neq$ co-NP, then P $\neq$ NP.

THEOREM 27.4 **(Complementation Theorems)** *Let t be a time-constructible function, and let s be a space-constructible function, with $s(n) \geq \log n$ for all n. Then*

(a) DTIME$[t]$ *is closed under complementation.*
(b) DSPACE$[s]$ *is closed under complementation.*

(c) **(Immerman–Szelepcsényi Theorem)** $\mathsf{NSPACE}[s]$ *is closed under complementation.*

The Complementation Theorems are used to prove the Hierarchy Theorems in the next section.

Hierarchy Theorems and Diagonalization

Diagonalization is the most useful technique for proving the existence of computationally difficult problems. In this section, we will see examples of two rather different types of arguments, both of which can be called "diagonalization," and we will see how these are used to prove hierarchy theorems in complexity theory.

A hierarchy theorem is a theorem that says "If you have more resources, you can compute more." As we saw in "Constructibility", this theorem is possible only if we restrict attention to constructible time and space bounds. Next, we state hierarchy theorems for deterministic and nondeterministic time and space classes. In the following, $\subset$ denotes *strict* inclusion between complexity classes.

THEOREM 27.5 **(Hierarchy Theorems)** *Let t_1 and t_2 be time-constructible functions, and let s_1 and s_2 be space-constructible functions, with $s_1(n), s_2(n) \geq \log n$ for all n.*

(a) If $t_1(n) \log t_1(n) = o(t_2(n))$, then $\mathsf{DTIME}[t_1] \subset \mathsf{DTIME}[t_2]$.
(b) If $t_1(n+1) = o(t_2(n))$, then $\mathsf{NTIME}[t_1] \subset \mathsf{NTIME}[t_2]$.
(c) If $s_1(n) = o(s_2(n))$, then $\mathsf{DSPACE}[s_1] \subset \mathsf{DSPACE}[s_2]$.
(d) If $s_1(n) = o(s_2(n))$, then $\mathsf{NSPACE}[s_1] \subset \mathsf{NSPACE}[s_2]$.

As a corollary of the Hierarchy Theorem for DTIME,

$$\mathsf{P} \subseteq \mathsf{DTIME}[n^{\log n}] \subset \mathsf{DTIME}[2^n] \subseteq \mathsf{E};$$

hence we have the strict inclusion $\mathsf{P} \subset \mathsf{E}$. Although we do not know whether $\mathsf{P} \subset \mathsf{NP}$, there exists a problem in E that cannot be solved in polynomial time. Other consequences of the Hierarchy Theorems are $\mathsf{NE} \subset \mathsf{NEXP}$ and $\mathsf{NL} \subset \mathsf{PSPACE}$.

In the Hierarchy Theorem for DTIME, the hypothesis on t_1 and t_2 is $t_1(n) \log t_1(n) = o(t_2(n))$, instead of $t_1(n) = o(t_2(n))$, for technical reasons related to the simulation of machines with multiple worktapes by a single universal Turing machine with a fixed number of worktapes. Other computational models, such as random access machines, enjoy tighter time hierarchy theorems.

All proofs of the Hierarchy Theorems use the technique of **diagonalization**. For example, the proof for DTIME constructs a Turing machine M of time complexity t_2 that considers all machines $M_1, M_2, \ldots$ whose time complexity is t_1; for each i, the proof finds a word x_i that is accepted by M if and only if $x_i \notin L(M_i)$, the language decided by M_i. Consequently, $L(M)$, the language decided by M, differs from each $L(M_i)$, hence $L(M) \notin \mathsf{DTIME}[t_1]$. The diagonalization technique resembles the classic method used to prove that the real numbers are uncountable, by constructing a number whose jth digit differs from the jth digit of the jth number on the list. To illustrate the diagonalization technique, we outline proofs of the Hierarchy Theorems for DSPACE and for NTIME. In this subsection, $\langle i, x \rangle$ stands for the string $0^i 1 x$, and *zeroes*(y) stands for the number of 0's that a given string y starts with. Note that *zeroes*$(\langle i, x \rangle) = i$.

PROOF (of the DSPACE Hierarchy Theorem)

We construct a deterministic Turing machine M that decides a language A such that $A \in \mathsf{DSPACE}[s_2] - \mathsf{DSPACE}[s_1]$.

Let U be a deterministic universal Turing machine, as described in Chapter 26, Section 26.2. On input x of length n, machine M performs the following:

1. Lay out $s_2(n)$ cells on a worktape.
2. Let $i = zeroes(x)$.
3. Simulate the universal machine U on input $\langle i, x\rangle$. Accept x if U tries to use more than s_2 worktape cells. (We omit some technical details, such as interleaving multiple worktapes onto the fixed number of worktapes of M, and the way in which the constructibility of s_2 is used to ensure that this process halts.)
4. If U accepts $\langle i, x\rangle$, then reject; if U rejects $\langle i, x\rangle$, then accept.

Clearly, M always halts and uses space $O(s_2(n))$. Let $A = L(M)$.

Suppose $A \in \mathsf{DSPACE}[s_1(n)]$. Then there is some Turing machine M_j accepting A using space at most $s_1(n)$. The universal Turing machine U can easily be given the property that its space needed to simulate a given Turing machine M_j is at most a constant factor higher than the space used by M_j itself. More precisely, there is a constant k depending only on j (in fact, we can take $k = |j|$), such that U, on inputs z of the form $z = \langle j, x\rangle$, uses at most $ks_1(|x|)$ space.

Since $s_1(n) = o(s_2(n))$, there is an n_0 such that $ks_1(n) \leq s_2(n)$ for all $n \geq n_0$. Let x be a string of length greater than n_0 such that the first $j + 1$ symbols of x are $0^j 1$. Note that the universal Turing machine U, on input $\langle j, x\rangle$, simulates M_j on input x and uses space at most $ks_1(n) \leq s_2(n)$. Thus, when we consider the machine M defining A, we see that on input x the simulation does not stop in Step 3, but continues on to Step 4, and thus $x \in A$ if and only if U rejects $\langle j, x\rangle$. Consequently, M_j does not accept A, contrary to our assumption. Thus $A \notin \mathsf{DSPACE}[s_1(n)]$.

A more sophisticated argument is required to prove the Hierarchy Theorem for NTIME. To see why, note that it is necessary to diagonalize against *nondeterministic* machines, and thus it is necessary to use a nondeterministic universal Turing machine as well. In the deterministic case, when we simulated an accepting computation of the universal machine, we would reject, and if we simulated a rejecting computation of the universal machine, we would accept. That is, we would do exactly the opposite of what the universal machine does, in order to "fool" each simulated machine M_i. If the machines under consideration are *nondeterministic,* then M_i can have both an accepting path and a rejecting path on input x, in which case the universal nondeterministic machine would accept input $\langle i, x\rangle$. If we simulate the universal machine on an input and accept upon reaching a rejecting leaf and reject if upon reaching an accepting leaf, then this simulation would still accept (because the simulation that follows the rejecting path now accepts). Thus, we would fail to do the opposite of what M_i does.

The following careful argument guarantees that each machine M_i is fooled on some input. It draws on a result of Book et al. [6] that every language in $\mathsf{NTIME}[t(n)]$ is accepted by a two-tape nondeterministic Turing machine that runs in time $t(n)$.

PROOF (of the NTIME Hierarchy Theorem)

Let $M_1, M_2, \ldots$ be an enumeration of two-tape nondeterministic Turing machines running in time $t_1(n)$. Let f be a rapidly growing function such that time $f(i, n, s)$ is enough time for a deterministic machine to compute the function

$$(i, n, s) \mapsto \begin{cases} 1 & \text{if } M_i \text{ accepts } 1^n \text{ in } \leq s \text{ steps} \\ 0 & \text{otherwise} \end{cases}$$

Letting $f(i, n, s)$ be greater than $2^{2^{i+n+s}}$ is sufficient.

Now divide Σ^* into regions, so that in region $j = \langle i, y\rangle$, we try to "fool" machine M_i. Note that each M_i is considered infinitely often. The regions are defined by functions $start(j)$ and $end(j)$, defined as follows: $start(1) = 1$, $start(j + 1) = end(j) + 1$, where taking $i = zeroes(j)$, we have $end(j) = f(i, start(j), t_2(start(j)))$. The important point is that, on input $1^{end(j)}$, a deterministic machine can, in time $t_2(end(j))$, determine whether M_i accepts $1^{start(j)}$ in at most $t_2(start(j))$ steps.

By picking f appropriately easy to invert, we can guarantee that, on input 1^n, we can in time $t_2(n)$ determine which region j contains n.

Now it is easy to verify that the following routine can be performed in time $t_2(n)$ by a nondeterministic machine. (In the pseudo-code below, U is a "universal" nondeterministic machine with 4 tapes, which is therefore able to simulate one step of machine M_i in $O(i^3)$ steps.)

1. On input 1^n, determine which region j contains n. Let $j = \langle i, y \rangle$.
2. If $n = end(j)$, then accept if and only if M_i does *not* accept $1^{start(j)}$ within $t_2(start(j))$ steps.
3. Otherwise, accept if and only if U accepts $\langle i, 1^{n+1} \rangle$ within $t_2(n)$ steps. (Here, it is important that we are talking about $t_2(n)$ steps of U, which may be only about $t_2(n)/i^3$ steps of M_i.)

Let us call the language accepted by this procedure A. Clearly $A \in \mathsf{NTIME}[t_2(n)]$. We now claim that $A \notin \mathsf{NTIME}[t_1(n)]$.

Assume otherwise, and let M_i be the nondeterministic machine accepting A in time $t_1(n)$. Recall that M_i has only two tapes. Let c be a constant such that $i^3 t_1(n+1) < t_2(n)$ for all $n \geq c$. Let y be a string such that $|y| \geq c$, and consider stage $j = \langle i, y \rangle$. Then for all n such that $start(j) \leq n < end(j)$, we have $1^n \in A$ if and only if $1^{n+1} \in A$. However this contradicts the fact that $1^{start(j)} \in A$ if and only if $1^{end(j)} \notin A$.

Although the diagonalization technique successfully separates some pairs of complexity classes, diagonalization does not seem strong enough to separate P from NP. (See Theorem 28.15 in Chapter 28.)

Padding Arguments

A useful technique for establishing relationships between complexity classes is the **padding argument.** Let A be a language over alphabet Σ, and let # be a symbol not in Σ. Let f be a numeric function. The **f-padded version of** A is the language

$$A' = \left\{ x\#^{f(n)} : x \in A \text{ and } n = |x| \right\}$$

That is, each word of A' is a word in A concatenated with $f(n)$ consecutive # symbols. The padded version A' has the same information content as A, but because each word is longer, the computational complexity of A' is smaller!

The proof of the next theorem illustrates the use of a padding argument.

THEOREM 27.6 *If* $\mathsf{P} = \mathsf{NP}$, *then* $\mathsf{E} = \mathsf{NE}$.

PROOF Since $\mathsf{E} \subseteq \mathsf{NE}$, we prove that $\mathsf{NE} \subseteq \mathsf{E}$.

Let $A \in \mathsf{NE}$ be decided by a nondeterministic Turing machine M in at most $t(n) = k^n$ time for some constant integer k. Let A' be the $t(n)$-padded version of A. From M, we construct a nondeterministic Turing machine M' that decides A' in linear time: M' checks that its input has the correct format, using the time-constructibility of t; then M' runs M on the prefix of the input preceding the first # symbol. Thus, $A' \in \mathsf{NP}$.

If $\mathsf{P} = \mathsf{NP}$, then there is a deterministic Turing machine D' that decides A' in at most $p'(n)$ time for some polynomial p'. From D', we construct a deterministic Turing machine D that decides A, as follows. On input x of length n, since $t(n)$ is time-constructible, machine D constructs $x\#^{t(n)}$, whose length is $n + t(n)$, in $O(t(n))$ time. Then D runs D' on this input word. The time complexity of D is at most $O(t(n)) + p'(n + t(n)) = 2^{O(n)}$. Therefore, $\mathsf{NE} \subseteq \mathsf{E}$.

A similar argument shows that the $\mathsf{E} = \mathsf{NE}$ question is equivalent to the question of whether $\mathsf{NP} - \mathsf{P}$ contains a subset of 1^*, that is, a language over a single-letter alphabet.

Padding arguments sometimes can be used to give tighter hierarchies than can obtained by straightforward diagonalization. For instance, Theorem 27.5 leaves open the question of whether, say, $\mathsf{DTIME}[n^3 \log^{1/2} n] = \mathsf{DTIME}[n^3]$. We can show that these classes are not equal, by using a padding argument. We will need the following lemma, whose proof is similar to that of Theorem 27.6.

LEMMA 27.1 (**Translational Lemma**) Let t_1, t_2, and f be time-constructible functions. If $\mathsf{DTIME}[t_1(n)] = \mathsf{DTIME}[t_2(n)]$, then $\mathsf{DTIME}[t_1(f(n))] = \mathsf{DTIME}[t_2(f(n))]$.

THEOREM 27.7 *For any real number $a > 0$ and natural number $k \geq 1$, $\mathsf{DTIME}[n^k] \subset \mathsf{DTIME}[n^k \log^a n]$.*

PROOF Suppose for contradiction that $\mathsf{DTIME}[n^k] = \mathsf{DTIME}[n^k \log^a n]$. For now let us also suppose that $a > 1/2$. Taking $f(n) = 2^{n/k}$, and using the linear speed-up property, we obtain from the Translational Lemma the identity $\mathsf{DTIME}[2^n n^a] = \mathsf{DTIME}[2^n]$. This does not yet give the desired contradiction to the DTIME Hierarchy Theorem—but it is close. We'll need to use the Translational Lemma twice more.

Assume that $\mathsf{DTIME}[2^n n^a] = \mathsf{DTIME}[2^n]$. Using the Translational Lemma with $f(n) = 2^n$ yields $\mathsf{DTIME}[2^{2^n} 2^{an}] = \mathsf{DTIME}[2^{2^n}]$. Applying the Lemma once again on the classes $\mathsf{DTIME}[2^n n^a] = \mathsf{DTIME}[2^n]$, this time using $f(n) = 2^n + an$, we obtain $\mathsf{DTIME}[2^{2^n} 2^{an} f(n)^a] = \mathsf{DTIME}[2^{2^n} 2^{an}]$. Combining these two equalities yields $\mathsf{DTIME}[2^{2^n} 2^{an} f(n)^a] = \mathsf{DTIME}[2^{2^n}]$. Since $f(n)^a > 2^{an}$, we have that $2^{an} f(n)^a > 2^{2an} = 2^n 2^{bn}$ for some $b > 0$ (since $a > 1/2$). Thus $\mathsf{DTIME}[2^{2^n} 2^n 2^{bn}] = \mathsf{DTIME}[2^{2^n}]$, and this result contradicts the DTIME Hierarchy Theorem, since $2^{2^n} \log 2^{2^n} = o(2^{2^n} 2^n 2^{bn})$.

Finally, for any fixed $a > 0$, not just $a > 1/2$, we need to apply the Translational Lemma several more times.

One consequence of this theorem is that within P, there can be no "complexity gaps" of size $(\log n)^{\Omega(1)}$.

Alternating Complexity Classes

In this section, we define time and space complexity classes for alternating Turing machines, and we show how these classes are related to the classes introduced already. Alternating Turing machines and their configurations are defined in Chapter 24.

The possible computations of an alternating Turing machine M on an input word x can be represented by a tree T_x in which the root is the initial configuration, and the children of a nonterminal node C are the configurations reachable from C by one step of M. For a word x in $L(M)$, define an **accepting subtree** S of T_x as follows:

- S is finite.
- The root of S is the initial configuration with input word x.
- If S has an existential configuration C, then S has exactly one child of C in T_x; if S has a universal configuration C, then S has all children of C in T_x.
- Every leaf is a configuration whose state is the accepting state q_A.

Observe that each node in S is an accepting configuration.

We consider only alternating Turing machines that always halt. For $x \in L(M)$, define the time taken by M to be the height of the shortest accepting tree for x, and the space to be the maximum number

of nonblank worktape cells among configurations in the accepting tree that minimizes this number. For $x \notin L(M)$, define the time to be the height of T_x, and the space to be the maximum number of non-blank worktape cells among configurations in T_x.

Let $t(n)$ be a time-constructible function, and let $s(n)$ be a space-constructible function. Define the following complexity classes:

- $\mathsf{ATIME}[t(n)]$ is the class of languages decided by alternating Turing machines of time complexity $O(t(n))$.
- $\mathsf{ASPACE}[s(n)]$ is the class of languages decided by alternating Turing machines of space complexity $O(s(n))$.

Because a nondeterministic Turing machine is a special case of an alternating Turing machine, for every $t(n)$ and $s(n)$, $\mathsf{NTIME}(t) \subseteq \mathsf{ATIME}(t)$ and $\mathsf{NSPACE}(s) \subseteq \mathsf{ASPACE}(s)$. The next theorem states further relationships between computational resources used by alternating Turing machines, and resources used by deterministic and nondeterministic Turing machines.

THEOREM 27.8 **(Alternation Theorems)** *Let $t(n)$ be a time-constructible function, and let $s(n)$ be a space-constructible function, $s(n) \geq \log n$.*

(a) $\mathsf{NSPACE}[s(n)] \subseteq \mathsf{ATIME}[s(n)^2]$

(b) $\mathsf{ATIME}[t(n)] \subseteq \mathsf{DSPACE}[t(n)]$

(c) $\mathsf{ASPACE}[s(n)] \subseteq \mathsf{DTIME}[2^{O(s(n))}]$

(d) $\mathsf{DTIME}[t(n)] \subseteq \mathsf{ASPACE}[\log t(n)]$

In other words, space on deterministic and nondeterministic Turing machines is polynomially related to time on alternating Turing machines. Space on alternating Turing machines is exponentially related to time on deterministic Turing machines. The following corollary is immediate.

THEOREM 27.9

(a) $\mathsf{ASPACE}[O(\log n)] = \mathsf{P}$.

(b) $\mathsf{ATIME}[n^{O(1)}] = \mathsf{PSPACE}$.

(c) $\mathsf{ASPACE}[n^{O(1)}] = \mathsf{EXP}$.

Note that Theorem 27.8(a) says, for instance, that NL is contained in $\mathsf{ATIME}(\log^2(n))$. For this to make sense, it is necessary to modify the definition of alternating Turing machines to allow them to read individual bits of the input in constant time, rather than requiring n time units to traverse the entire input tape. This has become the standard definition of alternating Turing machines, because it is useful in establishing relationships between Turing machine complexity and **circuit complexity,** as explained in the upcoming section.

27.3 Circuit Complexity

Up to now, this chapter has been concerned only with complexity classes that were defined in order to understand the nature of sequential computation. Although we called them "machines," the models discussed here and in Chapter 24 are closer in spirit to software, namely to sequential algorithms or to single-processor machine-language programs. Circuits were originally studied to model hardware. The hardware of electronic digital computers is based on digital gates, connected into combinational and

sequential networks. Whereas a software program can branch and even modify itself while running, hardware components on today's typical machines are fixed and cannot reconfigure themselves. Also, circuits capture well the notion of nonbranching, straight-line computation.

Furthermore, circuits provide a good model of parallel computation. Many machine models, complexity measures, and classes for parallel computation have been devised, but the circuit complexity classes defined here coincide with most of them. Chapter 45 in this volume surveys parallel models and their relation to circuits in more detail.

Kinds of Circuits

A *circuit* can be formalized as a directed graph with some number n of sources, called *input nodes* and labeled $x_1, \ldots, x_n$, and one sink, called the *output node.* The edges of the graph are called *wires.* Every noninput node v is called a *gate,* and has an associated *gate function* g_v that takes as many arguments as there are wires coming into v. In this survey we limit attention to Boolean circuits, meaning that each argument is 0 or 1, although arithmetical circuits with numeric arguments and $+$, $*$ (etc.) gates have also been studied in complexity theory. Formally g_v is a function from $\{0, 1\}^r$ to $\{0, 1\}$, where r is the *fan-in* of v. The value of the gate is transmitted along each wire that goes out of v. The *size* of a circuit is the number of nodes in it.

We restrict attention to circuits C in which the graph is acyclic, so that there is no "feedback." Then every Boolean assignment $x \in \{0, 1\}^n$ of values to the input nodes determines a unique value for every gate and wire, and the value of the output gate is the output $C(x)$ of the circuit. The circuit *accepts* x if $C(x) = 1$.

The sequential view of a circuit is obtained by numbering the gates in a manner that respects the edge relation, meaning that for all edges (u, v), g_u has a lower number than g_v. Then the gate functions in that order become a sequence of basic instructions in a straight-line program that computes $C(x)$. The size of the circuit becomes the number of steps in the program. However, this view presumes a single processing unit that evaluates the instructions in sequence, and ignores information that the graphical layout provides. A more powerful view regards the gates as simple processing units that can act in parallel. Every gate whose incoming wires all come from input nodes can act and compute its value at step 1, and every other gate can act and transmit its value at the first step after all gates on its incoming wires have computed their values. The number of steps for this process is the *depth* of the circuit. Depth is a notion of *parallel time complexity.* A circuit with small depth is a fast circuit. The circuit *size* in this view is the amount of hardware needed. Chapter 45 gives much more information on the correspondence between circuits and parallel machines, and gives formal definitions of size and depth.

A *circuit family* $\mathbf{C}$ consists of a sequence of circuits $\{C_1, C_2, \ldots\}$, where each C_n has n input nodes. The language accepted by the family is $L(\mathbf{C}) = \{x : C_{|x|} \text{ accepts } x\}$. (Circuit families computing functions $f : \{0, 1\}^* \to \{0, 1\}^*$ are defined in Chapter 45.)

The *size complexity* of the family is the function $z(n)$ giving the number of nodes in C_n. The *depth complexity* is the function $d(n)$ giving the depth of C_n.

Another aspect of circuits that must be specified in order to define complexity classes is the underlying technology. By technology we mean the types of gates that are used as components in the circuits. Three types of technology are considered in this chapter:

(1) Bounded fan-in gates, usually taken to be the "standard basis" of binary $\wedge$ (AND), binary $\vee$ (OR) and unary $\neg$ (NOT) gates. A notable alternative is to use NAND gates.

(2) Unbounded fan-in $\wedge$ and $\vee$ gates (together with unary $\neg$ gates).

(3) Threshold gates. For our purposes, it suffices to consider the simplest kind of threshold gate, called the MAJORITY gate, which also uses the Boolean domain. A MAJORITY gate outputs 1 if and only if at least $r/2$ of its r incoming wires have value 1. These gates can

simulate unbounded fan-in $\wedge$ and $\vee$ with the help of "dummy wires." Threshold circuits also have unary $\neg$ gates.

The difference between (1) and (2) corresponds to general technological issues about high-bandwidth connections, whether they are feasible and how powerful they are. Circuits of type (1) can be converted to equivalent circuits that also have bounded fan-*out,* with only a constant-factor penalty in size and depth. Thus the difference also raises issues about one-to-many broadcast and all-to-one reception.

Threshold gates model the technology of *neural networks,* which were formalized in the 1940s. The kind of threshold gate studied most often in neural networks uses Boolean arguments and values, with '1' for "firing" and '0' for "off." It has numerical *weights* $w_1, \ldots, w_r$ for each of the r incoming wires and a *threshold* t. Letting $a_1, \ldots, a_r$ stand for the incoming 0-1 values, the gate outputs 1 if $\Sigma_{i=1}^{r} a_i w_i \geq t$, 0 otherwise. Thus the MAJORITY gate is the special case with $w_1 = \cdots = w_r = 1$ and $t = r/2$. A depth-2 (sub-)circuit of MAJORITY gates can simulate this general threshold gate.

Uniformity and Circuit Classes

One tricky aspect of circuit complexity is the fact that many functions that are *not computable* have trivial circuit complexity! For instance, let K be a noncomputable set of numbers, such as the indices of halting Turing machines, and let A be the language $\{x : |x| \in K\}$. For each n, if $n \in K$, then define C_n by attaching a $\neg$ gate to input x_1 and an OR gate whose two wires come from the $\neg$ gate and x_1 itself. If $n \notin K$, then define C_n similarly but with an AND gate in place of the OR. The circuit family $[C_n]$ so defined accepts A and has size and depth 2. The rub, however, is that there is no algorithm to tell *which* choice for C_n to define for each n. A related anomaly is that there are uncountably many circuit families. Indeed, every language is accepted by some circuit family $[C_n]$ with size complexity $2^{O(n)}$ and depth complexity 3 (unbounded fan-in) or $O(n)$ (bounded fan-in). Consequently, for general circuits, size complexity is at most exponential, and depth complexity is at most linear.

The notion of **uniform circuit complexity** avoids both anomalies. A circuit family $[C_n]$ is *uniform* if there is an easy algorithm Q that, given n, outputs an encoding of C_n. Either the adjacency-matrix or the edge-list representation of the graphs of the circuits C_n, together with the gate type of each node, may serve for our purposes as the *standard encoding scheme* for circuit families. If Q runs in polynomial time, then the circuit family is P-*uniform,* and so on.

P-uniformity is natural because it defines those families of circuits that are feasible to construct. However, we most often use circuits to model computation in *subclasses* of P. Allowing powerful computation to be incorporated into the step of *building* $C_{|x|}$ may overshadow the computation done by the circuit $C_{|x|}$ itself. The following much more stringent condition has proved to be most useful for characterizing these subclasses, and also works well for circuit classes at the level of polynomial time.

DEFINITION 27.1 A circuit family $[C_n]$ is DLOGTIME-*uniform* if there is a Turing machine M that can answer questions of the forms "Is there a path of edges from node u to node v in C_n?" and "What gate type does node u have?" in $O(\log n)$ time.

This uniformity condition is sufficient to build an encoding of C_n in sequential time roughly proportional to the size of C_n, and even much faster in parallel time. We will not try to define DLOGTIME as a complexity class, but note that since the inputs u, v to M can be presented by strings of length $O(\log n)$, the computation by M takes linear time in the (scaled down) input length. This definition presupposes that the size complexity $z(n)$ of the family is polynomial, which will be our chief interest here. The definition can be modified for $z(n)$ more than polynomial by changing the time limit on M to $O(\log z(n))$. Many central results originally proved using L-uniformity extend without change to DLOGTIME-uniformity, as explained later in this section. Unless otherwise stated, "uniform" means DLOGTIME-uniform throughout this and the next two chapters. We define the following circuit complexity classes:

DEFINITION 27.2 Given complexity functions $z(n)$ and $d(n)$,

- SIZE$[z(n)]$ is the class of all languages accepted by DLOGTIME-uniform bounded fan-in circuit families whose size complexity is at most $z(n)$;
- DEPTH$[d(n)]$ is the class of all languages accepted by DLOGTIME-uniform bounded fan-in circuit families whose depth complexity is at most $d(n)$;
- SIZE,DEPTH$[z(n), d(n)]$ is the class of all languages accepted by DLOGTIME-uniform bounded fan-in circuit families whose size complexity is at most $z(n)$ and whose depth complexity is at most $d(n)$.

Non-uniform circuit classes can be approached by an alternative view introduced by Karp and Lipton [28], by counting the number of bits of information needed to set up the preprocessing. For integer-valued functions t, a, define DTIME$[t(n)]$/ADV$[a(n)]$ to be the class of languages accepted by Turing machines M as follows: for all n there is a word y_n of length at most $a(n)$ such that for all x of length n, on input (x, y_n), M accepts if and only if $x \in L$, and M halts within $t(n)$ steps. Here y_n is regarded as "advice" on how to accept strings of length n. The class DTIME$[n^{O(1)}]$/ADV$[n^{O(1)}]$ is called P/poly. Karp and Lipton observed that P/poly is equal to the class of languages accepted by polynomial-sized circuits. Indeed, P/poly is now the standard name for this class.

Circuits and Sequential Classes

The importance of P/poly and uniformity is shown by the following basic theorem. We give the proof since it is used often in the next chapter.

THEOREM 27.10 *Every language in* P *is accepted by a family of polynomial-sized circuits that is* DLOGTIME*-uniform. Conversely, every language with* P*-uniform polynomial-sized circuits belongs to* P.

PROOF Let $A \in$ P. By Example 24.10 in Chapter 24, A is accepted by a Turing machine M with just one tape and tape head that runs in polynomial time $p(n)$. Let δ be the transition function of M, whereby for all states q of M and characters c in the worktape alphabet Γ of M, $\delta(q, c)$ specifies the character written to the current cell, the movement of the head, and the next state of M. We build a circuit of "δ-gates" that simulates M on inputs x of a given length n as follows, and then show how to simulate δ-gates by Boolean gates.

Lay out a $p(n) \times p(n)$ array of cells. Each cell (i, j) $(0 \leq i, j \leq p(n))$ is intended to hold the character on tape cell j after step i of the computation of M, and if the tape head of M is in that cell, also the state of M after step i. Cells $(0, 0)$ through $(0, n-1)$ are the input nodes of C_n, while cells $(0, n)$ through $(0, p(n))$ can be treated as "dummy wires" whose value is the blank B in the alphabet Γ. The key idea is that the value in cell (i, j) for $i \geq 1$ depends only on the values in cells $(i-1, j-1)$, $(i-1, j)$, and $(i-1, j+1)$. Cell $(i-1, j-1)$ is relevant in case its value includes the component for the tape head being there, and the head moves right at step i; cell $(i-1, j+1)$ similarly for a left move.

When the boundary cases $j = 0$ or $j = p(n)$ are handled properly, each cell value is computed by the same finite function of the three cells above, and this function defines a "δ-gate" for each cell. (See Fig. 27.2.) Finally, we may suppose that M is coded to signal acceptance by moving its tape head to the left end and staying in a special state q_a. Thus node $(i, 0)$ becomes the output gate of the circuit, and the accepting output values are those with q_a in the state component. Since in $p(n)$ steps M can visit at most $p(n)$ tape cells, the array is large enough to hold all the computations of M on inputs of length n.

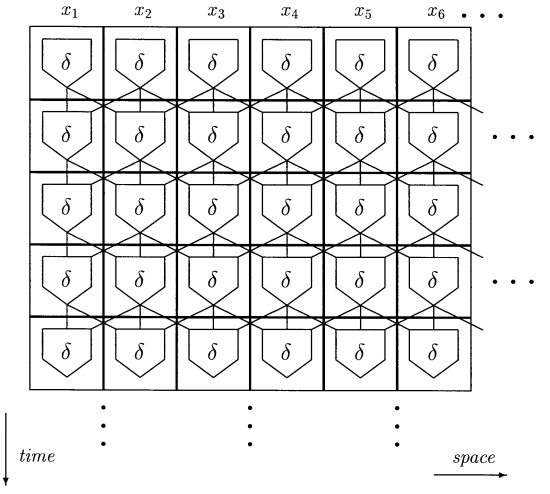

FIGURE 27.2 Conversion from Turing machine to Boolean circuits.

Since each argument and value of a δ-gate comes from a finite domain, we may take an (arbitrary) binary encoding of the domain, and replace all δ-gates by identical fixed-size subcircuits of Boolean gates that compute δ under the encoding. If the alphabet Σ over which A is defined is $\{0, 1\}$ then no recoding need be done at the inputs; otherwise, we similarly adopt a binary encoding of Σ. The Boolean circuits C_n thus obtained accept A. They also are DLOGTIME-uniform, intuitively by the very regular structure of the identical δ-gates.

Conversely, given a P-uniform family $\mathbf{C}$, a Turing machine can accept $L(\mathbf{C})$ in polynomial time given any input x by first constructing $C_{|x|}$ in polynomial time, and then evaluating $C_{|x|}(x)$.

A caching strategy that works for Turing machines with any fixed number of tapes yields the following improvement:

THEOREM 27.11 *If $t(n)$ is a time-constructible function, then* $\mathsf{DTIME}(t) \subseteq \mathsf{SIZE}(t \log t)$.

Connections between space complexity and circuit depth are shown by the next result.

THEOREM 27.12

(a) If $d(n) \geq \log n$, then $\mathsf{DEPTH}[d(n)] \subseteq \mathsf{DSPACE}[d(n)]$.
(b) If $s(n)$ is a space-constructible function and $s(n) \geq \log n$, then $\mathsf{NSPACE}[s(n)] \subseteq \mathsf{DEPTH}[s(n)^2]$.

Circuits and Parallel Classes

Since the 1970s, research on circuit complexity has focused on problems that can be solved quickly in parallel, with feasible amounts of hardware—circuit families of polynomial size and depth as small as possible. Note, however, that the meaning of the phrase "as small as possible" depends on the technology used. With unbounded fan-in gates, depth $O(1)$ is sufficient to carry out interesting computation, whereas with fan-in two gates, depth less than $\log n$ is impossible if the value at the output gate depends on all of the input bits. In any technology, however, a circuit with depth nearly logarithmic is considered to be very fast. This observation motivates the following definitions. Let $\log^k n$ stand for $(\log n)^k$.

DEFINITION 27.3
For all $k \geq 0$,

(a) NC^k denotes the class of languages accepted by DLOGTIME-uniform bounded fan-in circuit families of polynomial size and $O(\log^k n)$ depth. In other words, $\mathsf{NC}^k = \mathsf{SIZE,DEPTH}[n^{O(1)}, O(\log^k n)]$. NC denotes $\cup_{k\geq 0}\mathsf{NC}^k$.

(b) AC^k denotes the class of languages accepted by DLOGTIME-uniform families of circuits of unbounded fan-in $\wedge$, $\vee$, and $\neg$ gates, again with polynomial size and $O(\log^k n)$ depth.

(c) TC^k denotes the class of languages accepted by DLOGTIME-uniform families of circuits of MAJORITY and $\neg$ gates, again with polynomial size and $O(\log^k n)$ depth.

The case $k = 0$ in these definitions gives constant-depth circuit families. A function f is said to belong to one of these classes if the language $A_f = \{\langle x, i, b\rangle : 1 \leq i \leq |f(x)| \text{ and bit } i \text{ of } f(x) \text{ is } b\}$ belongs to the class. NC^0 is not studied as a language class in general, since the output gate can depend on only a constant number of input bits, but NC^0 is interesting as a function class.

Some notes on the nomenclature are in order. Nicholas Pippenger was one of the first to study polynomial-size, polylog-depth circuits in the late 1970s, and NC was dubbed "Nick's Class." There is no connotation of nondeterminism in NC. The "A" in AC^k connotes both alternating circuits and alternating Turing machines for reasons described below. The "T" in TC^k stands for the presence of threshold gates.

The following theorem expresses the relationships at each level of the hierarchies defined by these classes.

THEOREM 27.13 *For each $k \geq 0$,*

$$\mathsf{NC}^k \subseteq \mathsf{AC}^k \subseteq \mathsf{TC}^k \subseteq \mathsf{NC}^{k+1}.$$

PROOF The first inclusion is immediate (for each k), and the second conclusion follows from the observation noted above that MAJORITY gates can simulate unbounded fan-in AND and OR gates. The interesting case is $\mathsf{TC}^k \subseteq \mathsf{NC}^{k+1}$. For this, it suffices to show how to simulate a single MAJORITY gate with a fan-in two circuit of logarithmic depth. To simulate $\mathsf{MAJORITY}(w_1, \ldots, w_r)$, we add up the one-bit numbers $w_1, \ldots, w_r$ and test whether the sum is at least $r/2$. We may suppose for simplicity that the fan-in r is a power of 2, $r = 2^m$. The circuit has m distinguished nodes that represent the sum written as an m-bit binary number. Then the sum is at least $r/2 = 2^{m-1}$ if and only if the node representing the most significant bit of the sum has value 1.

To compute the sum efficiently, we use a standard "carry-save" technique: There is a simple $O(1)$ depth fan-in two circuit that takes as input three b-bit binary numbers a_1, a_2, a_3 and produces as output two $(b+1)$-bit numbers b_1, b_2 such that $a_1 + a_2 + a_3 = b_1 + b_2$. Thus in one phase, the original sum of r bits is reduced to taking the sum of $\frac{2}{3}r$ numbers, and after $O(\log r)$ additional phases, the problem is reduced to taking the sum of two $\log r$-bit numbers, and this sum can be produced by a full carry-lookahead adder circuit of $O(\log r)$ depth. Finally, since the circuits have polynomial size, r is polynomial in n, and so $O(\log r) = O(\log n)$.

Thus in particular, $\cup_k \mathsf{AC}^k = \cup_k \mathsf{TC}^k = \mathsf{NC}$. The only proper inclusion known, besides the trivial case $\mathsf{NC}^0 \subset \mathsf{AC}^0$, is $\mathsf{AC}^0 \subset \mathsf{TC}^0$, discussed below. For all we know at this time, TC^0 may be equal not only to NC, but even to NP!

Several relationships between complexity classes based on circuits and classes based on Turing machines are known:

THEOREM 27.14 $\mathsf{NC}^1 \subseteq \mathsf{L} \subseteq \mathsf{NL} \subseteq \mathsf{AC}^1$.

In fact, the connection with Turing machines is much closer than this theorem suggests. Using *alternating* Turing machines, we define the following complexity classes:

- $\mathsf{ASPACE,TIME}[s(n), t(n)]$ is the class of languages recognized by alternating Turing machines that use space at most $s(n)$ and also run in time at most $t(n)$.
- $\mathsf{ASPACE,ALTS}[s(n), a(n)]$ is the class of languages recognized by alternating Turing machines that use space at most $s(n)$ and make at most $a(n)$ alternations between existential and universal states.
- $\mathsf{ATIME,ALTS}[s(n), a(n)]$ is the class of languages recognized by alternating Turing machines that run in time $t(n)$ and make at most $a(n)$ alternations between existential and universal states.

THEOREM 27.15

(a) *For all* $k \geq 1$, $\mathsf{NC}^k = \mathsf{ASPACE,TIME}[O(\log n), O(\log^k n)]$.
(b) *For all* $k \geq 1$, $\mathsf{AC}^k = \mathsf{ASPACE,ALTS}[O(\log n), O(\log^k n)]$.
(c) $\mathsf{NC}^1 = \mathsf{ATIME}[O(\log n)]$.
(d) $\mathsf{AC}^0 = \mathsf{ATIME,ALTS}[O(\log n), O(1)]$.

For AC^1 and the higher circuit classes, changing the uniformity condition to L-uniformity does not change the class of languages. However, it is not known whether L-uniform NC^1 differs from NC^1, or L-uniform AC^0 from AC^0. Thus the natural extension (c,d) of the results in (a,b) is another advantage of $\mathsf{DLOGTIME}$-uniformity. Insofar as the containment of NC^1 in L is believed to be proper by many researchers, the definition of L-uniform NC^1 may allow more computing power to the "preprocessing stage" than to the circuits themselves. Avoiding this anomaly is a reason to adopt $\mathsf{DLOGTIME}$-uniformity.

As discussed in Chapter 45, many other models of parallel computation can be used to define NC. This robustness of NC supports the belief that NC is not merely an artifact of some arbitrary choices made in formulating the definitions, but instead captures a fundamental aspect of parallel computation. The criticism has been made that NC is overly generous in allowing polynomial size. Again, the justification in complexity theory is that the ultimate goal is to prove lower bounds, and a lower bound proved against a generous upper-bound notion is impervious to this criticism.

Why Focus on These Circuit Classes?

The class AC^0 is particularly important for the following reasons:

- It captures the complexity of important basic operations such as integer addition and subtraction.
- It corresponds closely to first-order logic, as described in Section 29.4.
- Most important, it is one of the few complexity classes for which lower bounds are actually known, instead of merely being conjectured.

It is known that AC^0 circuits, even non-uniform ones, cannot recognize the language PARITY of strings that have an odd number of 1's. Consequently, constant depth unbounded fan-in AND/OR/NOT circuits for PARITY must have super-polynomial size. However, PARITY does have constant-depth polynomial-size threshold circuits; indeed, it belongs to TC^0.

Note that this also implies that AC^0 is somehow "finer" than the notion of constant space, because the class of regular languages, which includes PARITY, can be decided in constant space. There has been

much progress on proving lower bounds for classes of constant-depth circuits. Still, the fact that TC^0 is not known to differ from NP is a wide gulf in our knowledge. Separating NC from P, or L from P, or L from NP would imply separating TC^0 from NP.

TC^0 is important because it captures the complexity of important basic operations such as integer multiplication and sorting. Further, integer division is known to be in P-uniform TC^0, and many suspect that DLOGTIME-uniformity would also be sufficient. Also, TC^0 is a good complexity-theoretic counterpart to popular models of neural networks.

NC^1 is important because it captures the complexity of the basic operation of evaluating a Boolean formula on a given assignment. The problem of whether NC^1 equals TC^0 thus captures the question of whether basic calculations in logic are harder than basic operations in arithmetic, or harder than basic neural processes. Several other characterizations of NC^1 besides the one given for $\mathsf{ATIME}[O(\log n)]$ are known. NC^1 equals the class of languages definable by polynomial-size Boolean *formulas* (as opposed to polynomial-sized *circuits;* a formula is equivalent to a circuit of fan-out 1). Also, NC^1 equals the class of languages recognized by bounded-width *branching programs* [3]. Finally, NC^1 captures the circuit complexity of regular expressions.

27.4 Research Issues and Summary

The complexity class is the fundamental notion of complexity theory. What makes a complexity class useful to the practitioner is the close relationship between complexity classes and real computational problems. The strongest such relationship comes from the concept of completeness, which is a chief subject of the next chapter. Even in the absence of lower bounds separating complexity classes, the apparent fundamental difference between models such as deterministic and nondeterministic Turing machines, for example, provides insight into the nature of problem solving on computers.

The initial goal when trying to solve a computational problem is to find an efficient polynomial-time algorithm. If this attempt fails, then one could attempt to prove that no efficient algorithm exists, but to date nobody has succeeded doing this for any problem in PSPACE. With the notion of a complexity class to guide us, however, we can attempt to discover the complexity class that exactly captures our current problem. A main theme of the next chapter is the surprising fact that most natural computational problems are *complete* for one of the canonical complexity classes. When viewed in the abstract setting provided by the model that defines the complexity class, the aspects of a problem that make an efficient algorithm difficult to achieve are easier to identify. Often this perspective leads to a redefinition of the problem in a way that is more amenable to solution.

Figure 27.1 shows the known inclusion relationships between canonical classes. Perhaps even more significant is what is currently not known. Although AC^0 differs from TC^0, TC^0 (let alone P!) is not known to differ from NP, or NP from EXP, or EXP from EXPSPACE. The only other proper inclusions known are (immediate consequences of) $\mathsf{L} \neq \mathsf{PSPACE} \neq \mathsf{EXPSPACE}$, $\mathsf{P} \neq \mathsf{E} \neq \mathsf{EXP}$, and $\mathsf{NP} \neq \mathsf{NE} \neq \mathsf{NEXP}$—and these follow simply from the hierarchy theorems proved in this chapter.

We have given two examples of diagonalization arguments. Diagonalization is still the main tool for showing the existence of hard-to-compute problems inside a complexity class. Unfortunately, the languages constructed by diagonalization arguments rarely correspond to computational problems that arise in practice. In some cases, however, one can show that there is an efficient reduction from a difficult problem (shown to exist by diagonalization) to a more natural problem—with the consequence that the natural problem is also difficult to solve. Thus diagonalization inside a complexity class (the topic of this chapter) can work hand in hand with reducibility (the topic of the next chapter) to produce intractability results for natural computational problems.

27.5 Defining Terms

Canonical complexity classes: The classes defined by logarithmic, polynomial, and exponential bounds on time and space, for deterministic and nondeterministic machines. These are the most central to the field, and classify most of the important computational problems.

Circuit: A network of input, output, and logic gates, contrasted with a **Turing machine** in that its hardware is static and fixed.

Circuit complexity: The study of the size, depth, and other attributes of circuits that decide specified languages or compute specified functions.

Diagonalization: A proof technique for showing that a given language does not belong to a given complexity class, used in many **separation theorems**.

Padding argument: A method for transferring results about one complexity bound to another complexity bound, by padding extra dummy characters onto the inputs of the machines involved.

Polynomial-time Church–Turing Thesis: An analogue of the classical **Church–Turing Thesis**, for which see Chapter 26, stating that the class P captures the true notion of feasible (polynomial time) sequential computation.

Separation theorems: Theorems showing that two complexity classes are distinct. Most known separation theorems have been proved by **diagonalization**.

Simulation theorems: Theorems showing that one kind of computation can be simulated by another kind within stated complexity bounds. Most known containment or equality relationships between complexity classes have been proved this way.

Space-constructible function: A function $s(n)$ that gives the actual space used by some Turing machine on all inputs of length n, for all n.

Time-constructible function: A function $t(n)$ that is the actual running time of some Turing machine on all inputs of length n, for all n.

Uniform circuit family: A sequence of circuits, one for each input length n, that can be efficiently generated by a Turing machine.

Uniform circuit complexity: The study of complexity classes defined by uniform circuit families.

Further Information

Primary sources for the results presented in this chapter are: Theorem 27.1 [9, 45]; Theorem 27.2 [5]; Theorems 27.3 and 27.4 [17, 24, 32, 39, 44]; Theorem 27.5 [17, 22, 40]; Theorem 27.6 [7]; Lemma 27.1 [37]; Theorems 27.8 and 27.9 [11]; Theorem 27.10 [39]; Theorem 27.11 [35]; Theorem 27.12 [10]; Theorem 27.15 [2, 12, 38, 41]. Theorems 27.13 and 27.14 are a combination of results in the last four papers; see also the influential survey by Cook [13]. Our proof of Theorem 27.5(b) follows [49].

For Section 27.3, a comparison of arithmetical circuits with Boolean circuits may be found in [47], the result that bounded fan-in circuits can be given bounded fan-out is due to [20], and the sharpest simulation of general weighted threshold gates by MAJORITY gates is due to [19]. The theorem in "Why Focus on These Circuit Classes?" that PARITY is not in AC^0 is due to [1, 14], and the strongest lower bounds known on the size of constant-depth circuits for PARITY are those in [18]. The results mentioned for TC^0 may be found in [2, 23, 36].

The texts [21] and [33] present many of these results in greater technical detail. Three chapters of the *Handbook of Theoretical Computer Science,* respectively [26], [46], and [8], describe more complexity classes, compare complexity measures for more machine models, and present more information on circuit complexity. Relationships between circuits and parallel and neural models are covered very accessibly in [34]. Average-case complexity is discussed by [16, 25, 48]. See also Chapter 29 and the notes at the end of that chapter for further sources.

Two important new research areas that challenge our arguments about feasible computation are *quantum computing* and *DNA computing.* Two new survey articles on these fields are [4] and [30].

State University of New York at Buffalo

28.1 Introduction

There is little doubt that the notion of *reducibility* is the most useful tool that complexity theory has delivered to the rest of the computer science community.

For most computational problems that arise in real-world applications, such as the Traveling Salesperson Problem, we still know little about their deterministic time or space complexity. We cannot now tell whether classes such as **P** and **NP** are distinct. And yet, even without such hard knowledge, it has been useful in practice to take some new problem A whose complexity needs to be analyzed, and announce that A has roughly the same complexity as Traveling Salesperson, by exhibiting efficient ways of reducing each problem to the other. Thus we can say a lot about problems being equivalent in complexity to each other, even if we cannot pinpoint what that complexity is.

[1] Eric Allender — Supported by the National Science Foundation under Grant CCR-9509603. Portions of this work were performed while a visiting scholar at the Institute of Mathematical Sciences, Madras, India.
Michael C. Loui — Supported by the National Science Foundation under Grant CCR-9315696.
Kenneth W. Regan — Supported by the National Science Foundation under Grant CCR-9409104.

One reason this has succeeded is that, when one partitions the many thousands of real-world computational problems into equivalence classes according to the reducibility relation, there is a surprisingly small number of classes of this partition. Thus, the complexity of almost any problem arising in practice can be classified by showing that it is equivalent to one of a short list of representative problems. It was not originally expected that this would be the case.

Even more amazingly, these "representative problems" correspond in a very natural way to abstract models of computation—that is, they correspond to complexity classes. These classes were defined in Chapter 27 using a small set of abstract machine concepts: Turing machines, nondeterminism, alternation, time, space. With this and a few simple functions that define time and space bounds, we are able to characterize the complexity of the overwhelming majority of natural computational problems—most of which bear no topical resemblance to any question about Turing machines. This tool has been much more successful than we had any right to expect it would be.

All this leads us to believe that it is no mere accident that problems easily lend themselves to being placed in one class or another. That is, we are disposed to think that these classes really *are* distinct, that the classification is *real,* and that the mathematics developed to deal with them really does describe some important aspect of nature. Nondeterministic Turing machines, with their ability to magically soar through immense search spaces, *seem* to be much more powerful than our mundane deterministic machines, and this reinforces our belief. However, until P vs. NP and similar longstanding questions of complexity theory are completely resolved, our best method of understanding the complexity of real-world problems is to use the classification provided by reducibility, and to trust in a few plausible conjectures.

In this chapter, we discuss reducibility. We will learn about different types of reducibility, and the related notion of *completeness.* It is especially useful to understand NP-completeness. We define NP-completeness precisely, and give examples of NP-complete problems. We show how to prove that a problem is NP-complete, and give some help for coping with NP-completeness. After that, we describe problems that are complete for other complexity classes, under the most efficient reducibility relations. Finally, we cover two other important topics in complexity theory that are motivated by reducibility: relativized computation and the study of **sparse languages.**

28.2 Reducibility Relations

In mathematics, as in everyday life, a typical way to solve a new problem is to reduce it to a previously solved problem. Frequently, an instance of the new problem is expressed completely in terms of an instance of the prior problem, and the solution is then interpreted in the terms of the new problem. This kind of **reduction** is called **many-one reducibility**, and is defined below.

A different way to solve the new problem is to use a subroutine that solves the prior problem. For example, we can solve an optimization problem whose solution is feasible and maximizes the value of an objective function g by repeatedly calling a subroutine that solves the corresponding decision problem of whether there exists a feasible solution x whose value $g(x)$ satisfies $g(x) \geq k$. This kind of reduction is called **Turing reducibility,** and is also defined below.

Let A_1 and A_2 be languages. A_1 is many-one reducible to A_2, written $A_1 \leq_m A_2$, if there exists a total recursive function f such that for all x, $x \in A_1$ if and only if $f(x) \in A_2$. The function f is called the **transformation function.** A_1 is Turing reducible to A_2, written $A_1 \leq_T A_2$, if A_1 can be decided by a deterministic oracle Turing machine M using A_2 as its oracle, i.e., $A_1 = L(M^{A_2})$. (Recursive functions are defined in Chapter 26, and oracle machines are defined in Chapter 24. The oracle for A_2 models a hypothetical efficient subroutine for A_2.)

If f or M above consumes too much time or space, the reductions they compute are not helpful. To study complexity classes defined by bounds on time and space resources, it is natural to consider resource-bounded reducibilities. Let A_1 and A_2 be languages.

- A_1 is **Karp reducible** to A_2, written $A_1 \leq_m^p A_2$, if A_1 is many-one reducible to A_2 via a transformation function that is computable deterministically in polynomial time.
- A_1 is **Cook reducible** to A_2, written $A_1 \leq_T^p A_2$, if A_1 is Turing reducible to A_2 via a deterministic **oracle Turing machine** of polynomial time complexity.

The term "polynomial-time reducibility" usually refers to Karp reducibility. If $A_1 \leq_m^p A_2$ and $A_2 \leq_m^p A_1$, then A_1 and A_2 are **equivalent** under Karp reducibility. Equivalence under Cook reducibility is defined similarly.

Karp and Cook reductions are useful for finding relationships between languages of high complexity, but they are not useful at all for distinguishing between problems in P, because all problems in P are equivalent under Karp (and hence Cook) reductions. (Here and later we ignore the special cases $A_1 = \emptyset$ and $A_1 = \Sigma^*$, and consider them to reduce to any language.) To investigate the many interesting complexity classes inside P, we will want to define more restrictive reducibilities, and this we do beginning in Section 28.5. For the time being, however, we focus on Cook and Karp reducibility.

The key property of Cook and Karp reductions is that they preserve polynomial-time feasibility. Suppose $A_1 \leq_m^p A_2$ via a transformation f. If M_2 decides A_2, and M_f computes f, then to decide whether an input word x is in A_1, we may use M_f to compute $f(x)$, and then run M_2 on input $f(x)$. If the time complexities of M_2 and M_f are bounded by polynomials t_2 and t_f, respectively, then on inputs x of length $n = |x|$, the time taken by this method of deciding A_1 is at most $t_f(n) + t_2(t_f(n))$, which is also a polynomial in n. In summary, if A_2 is feasible, and there is an efficient reduction from A_1 to A_2, then A_1 is feasible. Although this is a simple observation, this fact is important enough to state as a theorem. First, though, we need the concept of "closure."

A class of languages $\mathcal{C}$ is **closed under a reducibility** $\leq_r$ if for all languages A_1 and A_2, whenever $A_1 \leq_r A_2$ and $A_2 \in \mathcal{C}$, necessarily $A_1 \in \mathcal{C}$.

THEOREM 28.1 P *is closed under both Cook and Karp reducibility.*

Note that this is an instance of an idea that motivated our identification of P with the class of "feasible" problems in Chapter 27, namely that the composition of two feasible functions should be feasible. Similar considerations give us the following theorem.

THEOREM 28.2 *Karp reducibility and Cook reducibility are transitive; i.e.,*

1. *If* $A_1 \leq_m^p A_2$ *and* $A_2 \leq_m^p A_3$, *then* $A_1 \leq_m^p A_3$.
2. *If* $A_1 \leq_T^p A_2$ *and* $A_2 \leq_T^p A_3$, *then* $A_1 \leq_T^p A_3$.

We shall see the importance of closure under a reducibility in conjunction with the concept of completeness, which we define in the next section.

28.3 Complete Languages and Cook's Theorem

Let $\mathcal{C}$ be a class of languages that represent computational problems. A language A_0 is $\mathcal{C}$-**hard** under a reducibility $\leq_r$ if for all A in $\mathcal{C}$, $A \leq_r A_0$. A language A_0 is $\mathcal{C}$-**complete** under $\leq_r$ if A_0 is $\mathcal{C}$-hard, and $A_0 \in \mathcal{C}$. Informally, if A_0 is $\mathcal{C}$-hard, then A_0 represents a problem that is at least as difficult to solve as any problem in $\mathcal{C}$. If A_0 is $\mathcal{C}$-complete, then in a sense, A_0 is one of the most difficult problems in $\mathcal{C}$.

There is another way to view completeness. Completeness provides us with tight lower bounds on the complexity of problems. If a language A is complete for complexity class $\mathcal{C}$, then we have a lower bound on its complexity. Namely, A is as hard as the most difficult problem in $\mathcal{C}$, assuming that the complexity

of the reduction itself is small enough not to matter. The lower bound is tight because A is in $\mathcal{C}$; that is, the upper bound matches the lower bound.

In the case $\mathcal{C} = \mathsf{NP}$, the reducibility $\leq_r$ is usually taken to be Karp reducibility unless otherwise stated. Thus we say:

- A language A_0 is NP-**hard** if A_0 is NP-hard under Karp reducibility.
- A_0 is NP-**complete** if A_0 is NP-complete under Karp reducibility.

However, many sources take the term "NP-hard" to refer to Cook reducibility.

Many important languages are now known to be NP-complete. Before we get to them, let us discuss some implications of the statement "A_0 is NP-complete," and also some things this statement doesn't mean.

The first implication is that *if* there exists a deterministic Turing machine that decides A_0 in polynomial time—that is, if $A_0 \in \mathsf{P}$—then because P is closed under Karp reducibility (Theorem 28.1 in Section 28.2), it would follow that $\mathsf{NP} \subseteq \mathsf{P}$, hence $\mathsf{P} = \mathsf{NP}$. In essence, the question of whether P is the same as NP comes down to the question of whether any particular NP-complete language is in P. Put another way, *all* of the NP-complete languages stand or fall together: if one is in P, then all are in P; if one is not, then all are not. Another implication, which follows by a similar closure argument applied to co-NP, is that if $A_0 \in$ co-NP then $\mathsf{NP} =$ co-NP. It is also believed unlikely that $\mathsf{NP} =$ co-NP, as was noted in connection with whether all tautologies have short proofs in Chapter 27.

A common misconception is that the above property of NP-complete languages is actually their definition, namely: if $A \in \mathsf{NP}$, and $A \in \mathsf{P}$ implies $\mathsf{P} = \mathsf{NP}$, then A is NP-complete. This "definition" is wrong. A theorem due to Ladner [19] shows that $\mathsf{P} \neq \mathsf{NP}$ if and only if there exists a language A' in $\mathsf{NP} - \mathsf{P}$ such that A' is not NP-complete. Thus, if $\mathsf{P} \neq \mathsf{NP}$, then A' is a counterexample to the "definition."

Another common misconception arises from a misunderstanding of the statement "If A_0 is NP-complete, then A_0 is one of the most difficult problems in NP." This statement is true on one level: if there is any problem at all in NP that is not in P, then the NP-complete language A_0 is one such problem. However, note that there are NP-complete problems in $\mathsf{NTIME}[n]$—and these problems are, in some sense, much *simpler* than many problems in $\mathsf{NTIME}[n^{10^{500}}]$. We discuss the difficulty of NP-complete problems in more detail after studying several examples.

We now prove **Cook's Theorem,** which established the first important NP-complete problem. Recall the definition of SAT, the language of satisfiable Boolean formulas, from Section 27.2 of Chapter 27. In this and later Karp-reduction proofs, we highlight the *construction* of the transformation f, check that the *complexity* of f is polynomial, and verify the *correctness* of the reduction.

THEOREM 28.3 **(Cook's Theorem)** *SAT is* NP*-complete.*

PROOF Let $A \in \mathsf{NP}$. Without loss of generality we may assume that $A \subseteq \{0, 1\}^*$. There is a polynomial q and a polynomial-time computable relation R such that for all x,

$$x \in A \iff (\exists y : |y| = q(|x|))\ R(x, y)\ .$$

By the construction of the proof of Theorem 27.10 in Chapter 27, there is a polynomial p such that for all n, we can build in time $p(n)$ a Boolean circuit C_n, using only binary NAND gates, that decides R on inputs of length $n + q(n)$. C_n has n input nodes labeled $x_1, \ldots, x_n$ and $q = q(n)$ more input nodes labeled $y_1, \ldots, y_q$. C_n has at most $p(n)$ *wires,* which we label by $w_1, \ldots, w_m$, where $m \leq p(n)$ and w_m is a special wire leading out of the output gate.

Construction. We first write a Boolean formula ϕ_n in the x, y, *and* w variables to express that every gate in C_n functions correctly and C_n outputs 1. For every NAND gate in C_n with incoming wires u, v, and

for each outgoing wire w of the gate, we add to ϕ_n the following conjunction of three *clauses*

$$(u \vee w) \wedge (v \vee w) \wedge (\bar{u} \vee \bar{v} \vee \bar{w}).$$

These clauses are satisfied by those assignments to u, v, w such that $w = \neg(u \wedge v)$. Intuitively, they assert that the given NAND gate functions correctly.

Thus ϕ_n has three clauses for every wire w except those wires leading from the inputs, each of which carries the label of the corresponding input variable. Finally for the output wire, ϕ_n has the singleton clause (w_m). So ϕ_n has at most $3p(n) + 1$ clauses in all.

Now given x, we form the desired formula $f(x) = \phi_x$ by building ϕ_n, where $n = |x|$, and simply appending n singleton clauses that force the corresponding assignment to the $x_1, \ldots, x_n$ variables. (For example, if $x = 1001$, append $x_1 \wedge \bar{x}_2 \wedge \bar{x}_3 \wedge x_4$.)

Complexity. C_n is built up in roughly $O(p(n))$ time. Building ϕ_n from C_n, and appending the singleton clauses for x, takes a similar polynomial amount of time.

Correctness. Formally, we need to show that for all x, $x \in A \iff f(x) \in \text{SAT}$. By construction, for all x, $x \in A$ if and only if there exists an assignment to the y variables and to the w variables that satisfies ϕ_x. Hence the reduction is correct.

A glance at the proof shows that ϕ_x is always a Boolean formula in conjunctive normal form (CNF) with clauses of one, two, or three literals each. By introducing some new "dummy" variables, we can arrange that each clause has exactly three literals. Thus we have actually shown that the following *restricted form* of the satisfiability problem is NP-complete:

3-SATISFIABILITY (3SAT)
Instance: A Boolean expression ϕ in conjunctive normal form with three literals per clause.
Question: Is ϕ satisfiable?

One concrete implication of Cook's Theorem is that if deciding SAT is easy (i.e., in polynomial time), then factoring integers is likewise easy, because the decision version of factoring belongs to NP. (See Chapter 39.) This is a surprising connection between two ostensibly unrelated problems.

The main impact, however, is that once one language has been proved complete for a class such as NP, others can be proved complete by constructing transformations. If A_0 is NP-complete, then to prove that another language A_1 is NP-complete, it suffices to prove that $A_1 \in \text{NP}$, and to construct a polynomial-time transformation that establishes $A_0 \leq_m^p A_1$. Since A_0 is NP-complete, for every language A in NP, $A \leq_m^p A_0$, hence by transitivity (Theorem 28.2 in Section 28.2), $A \leq_m^p A_1$.

Hundreds of computational problems in many fields of science and engineering have been proved to be NP-complete, almost always by reduction from a problem that was previously known to be NP-complete. We give some practically-motivated examples of these reductions, and also some advice on how to cope with NP-completeness.

28.4 NP-Complete Problems and Completeness Proofs

This and the next two sections are directed toward practitioners who have a computational problem, don't know how to solve it, and want to know how hard it is—specifically, is it NP-complete, or NP-hard? The following step-by-step procedure will help in answering these questions, and may help in identifying cases of the problem that are tractable even if the problem is NP-hard for general cases. In brief, the steps are:

1. State the problem in general mathematical terms, and formalize the statement.
2. Ascertain whether the problem belongs to NP.
3. If so, try to find it in a compendium of known NP-complete problems.

4. If you cannot find it, try to construct a *reduction* from a related problem that is known to be NP-complete or NP-hard.
5. Try to identify special cases of your problem that are (i) hard, (ii) easy, and/or (iii) the ones you need. Your work in Steps 1–4 may help you here.
6. Even if your cases are NP-hard, they may still be amenable to direct attack by sophisticated methods on high-powered hardware.

These steps are interspersed with a traditional "theorem–proof" presentation and several long examples, but the same sequence is maintained. We emphasize that trying to do the formalization and proofs asked for in these steps may give you useful positive information about your problem.

Step 1. Give a *formal statement* of the problem. State it without using terms that are specific to your own particular discipline. Use common terms from mathematics and data objects in computer science, e.g., graphs, trees, lists, vectors, matrices, alphabets, strings, logical formulas, mathematical equations. For example, a problem in evolutionary biology that a phylogenist would state in terms of "species" and "characters" and "cladograms" can be stated in terms of trees and strings, using an alphabet that represents the taxonomic characters. Standard notions of size, depth, and distance in trees can express the objectives of the problem.

If your problem involves computing a function that produces a lot of output, look for associated yes/no decision problems, because decision problems have been easier to characterize and classify. For instance, if you need to compute matrices of a certain kind, see whether the essence of your problem can be captured by yes/no questions about the matrices, perhaps about individual entries of them. Many optimization problems looking for a solution of a certain minimum cost or maximum value can be turned into decision problems by including a target cost/value "k" as an input parameter, and phrasing the question of whether a solution exists of cost less than (or value greater than) the target k. Several problems given in the examples below have this form.

It may also help to simplify, even over-simplify, your problem by removing or ignoring some particular elements of it. Doing so may make it easier to ascertain what general category of decision problem yours is in or closest to. In the process, you may learn useful information about the problem that tells you what the effects of those specific elements are—we say some more about this in "Significance of NP-Completeness".

Step 2. When you have an adequate formalization, ask first, does your decision problem belong to NP? This is true if and only if candidate solutions that would bring about a "yes" answer can be tested in polynomial time—see the extended discussion in Chapter 27, Section 27.2. If it does belong to NP, that's good news for now! Even if not, you may proceed to determine whether it is NP-hard. The problem may be complete for a class such as PSPACE that contains NP. Examples of such problems are given later in this chapter.

Step 3. See whether your problem is already listed in a compendium of (NP-)complete problems. The book [11] lists several hundred NP-complete problems arranged by category. The following is intended as a small representative sample. The first five (together with 3SAT) receive extended treatment in [11], while the last five receive comparable treatment here. (The language corresponding to each problem is the set of instances whose answers are "yes.")

VERTEX COVER
Instance: A graph G and an integer k.
Question: Does G have a set W of k vertices such that every edge in G is incident on a vertex in W?

CLIQUE
Instance: A graph G and an integer k.
Question: Does G have a set K of k vertices such that every two vertices in K are adjacent in G?

HAMILTONIAN CIRCUIT
Instance: A graph G.
Question: Does G have a circuit that includes every vertex exactly once?

3-DIMENSIONAL MATCHING
Instance: Sets W, X, Y with $|W| = |X| = |Y| = q$ and a subset $S \subseteq W \times X \times Y$.
Question: Is there a subset $S' \subseteq S$ of size q such that no two triples in S' agree in any coordinate?

PARTITION
Instance: A set S of positive integers.
Question: Is there a subset $S' \subseteq S$ such that the sum of the elements of S' equals the sum of the elements of $S - S'$?

INDEPENDENT SET
Instance: A graph G and an integer k.
Question: Does G have a set U of k vertices such that no two vertices in U are adjacent in G?

GRAPH COLORABILITY
Instance: A graph G and an integer k.
Question: Is there an assignment of colors to the vertices of G so that no two adjacent vertices receive the same color, and at most k colors are used overall?

TRAVELING SALESPERSON (TSP)
Instance: A set of m "cities" $C_1, \ldots, C_m$, with a distance $d(i, j)$ between every pair of cities C_i and C_j, and an integer D.
Question: Is there a tour of the cities whose total length is at most D, i.e., a permutation $c_1, \ldots, c_m$ of $\{1, \ldots, m\}$, such that $d(c_1, c_2) + \cdots + d(c_{m-1}, c_m) + d(c_m, c_1) \leq D$?

KNAPSACK
Instance: A set $U = \{u_1, \ldots, u_m\}$ of objects, each with an integer size *size* (u_i) and an integer profit *profit* (u_i), a target size s_0, and a target profit p_0.
Question: Is there a subset $U' \subseteq U$ whose total cost and total profit satisfy

$$\sum_{u_i \in U'} \textit{size}\ (u_i) \leq s_0 \qquad \textit{and} \qquad \sum_{u_i \in U'} \textit{profit}\ (u_i) \geq p_0?$$

The languages of all of these problems are easily seen to belong to NP. For example, to show that TSP is in NP, one can build a nondeterministic Turing machine that simply guesses a tour and checks that the tour's total length is at most D.

Some comments on the last two problems are relevant to Steps 1 and 2 above. TRAVELING SALESPERSON provides a single abstract form for many concrete problems about sequencing a series of test examples so as to minimize the variation between successive items. The KNAPSACK problem models the filling of a knapsack with items of various sizes, with the goal of maximizing the total value (profit) of the items. Many scheduling problems for multiprocessor computers can be expressed in the form of KNAPSACK instances, where the "size" of an item represents the length of time a job takes to run, and the size of the knapsack represents an available block of machine time.

If yours is on the list of NP-complete problems, you may skip Step 4, and the compendium may give you further information for Steps 5 and 6. You may still wish to pursue Step 4 if you need more study of particular transformations to and from your problem.

If your problem is not on the list, it may still be close enough to one or more problems on the list to help with the next step.

Step 4. Construct a reduction from an already-known NP*-complete problem.* Broadly speaking, Karp reductions come in three kinds.

- A *restriction* from your problem to a special case that is already known to be NP-complete.
- A *minor adjustment* of an already-known problem.
- A *combinatorial transformation.*

The first two kinds of reduction are usually quite easy to do, and we give several examples before proceeding to the third kind.

EXAMPLE 28.1:

PARTITION $\leq_m^p$ KNAPSACK, *by restriction:* Given a PARTITION instance with integers s_i, the corresponding instance of KNAPSACK takes *size* (u_i) = *profit* $(u_i) = s_i$ (for all i), and sets the targets s_0 and p_0 both equal to $(\Sigma_i s_i)/2$. The condition in the definition of the KNAPSACK problem of not exceeding s_0 nor being less than p_0 requires that the sum of the selected items meet the target $(\Sigma_i s_i)/2$ exactly, which is possible if and only if the original instance of PARTITION is solvable.

In this way, the PARTITION problem can be regarded as a *restriction* or special case of the KNAPSACK problem. Note that the reduction itself goes *from* the more-special problem *to* the more-general problem, even though one thinks of the more-general problem as the one being restricted. The implication is that if the restricted problem is NP-hard, then the more-general problem is NP-hard as well, not vice-versa.

EXAMPLE 28.2:

HAMILTONIAN CIRCUIT $\leq_m^p$ TSP *by restriction:* Let a graph G be given as an instance of the HAMILTONIAN CIRCUIT problem, and let G have m vertices $v_1, \ldots, v_m$. These vertices become the "cities" of the TSP instance that we build. Now define a distance function d as follows:

$$d(i, j) = \begin{cases} 1 & \text{if } (v_i, v_j) \text{ is an edge in } G \\ m+1 & \text{otherwise .} \end{cases}$$

Set $D = m$. Clearly, d and D can be computed in polynomial time from G. If G has a Hamiltonian circuit, then the length of the tour that corresponds to this circuit is exactly m. Conversely, if there is a tour whose length is at most m, then each step of the tour must have distance 1, not $m+1$. Then each step corresponds to an edge of G, so the corresponding sequence of vertices forms a Hamiltonian circuit in G. Thus the function f defined by $f(G) = (\{d(i, j) : 1 \leq i, j \leq m\}, D)$ is a polynomial-time transformation from HAMILTONIAN CIRCUIT to TSP.[2]

Minor Adjustments. Here we consider cases where two problems look different but are really closely connected. Consider CLIQUE, INDEPENDENT SET, and VERTEX COVER. A graph G has a clique of size k if and only if its complementary graph G' has an independent set of size k. It follows that the function f defined by $f(G, k) = (G', k)$ is a Karp reduction from INDEPENDENT SET to CLIQUE. To forge a link to the VERTEX COVER problem, note that all vertices *not* in a given vertex cover form an independent set, and vice versa. Thus a graph G on n vertices has a vertex cover of size at most k if and only if G has an

[2]Technically we need f to be a function from Σ^* to Σ^*. However, given a string x we can decide in polynomial time whether x encodes a graph G that can be given as an instance of HAMILTONIAN CIRCUIT. If x does not encode a well-formed instance, then define $f(x)$ to be a fixed instance I_0 of TSP for which the answer is "no." Because this sort of thing can generally always be done, we are free to regard the domain of a reduction function f to be the set of "well-formed instances" of the problem we are reducing from. Henceforth we try to ignore such encoding details.

independent set of size at least $n - k$. Hence the function $g(G, k) = (G, n - k)$ is a Karp reduction from INDEPENDENT SET to VERTEX COVER. (Note that the same f and g also provide reductions from CLIQUE to INDEPENDENT SET and from VERTEX COVER to INDEPENDENT SET, respectively. This does not happen for all reductions, and gives a sense in which these three problems are unusually close to each other.)

NP-Completeness by Combinatorial Transformation

The following examples show how the combinatorial mechanism of one problem (here, 3SAT) can be *transformed* by a reduction into the seemingly much different mechanism of another problem.

THEOREM 28.4 INDEPENDENT SET *is* NP*-complete. Hence also* CLIQUE *and* VERTEX COVER *are* NP*-complete.*

PROOF We have remarked already that the languages of these three problems belong to NP, and shown already that INDEPENDENT SET $\leq_m^p$ CLIQUE and INDEPENDENT SET $\leq_m^p$ VERTEX COVER. It suffices to show that 3SAT $\leq_m^p$ INDEPENDENT SET.

Construction. Let the Boolean formula ϕ be a given instance of 3SAT with variables $x_1, \ldots, x_n$ and clauses $C_1, \ldots, C_m$. The graph G_ϕ we build consists of a "ladder" on $2n$ vertices labeled $x_1, \bar{x}_1, \ldots, x_n, \bar{x}_n$, with edges $(x_i, \bar{x}_i)$ for $1 \leq i \leq n$ forming the "rungs," and m "clause components." Here the component for each clause C_j has one vertex for each literal x_i or $\bar{x}_i$ in the clause, and all pairs of vertices within each clause component are joined by an edge. Finally, each clause-component node with a label x_i is connected by a "crossing edge" to the node with the opposite label $\bar{x}_i$ in the ith "rung," and similarly each occurrence of $\bar{x}_i$ in a clause is joined to the rung node x_i. This finishes the construction of G_ϕ. See Fig. 28.1.

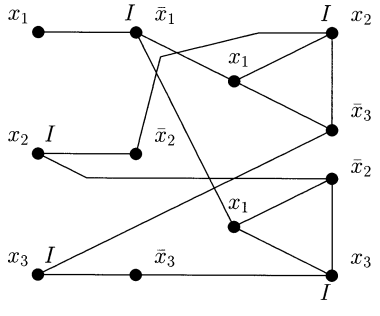

FIGURE 28.1 Construction in the proof of NP-completeness of INDEPENDENT SET for the formula $(x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$. The independent set of size 5 corresponding to the satisfying assignment $x_1 =$ `false`, $x_2 =$ `true`, and $x_3 =$ `true` is shown by nodes marked I.

Also set $k = n + m$. Then the reduction function f is defined for all arguments ϕ by $f(\phi) = (G_\phi, k)$.

Complexity. It is not hard to see that f is computable in polynomial time given (a straightforward encoding of) ϕ.

Correctness. To complete the proof, we need to argue that ϕ is satisfiable if and only if G_ϕ has an independent set of size $n + m$. To see this, first note that any independent set I of that size must contain exactly one of the two nodes from each "rung," and exactly one node from each clause component—because the edges in the rungs and the clause component prevent any more nodes from being added. And if I selects a node labeled x_i in a clause component, then I must also select x_i in the ith rung. If I

selects $\bar{x}_j$ in a clause component, then I must also select $\bar{x}_j$ in the rung. In this manner I induces a truth assignment in which $x_i = \texttt{true}$ and $x_j = \texttt{false}$, and so on for all variables. This assignment satisfies ϕ, because the node selected from each clause component tells how the corresponding clause is satisfied by the assignment. Going the other way, if ϕ has a satisfying assignment, then that assignment yields an independent set I of size $n + m$ in like manner.

Since the ϕ in this proof is a 3SAT instance, every clause component is a triangle. The idea, however, also works for CNF formulas with any number of variables in a clause, such as the ϕ_x in the proof of Cook's Theorem.

Now we modify the above idea to give another example of an NP-completeness proof by combinatorial transformation.

THEOREM 28.5 GRAPH COLORABILITY *is* NP*-complete*

PROOF *Construction.* Given the 3SAT instance ϕ, we build G_ϕ similarly to the last proof, but with several changes. See Fig. 28.2. On the left, we add a special node labeled "B" and connect it to all $2n$ rung nodes. On the right we add a special node "G" with an edge to B. In any possible 3-coloring of G_ϕ, without loss of generality B will be colored "blue" and the adjacent G will be colored "green." The third color "red" stands for literals made true, whereas green stands for falsity.

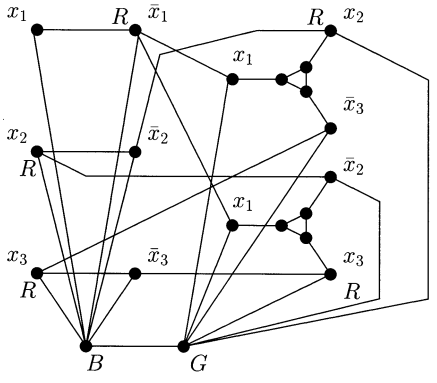

FIGURE 28.2 Construction in the proof of NP-completeness of GRAPH COLORABILITY for the formula $(x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$. The nodes shown colored R correspond to the satisfying assignment $x_1 = \texttt{false}$, $x_2 = \texttt{true}$, and $x_3 = \texttt{true}$, and these together with G and B essentially force a 3-coloring of the graph, which the reader may complete. Note the resemblance to Fig. 28.1.

Now for each occurrence of a positive literal x_i in a clause, the corresponding clause component has two nodes labeled x_i and x_i' with an edge between them; and similarly an occurrence of a negated literal $\bar{x}_j$ gives nodes $\bar{x}_j$ and $\bar{x}_j'$ with an edge between them. The primed ("inner") nodes in each component are connected by edges into a triangle, but the unprimed ("outer") nodes are not. Each outer node of each clause component is instead connected by an edge to G. Finally, each outer node x_i is connected by a "crossing edge" to the rung node $\bar{x}_i$, and each outer node $\bar{x}_j$ to rung node x_j, exactly as in the INDEPENDENT SET reduction. This finishes the construction of G_ϕ.

Complexity. The function f that given any ϕ outputs G_ϕ, also fixing $k = 3$, is clearly computable in polynomial time.

Correctness. The key idea is that every three-coloring of B, G, and the rung nodes, which corresponds to a truth assignment to the variables of ϕ, can be extended to a 3-coloring of a clause component *if and*

only if at least one of the three crossing edges from the component goes to a green rung node. If all three of these edges go to red nodes, then the links to G force each outer node in the component to be colored blue—but then it is impossible to three-color the inner triangle since blue cannot be used. Conversely, any crossing edge to a green node allows the outer node x_i or $\bar{x_j}$ to be colored red, so that one red and two blues can be used for the outer nodes, and this allows the inner triangle to be colored as well. Hence G_ϕ is 3-colorable if and only if ϕ is satisfiable.

Note that we have also shown that the restricted form of GRAPH COLORABILITY with k fixed to be 3 (i.e., given a graph G, is G 3-colorable?) is NP-complete. Had we stated the problem this way originally, we would now conclude instead that the more-general graph-colorability problem is NP-complete, similarly to the KNAPSACK and TSP examples above.

Many other reductions from 3SAT use the same basic pattern of a truth-assignment selection component for the variables, components for the clauses (whose behavior depends on whether a variable in the clause is satisfied), and links between these components that make the reduction work correctly. For another example of this pattern, a standard proof that HAMILTONIAN CIRCUIT is NP-complete uses subgraphs V_i for each pair $x_i, \bar{x}_i$ and C_j for each clause. There are two possible ways a circuit can enter V_i, and these correspond to the choices of $x_i =$ `true` or $x_i =$ `false` in an assignment. The whole graph is built so that if the circuit enters V_i on the "$x_i =$ `true`" side, then the circuit has the opportunity to visit all nodes in the C_j components for all clauses in which x_i occurs positively, and similarly for occurrences of $\bar{x}_i$ if the circuit enters on the negative side. Hence the circuit can run through every C_j if and only if ϕ is satisfiable. Full details may be found in the text by Papdimitriou [22]. For our last fully worked-out example, we show a somewhat different pattern in which the individual variables as well as the clauses correspond to top-level components of the following problem.

DISJOINT CONNECTING PATHS

Instance: A graph G with two disjoint sets of distinguished vertices $s_1, \ldots, s_k$ and $t_1, \ldots, t_k$, where $k \geq 1$.

Question: Does G contain paths $P_1, \ldots, P_k$, with each P_i going from s_i to t_i, such that no two paths share a vertex?

THEOREM 28.6 DISJOINT CONNECTING PATHS *is* NP*-complete.*

PROOF First, it is easy to see that DISJOINT CONNECTING PATHS belongs to NP: one can design a polynomial-time nondeterministic Turing machine that simply guesses k paths and then deterministically checks that no two of these paths share a vertex. Now let ϕ be a given instance of 3SAT with n variables and m clauses. Take $k = n + m$.

Construction and complexity. The graph G_ϕ we build has distinguished path-origin vertices $s_1, \ldots, s_n$ for the variables and $S_1, \ldots, S_m$ for the clauses of ϕ. G_ϕ also has corresponding sets of path-destination nodes $t_1, \ldots, t_n$ and $T_1, \ldots, T_m$. The other vertices in G_ϕ are nodes u_{ij} for each occurrence of a positive literal x_i in a clause C_j, and nodes v_{ij} for each occurrences of a negated literal $\bar{x}_i$ in C_j. For each i, $1 \leq i \leq n$, G_ϕ is given the edges for a directed path from s_i through all u_{ij} nodes to t_i, and another from s_i through all v_{ij} nodes to t_i. (If there are no occurrences of the positive literal x_i in any clause then the former path is just an edge from s_i right to t_i, and likewise for the latter path if the negated literal $\bar{x}_i$ does not appear in any clause.) Finally, for each j, $1 \leq j \leq m$, G_ϕ has an edge from S_j to every node u_{ij} or v_{ij} for the jth clause, and edges from those nodes to T_j. Clearly these instructions can be carried out to build G_ϕ in polynomial time given ϕ. (See Fig. 28.3.)

Correctness. The first point is that for each i, no path from s_i to t_i can go through both a "u-node" and a "v-node." Setting x_i *true* corresponds to avoiding u-nodes, and setting x_i *false* entails avoiding v-nodes. Thus the choices of such paths for all i represent a truth assignment. The key point is that for each j, one of the three nodes between S_j and T_j will be free for the taking if and only if the corresponding positive or negative literal was made *true* in the assignment, thus satisfying the clause. Hence G_ϕ has the $n + m$ required paths if and only if ϕ is satisfiable.

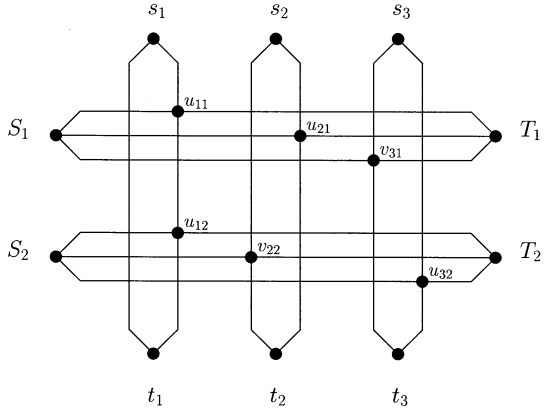

FIGURE 28.3 Construction in the proof of NP-completeness of DISJOINT CONNECTING PATHS for the formula $(x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$.

Significance of NP-Completeness

Suppose that you have proved that your problem is NP-complete. What does this mean, and how should you approach the problem now?

Exactly what it means is that your problem does not have a polynomial-time algorithm, *unless* every problem in NP has a polynomial-time algorithm; i.e., unless NP $\neq$ P. We have discussed above the reasons for believing that NP $\neq$ P. In practical terms, you can draw one definite conclusion: Don't bother looking for a "magic bullet" to solve the problem. A simple formula or an easily tested deciding condition will not be available; otherwise it probably would have been spotted already during the thousands of person-years that have been spent trying to solve similar problems. For example, the NP-completeness of GRAPH 3-COLORABILITY effectively ended hopes that an efficient mathematical formula for deciding the problem would pop out of research on "chromatic polynomials" associated to graphs. Notice that NP-hardness does not say that one needs to be "extra clever" to find a feasible solving algorithm—it says that one probably does not exist at all.

The proof itself means that the combinatorial mechanism of the problem is rich enough to simulate Boolean logic. The proof, however, may also unlock the door to finding saving graces in Steps 5 and 6.

Step 5. Analyze the instances of your problem that are in the range of the reduction. You may tentatively think of these as "hard cases" of the problem. If these differ markedly from the kinds of instances that you expect to see, then this difference may help you refine the statement and conditions of your problem in ways that may actually define a problem in P after all.

To be sure, avoiding the range of one reduction still leaves wide open the possibility that another reduction will map into your instances of interest. However, it often happens that special cases of NP-complete problems belong to P—and often the boundary between these and the NP-complete cases is

sudden and sharp. For one example, consider SAT. The restricted case of three variables per clause is NP-complete, but the case of two variables per clause belongs to P.

For another example, note that the proof of NP-completeness for DISJOINT CONNECTING PATHS given above uses instances in which $k = n + m$; i.e., in which k depends on the number of variables. The case $k = 2$, where you are given G and s_1, s_2, t_1, t_2 and need to decide whether there are vertex-disjoint paths from s_1 to t_1 and from s_2 to t_2, belongs to P. (The polynomial-time algorithm for this case is nontrivial and was not discovered until 1978 by Garey and Johnson [11].)

However, one must also be careful in one's expectations. Suppose we alter the statement of DISJOINT CONNECTING PATHS by requiring also that no two vertices in two different paths may have an edge between them. Then the case $k = 2$ of the new problem is NP-complete. (Showing this is a nice exercise; the idea is to make one path climb the "variable ladder" and send the other path through all the clause components.)

Strong NP-Completeness for Numerical Problems

An important difference between hard and easy cases applies to certain NP-complete problems that involve *numbers.* For example, above we stated that the PARTITION problem is NP-complete; thus, it is unlikely to be solvable by an efficient algorithm. Clearly, however, we can solve the PARTITION problem by a simple dynamic programming algorithm, as follows.

For an instance of PARTITION, let S be a set of positive integers $\{s_1, \ldots, s_m\}$, and let s^* be the total, $s^* = \Sigma_{i=1}^{m} s_i$. Initialize a linear array B of Boolean values so that $B[0] =$ `true`, and each other entry of B is `false`. For $i = 1$ to m, and for $t = s^*$ down to 0, if $B[t] =$ `true`, then set $B[t + s_i]$ to `true`. After the ith iteration, $B[t]$ is `true` if and only if a subset of $\{s_1, \ldots, s_i\}$ sums to t. The answer to this instance of PARTITION is "yes" if $B[s^*/2]$ is ever set to `true`.

The running time of this algorithm depends critically on the representation of S. If each integer in S is represented in binary, then the running time is exponential in the total length of the representation. If each integer is represented in unary—that is, each s_i is represented by s_i consecutive occurrences of the same symbol—then total length of the representation would be greater than s^*, and the running time would be only a polynomial in the length. Put another way, if the *magnitudes* of the numbers involved are bounded by a polynomial in m, then the above algorithm runs in time bounded by a polynomial in m. Since the length of the encoding of such a low-magnitude instance is $O(m \log m)$, the running time is polynomial in the length of the input. The bottom line is that these cases of the PARTITION problem *are* feasible to solve completely.

A problem is **NP-complete in the strong sense** if there is a fixed polynomial p such that for each instance x of the problem, the value of the largest number encoded in x is at most $p(|x|)$. That is, the integer values are polynomial in the length of the standard representation of the problem. By definition, the 3SAT, VERTEX COVER, CLIQUE, HAMILTONIAN CIRCUIT, and 3-DIMENSIONAL MATCHING problems defined in Section 28.4 are NP-complete in the strong sense, but PARTITION and KNAPSACK are not. The PARTITION and KNAPSACK problems can be solved in polynomial time if the integers in their statements are bounded by a polynomial in n—for instance, if numbers are written in unary rather than binary notation.

The concept of strong NP-completeness reminds us that the representation of information can have a major impact on the computational complexity of a problem.

Coping with NP-Hardness

Step 6. Even if you cannot escape NP-hardness, the cases you need to solve may still respond to sophisticated algorithmic methods, possibly needing high-powered hardware.

There are two broad families of direct attack that have been made on hard problems. *Exact solvers* typically take exponential time in the worst case, but provide feasible runs in certain concrete cases.

Whenever they halt, they output a correct answer—and some exact solvers also output a proof that their answer is correct. *Heuristic algorithms* typically run in polynomial time in all cases, and often aim to be correct only most of the time, or to find approximate solutions (see Sections 6.1 and 6.2 in the next chapter). They are more common. Popular heuristic methods include genetic algorithms, simulated annealing, neural networks, relaxation to linear programming, and stochastic (Markov) process simulation. Experimental systems dedicated to certain NP-complete problems have recently yielded some interesting results—an extensive survey on solvers for TRAVELING SALESPERSON is given by Johnson and McGeogh [15].

There are two ways to attempt to use this research. One is to find a problem close to yours for which people have produced solvers, and try to carry over their methods and heuristics to the specific features of your problem. The other (much more speculative) is to construct a Karp reduction from your problem to their problem, ask to run their program or machine itself on the transformed instance, and then try to map the answer obtained back to a solution of your problem. The hitches are (1) that the currently-known Karp reductions f tend to lose much of the potentially helpful structure of the source instance x when they form $f(x)$, and (2) that approximate solutions for $f(x)$ may map back to terribly suboptimal or even infeasible answers to x. (See, however, the notion of **L-reductions** in Section 29.6 of Chapter 29. All of this indicates that there is much scope for further research on important practical features of relationships between NP-complete problems. See also Chapter 34.

Beyond NP-Hardness

If your problem belongs to NP and you cannot prove that it is NP-hard, it may be an "NP-intermediate" problem; i.e., neither in P nor NP-complete. The theorem of Ladner mentioned in Section 28.3 shows that NP-intermediate problems exist, assuming NP $\neq$ P. However, very few natural problems are currently counted as good candidates for such intermediate status: *factoring, discrete logarithm, graph-isomorphism,* and several problems relating to *lattice bases* form a very representative list. For the first two, see Chapter 39. The vast majority of natural problems in NP have resolved themselves as being either in P or NP-complete. Unless you uncover a specific connection to one of those four intermediate problems, it is more likely offhand that your problem simply needs more work.

The observed tendency of natural problems in NP to "cluster" as either being in P or NP-complete, with little in between, reinforces the arguments made early in this chapter that P is really different from NP.

Finally, if your problem seems not to be in NP, or alternatively if some more stringent notion of feasibility than polynomial time is at issue, then you may desire to know whether your problem is *complete for some other complexity class.* We now turn to this question.

28.5 Complete Problems for NL, P, and PSPACE

We first investigate the log-space analogue of the P vs. NP question, namely whether NL = L. We show that there are natural computational problems that are NL-complete. The question is, under which reducibility? Polynomial-time reducibility is too blunt an instrument here, because NL is contained in P, and so all languages in NL are technically complete for NL under both $\leq_m^p$ and $\leq_T^p$ reductions. We need a reducibility that is fine enough to preserve the distinction between deterministic and nondeterministic log-space that we are attempting to establish and study. The simplest way is to replace the polynomial-time bound in $\leq_m^p$ reductions by a log-space bound.

- A language A_1 is **log-space reducible** to a language A_2, written $A_1 \leq_m^{log} A_2$, if A_1 is many-one reducible to A_2 via a transformation function that is computable by a deterministic Turing machine in $O(\log n)$ space.

There is a log-space analogue of $\leq_T^p$ reducibility, but we do not use it here. Now we show that $\leq_m^{log}$ reductions have the properties we desire:

THEOREM 28.7

(a) (Closure) If $A_1 \leq_m^{log} A_2$ *and* $A_2 \in \mathsf{L}$, *then* $A_1 \in \mathsf{L}$.
(b) (Transitivity) If $A_1 \leq_m^{log} A_2$ *and* $A_2 \leq_m^{log} A_3$, *then* $A_1 \leq_m^{log} A_3$.
(c) (Refinement of $\leq_m^p$ *reductions) If* $A_1 \leq_m^{log} A_2$, *then* $A_1 \leq_m^p A_2$.

The proof of (a) and (b) is somewhat tricky and rests on the fact that if two functions f and g from strings to strings are computable in log space, then so is the function h defined by $h(x) = g(f(x))$. The hitch is that a log space Turing machine M_f computing f can output the characters of $f(x)$ serially but does not have space to store them. This becomes a problem whenever the machine M_g computing g, whose input is the output from M_f, requests the ith character of $f(x)$, where i may be less than the index j of the previous request. The solution is that since only space and not time is constrained, we may *restart* the computation of $M_f(x)$ from scratch upon the request, and let M_g count the characters that M_f outputs serially until it sees the ith one. Such a counter, and similar ones tracking the movements of M_f's actual input head and M_g's "virtual" input head, can be maintained in $O(\log n)$ space. Thus we need no physical output tape for M_f or input tape for M_g, and we obtain a tandem machine that computes $g(f(x))$ in log space. Part (c) is immediate by the function-class counterpart of the inclusion $\mathsf{L} \subseteq \mathsf{P}$.

The definition of "NL-complete" is an instance of the general definition of completeness at the beginning of Section 28.3: A language A_1 is NL-complete ("under $\leq_m^{log}$ reductions" is assumed) if $A_1 \in \mathsf{NL}$ and for every language $A_2 \in \mathsf{NL}$, $A_2 \leq_m^{log} A_1$. One defines "P-complete" in a similar manner—again with $\leq_m^{log}$ reductions assumed. Together with the observation that whenever $A_1, A_2 \in \mathsf{L}$ we have $A_1 \leq_m^{log} A_2$ (ignoring technicalities for A_1 or A_2 equal to $\emptyset$ or Σ^*), we obtain a similar state of affairs to what is known about NP-completeness and the P vs. NP question:

THEOREM 28.8 *Let A be* NL*-complete. Then the following statements are equivalent:*

- $\mathsf{NL} = \mathsf{L}$.
- $A \in \mathsf{L}$.
- *Some* NL*-complete language belongs to* L.
- *All* NL*-complete languages belong to* L.
- *All languages in* L *are* NL*-complete.*

Substitute "P" for "NL" and the same equivalence holds. Note that here we are applying completeness to a class, namely P itself, whose definition does not involve nondeterminism.

Cook's Theorem provides two significant inferences: evidence of intractability, and a connection between computation and Boolean logic. NL-completeness is not to any comparable degree a notion of intractability, but does provide a fundamental link between computations and *graphs,* via the following important problem.

GRAPH ACCESSIBILITY PROBLEM (GAP)
Instance: A directed graph G, and two nodes s and t of G.
Question: Does G have a directed path from node s to node t?

Other names are the *s-t connectivity problem* and the *reachability problem.*

The link involves the concept of an **instantaneous description** (ID) of a Turing machine M. Let us suppose for simplicity that M has just two tapes: one read-only input tape that holds the input x, and one

work tape with alphabet $\{0, 1, B\}$, where B is the blank character. Let us also suppose that M never writes a B. Then any step of a computation of M on the fixed input x is describable by giving

- The current state q of M,
- The contents y of the work tape,
- The position i of the input tape head, and
- The position j of the work tape head.

Then the 4-tuple (q, y, i, j) is called an **ID** of M on input x. The restriction on writing B allows us to identify y with a string in $\{0, 1\}^*$. Without loss of generality, we always have $1 \leq i \leq n+1$, where $n = |x|$, and if $s(n)$ is a space bound on M, also $1 \leq j \leq s(n)$. An ID is also called a **configuration.**

Now define G_x to be the graph whose nodes are all possible IDs of M on input x, and whose directed edges comprise all pairs (I, J) such that M, if set up in configuration I, has a transition that takes it to configuration J in one step. If M is deterministic, then every node in G_x has at most one outgoing arc. Nondeterministic TMs, however, give rise to directed graphs G_x of out-degree more than one. Note that G_x does depend on x, since the step(s) taken from an ID (q, y, i, j) may depend on bit x_i of x.

THEOREM 28.9 GAP *is* NL*-complete.*

PROOF GAP belongs to NL because guessing successive edges in a path from 1 to R (when one exists) needs only $O(\log n)$ space to store the label of the current node, and to locate where on the input tape the adjacency information for the current node is stored. To show NL-hardness, let $A \in \mathsf{NL}$. Then A is accepted by a nondeterministic $O(\log n)$ space bounded Turing machine M. We prove that $A \leq_m^{log} GAP$.

Construction: It is easy to modify M to have the properties supposed in the above discussion of IDs and still run in $O(\log n)$ space. We may also code M so that any accepting computation has a final phase that blanks out all used work tape cells, leaves the input head in cell $n+1$, and halts in a special accepting state q_a. This ensures that every accepting computation (if any) ends in the unique ID $I_t = (q_a, \lambda, n+1, 1)$.

Now given any x, define G_x as above. Let node s be the unique starting ID $I_s = (q_0, \lambda, 1, 1)$, and let node t be I_t. Note that the size of G_x is polynomial—if M runs in $k \log n$ space, then the size is $O(n^{k+2})$.

Complexity: We show that the transformation f that takes a string x as input and produces the list of edges in G_x as output can be computed by a machine M_f that uses $O(\log n)$ space. For each node $I = (q, y, i, j)$ in turn, M_f reads the ith symbol of x and then produces an edge (I, J) for each J such that M can move from I to J when reading that symbol. The only memory space that M_f needs is the space to step through each I in turn, and count up to the ith input position, and produce each J. $O(\log n)$ space is sufficient for all of this.

Correctness: By the construction, paths in G_x correspond to valid sequences of transitions by M on input x. Hence there exists a path from s to t in G_x if and only if M has an accepting computation on input x.

To see an example of a reduction between two NL-complete problems, consider the related problem SC of whether a given directed graph is *strongly connected,* meaning that there is a path from every node u to every other node v. Then GAP $\leq_m^{log}$ SC: Take an instance graph G with distinguished nodes s and t and add an edge from every node to s and from t to every node. Computing this transformation needs only $O(\log n)$ space to store the labels of nodes s and t and find their adjacency information on the input tape, changing '0' for "non-edge" to '1' for "edge" as appropriate while writing to the output tape. This transformation is correct because the new edges cannot cause a path from s to t to exist when there wasn't one beforehand, but do allow any such path to be extended to and from any other pair of nodes. SC belongs to NL since a log-space machine can cycle through all pairs (u, v) and nondeterministically guess a path in each case, so SC is NL-complete.

Further variations of the connectivity theme and many other problems are NL-complete. For an interesting contrast to the current situation with NP-completeness, the *complements* of all these problems are also NL-complete under $\leq_m^{log}$ reductions! This is true because NL is closed under complementation (Theorem 27.4(c) in Chapter 27). The next problem, however, is apparently harder than the NL-complete problems.

CIRCUIT VALUE PROBLEM (CVP)
Instance: A Boolean circuit C (see Section 3 of Chapter 33) and an assignment I to the inputs of C.
Question: Does $C(I)$ evaluate to `true`?

THEOREM 28.10 CVP *is* P*-complete under* $\leq_m^{log}$ *reductions.*

PROOF That CVP $\in$ P is clear, and completeness is essentially proved by the construction in the proof of Theorem 27.10 in Chapter 27, which gives a polynomial-size circuit family $\{C_n\}$ that accepts any given language in P.

Thus CVP belongs to L if and only if P = L, to NL if and only if P = NL, and (owing to NC likewise being closed under $\leq_m^{log}$ reductions), to NC if and only if P = NC. For more P-complete problems, more detail, and discussion of the kind of "intractability" that P-completeness is evidence for, see Chapter 45 in this volume.

The last problem we consider here is a generalization of SAT. *Quantified Boolean formulas* may use the quantifiers $\forall$ and $\exists$ as well as $\{\wedge, \vee, \neg\}$. The formula is *closed* if every variable is quantified. For example, an instance $\phi(x_1, \ldots, x_n)$ of SAT is satisfiable if and only if the closed quantified Boolean formula $\phi' = (\exists x_1)(\exists x_2)\ldots(\exists x_n)\phi$ is true. Another example of a quantified Boolean formula is $\forall x \forall y \exists z(x \wedge (\overline{y} \vee z))$, and this one happens to be false.

QUANTIFIED BOOLEAN FORMULAS (QBF)
Instance: A closed quantified Boolean formula ϕ.
Question: Is ϕ true?

THEOREM 28.11 QBF *is* PSPACE*-complete under* $\leq_m^{log}$ *reductions, hence also under* $\leq_m^{p}$ *reductions.*

PROOF Given an n-variable instance ϕ, $O(n)$ space suffices to maintain a stack with current assignments to each variable, and with this stack one can evaluate ϕ by unwinding one quantifier at a time. So QBF $\in$ PSPACE. For hardness, let $A \in$ PSPACE, and let M be a Turing machine that accepts A in polynomial space. We prove that $A \leq_m^{log}$ QBF.

Construction: Given an input x to M, define the ID graph of G_x as before the proof of Theorem 28.9, but for a polynomial rather than logarithmic space bound. The size of G_x is bounded by $2^{s(n)}$ for some polynomial s, where $n = |x|$. We first define, by induction on r, formulas $\Phi_r(I, J)$ expressing that M started in configuration I can reach configuration J in at most 2^r transitions. The base case formula $\Phi_0(I, J)$ asserts that (I, J) is an edge of G_x.

The idea of the induction is to assert that there is an ID K that is "halfway between" I and J. The straightforward definition $\Phi_r(I, J) := (\exists K)[\Phi_{r-1}(I, K) \wedge \Phi_{r-1}(K, J)]$, however, blows Φ_r up to size exponential in r because of the two occurrences of "Φ_{r-1}" on the right-hand side. The trick is to define, for $r \geq 1$,

$$\Phi_r(I, J) := (\exists K)\left(\forall I', J'\right) : \left[\left(I' = I \wedge J' = K\right) \vee \left(I' = K \wedge J' = J\right)\right] \rightarrow \Phi_{r-1}\left(I', J'\right) .$$

The single occurrence of "Φ_{r-1}" makes the size of $\Phi_r(I, J)$ roughly proportional to r. Now let I_s be the starting ID of M on input x, and I_t the unique accepting ID, from the proof of Theorem 28.9. Then M accepts x if and only if $\Phi_{s(n)}(I_s, I_t)$ is true.

To convert $\Phi_{s(n)}(I_s, I_t)$ into an equivalent instance ϕ_x of QBF, we can represent IDs by blocks of $s(n)$ Boolean variables. All we need to do is code up polynomially-many instances of the predicates "$I = J$" and "M has a transition from I to J." This is similar to the coding done in the proof of Theorem 28.3, since levels of the circuits C_n in that proof are essentially IDs.

Complexity and Correctness. The only real care needed in the straightforward buildup of $\Phi_{s(n)}(I_1, I_R)$ and then ϕ_x is keeping track of the variables. Since there are only polynomially many of them, each has a tag of length $O(\log n)$, and the housekeeping can be done by a deterministic log-space machine. The reduction is correct since $x \in A$ if and only if $\phi_x \in$ QBF.

Remarks. This construction is unaffected if M is nondeterministic, and works for any constructible space bound $s(n) \geq \log n$, producing a formula ϕ_x with $O(s(n)^2)$ Boolean variables. Since ϕ_x can be evaluated deterministically in $O(s(n)^2)$ space, we have also proved Savitch's Theorem (Theorem 27.3(d) in Chapter 27), namely that $\mathsf{NSPACE}[s(n)] \subseteq \mathsf{DSPACE}[s(n)^2]$. We have also essentially proved that PSPACE equals alternating polynomial time (Theorem 27.9(b) in Chapter 27), since ϕ_x can be evaluated in $O(s(n)^2)$ *time* by an ATM M that makes existential and universal moves corresponding to the leading "$\exists$" and "$\forall$" quantifier blocks in ϕ_x. This also yields an alternative reduction from any language A in PSPACE to QBF, since the proof method for Cook's Theorem (28.3) extends to convert this M directly into a quantified Boolean formula.

One family of PSPACE-complete problems consists of connectivity problems for graphs that, although of exponential size, are specified by a "hierarchical," recursive, or some other scheme that enables one to test whether (u, v) is an edge in time polynomial in the length of the labels of u and v. The graph G_x in the last proof is of this kind, since its edge relation $\Phi_1(I, J)$ is polynomial-time decidable. Another family comprises many two-player combinatorial games, where the question is whether the player to move has a winning strategy. A reduction from QBF to the game question transforms a formula such as $(\exists x)(\forall y)(\exists z) \ldots B$ into reasoning of the form "there exists a move for Black such that for all moves by White, there exists a move for Black such that . . . Black wins," starting from a carefully constructed position. Decision problems that exhibit this kind of "there exists. . . for all. . . " alternation (with polynomially many turns) are often PSPACE-complete.

All PSPACE-complete problems are NP-hard, since $\mathsf{NP} \subseteq \mathsf{PSPACE}$; hence $\mathsf{PSPACE} = \mathsf{P}$ if and only if any one of them belongs to P. The only definite lower bound that follows from the results in this section is that no problem that is PSPACE-complete under $\leq_m^{log}$ reductions belongs to L or even NL, because these classes are closed under $\leq_m^{log}$ reductions and $\mathsf{PSPACE} \neq \mathsf{NL}$. It is, however, still possible to have a problem that is PSPACE-complete under $\leq_m^p$ reductions belong to L, since if $\mathsf{PSPACE} = \mathsf{P}$ then all languages in P are PSPACE-complete under $\leq_m^p$ reductions.

To investigate problems and classes within L, we need even finer reducibility relations than $\leq_m^{log}$. Recent results have brought the reductions defined in the next section to the fore. Amazingly, these new reductions, which are based on our tiniest canonical complexity class, are effective not just within L but for natural problems in all the complexity classes in these chapters, including all the problems defined above.

28.6 AC^0 Reducibilities

Recall that a function f belongs to AC^0 if and only if the language $\{\langle x, i, b\rangle : i \leq |f(x)| \wedge \text{bit } i \text{ of } f(x) \text{ equals } b\}$ belongs to AC^0.

- A language A_1 is AC^0 **reducible** to a language A_2, written $A_1 \leq_m^{AC^0} A_2$, if A_1 is many-one reducible to A_2 via a transformation in AC^0.

- A_1 is AC^0-**Turing reducible** to A_2, written $A_1 \leq_T^{AC^0} A_2$, if A_1 is recognized by a DLOGTIME-uniform family of circuits of polynomial size and constant depth, consisting of $\neg$ gates, unbounded fan-in $\wedge$ and $\vee$ gates, and oracle gates for A_2. (An oracle gate for A_2 takes m inputs $x_1, \ldots, x_m$ and outputs 1 if $x_1 \ldots x_m$ is in A_2, and outputs 0 otherwise.)

The next theorem summarizes basic relationships among the five reducibility relations defined thus far.

THEOREM 28.12 *For any languages A_1, A_2, and A_3:*
(Transitivity)

(a) *If $A_1 \leq_m^{AC^0} A_2$ and $A_2 \leq_m^{AC^0} A_3$, then $A_1 \leq_m^{AC^0} A_3$.*
(b) *If $A_1 \leq_T^{AC^0} A_2$ and $A_2 \leq_T^{AC^0} A_3$, then $A_1 \leq_T^{AC^0} A_3$.*

(Refinement)

(c) $A_1 \leq_m^{AC^0} A_2 \Longrightarrow A_1 \leq_m^{log} A_2 \Longrightarrow A_1 \leq_m^{p} A_2 \Longrightarrow A_1 \leq_T^{p} A_2$.
(d) $A_1 \leq_m^{AC^0} A_2 \Longrightarrow A_1 \leq_T^{AC^0} A_2 \Longrightarrow A_1 \leq_T^{p} A_2$.

In prose, (c) says that AC^0 reducibility implies log-space reducibility, which implies Karp reducibility, which implies Cook reducibility; and (d) says that AC^0 reducibility implies AC^0-Turing reducibility, which implies Cook reducibility. However, AC^0-Turing reducibility is known *not* to imply log-space reducibility or even Karp reducibility—any language that does not many-one reduce to its complement shows this.

Next, we list which of our canonical complexity classes are closed under which reducibilities. Note that the subclasses of P are not known to be closed under the more powerful reducibilities, and that the nondeterministic time classes are not known to be closed under the Turing reducibilities—mainly because they are not known to be closed under complementation.

THEOREM 28.13

(a) P, PSPACE, EXP, *and* EXPSPACE *are closed under Cook reducibility, and hence under* AC^0 *reducibility,* AC^0*-Turing reducibility, log-space reducibility, and Karp reducibility as well.*
(b) NP *and* NEXP *are closed under Karp reducibility, hence also under* AC^0 *reducibility and log-space reducibility.*
(c) L, NL, *and* NC *are closed under both log-space reducibility and* AC^0*-Turing reducibility, hence also under* AC^0 *reducibility.*
(d) NC^1, TC^0, *and* AC^0 *are closed under* AC^0*-Turing reducibility, hence also under* AC^0 *reducibility.*

For contrast, note that E and NE are *not* closed under AC^0 reducibility—hence they are not closed under any of the other reducibilities, either. To see this, let A be any language in $\mathsf{EXP} - \mathsf{E}$; such languages exist by the time hierarchy theorem (Theorem 27.5 in Chapter 27). Then for some $k > 0$, the language $A_k = \{x10^{|x|^k} \mid x \in A\}$ belongs to E, and it is easy to see that $A \leq_m^{AC^0} A_k$. If E were closed under $\leq_m^{AC^0}$ reductions, A would be in E, a contradiction. The same can be done for NE using NEXP in place of EXP.

Note that this gives an easy proof that $\mathsf{E} \neq \mathsf{NP}$, because NP has a closure property that E does not share. On the other hand, although this inequality tells us that exactly one of the following must hold,

- $\mathsf{NP} \subset \mathsf{E}$
- $\mathsf{E} \subset \mathsf{NP}$
- $\mathsf{NP} \not\subseteq \mathsf{E}$ and $\mathsf{E} \not\subseteq \mathsf{NP}$,

it is not known *which* of these is true.

Why Have So Many Kinds of Reducibility?

We have already discussed one reason to consider different kinds of reducibility: in order to explore the important subclasses of P, more restrictive notions such as $\leq_m^{AC^0}$ and $\leq_m^{log}$ are required. However, that does not explain why we study both Karp *and* Cook reducibility, or both AC^0 and AC^0-Turing reductions. It is worth taking a moment to explain this.

If our goal were merely to classify the deterministic complexity of problems, then Cook reducibility ($\leq_T^p$) would be the most natural notion to study. The class of problems that are Cook reducible to A (usually denoted by P^A) characterizes what can be computed quickly if A is easy to compute. Note in particular that A is Cook-reducible to its complement $\overline{A}$, and A and $\overline{A}$ have the same deterministic complexity.

However, if A is an NP-complete language, then A probably does *not* have the same *nondeterministic* complexity as $\overline{A}$. That is, $\overline{A} \in \mathsf{NP}$ only if $\mathsf{NP} = \mathsf{co\text{-}NP}$. It is worth emphasizing that, if we know only that A is complete for NP under $\leq_T^p$ reductions, the hypothesis $\overline{A} \in \mathsf{NP}$ does not allow us to conclude $\mathsf{NP} = \mathsf{co\text{-}NP}$. That is, we get *stronger* evidence that $\overline{A}$ has high nondeterministic complexity, if we know that A is complete for NP under the more restrictive kind of reducibility.

This is a general phenomenon: if we know that a language is complete under more restrictive kind of reducibility, then we know more about its complexity. We have already seen one other example: knowing a language A is complete for PSPACE under $\leq_m^{log}$ reductions tells you that $A \notin \mathsf{NL}$, whereas completeness under $\leq_m^p$ reductions does not even entail that $A \notin \mathsf{L}$. In the latter case we must appeal to the unproven conjecture that $\mathsf{P} \neq \mathsf{PSPACE}$ to infer that A is not in L. For another example, if A is complete for NP under $\leq_m^{AC^0}$ reductions, then we know that $A \notin \mathsf{AC}^0$, whereas if we know only that A is NP-complete under $\leq_m^{log}$ reductions, then we cannot conclude anything about the complexity of A, because we cannot yet rule out the possibility that $\mathsf{L} = \mathsf{NP}$.

Canonical Classes and Complete Problems

It is an amazing and surprising fact that most computational problems that arise in practice turn out to be complete for some natural complexity class—and complete under some extremely restrictive reducibility such as $\leq_m^{AC^0}$. Indeed, the lion's share of those natural problems known to be complete for NP under $\leq_m^p$ reductions, and for P under $\leq_m^{log}$ reductions, etc., are in fact complete under $\leq_m^{AC^0}$ reductions, too. We observe this after filling out our spectrum of complexity classes with some more decision problems.

Integer Multiplication
Instance: The binary representation of integers x and y, and a number i.
Question: Is the ith bit of the binary representation of $x \cdot y$ equal to 1?

Boolean Formula Value Problem (BFVP)
Instance: A Boolean formula ϕ and a 0-1 assignment I to the variables in ϕ.
Question: Does $\phi(I)$ evaluate to `true`?

Degree-One Connectivity (GAP_1)
Instance: A directed graph in which each node has at most one outgoing edge, and nodes s, t of G.
Question: Is there a path from node s to node t in G?

Regular Expressions with $(\cup, \cdot, ^*)$
Instance: A regular expression α with the standard union, concatenation, and Kleene-star operations (see Chapter 25).
Question: Is there a string that does *not* match α?

REGULAR EXPRESSIONS WITH $(\cup, \cdot, ^2)$
Instance: A regular expression α with union, concatenation, and "squaring" operators (where α^2 denotes $\alpha \cdot \alpha$).
Question: Is there a string that does not match α?

REGULAR EXPRESSIONS WITH $(\cup, \cdot, ^*, ^2)$
Instance: A regular expression α composed of the union, concatenation, "squaring," and Kleene star operators.
Question: Is there a string that does not match α?

N × N CHECKERS
Instance: A position in checkers played on an $N \times N$ board, with Black to move.
Question: Is this a winning position for Black?

THEOREM 28.14 *The following problems are complete for the given complexity classes under $\leq_m^{AC^0}$ reductions, except that* INTEGER MULTIPLICATION *is only known to be complete under $\leq_T^{AC^0}$ reductions.*

- TC^0 : INTEGER MULTIPLICATION.
- NC^1 : BFVP.
- L : GAP_1.
- NL : GAP.
- P : CVP.
- NP : SAT, CLIQUE, VERTEX COVER, *and so on.*
- PSPACE : QBF, REGULAR EXPRESSIONS WITH $(\cup, \cdot, ^*)$.
- EXP : N × N CHECKERS.
- NEXP : REGULAR EXPRESSIONS WITH $(\cup, \cdot, ^2)$.
- $\mathsf{EXPSPACE}$: REGULAR EXPRESSIONS WITH $(\cup, \cdot, ^*, ^2)$.

The last three problems also belong to E, NE, and $\mathsf{DSPACE}[2^{O(n)}]$, respectively (under suitable encodings), and so they are complete for these respective classes as well. Note that a "tiny" reducibility still gives complete problems for a big class! However, TC^0 is not known to have any complete problems under $\leq_m^{AC^0}$ reductions.

Note that the class NC does not appear anywhere in the list above. NC is not known (or generally believed) to have any complete language under log-space reductions. In fact, if NC does have a language that is complete under $\leq_m^{log}$ reducibility, then there is some k such that $\mathsf{NC}^k = \mathsf{NC}^{k+1} = \cdots = \mathsf{NC}$. This is considered unlikely. This behavior is typical of certain "hierarchy classes," and the *polynomial hierarchy* class PH (defined in the next chapter) behaves similarly with regard to $\leq_m^p$ reductions.

To (im)prove the claim about $\leq_m^{AC^0}$ reductions in Theorem 28.14, we can show that all the reductions in this chapter are computable by uniform AC^0 circuits *without any* $\wedge$ *or* $\vee$ *gates at all!* The circuits have only the constants 0 and 1, the inputs $x_1, \ldots, x_n$, and $\neg$ gates. A function $f : \{0,1\}^* \to \{0,1\}^*$ computed by circuits of this kind is called a *projection.* In a projection, every bit j of the output depends on at most one bit i of the input: it is either always 0, always 1, always x_i, or always the complement of x_i. An AC^0 projection f can be defined without reference to circuits: there is a deterministic Turing machine M that, given binary numbers n and j, decides in $O(\log n)$ time which of these four cases holds, also computing i in the latter two cases. (Note that $m = |f(x)|$ depends only on $n = |x|$; M must also test whether $j > m$ in $O(\log n)$ time.) Now observe:

- Most of the construction of ϕ in our proof of Cook's Theorem depended only on the length n of the argument x. The only dependence on x itself was in the very last piece of ϕ, and under the encoding, x was basically copied bit by bit as the signs of the literals. The construction for P-completeness of CVP has the same property.
- In the reductions shown from SAT to graph problems, each *edge* of the target graph depended on only one bit of information of the form, "is variable x_i in clause C_j?" (To meet the technical requirements for projections we must use a convoluted encoding of formulas and graphs, but this is the essential idea.)
- In the construction for NL-completeness of GAP, each edge of G_x depended on what the machine N could do while reading just one bit of x.
- Even in the trickiest proof in this chapter, for PSPACE-completeness of QBF, the only ID whose dependence on x needs to be made explicit is the starting ID I_s, and for this x is just copied bit by bit.

Similar ideas work for BFVP, and GAP_1; the reader is invited to investigate the remaining problems.

Our point is not to emphasize projections at the expense of other reductions, but to show that the reductions themselves can be incredibly easy to compute. Thus the complexity levels shown in these completeness results are entirely intrinsic to the target problems. In practice, with classes around P or NP, finding and proving a $\leq_m^p$ or $\leq_m^{log}$ reduction is usually easier, free of encoding fuss, and sufficient for one's purposes.

The list in Theorem 28.14 only begins to illustrate the phenomenon of completeness. Take a computational problem from the practical literature, and chances are it is complete for one of our short list of canonical classes. Here are some more examples, all complete under AC^0 reductions: Does a given deterministic finite automaton M accept a given input x?—L-complete. For certain fixed M, however, the problem is NC^1-complete, and since every regular language belongs to NC^1, this gives a sense in which NC^1 characterizes the complexity of regular languages. Do $N-1$ pairs (i, j) of numbers in $\{1, \ldots, N\}$ form one linked list starting from 1 and ending at N?—L-complete. Various related problems about permutations, list-ranking, depth-first search, and breadth-first search are also L-complete. Satisfiability for 2CNF formulas?—NL-complete. Is $L(G) = \emptyset$ for a given context-free grammar G?—P-complete. REGULAR EXPRESSIONS WITH $(\cup, \cdot)$ only?—NP-complete. Can a multithreaded finite-state program avert deadlock?—PSPACE-complete. Game problems in which play must halt after polynomially many moves tend to be PSPACE-complete, but if exponentially long games are possible, as with suitably generalized versions of Chess and Go as well as Checkers to arbitrarily large boards, they tend to be EXP-complete—and hence intractable to solve!

There are some exceptional problems: connectivity for undirected graphs (L-hard, not known to be in L), matrix determinant, matrix permanent (see Chapter 29), and the "NP-intermediate" problems mentioned at the end of the Section 28.4. But overall, no one would have expected thirty years ago that so many well-studied problems would quantize into so few complexity levels under efficient reductions.

Changing the conditions on a problem also often makes it jump into a new canonical completeness level. The regular-expression problems show this amply. Special cases of NP-complete problems overwhelmingly tend either to remain NP-hard or jump all the way down to P. BFVP is the special case of CVP where every gate in the circuit has fanout 1. Even SAT itself is a restricted case of QBF.

Problems complete for a given class share an underlying mathematical structure that is brought out by the reductions between them. Note that the transformations map tiny local features of one instance x

to tiny local features of $f(x)$—particularly when f is a projection! How such local transformations can propagate global decision properties between widely varying problems is a scientific phenomenon that has been studied for itself.

The main significance of completeness, however, is the evidence of intractability it provides. Although in many cases this evidence is based on an unproven conjecture, sometimes it is absolute. Consider the problem REGULAR EXPRESSIONS WITH $(\cup, ^2, \cdot)$, which is complete for NEXP. If this problem were in P, then by closure under Karp reducibility (Theorem 28.1 in Section 28.2), we would have $\mathsf{NEXP} \subseteq \mathsf{P}$, a contradiction of the Hierarchy Theorems (Theorem 27.5 in Chapter 27). Therefore, this decision problem is infeasible: it has no polynomial-time algorithm. In contrast, decision problems in $\mathsf{NEXP} - \mathsf{P}$ that have been constructed by diagonalization are artificial problems that nobody would want to solve anyway. It is an important point that although diagonalization produces unnatural problems by itself, the combination of diagonalization and completeness shows that *natural* problems are intractable.

However, the next section points out some limitations of current diagonalization techniques.

28.7 Relativization of the P vs. NP Problem

Let A be a language. Define P^A (respectively, NP^A) to be the class of languages accepted in polynomial time by deterministic (nondeterministic) oracle Turing machines with oracle A.

Proofs that use the diagonalization technique on Turing machines without oracles generally carry over to oracle Turing machines. Thus, for instance, the proof of DTIME hierarchy theorem also shows that, for *any* oracle A, $\mathsf{DTIME}^A[n^2]$ is properly contained in $\mathsf{DTIME}^A[n^3]$. This can be seen as a *strength* of the diagonalization technique, since it allows an argument to "relativize" to computation carried out relative to an oracle. In fact, there are examples of lower bounds (for deterministic, "unrelativized" circuit models) that make crucial use of the fact that the time hierarchies relativize in this sense.

But it can also be seen as a weakness of the diagonalization technique. The following important theorem demonstrates why.

THEOREM 28.15 *There exist languages A and B such that $\mathsf{P}^A = \mathsf{NP}^A$, and $\mathsf{P}^B \neq \mathsf{NP}^B$.*

This shows that resolving the P vs. NP question requires techniques that do not relativize, i.e., that do not apply to oracle Turing machines too. Thus, diagonalization as we currently know it is unlikely to succeed in separating P from NP, because the diagonalization arguments we know (and in fact *most* of the arguments we know) relativize. The only major nonrelativizing proof technique in complexity theory appears to be the technique used to prove that $\mathsf{IP} = \mathsf{PSPACE}$. (See Section 29.5 and the end notes to Chapter 29.)

28.8 Sparse Languages

Despite their variety, the known NP-complete languages are similar in the following sense. Two languages A and B are **P-isomorphic** if there exists a function h such that

- For all x, $x \in A$ if and only if $h(x) \in B$,
- h is bijective (i.e., one-to-one and onto), and
- Both h and its inverse h^{-1} are computable in polynomial time.

All known NP-complete languages are P-isomorphic. Thus, in some sense, they are merely different encodings of the same problem. This is yet another example of the "amazing fact" alluded to in Section 28.6 that natural NP-complete languages exhibit unexpected similarities.

Because of this and other considerations, Berman and Hartmanis [5] conjectured that *all* NP-complete languages are P-isomorphic. This conjecture implies that $\mathsf{P} \neq \mathsf{NP}$, because if $\mathsf{P} = \mathsf{NP}$, then there are finite NP-complete languages, and no infinite language (such as SAT) can be isomorphic to a finite language.

Between the finite languages and the infinite languages lie the sparse languages, which are defined as follows. For a language A over an alphabet Σ, the **census function** of A, denoted $c_A(n)$, is the number of words x in A such that $|x| \leq n$. Clearly, $c_A(n) < |\Sigma|^{n+1}$. If $c_A(n)$ is bounded by a polynomial in n, then A is **sparse**. From the definitions, it follows that if A is sparse, and A is P-isomorphic to B, then B is sparse.

If a sparse NP-complete language S exists, then we could use S to solve NP-complete problems efficiently, by the following method. Let A be a language in NP, and let f be a transformation function that reduces A to S in polynomial time $t_f(n)$. To quickly decide membership in A for every word x whose length is at most n, deterministically, compute $f(x)$ and check whether $f(x) \in S$ by looking up $f(x)$ in a table. The table would consist of all words in S whose length is at most $t_f(n)$. The number of entries in this table would be $c_S(t_f(n))$, which is polynomial in n, and hence the total space occupied by the table would be bounded by a polynomial in n.

The Berman–Hartmanis conjecture implies that there is no sparse NP-complete language, however, because SAT is not sparse. A stronger reason for believing there are no such languages is:

THEOREM 28.16 *If a sparse* NP*-complete language exists, then* $\mathsf{P} = \mathsf{NP}$.

Very recently, it has been shown that other complexity classes are similarly unlikely to possess sparse complete languages.

THEOREM 28.17

1. *If there is a sparse language that is complete for* P *under log-space reducibility, then* $\mathsf{L} = \mathsf{P}$.
2. *If there is a sparse language that is complete for* NL *under log-space reducibility, then* $\mathsf{L} = \mathsf{NL}$.

28.9 Advice, Circuits, and Sparse Oracles

In the computation of an oracle Turing machine, the oracle language provides assistance in the form of answers to queries, which may depend on the input word. A different kind of assistance, called "advice," depends only on the length of the input word.

Recall the following definitions from Section 27.3: A function α is an **advice function** if for every nonnegative integer n, $\alpha(n)$ is a binary word whose length is bounded by a polynomial in n. (An advice function need not be total recursive.)

- $\mathsf{P/poly}$ is the class of languages $A = \{x : \langle x, \alpha(|x|)\rangle \in A'\}$ for some advice function α and some language A' in P.

As was pointed out in that section, $\mathsf{P/poly}$ comprises those problems that can be solved by (nonuniform) circuit families of polynomial size.

Berman and Hartmanis also pointed out the following connection between sparse languages and circuit complexity.

THEOREM 28.18 *The following are equivalent:*

1. $A \in \mathsf{P/poly}$.

2. *A is decided by a circuit family of polynomial size complexity.*
3. *$A \in \mathsf{P}^S$ for some sparse language S, that is, A is Cook reducible to a sparse language.*

In Section 28.8 we discussed the consequences of having a sparse language complete for NP under Karp reducibility. Namely, for any n and for any problem A in NP, there would exist a small table that one could use to efficiently solve A on instances of length at most n. This would also be true if there were a sparse language complete for NP under Cook reducibility. This is equivalent to having $\mathsf{NP} \subseteq \mathsf{P/poly}$. But there is one notable difference between these two situations. By Theorem 28.16, if there is a sparse language complete under Karp reductions, then $\mathsf{P} = \mathsf{NP}$. It is not known if we can conclude that $\mathsf{P} = \mathsf{NP}$ assuming only that there is a sparse language complete under Cook reductions. The reasons for believing that $\mathsf{NP} \not\subseteq \mathsf{P/poly}$ are nearly as strong as those for believing that $\mathsf{NP} \neq \mathsf{P}$; for one, $\mathsf{NP} \subseteq \mathsf{P/poly}$ would imply that there are polynomial-size lookup tables to help one efficiently solve instances of SAT or factor integers, etc. There is other evidence against $\mathsf{NP} \subseteq \mathsf{P/poly}$ that we present in Section 29.2.

These connections to circuit complexity and to the isomorphism conjecture have motivated a great deal of research into the complexity of sparse languages under various types of reducibility.

28.10 Research Issues and Summary

Thanks to the notions of reducibility and completeness, it is possible to give "tight lower bounds" on the complexity of many natural problems, even without yet knowing whether $\mathsf{P} = \mathsf{NP}$. In this chapter, we have seen some examples showing how to prove that problems are NP-complete. We have also explored some of the other notions to which reducibility gives rise, including the notions of relativized computation, P-isomorphism, and the complexity of sparse languages.

There are many natural and important problems that are complete for complexity classes that do not appear in our list of "canonical" complexity classes. In order that these problems can be better understood, it is necessary to introduce some additional complexity classes. That is the topic of Chapter 29.

28.11 Defining Terms

Configuration: For a Turing machine, synonymous with **instantaneous description**.

Cook reduction ($\leq_T^p$): A **reduction** computed by a deterministic polynomial time **oracle Turing machine**.

Cook's theorem: The theorem that the language SAT of satisfiable Boolean formulas (defined in Chapter 33) is **NP-complete.**

Instantaneous description (ID): A string that encodes the current state, head position, and (work) tape contents at one step of a Turing machine computation.

Karp reduction ($\leq_m^p$): A **reduction** given by a polynomial-time computable **transformation function**.

NP: The class of languages accepted by **N**ondeterministic **P**olynomial-time Turing machines. The acronym does not stand for "nonpolynomial"—every problem in P belongs to NP.

NP-complete: A language A is NP-complete if A belongs to NP and every language in NP **reduces** to A. Usually this term refers to **Karp reducibility**.

NP-hard: A language A is NP-hard if every language in NP **reduces** to A. Usually this term refers to **Cook reducibility**.

Oracle Turing machine: A Turing machine that may write "query strings" y on a special tape and learn instantly whether y belongs to a language A_2 given as its *oracle.* These are defined in more detail in Chapter 24.

P: The class of languages accepted by (equivalently, decision problems solved by) deterministic polynomial-time Turing machines. Less technically, the class of feasibly solvable problems.

Reduction: A function or algorithm that maps a given instance of a (decision) problem A_1 into one or more instances of another problem A_2, such that an efficient solver for A_2 could be plugged in to yield an efficient solver for A_1.

Sparse language: A language with a polynomially bounded number of strings of any given length.

Transformation function: A function f that maps instances x of one decision problem A_1 to those of another problem A_2 such that for all such x, $x \in A_1 \iff f(x) \in A_2$. (Here we identify a decision problem with the language of inputs for which the answer is "yes.")

Further Information

Cook's Theorem was originally stated and proved for Cook reductions [9], and later for Karp reductions [17]. Independently, Levin [20] proved an equivalent theorem using a variant of Karp reductions; sometimes Theorem 28.3 is called the *Cook–Levin theorem.* Our circuit-based proof stems from Schnorr [24], where SAT is shown to be complete for nondeterministic quasi-linear time under deterministic quasi-linear time reductions. Karp [17] showed the large-scale impact of NP-completeness, and Theorems 28.4, 28.5, and 28.6 come from there.

A much more extensive discussion of NP-completeness and techniques for proving problems to be NP-complete may be found in [11]. This classic reference also contains a list of hundreds of NP-complete problems. An analogous treatment of problems complete for P can be found in [12]—see also Chapter 48 in this volume. Most textbooks on algorithm design or complexity theory also contain a discussion of NP-completeness.

Primary sources for other completeness results in this chapter include: Theorem 28.9 [23]; Theorem 28.10 [18]; Theorem 28.11 [25]. Jones [16] studied log-space reductions in detail, and also introduced $\leq_m^{AC^0}$ reductions under the name "log-bounded rudimentary reductions." An important paper for the theory of AC^0 is [4], which also discusses the complete problems in for TC^0 and NC^1 in Theorem 28.14. The remaining problems in Theorem 28.14 may be found in [27]. The texts by Hopcroft and Ullman [14] and Papadimitriou [22] give more examples of problems complete for other classes.

There are many other notions of reducibility, including *truth-table, randomized,* and *truth-table* reductions. A good treatment of this material can be found in the two volumes of [3].

The first relativization results, including Theorem 28.15, are due to Baker et al. [2], and many papers have proved more of them. The role of relativization in complexity theory (and even the question of what constitutes a nonrelativizing proof technique) is fraught with controversy. Longer discussions of the issues involved may be found in [1, 10, 13].

Sparse languages came to prominence in connection with the Berman–Hartmanis conjecture [5], where Theorem 28.18 is ascribed to Albert Meyer. Theorem 28.16 is from [21], and Theorem 28.17 from [7, 8]. Two new surveys of sparse languages and their impact on complexity theory are [6] and [26].

Information about practical efforts to solve instances of NP-complete and other hard problems is fairly easy to find on the World Wide Web, by searches on problem names such as `Traveling Salesman` (note that variants such as "Salesperson" and the British "Travelling" are also used). Three helpful sites with further links are the Center for Discrete Mathematics and Computer Science (DIMACS), the *TSP Library* (TSPLIB), and the *Genetic Algorithms Archive;*

`http://dimacs.rutgers.edu/`
`http://www.iwr.uni-heidelberg.de/iwr/comopt/soft/TSPLIB95/TSPLIB.html`
`http://www.aic.nrl.navy.mil:80/galist/`

are the current URLs. TSPLIB has downloadable test instances of the TSP problem drawn mostly from practical sources. There is also an extensive bibliography on the TSP problem called TSPBIB, maintained by P. Moscato at: `http://www.ing.unlp.edu.ar/cetad/mos/TSPBIB_home.html`.

29.1 Introduction

In the previous two chapters, we have

- Introduced the basic complexity classes,
- Summarized the known relationships between these classes, and
- Seen how reducibility and completeness can be used to establish tight links between natural computational problems and complexity classes.

Some natural problems seem not to be complete for any of the complexity classes we have seen so far. For example, consider the problem of taking as input a graph G and a number k, and deciding whether k

Kenneth W. Regan — Supported by the National Science Foundation under Grant CCR-9409104.

is exactly the length of the shortest traveling salesperson's tour. This is clearly related to the TSP problem discussed in Chapter 28, but in contrast to TSP, it seems not to belong to NP, and also seems not to belong to co-NP.

To classify and understand this and other problems, we will introduce a few more complexity classes. We cannot discuss all of the classes that have been studied—there are further pointers to the literature at the end of this chapter. Our goal is to describe some of the most important classes, such as those defined by probabilistic and interactive computation.

A common theme is that the new classes arise from the interaction of complexity theory with other fields, such as randomized algorithms, formal logic, combinatorial optimization, and matrix algebra. Complexity theory provides a common formal language for analyzing computational performance in these areas. Other examples can be found in other chapters of this *Handbook.*

29.2 The Polynomial Hierarchy

Recall from Theorem 27.9(b) in Chapter 27 that PSPACE is equal to the class of languages that can be recognized in polynomial time on an alternating Turing machine, and that NP corresponds to polynomial time on a nondeterministic Turing machine, which is just an alternating Turing machine that uses only existential states. Thus, in some sense, NP sits near the very "bottom" of PSPACE, and as we allow more use of the power of alternation, we slowly climb up toward PSPACE.

Many natural and important problems reside near the bottom of PSPACE in this sense, but are neither known nor believed to be in NP. (We shall see some examples later in this chapter.) Most of these problems can be accepted quickly by alternating Turing machines that make only two or three alternations between existential and universal states. This observation motivates the definition in the next paragraph.

With reference to Chapter 24, define a k-**alternating Turing machine** to be a machine such that on every computation path, the number of changes from an existential state to universal state, or from a universal state to an existential state, is at most $k-1$. Thus, a nondeterministic Turing machine, which stays in existential states, is a 1-alternating Turing machine.

It turns out that the class of languages recognized in polynomial time by 2-alternating Turing machines is precisely $\mathsf{NP}^{\mathrm{SAT}}$. This is a manifestation of something more general, and it leads us to the following definitions.

Let $\mathcal{C}$ be a class of languages. Define

- $\mathsf{NP}^{\mathcal{C}} = \bigcup_{A\in\mathcal{C}} \mathsf{NP}^{A}$,
- $\Sigma_0^P = \Pi_0^P = \mathsf{P}$;

and for $k \geq 0$, define

- $\Sigma_{k+1}^P = \mathsf{NP}^{\Sigma_k^P}$,
- $\Pi_{k+1}^P = \text{co-}\Sigma_{k+1}^P$.

Observe that $\Sigma_1^P = \mathsf{NP}^{\mathsf{P}} = \mathsf{NP}$, because each of polynomially many queries to an oracle language in P can be answered directly by a (nondeterministic) Turing machine in polynomial time. Consequently, $\Pi_1^P = \text{co-NP}$. For each k, $\Sigma_k^P \subseteq \Sigma_{k+1}^P$, and $\Pi_k^P \subseteq \Sigma_{k+1}^P$, but these inclusions are not known to be strict. See Fig. 29.1.

The classes Σ_k^P and Π_k^P constitute the **polynomial hierarchy.** Define

$$\mathsf{PH} = \bigcup_{k\geq 0} \Sigma_k^P .$$

It is straightforward to prove that $\mathsf{PH} \subseteq \mathsf{PSPACE}$, but it is not known whether the inclusion is strict. In fact, if $\mathsf{PH} = \mathsf{PSPACE}$, then the polynomial hierarchy collapses to some level, i.e., $\mathsf{PH} = \Sigma_m^P$ for some m.

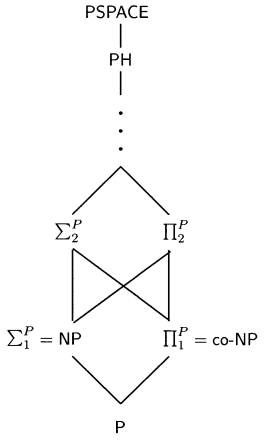

FIGURE 29.1 The polynomial hierarchy.

We have already hinted that the levels of the polynomial hierarchy correspond to k-alternating Turing machines. The next theorem makes this correspondence explicit, and also gives us a third equivalent characterization.

THEOREM 29.1 *For any language A, the following are equivalent:*

1. $A \in \Sigma_k^P$.
2. *A is decided in polynomial time by a k-alternating Turing machine that starts in an existential state.*
3. *There exists a language $B \in \mathsf{P}$ and a polynomial p such that for all x, $x \in A$ if and only if*

$$(\exists y_1 : |y_1| \leq p(|x|))\ (\forall y_2 : |y_2| \leq p(|x|)) \cdots (Q y_k : |y_k| \leq p(|x|))\ [(x, y_1, \ldots, y_k) \in B]\ ,$$

where the quantifier Q is $\exists$ if k is odd, $\forall$ if k is even.

In Section 28.9 we discussed some of the startling consequences that would follow if NP were included in P/poly, but observed that this inclusion was not known to imply P = NP. It is known, however, that if NP $\subseteq$ P/poly, then PH collapses to its second level, Σ_2^P [32]. It is generally considered likely that PH does not collapse to any level, and hence that all of its levels are distinct. Hence this result is considered strong evidence that NP is not a subset of P/poly.

Also inside the polynomial hierarchy is the important class BPP of problems that can be solved efficiently and reliably by probabilistic algorithms, to which we now turn.

29.3 Probabilistic Complexity Classes

Since the 1970s, with the development of randomized algorithms for computational problems (see Chapter 15), complexity theorists have placed randomized algorithms on a firm intellectual foundation. In this section, we outline some basic concepts in this area.

A **probabilistic Turing machine** M can be formalized as a nondeterministic Turing machine with exactly two choices at each step. During a computation, M chooses each possible next step with independent probability 1/2. Intuitively, at each step, M flips a fair coin to decide what to do next. The probability of a computation path of t steps is $1/2^t$. The probability that M accepts an input string x, denoted by $p_M(x)$, is the sum of the probabilities of the accepting computation paths.

Throughout this section, we consider only machines whose time complexity $t(n)$ is time-constructible. Without loss of generality, we may assume that every computation path of such a machine halts in exactly t steps.

Let A be a language. A probabilistic Turing machine M decides A with

		for all $x \in A$	for all $x \notin A$
unbounded two-sided error	if	$p_M(x) > 1/2$	$p_M(x) \leq 1/2$
bounded two-sided error	if	$p_M(x) > 1/2 + \epsilon$	$p_M(x) < 1/2 - \epsilon$
		for some constant ϵ	
one-sided error	if	$p_M(x) > 1/2$	$p_M(x) = 0$

Many practical and important probabilistic algorithms make one-sided errors. For example, in the Solovay–Strassen primality testing algorithm of Chapter 15 (on randomized algorithms), when the input x is a prime number, the algorithm *always* says "prime;" when x is composite, the algorithm *usually* says "composite," but may occasionally say "prime." Using the definitions above, this means that the Solovay–Strassen algorithm is a one-sided error algorithm for the set A of composite numbers. It also is a bounded two-sided error algorithm for $\overline{A}$, the set of prime numbers.

These three kinds of errors suggest three complexity classes:

- PP is the class of languages decided by probabilistic Turing machines of polynomial time complexity with unbounded two-sided error.
- BPP is the class of languages decided by probabilistic Turing machines of polynomial time complexity with bounded two-sided error.
- RP is the class of languages decided by probabilistic Turing machines of polynomial time complexity with one-sided error.

In the literature, RP is also called R.

A probabilistic Turing machine M is a **PP-machine** (respectively, a **BPP-machine,** an **RP-machine**) if M has polynomial time complexity, and M decides with two-sided error (bounded two-sided error, one-sided error).

Through repeated Bernoulli trials, we can make the error probabilities of BPP-machines and RP-machines arbitrarily small, as stated in the following theorem. (Among other things, this theorem implies that $\mathsf{RP} \subseteq \mathsf{BPP}$.)

THEOREM 29.2 *If $L \in \mathsf{BPP}$, then for every polynomial $q(n)$, there exists a BPP-machine M such that $p_M(x) > 1 - 1/2^{q(n)}$ for every $x \in L$, and $p_M(x) < 1/2^{q(n)}$ for every $x \notin L$.*

If $L \in \mathsf{RP}$, then for every polynomial $q(n)$, there exists an RP-machine M such that $p_M(x) > 1 - 1/2^{q(n)}$ for every x in L.

It is important to note just how minuscule the probability of error is (provided that the coin flips are truly random). If the probability of error is less than $1/2^{5000}$, then it is less likely that the algorithm produces an incorrect answer than that the computer will be struck by a meteor. An algorithm whose probability of error is $1/2^{5000}$ is essentially as good as an algorithm that makes no errors. For this reason, many computer scientists consider BPP to be the class of practically feasible computational problems.

Next, we define a class of problems that have probabilistic algorithms that make no errors. Define

- $\mathsf{ZPP} = \mathsf{RP} \cap \text{co-RP}$.

The letter Z in ZPP is for zero probability of error, as we now demonstrate. Suppose $A \in \mathsf{ZPP}$. Here is an algorithm that checks membership in A. Let M be an RP-machine that decides A, and let M' be

an RP-machine that decides $\overline{A}$. For an input string x, alternately run M and M' on x, repeatedly, until a computation path of one machine accepts x. If M accepts x, then accept x; if M' accepts x, then reject x. This algorithm works correctly because when an RP-machine accepts its input, it does not make a mistake. This algorithm might not terminate, but with very high probability, the algorithm terminates after a few iterations.

The next theorem expresses some known relationships between probabilistic complexity classes and other complexity classes, such as classes in the polynomial hierarchy (see Section 29.2).

THEOREM 29.3

(a) $\mathsf{P} \subseteq \mathsf{ZPP} \subseteq \mathsf{RP} \subseteq \mathsf{BPP} \subseteq \mathsf{PP} \subseteq \mathsf{PSPACE}$.
(b) $\mathsf{RP} \subseteq \mathsf{NP} \subseteq \mathsf{PP}$.
(c) $\mathsf{BPP} \subseteq \Sigma_2^P \cap \Pi_2^P$.
(d) $\mathsf{PH} \subseteq \mathsf{P}^{\mathsf{PP}}$.
(e) $\mathsf{TC}^0 \subset \mathsf{PP}$.

(Note that the last inclusion is strict! TC^0 is not known to be different from NP, but it is a proper subset of PP.) Figure 29.2 illustrates many of these relationships. PP is not considered to be a feasible class because it contains NP.

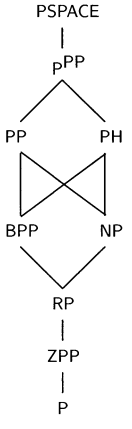

FIGURE 29.2 Probabilistic complexity classes.

Even though it is not clear that there is a good physical source of randomness that can be used to execute probabilistic algorithms and obtain the desired low error bounds, pseudo-random generators are often used and seem to work well. There is currently great interest in de-randomizing probabilistic algorithms, but that topic is beyond the scope of this chapter. There is a simple sense in which a probabilistic algorithm can be de-randomized, however. If an algorithm has very small error probability (in particular, if it has error probability a little less than $1/2^n$), then there is one sequence of coin flips that gives the right answer on all inputs of length n, and this sequence can be hard-wired into the algorithm to yield a deterministic (but *nonuniform*) circuit family. More formally:

THEOREM 29.4 $\mathsf{BPP} \subseteq \mathsf{P/poly}$.

There is another important way in which BPP, RP, and ZPP differ from PP (as well as from NP and

all of the other complexity classes we have discussed thus far): BPP, RP, and ZPP are not known to have any complete languages. Intuitively, BPP is believed to lack complete sets because there is no computable way to weed out those polynomial-time probabilistic Turing machines that are not BPP-machines from those that are. The same goes for RP and ZPP—a more detailed discussion of this point may be found in [6, 45]. To be sure, if these classes equal P then trivially they have complete languages. Recent work [30] proves that a highly plausible hardness assertion for languages in exponential time implies P = BPP.

Log-space analogues of these probabilistic classes have also been studied, of which the most important is RL, defined by probabilistic TMs with one-sided error that run in log space and may use polynomially many random bits in any computation. An important problem in RL that is not known to be in L is that of whether there is a path from node s to node t in an *un*directed graph, or much the same thing, whether an undirected graph is connected.

29.4 Formal Logic and Complexity Classes

There is a surprisingly close connection between important complexity classes and natural notions that arise in the study of formal logic. This connection has led to important applications of complexity theory to logic, and vice-versa. Below, we present some basic notions from formal logic, and then we show some of the connections between logic and complexity theory.

Descriptive complexity refers to the ability to describe and characterize individual problems and whole complexity classes by certain kinds of formulas in formal logic. These descriptions do not depend on an underlying machine model—they are machine-independent. Furthermore, computational problems can be described in terms of their native data structures, rather than under *ad hoc* string encodings.

A **relational structure** consists of a set V (called the *universe*), a tuple $E_1, \ldots, E_k$ of relations on V, and a tuple $c_1, \ldots, c_\ell$ of elements of V ($k, \ell \geq 0$). Its *type* τ is given by the tuple $(a_1, \ldots, a_k)$ of arities of the respective relations, together with ℓ. In this chapter, V is always finite. For example, directed graphs $G = (V, E)$ are relational structures with the one binary relation E, and their type has $k = 1, a_1 = 2$, and $\ell = 0$, the last since there are no distinguished vertices. For another example, instances of the GRAPH ACCESSIBILITY PROBLEM (GAP) from Section 28.5 consist of a directed graph $G = (V, E)$ along with two distinguished vertices $s, t \in V$, so they have $\ell = 2$.

An ordinary binary string x can be regarded as a structure $(V, X, \leq)$, where $\leq$ is a total order on V that sequences the bits, and for all i ($1 \leq i \leq |x|$), $x_i = 1$ if and only if $X(u_i)$ holds. Here u_i is the ith element of V under the total order, and x_i is the ith bit of x. It is often desirable to regard the ordering $\leq$ as fixed, and focus attention on the single unary relation $X(\cdot)$ as the essence of the string.

Systems of Logic

For our purposes, a **system of logic** (or *logic language*) $\mathcal{L}$ consists of the following:

1. A tuple $(\mathbf{E}_1, \ldots, \mathbf{E}_k)$ of *relation symbols,* with corresponding arities $a_1, \ldots, a_k \geq 1$, and a tuple $(\mathbf{c}_1, \ldots, \mathbf{c}_\ell)$ of *constant symbols* ($k, \ell \geq 0$). These symbols constitute the *vocabulary* of $\mathcal{L}$, and can be identified with the corresponding type τ of relational structures.
2. Optionally, a further finite collection of relation and constant symbols whose interpretations are fixed in all universes V under consideration. By default this collection contains the symbol $=$, which is interpreted as the equality relation on V.
3. An unbounded supply of variable symbols $u, v, w, \ldots$ ranging over elements of V, and optionally, an unbounded supply of variable relation symbols $R_1, R_2, R_3, \ldots$, each with an associated arity and ranging over relations on V.
4. A complete set of Boolean connectives, for which we use $\wedge, \vee, \neg, \rightarrow$, and $\leftrightarrow$, and the quantifiers $\forall, \exists$. Additional kinds of operators for building up formulas are discussed later.

The *well-formed formulas* of $\mathcal{L}$, and the *free, bound, positive,* and *negative* occurrences of symbols in a formula, are defined in the usual inductive manner. A *sentence* is a formula ϕ with no free variables. A formula, or a whole system, is called **first-order** if it has no relation *variables* R_i; otherwise it is **second-order.**

Just as machines of a particular type define complexity classes, so also do logical formulas of a particular type define important classes of languages. The most common nomenclature for these classes begins with a prefix such as FO or F_1 for first-order systems, and SO or F_2 for second-order. SO$\exists$ denotes systems whose second-order formulas are restricted to the form $(\exists R_1)(\exists R_2)\ldots(\exists R_k)\psi$ with ψ first-order. After this prefix, in parentheses, we list the vocabulary, and any extra fixed-interpretation symbols or additions to formulas. For instance, SO$\exists$(*Graphs,* $\leq$) stands for the second-order existential theory of graphs whose nodes are labeled and ordered. (The predicate $=$ is always available in the logics we study, and thus it is not explicitly listed with the other fixed-interpretation symbols such as $\leq$.)

The fixed-interpretation symbols deserve special mention. Many authorities treat them as part of the vocabulary. A finite universe V may without loss of generality be identified with the set $\{1, \ldots, n\}$, where $n \in \mathbb{N}$. Important fixed-interpretation symbols for these sets, besides $=$ and $\leq$, are *suc* , $+$, and $*$, respectively standing for the successor, addition, and multiplication relations. (Here $+(i, j, k)$ stands for $i + j = k$, etc.) Insofar as they deal with the numeric coding of V and do not depend on any structures that are being built on V, such fixed-interpretation symbols are commonly called *numerical predicates.*

Languages, Logics, and Complexity Classes

Let us see how a logical formula describes a language, just as a Turing machine or a program does. A formal inductive definition of the following key notion, and much further information on systems of logic, may be found in the standard text [19].

DEFINITION 29.1 Let ϕ be a sentence in a system $\mathcal{L}$ with vocabulary τ. A relational structure $\mathcal{R}$ of type τ *satisfies* (or *models*) ϕ, written $\mathcal{R} \models \phi$, if ϕ becomes a true statement about $\mathcal{R}$ when the elements of $\mathcal{R}$ are substituted for the corresponding vocabulary symbols of ϕ. The **language of** ϕ is $L_\phi = \{\mathcal{R} : \mathcal{R} \models \phi\}$.

We say that ϕ *describes* L_ϕ, or describes the property of belonging to L_ϕ. Finally, given a system $\mathcal{L}$ of vocabulary τ, $\mathcal{L}$ itself stands for the class of structures of type τ that are described by formulas in $\mathcal{L}$. If τ is the vocabulary *Strings* of binary strings, then L_ϕ is a language in the familiar sense of a subset of $\{0, 1\}^*$, and systems $\mathcal{L}$ over τ define ordinary classes of languages. Thus defining sets of structures over τ generalizes the notion of defining languages over an alphabet.

For example, the formula $(\forall u)X(u)$ over binary strings describes the language 1^*, while $(\forall v, w)[v \neq w \leftrightarrow E(v, w)]$ defines complete (loop-free) graphs. The formula

$$Undir = (\forall v, w)[E(v, w) \rightarrow E(w, v)] \wedge (\forall u)\neg E(u, u)$$

describes the property of being an undirected simple graph, treating an undirected edge as a pair of directed edges, and ruling out "self-loops." Given unary relation symbols $X_1, \ldots, X_k$, the formula

$$Uniq_{X_1,\ldots,X_k} = (\forall v)\left[\bigvee_{1\leq i\leq k} X_i(v) \wedge \bigwedge_{1\leq i<j\leq k} \neg\left(X_i(v) \wedge X_j(v)\right)\right]$$

expresses that every element v is assigned exactly one i such that $X_i(v)$ holds. Given an arbitrary finite alphabet $\Sigma = \{c_1, \ldots, c_k\}$, the vocabulary $\{X_1, \ldots, X_k\}$, together with this formula, enables us to define languages of strings over Σ. (Since the presence of *Uniq* does not affect any of the syntactic characterizations that follow, we may now regard *Strings* as a vocabulary over any Σ.) Given a unary relation symbol R and

the numerical predicate *suc* on V, the formula

$$Alts_R = (\exists s, t)(\forall u, v)[\neg Suc(u, s) \wedge \neg Suc(t, u) \wedge R(s) \wedge \neg R(t) \wedge (Suc(u, v) \rightarrow (R(u) \leftrightarrow \neg R(v))]$$

says that R is true of the first element s, false of the last element t, and alternates true and false in-between. This requires $|V|$ to be even. The following examples are used again below.

(1) The regular language $(10)^*$ is described by the first-order formula $\phi_1 = Alts_X$.

(2) $(11)^*$ is described by the second-order formula $\phi_2 = (\exists R)(\forall u)[X(u) \wedge Alts_R]$.

(3) GRAPH THREE-COLORABILITY:

$$\phi_3 = Undir \wedge (\exists R_1, R_2, R_3)\left[Uniq_{R_1,R_2,R_3} \wedge (\forall v, w)(E(v, w) \rightarrow \bigvee_{1 \le i \le 3} R_i(v) \wedge \neg R_i(w))\right].$$

(4) GAP (i.e., s-t connectivity for directed graphs):

$$\phi_4 = (\forall R)\neg(\forall u, v)[R(s) \wedge \neg R(t) \wedge (R(u) \wedge E(u, v) \rightarrow R(v))]\,.$$

Formula ϕ_4 says that there is no set $R \subseteq V$ that is closed under the edge relation and contains s but doesn't contain t, and this is equivalent to the existence of a path from s to t. Much trickier is the fact that deleting "$Uniq_{R_1,R_2,R_3}$" from ϕ_3 leaves a formula that still defines exactly the set of undirected 3-colorable graphs. This fact hints at the delicacy of complexity issues in logic.

Much of this study originated in research on database systems, because data base query languages correspond to logics. First-order logic is notoriously limited in expressive power, and this limitation has motivated the study of extensions of first-order logic, such as the following *first-order operators.*

DEFINITION 29.2

(a) *Transitive closure* (TC): Let ϕ be a formula in which the first-order variables $u_1, \ldots, u_k$ and $v_1, \ldots, v_k$ occur freely, and regard ϕ as implicitly defining a binary relation S on V^k. That is, S is the set of pairs $(\vec{u}, \vec{v})$ such that $\phi(\vec{u}, \vec{v})$ holds. Then $\mathrm{TC}_{(u_1,\ldots,u_k,v_1,\ldots,v_k)}\,\phi$ is a formula, and its semantics is the reflexive-transitive closure of S.

(b) *Least fixed point* (LFP): Let ϕ be a formula with free first-order variables $u_1, \ldots, u_k$ and a free k-ary relation symbol R that occurs only positively in ϕ. In this case, for any relational structure $\mathcal{R}$ and $S \subseteq V^k$, the mapping $f_\phi(S) = \{(e_1, \ldots, e_k) : \mathcal{R} \models \phi(S, e_1, \ldots, e_k)\}$ is monotone. That is, if $S \subseteq T$, then for every tuple of domain elements $(e_1, \ldots, e_k)$, if $\phi(R, u_1, \ldots, u_k)$ evaluates to `true` when R is set to S and each u_i is set to e_i, then ϕ also evaluates to `true` when R is set to T, because R appears positively. Thus the mapping f_ϕ has a least fixed point in V^k. Then $\mathrm{LFP}_{(R,u_1,\ldots,u_k)}\,\phi$ is a formula, and its semantics is the least fixed point of f_ϕ, i.e., the smallest S such that $f_\phi(S) = S$.

(c) *Partial fixed point* (PFP): Even if f_ϕ above is not monotone, $\mathrm{PFP}_{(R,u_1,\ldots,u_k)}\,\phi$ is a formula whose semantics is the first fixed point found in the sequence $f_\phi(\emptyset)$, $f_\phi(f_\phi(\emptyset))$, ..., if it exists, $\emptyset$ otherwise.

The first-order variables $u_1, \ldots, u_k$ remain free in these formulas. The relation symbol R is bound in $\mathrm{LFP}_{(R,u_1,\ldots,u_k)}\,\phi$, but since this formula is fixing R uniquely rather than quantifying over it, the formula $\mathrm{LFP}_{(R,u_1,\ldots,u_k)}\,\phi$ is still regarded as first-order (provided ϕ is first-order).

A somewhat less natural but still useful operation is the "deterministic transitive closure" operator. We write "DTC" for the restriction of (a) above to cases where the implicitly defined binary relation S is a partial function. The DTC restriction is enforcible syntactically by replacing any (sub)-formula ϕ to which

TC is applied by $\phi'' = \phi \wedge (\forall w_1, \ldots, w_k)[\phi' \rightarrow \wedge_{i=1}^{k} v_i = w_i]$, where ϕ' is the result of replacing each v_i in ϕ by w_i, $1 \leq i \leq k$.

For example, s-t connectivity is definable by the FO(TC) and FO(LFP) formulas

$$\begin{aligned} \phi_4' &= (\exists u, v)\left[u = s \wedge v = t \wedge \mathrm{TC}_{(u,v)}\, E(u, v)\right], \\ \phi_4'' &= (\exists u, v)\left[u = s \wedge v = t \wedge \mathrm{LFP}_{(R,u,v)}\, \psi\right], \end{aligned}$$

where $\psi = (u = v \vee E(u, v) \vee (\exists w)[R(u, w) \wedge R(w, v)])$. To understand how ϕ_4'' works, starting with S as the empty binary relation and substituting the current S for R at each turn, the first iteration yields $S = \{(u, v) : u = v \vee E(u, v)\}$, the second iteration gives pairs of vertices connected by a path of length at most 2, then 4, ..., and the fixed-point is the reflexive-transitive closure E^* of E. Then ϕ_4'' is read as if it were $(\exists u, v)(u = s \wedge v = t \wedge E^*(u, v))$, or more simply, as if it were $E^*(s, t)$.

Note however, that writing DTC ... in place of TC ... in ϕ_4' changes the property defined by restricting it to directed graphs in which each non-sink vertex has out-degree 1. It is not known whether s-t connectivity can be expressed using the DTC operator. This question is equivalent to whether L = NL.

Logical Characterizations of Complexity Classes

As discussed by [21], there is a uniform encoding method *Enc* such that for any vocabulary τ and (finite) relational structure $\mathcal{R}$ of type τ, *Enc* ($\mathcal{R}$) is a standard string encoding of $\mathcal{R}$. For instance with $\tau = \mathit{Graphs}$, an n-vertex graph becomes the size-n^2 binary string that lists the entries of its adjacency matrix in row-major order. Thus one can say that a language L_ϕ over any vocabulary belongs to a complexity class $\mathcal{C}$ if the string language $\mathit{Enc}\,(L_\phi) = \{\mathit{Enc}\,(\mathcal{R}) : \mathcal{R} \models \phi\}$ is in $\mathcal{C}$.

The following theorems of the form "$\mathcal{C} = \mathcal{L}$" all hold in the following strong sense: for every vocabulary τ and $\mathcal{L}(\tau)$-formula ϕ, $\mathit{Enc}\,(L_\phi) \in \mathcal{C}$; and for every language $A \in \mathcal{C}$, there is a $\mathcal{L}(\mathit{Strings})$-formula ϕ such that $L_\phi = A$. Although going to strings via *Enc* may seem counter to the motivation expressed in the first paragraph of this whole section, the generality and strength of these results has a powerful impact in the desired direction: they define the right notion of complexity class $\mathcal{C}$ for any vocabulary τ. Hence we omit the vocabulary τ in the following statements.

THEOREM 29.5

(a) PSPACE = FO(PFP, $\leq$).
(b) PH = SO.
(c) **(Fagin's Theorem)** NP = SO$\exists$.
(d) P = FO(LFP, $\leq$).
(e) NL = FO(TC, $\leq$).
(f) L = FO(DTC, $\leq$).
(g) AC^0 = FO(+, $*$).

One other result should be mentioned with the above. Define the *spectrum* of a formula ϕ by $S_\phi = \{n :$ for some $\mathcal{R}$ with n elements, $\mathcal{R} \models \phi\}$. Jones and Selman [31] proved that a language A belongs to NE if and only if there is a vocabulary τ and a sentence $\phi \in \mathsf{FO}(\tau)$ such that $A = S_\phi$ (identifying numbers and strings). Thus spectra characterize NE.

The ordering $\leq$ is needed in results (a), (d), (e), and (f). Chandra and Harel [15] proved that FO(LFP) without $\leq$ cannot even define (11)* (and their proof works also for FO(PFP)). Put another way, without an (ad-hoc) ordering on the full database, one cannot express queries of the kind "Is the number of widgets in Toledo even?" even in the powerful system of first-order logic with PFP. Note that, as a consequence of what we know about complexity classes, it follows that FO(PFP, $\leq$) is more expressive

than FO(TC, $\leq$). This result is an example of an application of complexity theory to logic. In contrast, when the ordering is not present, it is much easier to show directly that FO(PFP) is more powerful than FO(TC) than to use the tools of complexity theory. Furthermore, the hypotheses FO(LFP) = FO(PFP) and FO(LFP, $\leq$) = FO(PFP, $\leq$) are *both* equivalent to P = PSPACE [2]. This shows how logic can apply to complexity theory.

A Short Digression: Logic and Formal Languages

There are two more logical characterizations that seem at first to have little to do with complexity theory. Characterizations such as these have been important in circuit complexity, but those considerations are beyond the scope of this chapter.

Let SF stand for the class of *star-free regular languages,* which are defined by regular expressions without Kleene stars, but with $\emptyset$ as an atom and complementation ($\sim$) as an operator. For example, $(10)^* \in$ SF via the equivalent expression $\sim[(\sim\emptyset)(00+11)(\sim\emptyset)+0(\sim\emptyset)+(\sim\emptyset)1]$.

A formula is *monadic* if each of its relation symbols is unary. A second-order system is *monadic* if every relation variable is unary. Let mSO denote the monadic second-order formulas. The formula ϕ_2 above defines $(11)^*$ in mSO$\exists$(*suc*). The following results are specific to the vocabulary of strings.

THEOREM 29.6

(a) REG = mSO(*Strings,* $\leq$) = mSO$\exists$(*Strings,suc*).
(b) SF = FO(*Strings,* $\leq$).

Theorem 29.6, combined with Theorem 29.5 (b) and (c), shows that SO is much more expressive than mSO, and SO$\exists(\leq)$ is similarly more expressive than mSO$\exists(\leq)$. A seemingly smaller change to mSO$\exists$ also results in a leap of expressiveness from the regular languages to the level of NP. Lynch [39] showed that if we consider mSO$\exists(+)$ instead of mSO$\exists(\leq)$ (for strings), then the resulting class contains NTIME$[n]$, and hence contains many NP-complete languages, such as GRAPH THREE-COLORABILITY.

29.5 Interactive Models and Complexity Classes

Interactive Proofs

In Section 27.2, we characterized NP as the set of languages whose membership proofs can be checked quickly, by a deterministic Turing machine M of polynomial time complexity. A different notion of proof involves interaction between two parties, a prover P and a verifier V, who exchange messages. In an **interactive proof system,** the prover is an all-powerful machine, with unlimited computational resources, analogous to a teacher. The verifier is a computationally limited machine, analogous to a student. Interactive proof systems are also called "Arthur–Merlin games:" the wizard Merlin corresponds to P, and the impatient Arthur corresponds to V.

Formally, an **interactive proof system** comprises the following:

- A read-only input tape on which an input string x is written.
- A *prover* P, whose behavior is not restricted.
- A *verifier* V, which is a probabilistic Turing machine augmented with the capability to send and receive messages. The running time of V is bounded by a polynomial in $|x|$.
- A tape on which V writes messages to send to P, and a tape on which P writes messages to send to V. The length of every message is bounded by a polynomial in $|x|$.

A computation of an interactive proof system (P, V) proceeds in rounds, as follows. For $j = 1, 2, \ldots$, in round j, V performs some steps, writes a message m_j, and temporarily stops. Then P reads m_j and responds with a message m'_j, which V reads in round $j + 1$. An interactive proof system (P, V) **accepts** an input string x if the probability of acceptance by V satisfies $p_V(x) > 1/2$.

In an interactive proof system, a prover can convince the verifier about the truth of a statement without exhibiting an entire proof, as the following example illustrates.

EXAMPLE 29.1:

Consider the graph non-isomorphism problem: the input consists of two graphs G and H, and the decision is "yes" if and only if G is not isomorphic to H. Although there is a short proof that two graphs *are* isomorphic (namely: the proof consists of the isomorphism mapping G onto H), nobody has found a general way of proving that two graphs are *not* isomorphic that is significantly shorter than listing all $n!$ permutations and showing that each fails to be an isomorphism. (That is, the graph nonisomorphism problem is in co-NP, but is not known to be in NP.) In contrast, the verifier V in an interactive proof system is able to take statistical evidence into account, and determine "beyond all reasonable doubt" that two graphs are nonisomorphic, using the following protocol.

In each round, V randomly chooses either G or H with equal probability; if V chooses G, then V computes a random permutation G' of G, presents G' to P, and asks P whether G' came from G or from H (and similarly if V chooses H). If P gave an erroneous answer on the first round, and G is isomorphic to H, then after k subsequent rounds, the probability that P answers all the subsequent queries correctly is $1/2^k$. (To see this, it is important to understand that the prover P does not see the coins that V flips in making its random choices; P sees only the graphs G' and H' that V sends as messages.) V accepts the interaction with P as "proof" that G and H are nonisomorphic if P is able to pick the correct graph for 100 consecutive rounds. Note that V has ample grounds to accept this as a convincing demonstration: if the graphs are indeed isomorphic, the prover P would have to have an incredible streak of luck to fool V.

The complexity class IP comprises the languages A for which there exists a verifier V and an ϵ such that

- There exists a prover $\hat{P}$ such that for all x in A, the interactive proof system $(\hat{P}, V)$ accepts x with probability greater than $1/2 + \epsilon$; and
- For every prover P and every $x \notin A$, the interactive proof system (P, V) rejects x with probability greater than $1/2 + \epsilon$.

By substituting random choices for existential choices in the proof that $\mathsf{ATIME}(t) \subseteq \mathsf{DSPACE}(t)$ (Theorem 27.8(b) in Chapter 27), it is straightforward to show that $\mathsf{IP} \subseteq \mathsf{PSPACE}$. It was originally believed likely that IP was a small subclass of PSPACE. Evidence supporting this belief was the construction by Fortnow and Sipser [24] of an oracle language B for which $\text{co-NP}^B - \mathsf{IP}^B \neq \emptyset$, so that IP^B is strictly included in PSPACE^B. Using a proof technique that does not relativize, however, Shamir [44] (building on the work of Lund et al. [37]) proved that in fact, IP and PSPACE are the same class.

THEOREM 29.7 $\mathsf{IP} = \mathsf{PSPACE}$.

If NP is a proper subset of PSPACE, as is widely believed, then Theorem 29.7 says that interactive proof systems can decide a larger class of languages than NP.

Probabilistically Checkable Proofs

In an interactive proof system, the verifier does not need a complete conventional proof to become convinced about the membership of a word in a language, but uses random choices to query parts of

a proof that the prover may know. This interpretation inspired another notion of "proof": a proof consists of a (potentially) large amount of information that the verifier need only inspect in a few places in order to become convinced. The following definition makes this idea more precise.

A language L has a **probabilistically checkable proof** if there exists an oracle BPP-machine M such that

- For all $x \in L$, there exists an oracle language B_x such that M^{B_x} accepts x.
- For all $x \notin L$, and for every language B, machine M^B rejects x.

Intuitively, the oracle language B_x represents a proof of membership of x in L. Notice that B_x can be finite since the length of each possible query during a computation of M^{B_x} on x is bounded by the running time of M. The oracle language takes the role of the prover in an interactive proof system—but in contrast to an interactive proof system, the prover cannot change strategy adaptively in response to the questions that the verifier poses. This change results in a potentially stronger system, since a machine M that has bounded error probability relative to all languages B might not have bounded error probability relative to some adaptive prover. Although this change to the proof system framework may seem modest, it leads to a characterization of a class that seems to be much larger than PSPACE.

THEOREM 29.8 *A has a probabilistically checkable proof if and only if* $A \in \mathsf{NEXP}$.

Although the notion of probabilistically checkable proofs seems to lead us away from feasible complexity classes, by considering natural restrictions on how the proof is accessed, we can obtain important insights into familiar complexity classes.

Let $\mathsf{PCP}(r(n), q(n))$ denote the class of languages with probabilistically checkable proofs in which the probabilistic oracle Turing machine M makes $O(r(n))$ random binary choices, and queries its oracle $O(q(n))$ times. (For this definition, we assume that M has either one or two choices for each step.) It follows from the definitions that $\mathsf{BPP} = \mathsf{PCP}(n^{O(1)}, 0)$, and $\mathsf{NP} = \mathsf{PCP}(0, n^{O(1)})$.

THEOREM 29.9 $\mathsf{NP} = \mathsf{PCP}(\log n, 1)$.

Theorem 29.9 asserts that for every language L in NP, a proof that $x \in L$ can be encoded so that the verifier can be convinced of the correctness of the proof (or detect an incorrect proof) by using only $O(\log n)$ random choices, and inspecting only a *constant* number of bits of the proof!

This surprising characterization of NP has important applications to the complexity of finding approximate solutions to **optimization problems,** as discussed in the next section.

29.6 Classifying the Complexity of Functions

Up to now, we have considered only the complexity of decision problems. (Recall that a decision problem is a problem in which, for every input, the output is either "yes" or "no.") Most of the functions that we actually compute are functions that produce more than one bit of output. For example, instead of merely deciding whether a graph has a clique of size m, we often want to *find* a clique. Problems in NP are naturally associated with this kind of search problem.

Of course, any function f can be analyzed in terms of a decision problem in a straightforward way by considering the decision problem A_f that takes as input x and i, and answers "yes" if the ith bit of $f(x)$ is 1. But there are other ways of formulating functions as decision problems, and sometimes it is instructive to study the complexity of functions directly instead of their associated decision problems. In this section and the sections that follow, we will discuss some of the more useful classifications.

The most important class of functions is the class that we can compute quickly.

- FP is the set of functions computable in polynomial time by deterministic Turing machines.

In an analogous way, we define FL, FNC^k, etc., to be the set of functions computable by deterministic log-space machines, by NC^k circuits, etc. We also define FPSPACE to be the class of functions f computable by deterministic machines in polynomial space, such that also $|f(x)|$ is bounded by a polynomial in $|x|$. This restriction is essential because a machine that uses polynomial space could run for an exponential number of steps, producing an exponentially long output.

To study functions that appear to be difficult to compute, we again use the notions of reducibility and completeness. Analogous to Cook reducibility to oracle *languages,* we consider Cook reducibility to a *function* given as an oracle. For a function f whose length $|f(x)|$ is bounded by a polynomial in $|x|$, we say that a language A is Cook reducible to f if there is a polynomial-time oracle Turing machine M that accepts A, where the oracle is accessed as follows: M writes a string y on the query tape, and in the next step y is replaced by $f(y)$. As usual, we let P^f and FP^f denote the class of languages and functions computable in polynomial time with oracle f, respectively.

Let $\mathcal{C}$ be a class of functions. When $\mathcal{C}$ is at least as big as FP, then we will use Cook reducibility to define completeness. That is, a function f is $\mathcal{C}$-complete, if f is in $\mathcal{C}$ and $\mathcal{C} \subseteq \mathsf{FP}^f$. When we are discussing smaller classes $\mathcal{C}$ (where polynomial-time is too powerful to give a meaningful notion of reducibility), then when we say that a function f is $\mathcal{C}$-complete, it refers to completeness under AC^0-Turing reducibility, which was defined in Section 28.6. In this chapter, we consider only these two variants of Turing reducibility. There are many other ways to reduce one function to another, just as there are many kinds of reductions between languages.

We use these notions to study optimization problems in this section and counting problems in Section 29.7.

Optimization Classes

Given an optimization (minimization) problem, we most often study the following associated decision problem:

> "Is the optimal value at most k"?

Alternatively, we could formulate the decision problem as the following:

> "Is the optimal value exactly k?"

For example, consider the TRAVELING SALESPERSON problem (TSP) again. TSP asks whether the length of the optimal tour is at most d_0. Define EXACT TSP to be the decision problem that asks whether the length of the optimal tour is exactly d_0. It is not clear that EXACT TSP is in NP or in co-NP, but EXACT TSP *can* be expressed as the intersection of TSP and its complement $\overline{\text{TSP}}$: the length of the optimal tour is d_0 if there is a tour whose length is at most d_0, and no tour whose length is at most $d_0 - 1$. Similar remarks apply to the optimization problem MAX CLIQUE: given an undirected graph G, find the maximum size of a clique in G.

Exact versions of many optimization problems can be expressed as the intersection of a language in NP and a language in co-NP. This observation motivates the definition of a new complexity class:

- D^P is the class of languages A such that $A = A_1 \cap A_2$ for some languages A_1 in NP and A_2 in co-NP.

The letter D in D^P means difference: $A \in \mathsf{D}^P$ if and only if A is the difference of two languages, i.e., $A = A_1 - A_3$ for some languages A_1 and A_3 in NP.

Not only is EXACT TSP in D^P, but also EXACT TSP is D^P-complete. Exact versions of many other NP-complete problems, including CLIQUE, are also D^P-complete [41].

Although it is not known whether D^P is contained in NP, it is straightforward to prove that

$$\mathsf{NP} \subseteq \mathsf{D}^P \subseteq \mathsf{P}^{\mathsf{NP}} \subseteq \Sigma_2^P \cap \Pi_2^P .$$

Thus, D^P lies between the first two levels of the polynomial hierarchy.

We have characterized the complexity of computing the optimal value of an instance of an optimization problem, but we have not yet characterized the complexity of computing the optimal solution itself. An optimization algorithm produces not only a "yes" or "no" answer, but also, when feasible solutions exist, an optimal solution.

First, for a maximization problem, suppose that we have a subroutine that solves the decision problem "Is the optimal value at least k?" Sometimes, with repeated calls to the subroutine, we can construct an optimal solution. For example, suppose subroutine S solves the CLIQUE problem; for an input graph G and integer k, the subroutine outputs "yes" if G has a clique of k (or more) vertices. To construct the largest clique in an input graph, first, determine the size K of the largest clique by binary search on $\{1, \ldots, n\}$ with $\log_2 n$ calls to S. Next, for each vertex v, in sequence, determine whether deleting v produces a graph whose largest clique has size K by calling S. If so, then delete v and continue with the remaining graph. If not, then look for a clique of size $K - 1$ among the neighbors of v.

The method outlined in the last paragraph uses S in the same way as an oracle Turing machine queries an oracle language in NP. With this observation, we define the following classes:

- $\mathsf{FP}^{\mathsf{NP}}$ is the set of functions computable in polynomial time by deterministic oracle Turing machines with oracle languages in NP.
- $\mathsf{FP}^{\mathsf{NP}[\log n]}$ is the set of functions computable in polynomial time by deterministic oracle Turing machines with oracle languages in NP that make $O(\log n)$ queries during computations on inputs of length n

$\mathsf{FP}^{\mathsf{NP}}$ and $\mathsf{FP}^{\mathsf{NP}[\log n]}$ contain many well-studied optimization problems [33]. The problem of producing the optimal tour in the TRAVELING SALESPERSON problem is $\mathsf{FP}^{\mathsf{NP}}$-complete. The problem of determining the size of the largest clique subgraph in a graph is $\mathsf{FP}^{\mathsf{NP}[\log n]}$-complete.

Approximability and Complexity

As discussed in Chapter 34 because polynomial-time algorithms for NP-complete optimization problems are unlikely to exist, we ask whether a polynomial-time algorithm can produce a feasible solution that is *close* to optimal.

Fix an optimization problem Π with a positive integer-valued objective function g. For each problem instance x, let $\mathsf{OPT}(x)$ be the optimal value, that is, $g(z)$, where z is a feasible solution to x that achieves the best possible value of g. Let M be a deterministic Turing machine that on input x produces as output a feasible solution $M(x)$ for Π. We say M is an **ϵ-approximation algorithm** if for all x,

$$\frac{|g(M(x)) - \mathsf{OPT}(x)|}{\max\{g(M(x)), \mathsf{OPT}(x)\}} \leq \epsilon .$$

(This definition handles both minimization and maximization problems.) The problem Π has a **polynomial-time approximation scheme** if for every fixed ϵ, there is a polynomial-time ϵ-approximation algorithm. Although the running time is polynomial in $|x|$, the time could be exponential in $1/\epsilon$.

Several NP-complete problems, including KNAPSACK, have polynomial-time approximation schemes. It is natural to ask whether *all* NP-complete optimization problems have polynomial-time approximation schemes. We define an important class of optimization problems, $\mathsf{MAX\text{-}SNP}$, whose complete problems apparently do not.

First, we define a reducibility between optimization problems that preserves the quality of solutions. Let Π_1 and Π_2 be optimization problems with objective functions g_1 and g_2, respectively. An **L-reduction** from Π_1 to Π_2 is defined by a pair of polynomial-time computable functions f and f' that satisfy the following properties:

1. If x is an instance of Π_1 with optimal value $\mathsf{OPT}(x)$, then $f(x)$ is an instance of Π_2 whose optimal value satisfies $\mathsf{OPT}(f(x)) \leq c \cdot \mathsf{OPT}(x)$ for some constant c.
2. If z is a feasible solution of $f(x)$, then $f'(z)$ is a feasible solution of x, such that

$$\left|\mathsf{OPT}(x) - g_1(f'(z))\right| \leq c' \left|\mathsf{OPT}(f(x)) - g_2(z)\right|$$

   for some constant c'.

The second property implies that if z is an optimal solution to $f(x)$, then $f'(z)$ is an optimal solution to x. From the definitions, it follows that if there is an L-reduction from Π_1 to Π_2, and there is a polynomial-time approximation scheme for Π_2, then there is a polynomial-time approximation scheme for Π_1.

To define MAX-SNP, it will help to recall the characterization of NP as SO$\exists$ in Section 29.4. This characterization says that for any A in NP, there is a first-order formula ψ such that $x \in A$ if and only if

$$\exists S_1 \ldots \exists S_l \; \psi(x, S_1, \ldots, S_l) \; .$$

For many important NP-complete problems, it is sufficient to consider having only a single second-order variable S, and to consider formulas ψ having only universal quantifiers. Thus, for such a language A we have a quantifier-free formula ϕ such that $x \in A$ if and only if

$$\exists S \forall u_1 \ldots \forall u_k \; \phi \, (S, u_1, \ldots, u_k) \; .$$

Now define MAX-SNP$_0$ to be the class of optimization problems mapping input x to

$$\max_S \left|\{(y_1, \ldots, y_k) : \phi \, (S, y_1, \ldots, y_k)\}\right| \; .$$

For example, we can express in this form the MAX CUT problem, the problem of finding the largest cut in an input graph $G = (V, E)$ with vertex set V and edge set E. A set of vertices S is the optimal solution if it maximizes

$$\left|\{(v, w) : E(v, w) \wedge S(v) \wedge \neg S(w)\}\right| \; .$$

That is, the optimal solution S maximizes the number of edges (v, w) between vertices v in S and vertices w in $V - S$.

Define MAX-SNP to be the class of all optimization problems that are L-reducible to a problem in MAX-SNP$_0$. MAX-SNP contains many natural optimization problems. MAX CUT is MAX-SNP-complete, and MAX CLIQUE is MAX-SNP-hard, under L-reductions.

A surprising connection between the existence of probabilistically checkable proofs (Section 29.5) and the existence of approximation algorithms comes out in the next major theorem.

THEOREM 29.10 *If there is a polynomial-time approximation scheme for some* MAX-SNP*-hard problem, then* P = NP.

In particular, unless P = NP, there is no polynomial-time approximation scheme for MAX CUT or MAX CLIQUE. To prove this theorem, all we need to do is show its statement for a particular problem that is MAX-SNP-complete under L-reductions. However, we prefer to show the *idea* of the proof for the MAX CLIQUE problem, which although MAX-SNP-hard is not known to belong to MAX-SNP. It gives a strikingly different kind of reduction from an arbitrary language A in NP to CLIQUE over the

reduction from A to SAT to CLIQUE in Section 28.4, and its discovery by Feige et al. [22] [23] stimulated the whole area.

PROOF Let $A \in \mathsf{NP}$. By Theorem 29.9, namely $\mathsf{NP} = \mathsf{PCP}[O(\log n), O(1)]$, there is a probabilistic oracle Turing machine M constrained to use $r(n) = O(\log n)$ random bits and make at most a constant number ℓ of queries in any computation path, such that

- For all $x \in A$, there exists an oracle language B_x such that $\text{Prob}_{s \in \{0,1\}^{r(n)}}[M^{B_x}(x, s) = 1] > 3/4$;
- For all $x \notin A$, and for every language B, $\text{Prob}_{s \in \{0,1\}^{r(n)}}[M^{B}(x, s) = 1] < 1/4$.

Now define a *transcript* of M on input x to consist of a string $s \in \{0, 1\}^{r(n)}$ together with a sequence of ℓ pairs (w_i, a_i), where w_i is an oracle query and $a_i \in \{0, 1\}$ is a possible yes/no answer. In addition, a transcript must be *valid:* for all i, $0 \leq i < \ell$, on input x with random bits s, having made queries $w_1, \ldots, w_i$ to its (unspecified) oracle and received answers $a_1, \ldots, a_i$, machine M writes w_{i+1} as its next query string. Thus a transcript provides enough information to determine a full computation path of M on input x, and the transcript is *accepting* if and only if this computation path accepts. Finally, call two transcripts *consistent* if whenever a string w appears as "w_i" in one transcript and "w_j" in the other, the corresponding answer bits a_i and a_j are the same.

Construction: Let G_x be the undirected graph whose node set V_x is the set of all accepting transcripts, and whose edges connect pairs of transcripts that are consistent.

Complexity: Since $r(n) + \ell = O(\log n)$, there are only polynomially many transcripts, and since consistency is easy to check, G_x is constructed in polynomial time.

Correctness: If $x \in A$, then take the oracle B_x specified above and let C be the set of accepting transcripts whose answer bits are given by B_x. These transcripts are consistent with each other, and there are at least $(3/4)2^{r(n)}$ such accepting transcripts, so C forms a clique of size at least $(3/4)2^{r(n)}$ in G_x. Now suppose $x \notin A$, and suppose C' is a clique of size greater than $(1/4)2^{r(n)}$ in G_x. Because the transcripts in C' are mutually consistent, there exists a single oracle B that produces all the answer bits to queries in transcripts in C'. But then $\text{Prob}_s[M^B(x, s) = 1] > 1/4$, contradicting the PCP condition on M.

Thus we have proved the statement of the theorem for MAX CLIQUE. The proof of the general statement is similar.

Note that the cases $x \in A$ and $x \notin A$ in this proof lead to a "(3/4,1/4) gap" in the maximum clique size ω of G_x. If there were a polynomial-time algorithm guaranteed to determine ω within a factor better than 3, then this algorithm could tell the "3/4" case apart from the "1/4" case, and hence decide whether $x \in A$. Since G_x can be constructed in polynomial time (in particular, G_x has size at most $2^{r(n)+\ell} = n^{O(1)}$), $\mathsf{P} = \mathsf{NP}$ would follow. Hence we can say that CLIQUE is NP-*hard to approximate within a factor of 3.* A long sequence of improvements to this basic construction has pushed the hardness-of-approximation not only to any fixed constant factor, but also to factors that increase with n. Moreover, approximation-preserving reductions have extended this kind of hardness result to many other optimization problems.

29.7 Counting

Two other important classes of functions deserve special mention:

- $\#\mathsf{P}$ is the class of functions f such that there exists a nondeterministic polynomial-time Turing machine M with the property that $f(x)$ is the number of accepting computation paths of M on input x.
- $\#\mathsf{L}$ is the class of functions f such that there exists a nondeterministic log-space Turing machine M with the property that $f(x)$ is the number of accepting computation paths of M on input x.

Some functions in #P are clearly at least as difficult to compute as some NP-complete problems are to decide. For instance, consider the following problem.

NUMBER OF SATISFYING ASSIGNMENTS TO A 3CNF FORMULA (#3CNF)
Instance: A Boolean formula in conjunctive normal form with at most three variables per clause.
Output: The number of distinct assignments to the variables that cause the formula to evaluate to `true`.

Note that #3CNF is in #P, and note also that the NP-complete problem of determining whether $x \in 3\mathrm{SAT}$ is merely the question of whether $\#3\mathsf{CNF}(x) = 0$.

In apparent contrast to #P, all functions in #L can be computed by NC circuits.

THEOREM 29.11 *Relationships between counting classes.*

- $\mathsf{FP} \subseteq \#\mathsf{P} \subseteq \mathsf{FPSPACE}$
- $\mathsf{P}^{\mathsf{PP}} = \mathsf{P}^{\#\mathsf{P}}$ *(and thus also* $\mathsf{FP}^{\mathsf{NP}} \subseteq \mathsf{FP}^{\#\mathsf{P}}$*)*
- $\mathsf{FL} \subseteq \#\mathsf{L} \subseteq \mathsf{FNC}^2$.

It is not surprising that #P and #L capture the complexity of various functions that involve counting, but as the following examples illustrate, it sometimes is surprising which functions are difficult to compute.

The proof of Cook's Theorem that appears in Chapter 28 also proves that #3CNF is complete for #P, because it shows that for every nondeterministic polynomial-time machine M and every input x, one can efficiently construct a formula with the property that each accepting computation of M on input x corresponds to a distinct satisfying assignment, and vice versa. Thus the number of satisfying assignments equals the number of accepting computation paths. A reduction with this property is called *parsimonious.*

Most NP-complete languages that one encounters in practice are known to be complete under parsimonious reductions. (The reader may wish to check which of the reductions presented in Chapter 28 are parsimonious.) For any such complete language, it is clear how to define a corresponding complete function in #P.

Similarly, for the GRAPH ACCESSIBILITY PROBLEM (GAP), which is complete for NL, we can define the function that counts the number of paths from the start vertex s to the terminal vertex t. For reasons that will become clear soon, we consider two versions of this problem: one for general directed graphs, and one for directed acyclic graphs. (The restriction of GAP to acyclic graphs remains NL-complete.)

NUMBER OF PATHS IN A GRAPH (#PATHS)
Instance: A directed graph on n vertices, with two vertices s and t.
Output: The number of simple paths from s to t.
(A path is a *simple path* if it visits no vertex more than once.)

NUMBER OF PATHS IN A DIRECTED ACYCLIC GRAPH (#DAG-PATHS)
Instance: A directed acyclic graph on n vertices, with two vertices s and t.
Output: The number of paths from s to t.
(In an acyclic graph, all paths are simple.)

As one might expect, the problem #DAG-PATHS is complete for #L, but it may come as a surprise that #PATHS is complete for #P [52]! That is, although it is easy to decide whether there is a path between two vertices, it seems quite difficult to count the number of distinct paths, unless the underlying graph is acyclic.

As another example of this phenomenon, consider the problem 2SAT, which is the same as 3SAT except that each clause has at most two literals. 2SAT is complete for NL, but the problem of counting the number of satisfying assignments for these formulas is complete for #P.

A striking illustration of the relationship between #P and #L is provided by the following two important problems from linear algebra.

DETERMINANT
Instance: An integer matrix.
Output: The determinant of the matrix.

Recall that the determinant of a matrix M with entries $M_{i,j}$ is given by

$$\sum_{\pi} \text{sign}(\pi) \prod_{i=1}^{n} M_{i,\pi(i)} ,$$

where the sum is over all permutations π on $\{1, \ldots, n\}$, and $\text{sign}(\pi)$ is -1 if π can be written as the composition of an odd number of transpositions, and $\text{sign}(\pi)$ is 1 otherwise.

PERMANENT
Instance: An integer matrix.
Output: The permanent of the matrix. The permanent of a matrix is given by

$$\sum_{\pi} \prod_{i=1}^{n} M_{i,\pi(i)} .$$

The reader is probably familiar with the determinant function, which can be computed efficiently by Gaussian elimination. The permanent may be less familiar, although its definition is formally simpler. Nobody has ever found an efficient way to compute the permanent, however.

We need to introduce slight modification of our function classes to classify these problems, however, because #L and #P consist of functions that take only non-negative values, whereas both the permanent and determinant can be negative.

Define GapL to be the class of functions that can be expressed as the difference of two #L functions, and define GapP to be the difference of two #P functions.

THEOREM 29.12

(a) PERMANENT *is complete for* GapP.
(b) DETERMINANT *is complete for* GapL

The class of problems that are AC^0-Turing reducible to DETERMINANT is one of the most important subclasses of NC, and in fact contains most of the natural problems for which NC algorithms are known.

29.8 Kolmogorov Complexity

Until now, we have considered only dynamic complexity measures, namely, the time and space used by Turing machines. **Kolmogorov complexity** is a static complexity measure that captures the difficulty of describing a string. For example, the string consisting of three million zeroes can be described with fewer than three million symbols (as in this sentence). In contrast, for a string consisting of three million randomly generated bits, with high probability there is no shorter description than the string itself.

Let U be a universal Turing machine (see Section 26.2 of Chapter 26). Let ϵ denote the empty string. The **Kolmogorov complexity** of a binary string y with respect to U, denoted by $K_U(y)$, is the length of the shortest binary string i such that on input $\langle i, \epsilon \rangle$, machine U outputs y. In essence, i is a description of y, for it tells U how to generate y.

The next theorem states that different choices for the universal Turing machine affect the definition of Kolmogorov complexity in only a small way.

THEOREM 29.13 **(Invariance Theorem)** *There exists a universal Turing machine U such that for every universal Turing machine U', there is a constant c such that for all y, $K_U(y) \leq K_{U'}(y) + c$.*

Henceforth, let K be defined by the universal Turing machine of Theorem 29.13. For every integer n and every binary string y of length n, because y can be described by giving itself explicitly, $K(y) \leq n + c'$ for a constant c'. Call y **incompressible** if $K(y) \geq n$. Since there are 2^n binary strings of length n, and only $2^n - 1$ possible shorter descriptions, there exists an **incompressible string** for every length n.

Kolmogorov complexity gives a precise mathematical meaning to the intuitive notion of "randomness." If someone flips a coin fifty times and it comes up "heads" each time, then intuitively, the sequence of flips is not random—although from the standpoint of probability theory the all-heads sequence is precisely as likely as any other sequence. Probability theory does not provide the tools for calling one sequence "more random" than another; Kolmogorov complexity theory does.

Kolmogorov complexity provides a useful framework for presenting combinatorial arguments. For example, when one wants to prove that an object with some property P exists, then it is sufficient to show that any object that does *not* have property P has a short description; thus any incompressible (or "random") object must have property P. This sort of argument has been useful in proving lower bounds in complexity theory. For example, Dietzfelbinger et al. [17] use Kolmogorov complexity to show that no Turing machine with a single worktape can compute the transpose of a matrix in less than time $\Omega(n^{3/2}/\sqrt{\log n})$.

29.9 Research Issues and Summary

As stated in the introduction to Chapter 27, the goals of complexity theory are (1) to ascertain the amount of computational resources required to solve important computational problems, and (2) to classify problems according to their difficulty. The preceding two chapters have explained how complexity theory has devised a classification scheme in order to meet the second goal. The present chapter has presented a few of the additional notions of complexity that have been devised in order to capture more problems in this scheme. Progress toward the first goal (proving lower bounds) depends on knowing that levels in this classification scheme are in fact distinct. Thus the core research questions in complexity theory are expressed in terms of separating complexity classes:

- Is L different from NL?
- Is P different from RP or BPP?
- Is P different from NP?
- Is NP different from PSPACE?

Motivated by these questions, much current research is devoted to efforts to understand the power of nondeterminism, randomization, and interaction. In these studies, researchers have gone well beyond the theory presented in Chapters 27, 28, and 29:

- Beyond Turing machines and Boolean circuits, to restricted and specialized models in which nontrivial lower bounds on complexity can be proved;

- Beyond deterministic reducibilities, to nondeterministic and probabilistic reducibilities, and refined versions of the reducibilities considered here;
- Beyond worst-case complexity, to average-case complexity.

We have illustrated how recent research in complexity theory has had direct applications to other areas of computer science and mathematics. Probabilistically checkable proofs were used to show that obtaining approximate solutions to some optimization problems is as difficult as solving them exactly. Complexity theory provides new tools for studying questions in finite model theory, a branch of mathematical logic. Fundamental questions in complexity theory are intimately linked to practical questions about the use of cryptography for computer security, such as the existence of one-way functions and the strength of public key cryptosystems.

This last point illustrates the urgent practical need for progress in computational complexity theory. Many popular cryptographic systems in current use are based on unproven assumptions about the difficulty of computing certain functions (such as the factoring and discrete logarithm problems; see Chapters 38–44 of this *Handbook* for more background on cryptography). All of these systems are thus based on wishful thinking and conjecture. The need to resolve these open questions and replace conjecture with mathematical certainty should be self-evident. (In the brief history of complexity theory, we have learned that many popular conjectures turn out to be incorrect.)

With precisely defined models and mathematically rigorous proofs, research in complexity theory will continue to provide sound insights into the difficulty of solving real computational problems.

29.10 Defining Terms

Descriptive complexity: The study of classes of languages described by formulas in certain systems of logic.

Incompressible string: A string whose **Kolmogorov complexity** equals its length, so that it has no shorter encodings.

Interactive proof system: A protocol in which one or more *provers* try to convince another party called the *verifier* that the prover(s) possess certain true knowledge, such as the membership of a string x in a given language, often with the goal of revealing no further details about this knowledge. The prover(s) and verifier are formally defined as **probabilistic Turing machines** with special "interaction tapes" for exchanging messages.

Kolmogorov complexity: The minimum number of bits into which a string can be compressed without losing information. This is defined with respect to a fixed but *universal* decompression scheme, given by a universal Turing machine.

L-reduction: A Karp reduction that preserves approximation properties of optimization problems.

Optimization problem: A computational problem in which the object is not to decide some yes/no property, as with a decision problem, but to find the best solution in those "yes" cases where a solution exists.

Polynomial hierarchy: The collection of classes of languages accepted by k-alternating Turing machines, over all $k \geq 0$ and with initial state existential or universal. The bottom level ($k = 0$) is the class P, and the next level ($k = 1$) comprises NP and co-NP.

Polynomial time approximation scheme (PTAS): A meta-algorithm that for every $\epsilon > 0$ produces a polynomial time ϵ-approximation algorithm for a given optimization problem.

Probabilistic Turing machine: A Turing machine in which some transitions are random choices among finitely many alternatives.

Probabilistically checkable proof: An interactive proof system in which provers follow a fixed strategy, one not affected by any messages from the verifier. The prover's strategy for a given instance

x of a decision problem can be represented by a finite oracle language B_x, which constitutes a proof of the correct answer for x.

Relational structure: The counterpart in formal logic of a data structure or class instance in the object-oriented sense. Examples are strings, directed graphs, and undirected graphs. Sets of relational structures generalize the notion of languages as sets of strings.

Further Information

Primary sources for major theorems presented in this chapter include Theorem 29.1 [16, 49, 57]; Theorem 29.3(a,b) [25], (c) [34, 46], (d) [51], (e) [4]; Theorem 29.4 [3]; Theorem 29.5(a) [1], (b) [49], (c) [20], (d,e,f) [29], (g) ([36], cf. [12]); Theorem 29.6(a) [14], (b) [40, 43]; Theorem 29.7 [44]; Theorem 29.8 [10]; Theorem 29.9 [7]; Theorem 29.10 [8]; Theorem 29.12(a) [52], (b) [54]. The operators in Definition 29.2 are from [29] and [1]. Interactive proof systems were defined by Goldwasser et al. [26], and in the "Arthur-Merlin" formulation, by Babai and Moran [9]. A large compendium of optimization problems and hardness results collected by P. Crescenzi and V. Kann is available at:

http://www.nada.kth.se/~viggo/index-en.html

The class #P was introduced by Valiant [52], and #L by Alvarez and Jenner [5]. Li and Vitányi [35] give a far-reaching and comprehensive scholarly treatment of Kolmogorov complexity, with many applications, as well as the source of Theorem 29.13.

Three contemporary textbooks on complexity theory are [11], [13], and [42]. Wagner and Wechsung [55] provide is an exhaustive survey of complexity theory that covers work published before 1986. Another perspective of some of the issues covered in these three chapters may be found in the survey [50].

A good general reference is the *Handbook of Theoretical Computer Science* [53], volume A. The following chapters in the *Handbook* are particularly relevant: "Machine Models and Simulations," by P. van Emde Boas, pp. 1–66; "A Catalog of Complexity Classes," by D.S. Johnson, pp. 67–161; "Machine-Independent Complexity Theory," by J.I. Seiferas, pp. 163–186; "Kolmogorov Complexity and Its Applications," by M. Li and P.M.B. Vitányi, pp. 187–254; and "The Complexity of Finite Functions," by R.B. Boppana and M. Sipser, pp. 757–804, which covers circuit complexity.

A collection of articles edited by Hartmanis [27] includes an overview of complexity theory, and chapters on sparse complete languages, on relativizations, on interactive proof systems, and on applications of complexity theory to cryptography. For historical perspectives on complexity theory, see [28], [47], and [48].

There are many areas of complexity theory that we have not been able to cover in these chapters. Some of them cross-pollinate with other fields of computer science and are reflected in other chapters of this *Handbook*. Three others are *average-case complexity, resource-bounded measure theory,* and *parameterized complexity.* Recent surveys on the first two are by Lutz [38] and Wang [56], while the third stems from Downey and Fellows [18] and has its own Web site, currently maintained by M. Hallett at

`http://csr.uvic.ca/home/mhallett/W.hier/compendium.html`

Surveys and lecture notes on complexity theory that can be obtained via WWW are maintained by A. Czumaj and M. Kutylowski at

`http://www.uni-paderborn.de/fachbereich/AG/agmadh/WWW/english/scripts.html`

As usual with the WWW, these links are subject to change. A good stem page to begin searches is the site for SIGACT, the ACM Special Interest Group on Algorithms and Computation Theory:

`http://sigact.acm.org/`

This has a pointer to a "Virtual Address Book" that indexes the personal Web pages of over 1,000 computer scientists, including all three authors of these chapters. Many of these pages have downloadable papers and links to further research resources.

Research papers on complexity theory are presented at several annual conferences, including the annual ACM Symposium on Theory of Computing; the annual International Colloquium on Automata, Languages, and Programming, sponsored by the European Association for Theoretical Computer Science (EATCS); and the annual Symposium on Foundations of Computer Science, sponsored by the IEEE. The annual Conference on Computational Complexity (formerly Structure in Complexity Theory), also sponsored by the IEEE, is entirely devoted to complexity theory. Research articles on complexity theory regularly appear in the following journals, among others: *Chicago Journal on Theoretical Computer Science, Computational Complexity, Information and Computation, Journal of the ACM, Journal of Computer and System Sciences, Mathematical Systems Theory, SIAM Journal on Computing,* and *Theoretical Computer Science.* Each issue of *ACM SIGACT News* and *Bulletin of the EATCS* contains a column on complexity theory.

Computational Learning Theory

Sally A. Goldman
Washington University,
St. Louis Missouri

30.1 Introduction

Since the late 1950s, computer scientists (particularly those working in the area of artificial intelligence) have been trying to understand how to construct computer programs that perform tasks we normally think of as requiring human intelligence, and which can improve their performance over time by modifying their behavior in response to experience. In other words, one objective has been to design computer programs that can learn. For example, Samuels designed a program to play checkers in the early 1960s that could improve its performance as it gained experience playing against human opponents. More recently, research on artificial neural networks has stimulated interest in the design of systems capable of performing tasks that are difficult to describe algorithmically (such as recognizing a spoken word or identifying an object in a complex scene), by exposure to many examples.

As a concrete example consider the task of hand-written character recognition. A learning algorithm is given a set of examples where each contains a hand-written character as specified by a set of *attributes* (e.g., the height of the letter) along with the name (*label*) for the intended character. This set of examples is often called the *training data*. The goal of the learner is to efficiently construct a rule (often referred to as a *hypothesis* or *classifier*) that can be used to take some previously unseen character and with high accuracy determine the proper label.

Computational learning theory is a branch of theoretical computer science that formally studies how to design computer programs that are capable of learning, and identifies the computational limits of learning by machines. Historically, researchers in the artificial intelligence community have judged learning algorithms empirically, according to their performance on sample problems. While such evaluations provide much useful information and insight, often it is hard using such evaluations to make meaningful comparisons among competing learning algorithms.

Computational learning theory provides a formal framework in which to precisely formulate and address questions regarding the performance of different learning algorithms so that careful comparisons of both the predictive power and the computational efficiency of alternative learning algorithms can be made. Three key aspects that must be formalized are the way in which the learner interacts with its environment, the definition of successfully completing the learning task, and a formal definition of efficiency of both data usage (*sample complexity*) and processing time (*time complexity*). It is important to remember that the theoretical learning models studied are abstractions from real-life problems. Thus close connections with experimentalists are useful to help validate or modify these abstractions so that the theoretical results help to explain or predict empirical performance. In this direction, computational learning theory research has close connections to machine learning research. In addition to its predictive capability, some other important features of a good theoretical model are simplicity, robustness to variations in the learning scenario, and an ability to create insights to empirically observed phenomena.

The first theoretical studies of machine learning were performed by inductive inference researchers (see [10]) beginning with the introduction of the first formal definition of learning given by Gold [24]. In Gold's model, the learner receives a sequence of examples and is required to make a sequence of guesses as to the underlying rule (*concept*) such that this sequence converges at some finite point to a single guess that correctly names the unknown rule. A key distinguishing characteristic is that Gold's model does not attempt to capture any notion of the efficiency of the learning process, whereas the field of computational learning theory emphasizes the computational feasibility of the learning algorithm.

Another closely related field is that of pattern recognition (see [21] and [20]). Much of the theory developed by learning theory researchers to evaluate the amount of data needed to learn directly adapts results from the fields of statistics and pattern recognition. A key distinguishing factor is that learning theory researchers study both the data (information) requirements for learning *and* the time complexity of the learning algorithm. (In contrast, pattern recognition researchers tend to focus on issues related to the data requirements.) Finally, there are a lot of close relations to work on artificial neural networks. While much of neural network research is empirical, there is also a good amount of theoretical work (see [20]).

This chapter is structured as follows. In Section 30.2 we describe the basic framework of concept learning and give notation that we use throughout the chapter. Next, in Section 30.3 we describe the *PAC* (*distribution-free*) model that began the field of computational learning theory. An important early result in the field is the demonstration of the relationships between the *VC-dimension,* a combinatorial measure, and the data requirements for **PAC learning.** We then discuss some commonly studied noise models and general techniques for PAC learning from noisy data.

In Section 30.4 we cover some of the other commonly studied formal learning models. First we study an **on-line learning model.** Unlike the PAC model in which there is a training period, in the on-line learning model the learner must improve the quality of its predictions as it functions in the world. Next we study the query model which is very similar to the on-line model except that the learner plays a more active role.

As in other theoretical fields, along with having techniques to prove positive results, another important component of learning theory research is to develop and apply methods to prove when a learning problem is hard. In Section 30.5 we describe some techniques used to show that learning problems are hard. Next, in Section 30.6, we explore a variation of the PAC model called the **weak learning model,** and study techniques for boosting the performance of a mediocre learning algorithm. Finally, we close with a brief overview of some of the many current research issues being studied within the field of computational learning theory.

30.2 General Framework

For ease of exposition, we initially focus on *concept learning* in which the learner's goal is to infer how an unknown target function classifies (as positive or negative) examples from a given domain. In the character recognition example, one possible task of the learner would be to classify each character as a numeral or non-numeral. Most of the definitions given here naturally extend to the general setting of learning functions with multiple-valued or real-valued outputs. Later in Section 30.4 we briefly discuss the more general problem of learning a real-valued function.

Notation

The *instance space* (*domain*) $\mathcal{X}$ is the set of all possible objects (instances) to be classified. Two very common domains are the Boolean hypercube $\{0, 1\}^n$ and continuous n-dimensional space $\Re^n$. For example, if there are n Boolean attributes then each example can be expressed as an element of $\{0, 1\}^n$. Likewise, if there are n real-valued attributes, then $\Re^n$ can be used. A *concept* f is a Boolean function over domain $\mathcal{X}$. Each $x \in \mathcal{X}$ is referred to as an *example* (*point*).

A **concept class** $\mathcal{C}$ is a collection of subsets of $\mathcal{X}$. That is $\mathcal{C} \subseteq 2^{\mathcal{X}}$. Typically (but not always), it is assumed that the learner has prior knowledge of $\mathcal{C}$. Examples are classified according to membership of a *target concept* $f \in \mathcal{C}$. Often, instead of using this set theoretic view of $\mathcal{C}$, a functional view is used in which $f(x)$ gives the classification of concept $f \in \mathcal{C}$ for each example $x \in \mathcal{X}$. An example $x \in \mathcal{X}$ is a *positive example* of f if $f(x) = 1$ (equivalently $x \in f$), or a *negative example* of f if $f(x) = 0$ (or equivalently $x \notin f$). Often $\mathcal{C}$ is decomposed into subclasses $\mathcal{C}_n$ according to some natural size measure n for encoding an example. For example, in the Boolean domain, n is the number of Boolean attributes. Let $\mathcal{X}_n$ denote the set of examples to be classified for each problem of size n, $\mathcal{X} = \bigcup_{n \geq 1} \mathcal{X}_n$.

We use the class $\mathcal{C}_{\text{halfspace}}$, the set of halfspaces in $\Re^n$, and the class $\mathcal{C}^{\cap_s}_{\text{halfspace}}$, the set of all the intersections of up to s halfspaces in $\Re^d$, to illustrate some of the basic techniques for designing learning algorithms[1] (see Fig. 30.1). We now formally define a halfspace in $\Re^n$ and describe how the points in $\Re^n$ are classified

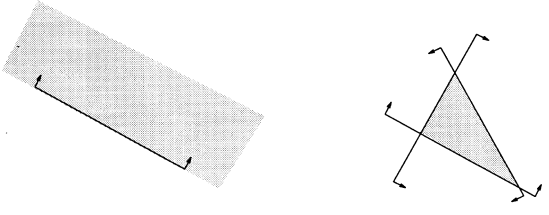

FIGURE 30.1 The left figure shows (in $\Re^2$) a concept from $\mathcal{C}_{\text{halfspace}}$ and the right figure shows a concept for $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ for $s = 3$. The points from $\Re^2$ that are classified as positive are shaded. The unshaded points are classified as negative.

by it. Let $\vec{x} = (x_1, \ldots, x_n)$ denote an element of $\Re^n$. A halfspace defined by $\vec{a} \in \Re^n$ and $b \in \Re$ classifies as positive the set of points $\{\vec{x} \mid \vec{a} \cdot \vec{x} \geq b\}$. For example, in two dimensions (i.e., $n = 2$), $5x_1 - 2x_2 \geq -3$

[1] As a convention, when the number of dimensions can be arbitrary we use n, and when the number of dimensions must be a constant we use d.

defines a halfspace. The point (0, 0) is a positive example and (2, 10) is a negative example. For $\mathcal{C}^{\cap_s}_{\text{halfspace}}$, an example is positive exactly when it is classified as positive by each of the halfspaces forming the intersection. Thus the set of positive points forms a (possibly open) convex polytope in $\Re^n$.

We also study some Boolean concepts. For these concepts the domain is $\{0, 1\}^n$. Let $x_1, \ldots, x_n$ denote the n Boolean attributes. A *literal* is either x_i or $\overline{x_i}$ where $i = 1, \ldots, n$. A term is a conjunction of literals. Finally, a DNF formula is a disjunction of terms. One of the biggest open problems of computational learning theory is whether or not the concept class of DNF formulas is efficiently PAC learnable. Since the problem of learning general DNF formulas is a long-standing open problem, several subclasses have been studied. A *monotone DNF formula* is a DNF formula in which there are no negated variables. A *read-once DNF formula* is a DNF formula in which each variable appears at most once. In addition to adding a restriction that the formula be monotone and/or read-once, one can also limit either the size of each term or the number of terms. A *k-term DNF formula* is a DNF formula in which there are at most k terms. Finally, a *k-DNF formula* is a DNF formula in which at most k literals are used by each term.

As one would expect, the time and sample complexity of the learning algorithm depends on the complexity of the underlying target concept. For example, the complexity for learning a monotone DNF formula is likely to depend on the number of terms (conjuncts) in the formula. To give a careful definition of the size of a concept $f \in \mathcal{C}$, we associate a language $\mathcal{R}_\mathcal{C}$ with each concept class $\mathcal{C}$ that is used for representing concepts in $\mathcal{C}$. Each $r \in \mathcal{R}_\mathcal{C}$ denotes some $f \in \mathcal{C}$, and every $f \in \mathcal{C}$ has at least one representation $r \in \mathcal{R}_\mathcal{C}$. Each concept $f \in \mathcal{C}_n$ has a *size* denoted by $|f|$, which is the representation length of the shortest $r \in \mathcal{R}_\mathcal{C}$ that denotes f. For ease of exposition, in the remainder of this chapter we use $\mathcal{C}$ and $\mathcal{R}_\mathcal{C}$ interchangeably.

To appreciate the significance of the choice of the representation class, consider the problem of learning a regular language.[2] The question as to whether an algorithm is efficient depends heavily on the representation class. As defined more formally below, an *efficient* learning algorithm must have time and sample complexity polynomial in $|f|$ where f is the target concept. The target regular language could be represented as a deterministic finite-state automaton (DFA) or as a nondeterministic finite-state automaton (NFA). However, the length of the representation as a NFA can be exponentially smaller than the shortest representation as a DFA. Thus, the learner may be allowed exponentially more time when learning the class of regular languages as represented by DFAs versus when learning the class of regular languages as represented by NFAs. Often to make the representation class clear, the concept class names the representation. Thus instead of talking about learning a regular language, we talk about learning a DFA or an NFA. Thus the problem of learning a DFA is easier than learning an NFA. Similar issues arise when learning Boolean functions. For example, whether the function is represented as a decision tree, a DNF formula, or a Boolean circuit greatly affects the representation size.

30.3 PAC Learning Model

The field of computational learning theory began with Valiant's seminal work [48] in which he defined the *PAC*[3] (*distribution-free*) learning model. In the PAC model examples are generated according to an unknown probability distribution $\mathcal{D}$, and the goal of a learning algorithm is to classify with high accuracy (with respect to the distribution $\mathcal{D}$) any further (unclassified) examples.

We now formally define the PAC model. To obtain information about an unknown target function $f \in \mathcal{C}_n$, the learner is provided access to labeled (positive and negative) examples of f, drawn randomly according to some unknown target distribution $\mathcal{D}$ over $\mathcal{X}_n$. The learner is also given as input ϵ and δ

[2] See the section on "Notation" of Chapter 30 and Section 31.2 of Chapter 31 in this *Handbook* for background on regular languages, DFAs and NFAs.

[3] PAC is an acronym coined by Dana Angluin for probably approximately correct.

such that $0 < \epsilon, \delta < 1$, and an upper bound k on $|f|$. The learner's goal is to output, with probability at least $1 - \delta$, a *hypothesis* $h \in \mathcal{C}_n$ that has probability at most ϵ of disagreeing with f on a randomly drawn example from $\mathcal{D}$ (thus, h has *error* at most ϵ). If such a learning algorithm $\mathcal{A}$ exists (that is, an algorithm $\mathcal{A}$ meeting the goal for any $n \geq 1$, any target concept $f \in \mathcal{C}_n$, any target distribution $\mathcal{D}$, any $\epsilon, \delta > 0$, and any $k \geq |f|$), then $\mathcal{C}$ is **PAC learnable.** A PAC learning algorithm is a polynomial-time (*efficient*) algorithm if the number of examples drawn and the computation time are polynomial in n, k, $1/\epsilon$, and $1/\delta$. We note that most learning algorithms are really functions from samples to hypotheses (i.e., given a sample S the learning algorithm produces a hypothesis h). It is only for the analysis in which we say that for a given ϵ and δ, the learning algorithm is guaranteed with probability at least $1 - \delta$ to output a hypothesis with error at most ϵ given a sample whose size is a function of ϵ, δ, n and k. Thus, empirically, one can generally run a PAC algorithm on provided data and then empirically measure the error of the final hypothesis. One exception is when trying to empirically use statistical query algorithms since, for most of these algorithms, the algorithm uses ϵ for more than just determining the desired sample size. (See "Gaining Noise Tolerance in the PAC Model" for a discussion of statistical query algorithms, and Goldman and Scott [27] for a discussion of their empirical use).

As originally formulated, PAC learnability also required the hypothesis to be a member of the concept class $\mathcal{C}_n$. We refer to this more stringent learning model as *proper PAC-learnability.* The work of Pitt and Valiant [42] shows that a prerequisite for proper PAC-learning is the ability to solve the consistent hypothesis problem, which is the problem of finding a concept $f \in \mathcal{C}$ that is consistent with a provided sample. Their result implies that if the consistent hypothesis problem is NP-hard for a given concept class (as they show is the case for the class of k-term DNF formulas) and NP $\neq$ RP, then the learning problem is hard.[4] A more general form of learning in which the goal is to find any polynomial-time algorithm that classifies instances accurately in the PAC sense is commonly called *prediction.* In this less stringent variation of the PAC model, the algorithm need not output a hypothesis from the concept class $\mathcal{C}$ but instead is just required to make its prediction in polynomial time. This idea of prediction in the PAC model originated in the paper of Haussler et al. [30], and is discussed in Pitt and Warmuth [43]. Throughout the remainder of this chapter, when referring to the PAC learning model we allow the learner to output any hypothesis that can be evaluated in polynomial time. That is, given a hypothesis h and an example x, we require that $h(x)$ can be computed in polynomial time. We refer to the model in which the learner is required to output a hypothesis $h \in \mathcal{C}_n$ as the *proper PAC learning model.*

Many variations of the PAC model are known to be equivalent (in terms of what concept classes are efficiently learnable) to the model defined above. We now briefly discuss one of these variations. In the above definition of the PAC model, along with receiving ϵ, δ, and n as input, the learner also receives k, an upperbound on $|f|$. The learner must be given ϵ and δ. Further, by looking at just one example, the value of n is known. Yet giving the learner knowledge of k may appear to make the problem easier. However, if the demand of polynomial-time computation is replaced with expected polynomial-time computation, then the learning algorithm need not be given the parameter k, but could "guess" it instead. We now briefly review the standard *doubling technique* used to convert an algorithm A designed to have k as input to an algorithm B that has no prior knowledge of k. Algorithm B begins with an estimate, say 1, for its upperbound on k and runs algorithm A using this estimate to obtain hypothesis h. Then algorithm B uses a *hypothesis testing* procedure to determine if the error of h is at most ϵ. Since the learner can only gather a random sample of examples, it is not possible to distinguish a hypothesis with error ϵ from one with error just greater than ϵ. However, by drawing a sufficiently large sample and looking at the empirical performance of h on that sample, we can distinguish a hypothesis with error at most $\epsilon/2$ from one with

[4] For background on complexity classes see Chapter 33 (NP defined) and Chapter 35 (RP defined) of this *Handbook.*

error more than ϵ. In particular, given a sample[5] of size $m = \lceil \frac{32}{\epsilon} \ln \frac{2}{\delta} \rceil$, if h misclassifies at most $\frac{3\epsilon}{4} \cdot m$ examples then B accepts h. Otherwise, algorithm B doubles its estimate for k and repeats the process. For the technical details of the above argument as well as for a discussion the other equivalences, see [29].

Sample Complexity Bounds, the VC-Dimension, and Occam's Razor

Although we are concerned with the time complexity of the learning algorithm, a fundamental quantity to first compute is the sample complexity (data) requirements. Blumer et al. [16] identified a combinatorial parameter of a class of functions defined by Vapnik and Chervonenkis [50]. They give strong results relating this parameter, called the **VC-dimension,** to information-theoretic bounds on the sample size needed to have accurate generalization. Note that given a sufficiently large sample there is still the computational problem of finding a "good" hypothesis.

We now define the VC-dimension. We say that a finite set $S \subseteq \mathcal{X}$ is *shattered* by the concept class $\mathcal{C}$ if for each of the $2^{|S|}$ subsets $S' \subseteq S$, there is a concept $f \in \mathcal{C}$ that contains all of S' and none of $S - S'$. In other words, for any of the $2^{|S|}$ possible labelings of S (where each example $s \in S$ is either positive or negative), there is some $f \in \mathcal{C}$ that realizes the desired labeling (see Fig. 30.2). We can now define the VC-dimension of a concept class $\mathcal{C}$. The VC-dimension of $\mathcal{C}$, denoted $\mathrm{VCD}(\mathcal{C})$, is the smallest d for which no set of $d + 1$ examples is shattered by $\mathcal{C}$. Equivalently, $\mathrm{VCD}(\mathcal{C})$ is the cardinality of the largest finite set of points $S \subseteq X$ that is shattered by $\mathcal{C}$.

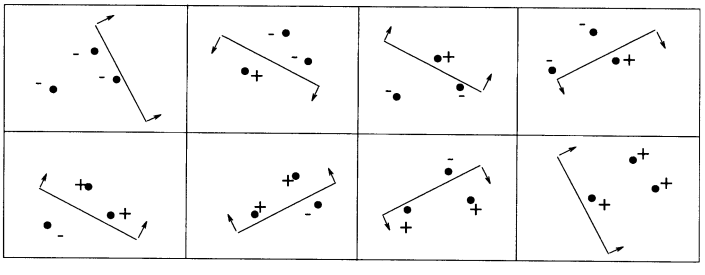

FIGURE 30.2 A demonstration that there are 3 points that are shattered by the class of two-dimensional halfspaces (i.e., $\mathcal{C}_{\text{halfspace}}$ with $n = 2$). Notice that all 8 possible ways that the points can be classified as positive or negative can be realized.

So to prove that $\mathrm{VCD}(\mathcal{C}) \geq d$ it suffices to give d examples that can be shattered. However, to prove $\mathrm{VCD}(\mathcal{C}) \leq d$ one must show that *no* set of $d + 1$ examples can be shattered. Since the VC-dimension is so fundamental in determining the sample complexity required for PAC learning, we now go through several sample computations of the VC-dimension.

Axis-parallel rectangles in $\Re^2$. For this concept class the points lying on or inside the target rectangle are positive, and points lying outside the target rectangle are negative. First, it is easily seen that there is a set of four points (e.g., $\{(0, 1), (0, -1), (1, 0), (-1, 0)\}$) that can be shattered. Thus $\mathrm{VCD}(\mathcal{C}) \geq 4$. We now argue that no set of five points can be shattered. The smallest bounding axis-parallel rectangle defined by the five points is in fact defined by at most four of the points. For p a nondefining point in the set, we see that the set cannot be shattered since it is not possible for p to be classified as negative while also classifying the others as positive. Thus $\mathrm{VCD}(\mathcal{C}) = 4$.

[5] Chernoff bounds are used to compute the sample size so that the hypothesis testing procedure gives the desired output with high probability.

Halfspaces in $\Re^2$. Points lying in or on the halfspace are positive, and the remaining points are negative. It is easily shown that any three noncollinear points (e.g., (0, 1), (0, 0), (1, 0)) are shattered by $\mathcal{C}$ (recall Fig. 30.2). Thus $\mathrm{VCD}(\mathcal{C}) \geq 3$. We now show that no set of size four can be shattered by $\mathcal{C}$. If at least three of the points are collinear then there is no halfspace that contains the two extreme points but does not contain the middle points. Thus the four points cannot be shattered if any three are collinear. Next, suppose that the points form a quadrilateral. There is no halfspace which labels one pair of diagonally opposite points positive and the other pair of diagonally opposite points negative. The final case is that one point p is in the triangle defined by the other three. In this case there is no halfspace which labels p differently from the other three. Thus clearly the four points cannot be shattered. Therefore we have demonstrated that $\mathrm{VCD}(\mathcal{C}) = 3$. Generalizing to halfspaces in $\Re^n$, it can be shown that $\mathrm{VCD}(\mathcal{C}_{\text{halfspace}}) = n + 1$ (see [16]).

Closed sets in $\Re^2$. All points lying in the set or on the boundary of the set are positive, and all points lying outside the set are negative. Any set can be shattered by $\mathcal{C}$, since a closed set can assume any shape in $\Re^2$. Thus, the largest set that can be shattered by $\mathcal{C}$ is infinite, and hence $\mathrm{VCD}(\mathcal{C}) = \infty$.

We now briefly discuss techniques that aid in computing the VC-dimension of more complex concept classes. Suppose we wanted to compute the VC-dimension of $\mathcal{C}^{\cap_s}_{\text{halfspace}}$, the class of intersections of up to s halfspaces over $\Re^d$. We would like to make use of our knowledge of the VC-dimension of $\mathcal{C}_{\text{halfspace}}$, the class of halfspaces over $\Re^d$. Blumer et al. [16] gave the following result: let $\mathcal{C}$ be a concept class with $\mathrm{VCD}(\mathcal{C}) \leq D$. Then the class defined by the intersection of up to s concepts from $\mathcal{C}$ has VC-dimension[6] at most $2Ds\lg(3s)$. In fact, the above result applies when replacing intersection with any Boolean function. Thus the concept class $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ (where each halfspace is defined over $\Re^d$) has VC-dimension at most $2(d+1)s\lg(3s)$.

We now discuss the significance of the VC-dimension to the PAC model. One important property is that for $D = \mathrm{VCD}(\mathcal{C})$, the number of different labelings that can be realized (also referred to as *behaviors*) using $\mathcal{C}$ for a set S is at most $\left(\frac{e|S|}{D}\right)^D$. Thus for a constant D we have polynomial growth in the number of labelings versus the exponential growth of $2^{|S|}$. A key result in the PAC model [16] is an upperbound on the sample complexity needed to PAC learn in terms of ϵ, δ, and the VC-dimension of the **hypothesis class.** They proved that one can design a learning algorithm A for concept class $\mathcal{C}$ using hypothesis space $\mathcal{H}$ in the following manner. Any concept $h \in \mathcal{H}$ consistent with a sample of size $\max\left(\frac{4}{\epsilon}\lg\frac{2}{\delta}, \frac{8\,\mathrm{VCD}(\mathcal{H})}{\epsilon}\lg\frac{13}{\epsilon}\right)$ has error at most ϵ with probability at least $1-\delta$. To obtain a polynomial-time PAC learning algorithm what remains is to solve the algorithmic problem of finding a hypothesis from $\mathcal{H}$ consistent with the labeled sample. As an example application, see Fig. 30.3. Furthermore, Ehrenfencht and Haussler [22] proved an information-theoretic lower bound that learning any concept class $\mathcal{C}$ requires $\Omega\left(\frac{1}{\epsilon}\log\frac{1}{\delta} + \frac{\mathrm{VCD}(\mathcal{C})}{\epsilon}\right)$ examples in the worst case.

A key limitation of this technique to design a PAC learning algorithm is that the hypothesis must be drawn from some *fixed* hypothesis class $\mathcal{H}$. In particular, the complexity of the hypothesis class must be independent of the sample size. However, often the algorithmic problem of finding such a hypothesis from the desired class is NP-hard.

As an example suppose we tried to modify PAC-learn-halfspace from Fig. 30.3 to efficiently PAC learn the class of intersections of at most s halfspaces in $\Re^d$ for d the number of dimensions a constant.

[6]Note that throughout this chapter, lg is used for the base-2 logarithm. When the base of the logarithm is not significant (such as when using asymptotic notation), we use log.

PAC-learn-halfspace(n, ϵ, δ)

Draw a labeled sample S of size $\max\left(\frac{4}{\epsilon}\lg\frac{2}{\delta}, \frac{8(n+1)}{\epsilon}\lg\frac{13}{\epsilon}\right)$

Use a polynomial-time linear programming algorithm to find a halfspace h consistent with S

Output h

FIGURE 30.3 A PAC algorithm to learn a concept from $\mathcal{C}_{\text{halfspace}}$. Recall that $\text{VCD}(\mathcal{C}_{\text{halfspace}}) = n + 1$.

Suppose we are given a sample S of m example points labeled according to some $f \in \mathcal{C}^{\cap_s}_{\text{halfspace}}$. The algorithmic problem of finding a hypothesis from $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ can be formulated as a set covering problem in the following manner. An instance of the set covering problem is a set $\mathcal{U}$ and a family $\mathcal{T}$ of subsets of $\mathcal{U}$ such that $\left(\bigcup_{t\in\mathcal{T}} t\right) = \mathcal{U}$. A solution is a smallest cardinality subset $\mathcal{G}$ of $\mathcal{T}$ such that $\left(\bigcup_{g\in\mathcal{G}} g\right) = \mathcal{U}$. Consider any halfspace g that correctly classifies all positive examples from S. We say that g *covers* all of the negative examples from S that are also classified as negative by g. Thus $\mathcal{U}$ is the set of negative examples from S, and $\mathcal{T}$ is the set of representative halfspaces (one for each behavior with respect to S) that correctly classify all positive examples from S.

So finding a minimum sized hypothesis from $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ consistent with the sample S is exactly the problem of finding the minimum number of halfspaces that are required to cover all negative points in S. Given that the set covering problem is NP-complete, how can we proceed? We can apply the greedy approximation algorithm that has a ratio bound of $\ln|\mathcal{U}| + 1$ to find a hypothesis consistent with S that is the intersection of at most $\ln|S| + 1$ halfspaces. However, since the VC-dimension of the hypothesis grows with the size of the sample, the basic technique described above cannot be applied. In general, when using a set covering approach, the size of the hypothesis often depends on the size of the sample.

Blumer et al. [15, 16] extended this basic technique by showing that finding a hypothesis h consistent with a sample S for which the size of h is sublinear in $|S|$ is sufficient to guarantee PAC learnability. In other words, by obtaining sufficient data compression one obtains good generalization. More formally, let $\mathcal{H}^A_{k,n,m}$ be the hypothesis space used by algorithm A when each example has size n, the target concept has size k, and the sample size is m. We say that algorithm A is an **Occam algorithm** for concept class $\mathcal{C}$ if there exists a polynomial $p(k, n)$ and a constant β, $0 \le \beta < 1$, such that for any sample S with $|S| = m \ge 1$ and any k, n, A outputs a hypothesis[7] h consistent with S such that $|h| \le p(k, n)m^\beta$. Let A be an Occam algorithm for concept class $\mathcal{C}$ that has hypothesis space $\mathcal{H}^A_{k,n,m}$. If $\text{VCD}(\mathcal{H}^A_{k,n,m}) \le p(k, n)(\lg m)^\ell$ (so $|h| \le p(k, n)(\lg m)^\ell$) for some polynomial $p(k, n) \ge 2$ and $\ell \ge 1$, then A is a PAC learning algorithm for $\mathcal{C}$ using sample size

$$m = \max\left(\frac{4}{\epsilon}\lg\frac{2}{\delta}, \frac{2^{\ell+4}p(k,n)}{\epsilon}\left(\lg\frac{8(2\ell+2)^{\ell+1}p(k,n)}{\epsilon}\right)^{\ell+1}\right).$$

Figure 30.4 presents an Occam algorithm to PAC learn a concept from $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ (i.e., the intersection of at most s halfspaces over $\Re^d$). Since $\text{VCD}(\mathcal{C}^{\cap_s}_{\text{halfspace}}) \le 2(d+1)s\lg(3s)$, and the hypothesis consists of the intersection of at most $s(1+\ln m)$ halfspaces, it follows that $\text{VCD}(\mathcal{H}) \le 2(d+1)s(1+\ln m)\lg(3s(1+\ln m)) \le 3ds\ln^2 m$. The size of the sample S then follows by noting that $p(s, d) = 3ds$ and $\ell = 3$. By combining the fact that $\text{VCD}(\mathcal{C}_{\text{halfspace}}) = d+1$ and the general upper bound of $\left(\frac{e|S|}{D}\right)^D$ on the number of behaviors on a sample of size $|S|$ for a class of VC-dimension D, we get that $|\mathcal{T}| \le \left(\frac{em}{d+1}\right)^{d+1} = O(m^{d+1})$.

[7] Recall that we use $|h|$ to denote the number of bits required to represent h.

(For d constant this quantity is polynomial in the size of the sample.) We can construct $\mathcal{T}$ in polynomial time by either using simple geometric arguments or the more general technique of Blumer et al. [16]. Finally, the time complexity of the greedy set covering algorithm is $O(\Sigma_{t\in\mathcal{T}}|t|) = O(m \cdot m^{d+1})$, which is polynomial in s (the number of halfspaces), ϵ, and δ for d (the number of dimensions) constant.

PAC-learn-intersection-of-halfspaces(d, s, ϵ, δ)
Draw a labeled sample S of size $m = \max\left(\frac{4}{\epsilon}\lg\frac{2}{\delta}, \frac{192ds}{\epsilon}\left(6 + 4\lg 3 + \lg\frac{ds}{\epsilon}\right)^3\right)$
Form a set $\mathcal{T}$ of halfspaces that are consistent with the positive examples
Let N be the negative examples from S
Let h be the always true hypothesis

Find a halfspace $t \in \mathcal{T}$ consistent with the max. number of exs. from N
Let $h = h \cap t$
Remove the examples from N that were covered by t
Output h

FIGURE 30.4 An Occam algorithm to PAC learn a concept from $\mathcal{C}^{\cap_s}_{\text{halfspace}}$.

For the problem of learning the intersection of halfspaces the greedy covering technique provided substantial data compression. Namely, the size of our hypothesis only had a logarithmic dependence on the size of the sample. In general, only a sublinear dependence is required as given by the following result of Blumer et al. [15]. Let A be an Occam algorithm for concept class $\mathcal{C}$ that has hypothesis space $\mathcal{H}^A_{k,n,m}$. If $\text{VCD}(\mathcal{H}^A_{k,n,m}) \leq p(k,n)m^\beta$ (so $|h| \leq p(k,n)m^\beta$) for some polynomial $p(k,n) \geq 2$ and $\beta < 1$, then A is a PAC learning algorithm for $\mathcal{C}$ using sample size

$$m = \max\left(\frac{2}{\epsilon}\ln\frac{1}{\delta}, \left(\frac{2\ln 2}{\epsilon}\cdot p(k,n)\right)^{\frac{1}{1-\beta}}\right).$$

Models of Noise

The basic definition of PAC learning assumes that the data received is drawn randomly from $\mathcal{D}$ and properly labeled according to the target concept. Clearly, for learning algorithms to be of practical use they must be robust to noise in the training data. In order to theoretically study an algorithm's tolerance to noise, several formal models of noise have been studied. In the model of **random classification noise** [9], with probability $1-\eta$, the learner receives the uncorrupted example (x, ℓ). However, with probability η, the learner receives the example $(x, \bar{\ell})$. So in this noise model, learner usually gets a correct example, but some small fraction η of the time the learner receives an example in which the label has been inverted. In the model of *malicious classification noise* [47], with probability $1-\eta$, the learner receives the uncorrupted example (x, ℓ). However, with probability η, the learner receives the example (x, ℓ') in which x is unchanged, but the label ℓ' is selected by an adversary who has infinite computing power and has knowledge of the learning algorithm, the target concept, and the distribution $\mathcal{D}$. In the previous two models, only the labels are corrupted. Another noise model is that of *malicious noise* [49]. In this model, with probability $1-\eta$, the learner receives the uncorrupted example (x, ℓ). However, with probability η, the learner receives an example (x', ℓ') about which no assumptions whatsoever may be made. In particular, this example (and its label) may be maliciously selected by an adversary. Thus in this model, the learner usually gets a correct example, but some small fraction η of the time the learner gets noisy examples and the nature of the noise is unknown.

We now define two noise models that are only defined when the instance space is $\{0, 1\}^n$. In the model of *uniform random attribute noise* [47], the example $(b_1 \cdots b_n, \ell)$ is corrupted by a random process that independently flips each bit b_i to $\bar{b}_i$ with probability η for $1 \leq i \leq n$. Note that the label of the "true" example is never altered. In this noise model, the attributes' values are subject to noise, but that noise is as benign as possible. For example, the attributes' values might be sent over a noisy channel, but the label is not. Finally, in the model of *product random attribute noise* [26], the example $(b_1 \cdots b_n, \ell)$ is corrupted by a random process of independently flipping each bit b_i to $\bar{b}_i$ with some fixed probability $\eta_i \leq \eta$ for each $1 \leq i \leq n$. Thus unlike the model of uniform random attribute noise, the noise rate associated with each bit of the example may be different.

Gaining Noise Tolerance in the PAC Model

Some of the first work on designing noise-tolerant PAC algorithms was done by Angluin and Laid [9]. They gave an algorithm for learning Boolean conjunctions that tolerates random **classification noise** of a rate approaching the information-theoretic barrier of 1/2. Furthermore, they proved that the general technique of finding a hypothesis that minimizes disagreements with a sufficiently large sample allows one to handle random classification noise of any rate approaching 1/2. However, they showed that even the very simple problem of minimizing disagreements (when there are no assumptions about the noise) is NP-hard. Until recently, there have been a small number of efficient noise-tolerant PAC algorithms, but no general techniques were available to design such algorithms, and there was little work to characterize which concept classes could be efficiently learned in the presence of noise.

The first (computationally feasible) tool to design noise-tolerant PAC algorithms was provided by the **statistical query model,** first introduced by Kearns [31], and since improved by Aslam and Decatur [12]. In this model, rather than sampling labeled examples, the learner requests the value of various statistics. A *relative-error statistical query* [12] takes the form $\mathbf{SQ}(\chi, \mu, \theta)$ where χ is a predicate over labeled examples, μ is a *relative error bound,* and θ is a *threshold.* As an example, let χ to be "$(h(x) = 1) \wedge (\ell = 0)$" which is true when x is a negative example but the hypothesis classifies x as positive. So the probability that χ is true for a random example is the false positive error of hypothesis h. For target concept f, we define $P_\chi = \Pr_{\mathcal{D}}[\chi(x, f(x))) = 1]$ where $\Pr_{\mathcal{D}}$ is used to denote that x is drawn at random from distribution $\mathcal{D}$. If $P_\chi < \theta$ then $\mathbf{SQ}(\chi, \mu, \theta)$ may return $\perp$. If $\perp$ is not returned, then $\mathbf{SQ}(\chi, \mu, \theta)$ must return an estimate $\hat{P}_\chi$ such that $P_\chi(1 - \mu) \leq \hat{P}_\chi \leq P_\chi(1 + \mu)$. The learner may also request unlabeled examples (since we are only concerned about classification noise).

Let's take our algorithm, PAC-learn-intersection-of-halfspaces and reformulate it as a relative-error statistical query algorithm. First we draw an *unlabeled* sample S_u that we use to generate the set $\mathcal{T}$ of halfspaces to use for our covering. Similar to before, we place a halfspace in $\mathcal{T}$ corresponding to each possible way in which the points of S_u can be divided. Recall that before, we only place a halfspace in $\mathcal{T}$ if it properly labeled the positive examples. Since we have an unlabeled sample we cannot use such an approach. Instead, we use a statistical query (for each potential halfspace) to check if a given halfspace is consistent with most of the positive examples. Finally, when performing the greedy covering step we cannot pick the halfspace that covers the most negative examples, but rather the one that covers the "most" (based on our empirical estimate) negative weight. Figure 30.5 shows our algorithm in more depth.

We now cover the key ideas in proving that SQ-learn-intersection-of-halfspaces is correct. First, we pick S_u so that any hypothesis consistent with S_u (if we knew the labels) would have error at most $\frac{\epsilon}{6r}$ with probability $1 - \frac{\delta}{2}$. Since our hypothesis class is $\mathcal{C}^{\cap_r}_{\text{halfspace}}$, and $\text{VCD}(\mathcal{C}^{\cap_r}_{\text{halfspace}}) \leq 2(d + 1)r\lg(3r)$, we obtain the sample size for S_u.

For each of the s halfspaces that form the target concept, there is some halfspace in $\mathcal{T}$ consistent with that halfspace over S_u, and thus that has error at most $\epsilon/(6r)$ on the positive region. For each such halfspace t our estimate $\hat{P}_\chi$ (for the probability that $t(x) = 0$ and $\ell = 1$) is at most $\frac{\epsilon}{6r} \cdot \frac{3}{2} = \frac{\epsilon}{4r}$. Thus, we place s halfspaces in $\mathcal{T}_{good}$ that produce a hypothesis with false negative error $\leq \epsilon/(6r)$. Let

SQ-learn-intersection-of-halfspaces(d, s, ϵ)

Let $r = 2s\ln(3/\epsilon)$

Draw an unlabeled sample $S_u = \max\left\{\frac{24r}{\epsilon}\lg\frac{4}{\delta}, \frac{96(d+1)r^2\lg(3r)}{\epsilon}\lg\frac{78r}{\epsilon}\right\}$

Form the set $\mathcal{T}$ of halfspaces - one for each linear separation of S_u into two sets

$\mathcal{T}_{good} = \emptyset$

For each $t \in \mathcal{T}$

$\hat{P_\chi} = \mathbf{SQ}\left(t(x) = 0 \wedge \ell = 1, \frac{1}{2}, \frac{\epsilon}{2r}\right)$

If $\hat{P_\chi} \leq \frac{\epsilon}{4r}$ or $\perp$ Then $\mathcal{T}_{good} = \mathcal{T}_{good} \cup t$

Let h be the always true hypothesis

While $\mathbf{SQ}\left(h(x) = 1 \wedge \ell = 0, \frac{1}{9}, \frac{\epsilon}{2}\right) > \frac{4\epsilon}{9}$ and the loop has been executed $< r$ times

$t_{max} = \text{argmax}_{t \in \mathcal{T}_{good}} \mathbf{SQ}\left(h(x) = 1 \wedge \ell = 0 \wedge t(x) = 0, \frac{1}{3}, \frac{7\epsilon}{30s}\right)$

$h = h \cap t_{max}$

Output h

FIGURE 30.5 A relative-error statistical query algorithm to learn a concept from $\mathcal{C}^{\cap_s}_{\text{halfspace}}$ over $\Re^d$.

$e_i = \Pr[h(x) = 1 \wedge \ell = 0]$ (i.e., the false positive error) after i rounds of the while loop. Since e_i is our current error and $\epsilon/(6r)$ is a lower bound on the error we could achieve, by an averaging argument it follows that there is a $t \in \mathcal{T}_{good}$ for which

$$P = \Pr[(h(x) = 1) \wedge (\ell = 0) \wedge (t(x) = 0)] \geq \left(e_i - \frac{\epsilon}{6r}\right) \cdot \frac{1}{s} \geq \left(e_i - \frac{\epsilon}{6}\right) \cdot \frac{1}{s}.$$

Thus for the halfspace t_{max} selected to add to h we know that the statistical query returns an estimate $\hat{P} \geq \frac{2}{3} \cdot P \geq \frac{2}{3s}\left(e_i - \frac{\epsilon}{6}\right)$. Thus for t_{max} we know that $P \geq \frac{3}{4} \cdot \frac{2}{3s}\left(e_i - \frac{\epsilon}{6}\right) = \frac{1}{2s}\left(e_i - \frac{\epsilon}{6}\right)$. Solving the recurrence $e_{i+1} \leq e_i - \frac{1}{2s}\left(e_i - \frac{\epsilon}{6}\right)$ (with $e_i \leq 1$) yields that $e_i \leq \frac{\epsilon}{6} + \left(1 - \frac{1}{2s}\right)^i$. Picking $r = i = 2s\ln\frac{3}{\epsilon}$ suffices to ensure that $e_i \leq \epsilon/2$ as desired.

Once $e_i \leq 2\epsilon/5$, we exit the while loop (since $\frac{2\epsilon}{5} \cdot \frac{10}{9} = \frac{4\epsilon}{9}$). Thus we enter the loop only when $e_i > 2\epsilon/5$, and hence for t_{max}, $P \geq \frac{1}{s}(e_i - \frac{\epsilon}{6})$. So we choose $\theta = \frac{1}{s}(\frac{2\epsilon}{5} - \frac{\epsilon}{6}) = \frac{7\epsilon}{30s}$. Finally, when we exit the loop $\Pr[h(x) = 1 \wedge \ell = 0] \leq \frac{4\epsilon}{9} \cdot \frac{9}{8} = \frac{\epsilon}{2}$. Thus the total error is at most ϵ as desired.

Notice that in the statistical query model there is not a confidence parameter δ. This is because the SQ oracle guarantees that its estimates meet the given requirements. However, when we use random labeled examples to simulate the statistical queries, we can only guarantee that with high probability the estimates meet their requirements. Thus the results on converting an SQ algorithm into a PAC algorithm reintroduce the confidence parameter δ.

By applying uniform convergence results and Chernoff bounds it can be shown that if one draws a sufficiently large sample then a statistical query can be estimated by the fraction of the sample that satisfies the predicate. For example, in the relative-error SQ model with a set $\mathcal{Q}$ of possible queries, Aslam and Decatur [12] show that a sample of size $O\left(\frac{1}{\mu^2\theta}\log\frac{|\mathcal{Q}|}{\delta}\right)$ suffices to appropriately answer $[\chi, \mu, \theta]$ for every $\chi \in \mathcal{Q}$ with probability at least $1-\delta$. (If $\text{VCD}(\mathcal{Q}) = q$ then a sample of size $O\left(\frac{q}{\mu^2\theta}\log\frac{1}{\mu\theta} + \frac{1}{\mu^2\theta}\log\frac{1}{\delta}\right)$ suffices.)

To handle random classification noise of any rate approaching $1/2$ more complex methods are used for answering the statistical queries. Roughly, using knowledge of the noise process and a sufficiently accurate estimate of the noise rate (which must itself be determined by the algorithm), the noise process can be "inverted." The total sample complexity required to simulate an SQ algorithm in the presence of classification noise of rate $\eta \leq \eta_b$ is $\tilde{O}\left(\frac{\log(|\mathcal{Q}|/\delta)}{\mu_*^2\theta_*\rho(1-2\eta_b)^2}\right)$ where μ_* (respectively, θ_*) is the minimum value of μ (respectively, θ) across all queries and $\rho \in [\theta_*, 1]$, The soft-oh notation ($\tilde{O}$) is similar to the standard big-oh notation except log factors are also removed. Alternatively, for the query space $\mathcal{Q}$, the sample

complexity is $O\left(\frac{\mathrm{VCD}(\mathcal{Q})}{\mu_*^2\theta_*\rho_*(1-2\eta_b)^2}\left[\log\left(\frac{1}{\mu_*\theta_*\rho_*(1-2\eta_b)}\right)+\log\frac{1}{\delta}\right]\right)$. Notice that the amount by which η_b is less than $1/2$ is just $\frac{1}{1/2-\eta_b}=\frac{2}{1-2\eta_b}$. Thus the above are polynomial as long as $\frac{1}{2}-\eta_b$ is at least one over a polynomial.

30.4 Exact and Mistake Bounded Learning Models

The PAC learning model is a *batch model*—there is a separation between the *training phase* and the *performance phase.* In the training phase the learner is presented with labeled examples—no predictions are expected. Then at the end of the training phase the learner must output a hypothesis h to classify unseen examples. Also, since the learner never finds out the true classification for the unlabeled instances, all learning occurs in the training phase. In many settings, the learner does not have the luxury of a training phase but rather must learn as it performs. We now study two closely related learning models designed for such a setting.

On-Line Learning Model

To motivate the **on-line learning model** (also known as the *mistake-bounded learning model*), suppose that when arriving at work (in Boston) you may either park in the street or park in a garage. In fact, between your office building and the garage there is a street on which you can always find a spot. On most days, street parking is preferable since you avoid paying the $15 garage fee. Unfortunately, when parking on the street you risk being towed ($75) due to street cleaning, snow emergency, special events, etc. When calling the city to find out when they tow, you are unable to get any reasonable guidance and decide the best thing to do is just learn from experience. There are many pieces of information that you might consider in making your prediction, e.g., the date, the day of the week, the weather. We make the following assumption: after you commit yourself to one choice or the other you learn of the right decision. In this example, the city has rules dictating when they tow; you just don't know them. If you park on the street, at the end of the day you know if your car was towed; otherwise when walking to the garage you see if the street is clear (i.e., you learn if you would have been towed). The on-line model is designed to study algorithms for learning to make accurate predictions in circumstances such as these. Note that unlike the problems addressed by many techniques from reinforcement learning, here there is immediate (versus delayed) feedback.

We now define the on-line learning model for the general setting in which the target function has a real-valued output (without loss of generality, scaled to be between 0 and 1). An on-line learning algorithm for $\mathcal{C}$ is an algorithm that runs under the following scenario. A *learning session* consists of a set of *trials.* In each trial, the learner is given an unlabeled instance $x \in \mathcal{X}$. The learner uses its current hypothesis to predict a value $p(x)$ for the unknown (real-valued) target concept $f \in \mathcal{C}$ and then the learner is told the correct value for $f(x)$. Several *loss functions* have been considered to measure the quality of the learner's predictions. Three commonly used loss functions are the following: the *square loss* defined by $\ell_2(p(x), f(x)) = (f(x)-p(x))^2$, the *log loss* defined by $\ell_{\log}(p(x), f(x)) = -f(x)\log p(x) - (1-f(x))\log(1-p(x))$, and the *absolute loss* defined by $\ell_1(p(x), f(x)) = |f(x)-p(x)|$.

The goal of the learner is to make predictions so that total loss over all predictions is minimized. In this learning model, most often a worst-case model for the environment is assumed. There is some known concept class from which the target concept is selected. An adversary (with unlimited computing power and knowledge of the learner's algorithm) then selects both the target function and the presentation order for the instances. In this model there is no training phase. Instead, the learner receives *unlabeled instances* throughout the entire learning session. However, after each prediction the learner "discovers" the correct value. This feedback can then be used by the learner to improve its hypothesis.

We now discuss the special case when the target function is Boolean and correspondingly, predictions must be either 0 or 1. In this special case the loss function most commonly used is the absolute loss.

Notice that if the prediction is correct then the value of the loss function is 0, and if the prediction is incorrect then the value of the loss function is 1. Thus the total loss of the learner is exactly the number of prediction mistakes. Thus, in the worst-case model we assume that an adversary selects the order in which the instances are presented to the learner and we evaluate the learner by the maximum number of mistakes made during the learning session. Our goal is to minimize the worst-case number of mistakes using an efficient learning algorithm (i.e., each prediction is made in polynomial time). Observe that such mistake bounds are quite strong in that the order in which examples are presented does not matter; however, it is impossible to tell how early the mistakes will occur. Littlestone [37] has shown that in this learning model $\mathrm{VCD}(\mathcal{C})$ is a lower bound on the number of prediction mistakes.

Handling Irrelevant Attributes

Here we consider the common scenario in which there are many attributes the learner could consider, yet the target concept depends on a small number of them. Thus most of the attributes are *irrelevant* to the target concept. We now briefly describe one early algorithm, Winnow of [37], that handles a large number of irrelevant attributes. More specifically, for Winnow, the number of mistakes only grows logarithmically with the number of irrelevant attributes. Winnow (or modifications of it) have many nice features such as noise tolerance and the ability to handle the situation in which the target concept is changing. Also, Winnow can directly be applied to the *agnostic learning model* [35]. In the agnostic learning model no assumptions are made about the target concept. In particular, the learner is unaware of any concept class that contains the target concept. Instead, we compare the performance of an agnostic algorithm (typically in terms of the number of mistakes or based on some other loss function) to the performance of the best hypothesis selected from a comparison or "touchstone" class where the best hypothesis from the touchstone class is the one that incurs the minimum loss over all functions in the touchstone class.

Winnow is similar to the classical perceptron algorithm [45], except that it uses a multiplicative weight-update scheme that permits it to perform much better than classical perceptron training algorithms when many attributes are irrelevant. The basic version of Winnow is designed to learn the concept class of a *linearly separable Boolean function,* which is a map $f : \{0, 1\}^n \to \{0, 1\}$ such that there exists a hyperplane in $\Re^n$ that separates the inverse images $f^{-1}(0)$ and $f^{-1}(1)$ (i.e., the hyperplane separates the points on which the function is 1 from those on which it is 0). An example of a linearly separable function is any monotone disjunction: if $f(x_1,\ldots,x_n) = x_{i_1} \vee \cdots \vee x_{i_k}$, then the hyperplane $x_{i_1} + \cdots + x_{i_k} = 1/2$ is a separating hyperplane. For each attribute x_i there is an associated weight w_i. There are two parameters, θ which determines the threshold for predicting 1 (positive), and α which determines the adjustment made to the weight of an attribute that was partly responsible for a wrong prediction. The pseudo-code for Winnow is shown in Fig. 30.6.

Winnow(θ, α)
For $i = 1, \ldots, n$, initialize $w_i = 1$

To predict the value of $x = (x_1, \ldots, x_n) \in X$:
If $\sum_{i=1}^{n} w_i x_i > \theta$, then predict 1
Else predict 0

Let ρ be the correct prediction
If the prediction was 1 and $\rho = 0$ then
If $x_i = 1$ then let $w_i = w_i/\alpha$
If the prediction was 0 and $\rho = 1$ then
If $x_i = 1$ then let $w_i = w_i \cdot \alpha$

FIGURE 30.6 The algorithm Winnow.

Winnow has been successfully applied to many learning problems. It has the very nice property that one can prove that the number of mistakes only grows logarithmically in the number of variables (and linearly in the number of relevant variables). For example, it can be shown that for the learning of monotone disjunctions of at most k literals, if Winnow is run with $\alpha > 1$ and $\theta \geq 1/\alpha$, then the total number of mistakes is at most $\alpha k(\log_\alpha \theta + 1) + n/\theta$. Observe that Winnow need not have prior knowledge of k although the number of mistakes depends on k. Littlestone [37] showed how to optimally choose θ and α if an upperbound on k is known a priori. Also, while Winnow is designed to learn a linearly separable class, reductions (discussed in "Prediction-Preserving Reductions") can be used to apply Winnow to classes for which the positive and negative points are not linearly separable, e.g., k-DNF.

The Halving Algorithm and Weighted Majority Algorithm

We now discuss some of the key techniques for designing good on-line learning algorithms for the special case of concept learning (i.e., learning Boolean-valued functions). If one momentarily ignores the issue of computation time, then the *halving algorithm* [37] performs very well. It works as follows. Initially all concepts in the concept class $\mathcal{C}$ are candidates for the target concept. To make a prediction for instance x, the learner takes a majority vote based on all remaining candidates (breaking a tie arbitrarily). Then when the feedback is received, all concepts that disagree are removed from the set of candidates. It can be shown that at each step the number of candidates is reduced by a factor of at least 2. Thus, the number of prediction mistakes made by the halving algorithm is at most $\lg|\mathcal{C}|$.

Clearly, the halving algorithm will perform poorly if the data is noisy. We now briefly discuss the *weighted majority algorithm* [38], which is one of several multiplicative weight-update schemes for generalizing the halving algorithm to tolerate noise. Also, the weighted majority algorithm provides a simple and effective method for constructing a learning algorithm A that is provided with a pool of "experts," one of which is known to perform well, but A does not know which one. Associated with each expert is a weight that gives A's confidence in the accuracy of that expert. When asked to make a prediction, A predicts by combining the votes from its experts based on their associated weights. When an expert suggests the wrong prediction, A passes that information to the given expert and reduces its associated weight using a multiplicative weight-updating scheme. Namely, the weight associated with each expert that mispredicts is multiplied by some weight $0 \leq \beta < 1$. By selecting $\beta > 0$ this algorithm is robust against noise in the data. Figure 30.7 shows the weighted majority algorithm in more depth.

Weighted Majority Algorithm (WM)
Let w_i be the weight associated with algorithm A_i
For $1 \leq i \leq n$
Let $w_i = 1$
To make a prediction for an instance $x \in X$:
Let $\mathcal{A}_0$ be the set of algorithms that predicted 0
Let $\mathcal{A}_1$ be the set of algorithms that predicted 1
Let $q_0 = \sum_{A_i \in \mathcal{A}_0} w_i$
Let $q_1 = \sum_{A_i \in \mathcal{A}_1} w_i$
Predict 0 iff $q_0 \geq q_1$
If a mistake is made:
Let γ be the prediction
For $1 \leq i \leq n$
If A_i's prediction for x is γ
Let $w_i = w_i \cdot \beta$ (where $0 \leq \beta < 1$)
Inform A_i of the mistake

FIGURE 30.7 The weighted majority algorithm.

We now briefly discuss some learning problems in which weighted majority is applicable. Suppose one knows that the correct prediction comes from some target concept selected from a known concept class. Then one can apply the weighted majority algorithm where each concept in the class is one of the algorithms in the pool. For such situations, the weighted majority algorithm is a robust generalization of the halving algorithm. (In fact, the halving algorithm corresponds to the special case where $\beta = 0$.) As another example, the weighted majority algorithm can often be applied to help in situations in which the prediction algorithm has a parameter that must be selected and the best choice for the parameter depends on the target. In such cases one can build the pool of algorithms by choosing various values for the parameter.

We now describe some of the results known about the performance of the weighted majority algorithm. If the best algorithm in the pool $\mathcal{A}$ makes at most m mistakes, then the worst case number of mistakes made by the weighted majority algorithm is $O(\log |\mathcal{A}| + m)$ where the constant hidden within the big-oh notation depends on β. Specifically, the number of mistakes made by the weighted majority algorithm is at most $\frac{\log |\mathcal{A}| + m \log \frac{1}{\beta}}{\log \frac{2}{1+\beta}}$ if one algorithm in $\mathcal{A}$ makes at most m mistakes, $\frac{\log \frac{|\mathcal{A}|}{k} + m \log \frac{1}{\beta}}{\log \frac{2}{1+\beta}}$ if there exists a set of k algorithms in $\mathcal{A}$ such that each algorithm makes at most m mistakes, and $\frac{\log \frac{|\mathcal{A}|}{k} + \frac{m}{k} \log \frac{1}{\beta}}{\log \frac{2}{1+\beta}}$ if the total number of mistakes made by a set of k algorithms in $\mathcal{A}$ is m.

When $|\mathcal{A}|$ is not polynomial, the weighted majority algorithm (when directly implemented), is not computationally feasible. Recently, Mass and Warmuth [40] introduced what they call the *virtual weight technique* to implicitly maintain the exponentially large set of weights so that the time to compute a prediction and then update the "virtual" weights is polynomial. More specifically, the basic idea is to simulate Winnow by grouping concepts that "behave alike" on seen examples into blocks. For each block only one weight has to be computed and one constructs the blocks so that the number of concepts combined in each block as well as the weight for the block can be efficiently computed. While the number of blocks increases as new **counterexamples** are received, the total number of blocks is polynomial in the number of mistakes. Thus all predictions and updates can be performed in time polynomial in the number of blocks, which is in turn polynomial in the number of prediction mistakes of Winnow. Many variations of the basic weighted majority algorithm have also been studied. The results of Cesa-Bianchi et al. [19] demonstrate how to tune β as a function of an upper bound on the noise rate.

Query Learning Model

A very well-studied formal learning model is the membership and equivalence query model developed by Angluin [3]. In this model (often called the *exact learning model*) the learner's goal is to learn *exactly* how an unknown (Boolean) target function f, taken from some known concept class $\mathcal{C}$, classifies all instances from the domain. This goal is commonly referred to as *exact identification.* The learner has available two types of queries to find out about f: one is a **membership query,** in which the learner supplies an instance x from the domain and is told $f(x)$. The other query provided is an **equivalence query** in which the learner presents a candidate function h and either is told that $h \equiv f$ (in which case learning is complete), or else is given a **counterexample** x for which $h(x) \neq f(x)$. There is a very close relationship between this learning model and the on-line learning model (supplemented with membership queries) when applied to a classification problem. Using a standard transformation [3, 37], algorithms that use membership and equivalence queries can easily be converted to on-line learning algorithms that use membership queries. Under such a transformation the number of counterexamples provided to the learner in response to the learner's equivalence queries directly corresponds to the number of mistakes made by the on-line algorithm.

In this model a number of interesting polynomial time algorithms are known for learning deterministic finite automata [2], Horn sentences [5], read-once formulas [6], read-twice DNF formulas [1], decision trees [18], and many others. It is easily shown that membership queries alone are not sufficient for efficient

learning of these classes, and Angluin has developed a technique of "approximate fingerprints" to show that equivalence queries alone are also not enough [4]. (In both cases the arguments are information theoretic, and hold even when the computation time is unbounded.) The work of Bshouty et al. [17] extended Angluin's results to establish tight bounds on how many equivalence queries are required for a number of these classes. Maass and Turán studied upper and lower bounds on the number of equivalence queries required for learning (when computation time is unbounded), both with and without membership queries [39].

It is known that any class learnable exactly from equivalence queries can be learned in the PAC setting [3]. At a high level the exact learning algorithm is transformed to a PAC algorithm by having the learner use random examples to "search" for a counterexample to the hypothesis of the exact learner. If a counterexample is found, it is given as a response to the equivalence query. Furthermore, if a sufficiently large sample was drawn and no counterexample was found then the hypothesis has error at most ϵ (with probability at least $1 - \delta$). The converse does not hold [13]. That is, there are concept classes that are efficiently PAC learnable but cannot be efficiently learned in the exact model.

We now describe Angluin's algorithm for learning monotone DNF formulas (see Fig. 30.8). A *prime implicant* t of a formula f is a satisfiable conjunction of literals such that t implies f but no proper subterm of t implies f. For example, $f = (a \wedge c) \vee (b \wedge \bar{c})$ has prime implicants $a \wedge c$, $b \wedge \bar{c}$, and $a \wedge b$. The number of prime implicants of a general DNF formula may be exponentially larger than the number of terms in the formula. However, for monotone DNF the number of prime implicants is no greater than the number of terms in the formula. The key to the analysis is to show that at each iteration, the term t is a new prime implicant of f, the target concept. Since the loop iterates exactly once for each prime implicant there are at most m counterexamples where m is the number of terms in the target formula. Since at most n membership queries are performed during each iteration there are at most nm membership queries overall.

```
Learn-Monotone-DNF
    h ← false
    Do forever
        Make equivalence query with h
        If "yes," output h and halt
        Else let x = b_1 b_2 ··· b_n be the counterexample
            Let t = ⋀_{b_i=1} y_i
            For i = 1, ..., n
                If b_i = 1 perform membership query on x with i^th bit flipped
                If "yes," t = t \ {y_i} and x = b_1 ··· b̄_i ··· b_n
            Let h = h ∨ t
```

FIGURE 30.8 An algorithm that uses membership and equivalence queries to exactly learn an unknown monotone DNF formula over the domain $\{0, 1\}^n$. Let $\{y_1, y_2, \ldots, y_n\}$ be the Boolean variables and let h be the learner's hypothesis.

30.5 Hardness Results

In order to understand what concept classes are learnable, it is essential to develop techniques to prove when a learning problem is hard. Within the learning theory community, there are two basic type of hardness results that apply to all of the models discussed here. There are **representation-dependent hardness results** in which one proves that one cannot efficiently learn $\mathcal{C}$ using a hypothesis class of

$\mathcal{H}$. These hardness results typically rely on some complexity theory assumption[8] such as RP $\neq$ NP. For example, given that RP $\neq$ NP, Pitt and Warmuth [43] showed that k-term-DNF is not learnable using the hypothesis class of k-term-DNF. While such results provide some information, what one would really like to obtain is a hardness result for learning a concept class using any reasonable (i.e., polynomially evaluatable) hypothesis class. (For example, while we have a representation-dependent hardness result for learning k-term-DNF, there is a simple algorithm to PAC learn the class of k-term-DNF formulas using a hypothesis class of k-CNF formulas.) **Representation-independent hardness results** meet this more stringent goal. However, they depend on cryptographic (versus complexity theoretic) assumptions. Kearns and Valiant [32] gave representation-independent hardness results for learning several concept classes such as Boolean formulas, deterministic finite automata, and constant-depth threshold circuits (a simplified form of "neural networks"). These hardness results are based on assumptions regarding the intractability of various cryptographic schemes such as factoring Blum integers and breaking the RSA function.

Prediction-Preserving Reductions

Given that we have some representation-independent hardness result (assuming the security of various cryptographic schemes) one would like a "simple" way to prove that other problems are hard in a similar fashion as one proves a desired algorithm is intractable by reducing a known NP-complete problem to it.[9] Such a complexity theory for predictability has been provided by Pitt and Warmuth [43]. They formally define a *prediction preserving reduction* from concept class $\mathcal{C}$ over domain $\mathcal{X}$ to concept class $\mathcal{C}'$ over domain $\mathcal{X}'$ (denoted by $\mathcal{C} \leq \mathcal{C}'$) that allows an efficient learning algorithm for $\mathcal{C}'$ to be used to obtain any efficient learning algorithm for $\mathcal{C}$. The requirements for such a prediction-preserving reduction are (1) an efficient *instance transformation* g from $\mathcal{X}$ to $\mathcal{X}'$, and (2) the existence of an *image concept.* The instance transformation g must be polynomial time computable. Hence, if $g(x) = x'$ then the size of x' must be polynomially related to the size of x. So for $x \in \mathcal{X}_n$, $g(x) \in \mathcal{X}_{p(n)}$ where $p(n)$ is some polynomial function of n. It is also important that g be independent of the target function. We now define what is meant by the existence of an image concept. For every $f \in \mathcal{C}_n$ there must exist some $f' \in \mathcal{C}'_{p(n)}$ such that for all $x \in \mathcal{X}_n$, $f(x) = f'(g(x))$ and the number of bits to represent f' is polynomially related to the number of bits to represent f.

As an example, let $\mathcal{C}$ be the class of DNF formulas over $\mathcal{X} = \{0,1\}^n$, and $\mathcal{C}'$ be the class of monotone DNF formulas over $\mathcal{X}' = \{0,1\}^{2n}$. We now show that $\mathcal{C} \leq \mathcal{C}'$. Let $y_1, \ldots, y_n$ be the variables for each concept from $\mathcal{C}$. Let $y'_1, \ldots, y'_{2n}$ be the variables for $\mathcal{C}'$. The intuition behind the reduction is that variable y_i for the DNF problem is associated with variable y_{2i-1} for the monotone DNF problem. And variable $\overline{y_i}$ for the DNF problem is associated with variable y_{2i} for the monotone DNF problem. So for example $x = b_1 b_2 \cdots b_n$ where each $b_i \in \{0,1\}$ and $g(x) = b_1(1-b_1)b_2(1-b_2)\cdots b_n(1-b_n)$. Given a target concept $f \in \mathcal{C}$, the image concept f' is obtained by replacing each nonnegated variable y_i from f with y'_{2i-1} and each negated variable $\overline{y_i}$ from f with y'_{2i}. It is easily confirmed that all required conditions are met.

If $\mathcal{C} \leq \mathcal{C}'$, what implications are there with respect to learnability? Observe that if we are given a polynomial prediction algorithm A' for $\mathcal{C}'$, one can use A' to obtain a polynomial prediction algorithm A for $\mathcal{C}$ as follows. If A' requests a labeled example then A can obtain a labeled example $x \in \mathcal{X}$ from its oracle and give $g(x)$ to A'. Finally, when A' outputs hypothesis h', A can make a prediction for $x \in \mathcal{X}$ using $h(g(x))$. Thus if $\mathcal{C}$ is known not to be learnable then $\mathcal{C}'$ also is not learnable. Thus the reduction given above implies that the class of monotone DNF formulas is just as hard to learn in the PAC model as

[8] For background on complexity classes see Chapter 33 (NP defined) and Chapter 35 (RP defined) of this *Handbook.*
[9] See Chapter 34 of this *Handbook* for background on reducibility and completeness.

the class of arbitrary DNF formulas. Equivalently, if there were an efficient PAC algorithm for the class of monotone DNF formulas, then there would also be an efficient PAC algorithm for arbitrary DNF formulas.

Pitt and Warmuth [43] gave a prediction preserving reduction from the class of Boolean formulas to class of DFAs. Thus since Kearns and Valiant [32] proved that Boolean formula are not predictable (under cryptographic assumptions), it immediately follows that DFAs are not predictable. In other words, DFAs cannot be efficiently learned from random examples alone. Recall that any algorithm to exactly learn using only equivalence queries can be converted into an efficient PAC algorithm. Thus if DFAs are not efficiently PAC learnable (under cryptographic assumptions), it immediately follows that DFAs are not efficiently learnable from only equivalence queries (under cryptographic assumptions). Contrasting this negative result, recall that DFAs are exactly learnable from membership and equivalence queries [2], and thus are PAC learnable with membership queries.

Notice that for $\mathcal{C} \leq \mathcal{C}'$, the result that an efficient learning algorithm for $\mathcal{C}'$ also provides an efficient algorithm for $\mathcal{C}$ relies heavily on the fact that membership queries are NOT allowed. The problem created by membership queries (whether in the PAC or exact model) is that algorithm A' for $\mathcal{C}'$ may make a membership query on an example $x' \in \mathcal{X}'$ for which $g^{-1}(x')$ is not in $\mathcal{X}$. For example, the reduction described earlier demonstrates that if there is an efficient algorithm to PAC learn monotone DNF formulas then there is an efficient algorithm to PAC learn DNF formulas. Notice that we already have an algorithm Learn-Monotone-DNF that exactly learns this class with membership and equivalence queries (and thus can PAC learn the class when provided with membership queries). Yet, the question of whether or not there is an algorithm with access to a membership oracle to PAC learn DNF formulas remains one of the biggest open questions within the field. We now describe the problem with using the algorithm Learn-Monotone-DNF to obtain an algorithm for general DNF formulas. Suppose that we have 4 Boolean variables (thus the domain is $\{0, 1\}^4$). The algorithm Learn-Monotone-DNF could perform a membership query on the example 00100111. While this example is in the domain $\{0, 1\}^8$ there is no $x \in \{0, 1\}^4$ for which $g(x) = 00100111$. Thus the provided membership oracle for the DNF problem cannot be used to respond to the membership query posed by Learn-Monotone-DNF.

We now define a more restricted type of reduction $\mathcal{C} \leq_{wmq} \mathcal{C}'$ that yields results even when membership queries are allowed [7]. For these reductions, we just add the following third condition to the two conditions already described: for all $x' \in \mathcal{X}'$, if x' is not in the image of g (i.e., there is no $x \in \mathcal{X}$ such that $g(x) = x'$), then the classification of x' for the image concept must always be positive or always be negative. As an example, we show that $\mathcal{C} \leq_{wmq} \mathcal{C}'$ where $\mathcal{C}$ is the class of DNF formulas and $\mathcal{C}'$ is the class of read-thrice DNF formulas (meaning that each literal can appear at most three times). Thus learning a read-thrice DNF formula (even with membership queries) is as hard as learning general DNF formula (with membership queries). Let s be the number of literals in f. (If s is not known *a priori,* the standard doubling technique can be applied.) The mapping g maps from an $x \in \{0, 1\}^n$ to an $x' \in \{0, 1\}^{sn}$. More specifically, $g(x)$ simply repeats, s times, each bit of x. To see that there is an image concept, note that we have s variables for each concept in $\mathcal{C}'$ associated with each variable for a concept in $\mathcal{C}$. Thus we can rewrite $f \in \mathcal{C}$ as a formula $f' \in \mathcal{C}'$ in which each variable only appears once. At this point we have shown $\mathcal{C} \leq \mathcal{C}'$ but still need to do more to satisfy the new third condition. We want to ensure that the s variables (call them $\ell'_1, \ldots, \ell'_s$) for f' associated with one literal ℓ_i of f all take the same value. We do this by defining our final image concept as: $f' \wedge \Gamma_1 \wedge \cdots \wedge \Gamma_n$ where n is the number of variables and Γ_i is of the form $(\ell'_1 \rightarrow \ell'_2) \wedge \cdots \wedge (\ell'_{s-1} \rightarrow \ell'_s) \wedge (\ell'_s \rightarrow \ell'_1)$. This formula evaluates to true exactly when $\ell'_1, \ldots, \ell'_s$ have the same value. Thus an x' for which no $g(x) = x'$ will not satisfy some Γ_i and thus we can respond "no" to a membership query on x'. Finally, f' is a read-thrice DNF formula. This reduction also proves that Boolean formulas $\leq_{wmq}$ read-thrice Boolean formulas.

30.6 Weak Learning and Hypothesis Boosting

As originally defined, the PAC model requires the learner to produce, with arbitrarily high probability, a hypothesis that is arbitrarily close to the target concept. While for many problems it is easy to find simple

algorithms ("rules-of-thumb") that are often correct, it seems much harder to find a single hypothesis that is highly accurate. Informally, a **weak learning** algorithm is one that outputs a hypothesis that has some advantage over random guessing. (To contrast this sometimes a PAC learning algorithm is called a *strong learning* algorithm.) This motivates the question: are there concept classes for which there is an efficient weak learner, but there is no efficient PAC learner? Somewhat surprisingly the answer is no [46]. The technique used to prove this result is to take a weak learner and transform (boost) it into a PAC learner. The general method of converting a rough rule-of-thumb (weak learner) into a highly accurate prediction rule (PAC learner) is referred to as **hypothesis boosting**.[10]

We now formally define the weak learning model [32, 46]. As in the PAC model, there is the instance space $\mathcal{X}$ and the concept class $\mathcal{C}$. Also the examples are drawn randomly and independently according to a fixed but unknown distribution $\mathcal{D}$ on $\mathcal{X}$. The learner's hypothesis h must be a polynomial time function that given an $x \in \mathcal{X}$ returns a prediction of $f(x)$ for $f \in \mathcal{C}$, the unknown target concept. The accuracy requirements for the hypothesis of a weak learner are as follows. There is a polynomial function $p(n)$ and algorithm A such that, for all $n \geq 1$, $f \in \mathcal{C}_n$, for all distributions $\mathcal{D}$, and for all $0 < \delta \leq 1$, algorithm A, given n, δ, and access to labeled examples from $\mathcal{D}$, outputs a hypothesis h such that, with probability $\geq 1 - \delta$, $\text{error}_D(h)$ is at most $(1/2 - 1/p(n))$. Algorithm A should run in time polynomial in n and $1/\delta$.

If $\mathcal{C}$ is strongly learnable, then it is weakly learnable—just fix $\epsilon = 1/4$ (or any constant less than $1/2$). The converse (weak learnability implying strong learnability) is not at all obvious. In fact, if one restricts the distributions under which the weak learning algorithm runs then weak learnability *does not* imply strong learnability. Namely, Kearns and Valiant [32] have shown that under a uniform distribution, monotone Boolean functions are weakly, but not strongly, learnable. Thus it is important to take advantage of the requirement that the weak learning algorithm must work for all distributions. Using this property, Schapire [46] proved the converse result: if concept class $\mathcal{C}$ is weakly learnable, then it is strongly learnable.

Proving that weak learnability implies strong learnability has also been called the *hypothesis boosting problem,* because a way must be found to boost the accuracy of slightly-better-than-half hypothesis to be arbitrarily close to 1. There have been several boosting algorithms proposed since the original work of Schapire [46]. Figure 30.9 describes AdaBoost [23] that has shown promise in empirical use. The key to forcing the weak learner to output hypothesis that can be combined to create a highly accurate hypothesis is to create different distributions on which the weak learner is trained.

Freund and Schapire [23] have done some experiments showing that by applying AdaBoost to some simple rules of thumb or using C4.5 [44] as the weak learner they can perform better than previous algorithms on some standard benchmarks. Also, Freund and Schapire have presented a more general version for AdaBoost for the situation in which the predictions are real-valued (versus binary). Some of the practical advantages of AdaBoost are that is fast, simple and easy to program, requires no parameters to tune (besides T, the number of rounds), no prior knowledge is needed about the weak learner, it is provably effective, and it is flexible, since you can combine it with any classifier that finds weak hypothesis.

30.7 Research Issues and Summary

In this chapter, we have described the fundamental models and techniques of computational learning theory. There are many interesting research directions besides those discussed here. One general direction of research is in defining new, more realistic models, and models that capture different learning scenarios. Here are a few examples. Often, as in the problem of weather prediction, the target concept is probabilistic in nature. Thus Kearns and Schapire [34] introduced the p-concepts model. Also there has been a lot of

[10] We note that one can easily boost the confidence δ by first designing an algorithm A that works for say $\delta = 1/2$ and then running A several times taking a majority vote. For an arbitrary $\delta > 0$ the number of runs of A needed are polynomial in $\lg 1/\delta$.

AdaBoost

For $i = 1, \ldots, m$

$D_1(i) = 1/m$

For $t = 1, \ldots, T$

Call WeakLearn providing it with the distribution D_t to obtain the hypothesis h_t

Calculate the error of h_t : $\epsilon_t = \sum_{i:h_t(x_i) \neq y_i} D_t(i)$

If $\epsilon_t > 1/2$, set $T = t - 1$ and abort the loop

Let $\beta_t = \epsilon_t/(1 - \epsilon_t)$

Update distribution D_t:

Let Z_t be a normalization constant so D_{t+1} is a valid probability distribution

If $h_t(x_i) = y_i$

Let $D_{t+1} = \frac{D_t(i)}{Z_t} \cdot \beta_t$

Else

Let $D_{t+1} = \frac{D_t(i)}{Z_t}$

Output the final hypothesis:

$$h_{fin}(x) = \arg\max_{y \in Y} \sum_{t:h_t(x)=y} \log \frac{1}{\beta_t}$$

FIGURE 30.9 The procedure AdaBoost to boost the accuracy of a mediocre hypothesis (created by WeakLearn) to a very accurate hypothesis. The input is a sequence $\langle (x_1, y_1), \ldots, (x_m, y_m) \rangle$ of labeled examples where each label comes from the set $Y = \{1, \ldots, k\}$.

work in extending the VC theory to real-valued domains (e.g.,[28]). In both the PAC and on-line models, many algorithms use membership queries. While most work has assumed that the answers provided to the membership queries are reliable, in reality a learner must be able to handle inconclusive and noisy results from the membership queries. See Blum et al. [14] for a summary of several models introduced to address this situation. As one last example, there has been much work recently in exploring models of a "helpful teacher," since teaching is often used to assist human learning (e.g.,[8, 25]).

Finally, there has been work to bridge the computational learning research with the research from other fields such as neural networks, natural language processing, DNA analysis, inductive logic programming, information retrieval, expert systems, and many others.

30.8 Defining Terms

Classification noise: A model of noise in which the label may be reported incorrectly. In the *random classification noise model,* with probability η the label is inverted. In the *malicious classification noise* model, with probability η an adversary can choose the label. In both models with probability $1 - \eta$ the example is not corrupted. The quantity η is referred to as the *noise rate.*

Concept class: A set of rules from which the target function is selected.

Counterexample: A counterexample x to a hypothesis h (where the target concept is f) is either an example for which $f(x) = 1$ and $h(x) = 0$ (a *positive* counterexample) or for which $f(x) = 0$ and $h(x) = 1$ (a *negative* counterexample).

Equivalence query: A query to an oracle in which the learner provides a hypothesis h and is either told that h is logically equivalent to the target or otherwise given a counterexample.

Hypothesis boosting: The process of taking a weak learner that predicts correctly just over half of the time and transforming (boosting) it into a PAC (strong) learner whose predictions are as accurate as desired.

Hypothesis class: The class of functions from which the learner's hypothesis is selected.

Membership query: The learner supplies the membership oracle with an instance x from the domain and is told the value of $f(x)$.

Occam algorithm: An algorithm that draws a sample S and then outputs a hypothesis consistent with the examples in S such that the size of the hypothesis is sublinear in S (i.e., it performs some data compression).

On-line learning model: The learning session consists of a set of trials where in each trial, the learner is given an unlabeled instance $x \in \mathcal{X}$. The learner uses its current hypothesis to predict a value $p(x)$ for the unknown (real-valued) target and is then told the correct value for $f(x)$. The performance of the learner is measured in terms of the sum of the loss over all predictions.

PAC learning: This is a batch model in which first there is a training phase in which the learner sees examples drawn randomly from an unknown distribution $\mathcal{D}$, and labeled according to the unknown target concept f drawn from a known concept class $\mathcal{C}$. The learner's goal is to output a hypothesis that has error at most ϵ with probability at least $1 - \delta$. (The learner receives ϵ and δ as inputs.) In the *proper* PAC learning model the learner must output a hypothesis from $\mathcal{C}$. In the *nonproper* PAC learning model the learner can output any hypothesis h for which $h(x)$ can be computed in polynomial time.

Representation-dependent hardness result: A hardness result in which one proves that one cannot efficiently learn $\mathcal{C}$ using a hypothesis class of $\mathcal{H}$. These hardness results typically rely on some complexity theory assumption such as RP $\neq$ NP.

Representation-independent hardness result: A hardness result in which no assumption is made about the hypothesis class used by the learner (except the hypothesis can be evaluated in polynomial time). These hardness results typically rely on cryptographic assumptions such as the difficulty of breaking RSA.

Statistical query model: A learning model in which the learner does not have access to labeled examples, but rather only can ask queries about statistics about the labeled examples and receive unlabeled examples. Any statistical query algorithm can be converted to a PAC algorithm that can handle random classification noise (as well as some other types of noise).

Vapnik–Chervonenkis (VC) dimension: A finite set $S \subseteq \mathcal{X}$ is *shattered* by $\mathcal{C}$ if for each of the $2^{|S|}$ subsets $S' \subseteq S$, there is a concept $f \in \mathcal{C}$ that contains all of S' and none of $S - S'$. In other words, for any of the $2^{|S|}$ possible labelings of S (where each example $s \in S$ is either positive or negative), there is some $f \in \mathcal{C}$ that realizes the desired labeling (see Fig. 30.2). The **Vapnik–Chervonenkis dimension** of $\mathcal{C}$, denoted as $\mathrm{VCD}(\mathcal{C})$, is the smallest d for which no set of $d + 1$ examples is shattered by $\mathcal{C}$. Equivalently, $\mathrm{VCD}(\mathcal{C})$ is the cardinality of the largest finite set of points $S \subseteq X$ that is shattered by $\mathcal{C}$.

Weak learning model: A variant of the PAC model in which the learner is only required to output a hypothesis that with probability $\geq 1 - \delta$, has error at most $(1/2 - 1/p(n))$. I.e., it does noticeably better than random guessing. Recall in the standard PAC (strong learning) model the learner must output a hypothesis with arbitrarily low error.

31.1 Abstract

Linear programming has been a fundamental topic in the development of the computational sciences. The subject has its origins in the early work of L.B.J. Fourier on solving systems of linear inequalities, dating back to the 1820s. More recently, a healthy competition between the simplex and interior point methods has led to rapid improvements in the technologies of linear programming. This combined with remarkable advances in computing hardware and software have brought linear programming tools to the desktop, in a variety of application software for decision support. Linear programming has provided a fertile ground for the development of various algorithmic paradigms. Diverse topics such as symbolic computation, numerical analysis, computational complexity, computational geometry, combinatorial optimization, and randomized algorithms all have some linear programming connection. This chapter reviews this universal role played by linear programming in the science of algorithms.

[1] Dedicated to George Dantzig on this the 50^{th} Anniversary of the Simplex Algorithm.

31.2 Introduction

Linear programming has been a fundamental topic in the development of the computational sciences [50]. The subject has its origins in the early work of L.B.J. Fourier [30] on solving systems of linear inequalities, dating back to the 1820s. The revival of interest in the subject in the 1940s was spearheaded by G.B. Dantzig [19] in the U.S. and L.V. Kantorovich [45] in the former U.S.S.R. They were both motivated by the use of linear optimization for optimal resource utilization and economic planning. Linear programming, along with classical methods in the calculus of variations, provided the foundations of the field of mathematical programming, which is largely concerned with the theory and computational methods of mathematical optimization. The 1950s and 1960s marked the period when linear programming fundamentals (**duality, decomposition** theorems, network flow theory, **matrix factorizations**) were worked out in conjunction with the advancing capabilities of computing machinery [20].

The 1970s saw the realization of the commercial benefits of this huge investment of intellectual effort. Many large-scale **linear programs** were formulated and solved on mainframe computers to support applications in industry (for example, oil, airlines) and for the state (for example, energy planning, military logistics). The 1980s were an exciting period for linear programmers. The polynomial time-complexity of linear programming was established. A healthy competition between the simplex and interior point methods ensued that finally led to rapid improvements in the technologies of linear programming. This combined with remarkable advances in computing hardware and software have brought linear programming tools to the desktop, in a variety of application software (including spreadsheets) for decision support.

The fundamental nature of linear programming in the context of algorithmics is borne out by a few examples.

- Linear programming is at the starting point for variable elimination techniques on algebraic constraints [12], which in turn forms the core of algebraic and symbolic computation.
- Numerical linear algebra and particularly sparse matrix technology was largely driven in its early development by the need to solve large-scale linear programs [37, 61].
- The complexity of linear programming played an important role in the 1970s in the early stages of the development of the polynomial hierarchy and particularly in the $\mathcal{NP}$-completeness and $\mathcal{P}$-completeness in the theory of computation [67, 68].
- Linear-time algorithms based on "prune and search" techniques for low-dimensional linear programs have been used extensively in the development of computational geometry [25].
- Linear programming has been the testing ground for very exciting new developments in randomized algorithms [60].
- **Relaxation** strategies based on linear programming have played a unifying role in the construction of approximation algorithms for a wide variety of combinatorial optimization problems [17, 33, 75].

In this chapter we will encounter the basic algorithmic paradigms that have been invoked in the solution of linear programs. An attempt has been made to provide intuition about some fairly deep and technical ideas without getting bogged down in details. However, the details are important and the interested reader is invited to explore further through the references cited. Fortunately, there are many excellent texts, monographs, and expository papers on linear programming [5, 9, 16, 20, 62, 65, 67, 69, 71] that the reader can choose from, to dig deeper into the fascinating world of linear programming.

31.3 Geometry of Linear Inequalities

Two of the many ways in which linear inequalities can be understood are through algorithms or through nonconstructive geometric arguments. Each approach has its own merits (aesthetic and otherwise). Since

the rest of this chapter will emphasize the algorithmic approaches, in this section we have chosen the geometric version. Also, by starting with the geometric version, we hope to hone the reader's intuition about a convex **polyhedron,** the set of solutions to a finite system of linear inequalities[2]. We begin with the study of linear, homogeneous inequalities. This involves the geometry of (convex) **polyhedral cones.**

Polyhedral Cones

A homogeneous linear equation in n variables defines a *hyperplane* of dimension $(n-1)$ which contains the origin and is therefore a linear subspace. A homogeneous linear inequality defines a *halfspace* on one "side" of the hyperplane, defined by converting the inequality into an equation. A system of linear homogeneous inequalities therefore, defines an object which is the intersection of finitely many halfspaces, each of which contains the origin in its boundary. A simple example of such an object is the nonnegative orthant. Clearly the objects in this class resemble cones with the apex defined at the origin and with a prismatic boundary surface. We call them *convex polyhedral cones.*

A convex polyhedral cone is the set of the form

$$\mathcal{K} = \{x | Ax \leq 0\} .$$

Here A is assumed to be an $m \times n$ matrix of real numbers. A set is convex if it contains the line segment connecting any pair of points in the set. A convex set is called a convex cone if it contains all nonnegative scalar multiples of points in it. A convex set is polyhedral if it is represented by a finite system of linear inequalities. As we shall deal exclusively with cones that are both convex and polyhedral, we shall refer to them as cones.

The representation of a cone as the solutions to a finite system of homogeneous linear inequalities is sometimes, referred to as the "constraint" or "implicit" description. It is implicit because it takes an algorithm to generate points in the cone. An "explicit" or "edge" description can also be derived for any cone.

THEOREM 31.1 *Every cone $\mathcal{K} = \{x : Ax \leq 0\}$ has an "edge" representation of the following form. $\mathcal{K} = \{x : x = \Sigma_{j=1}^{L} e^j \mu_j, \quad \mu_j \geq 0 \ \ \forall j\}$ where each distinct edge of $\mathcal{K}$ is represented by a point e^j.*

Thus, for any cone we have two representations:

- CONSTRAINT REPRESENTATION. $\mathcal{K} = \{x : Ax \leq 0\}$.
- EDGE REPRESENTATION. $\mathcal{K} = \{x : x = E\mu, \quad \mu \geq 0\}$.

The matrix E is a representation of the edges of $\mathcal{K}$. Each column $E_{i.}$ of E contains the coordinates of a point on a distinct edge. Since positive scaling of the columns is permitted, we fix the representation by scaling each column so that the last non-zero entry is either 1 or -1. This scaled matrix E is called the Canonical Matrix of Generators of the cone $\mathcal{K}$.

Every point in a cone can be expressed as a positive combination of the columns of E. Since the number of columns of E can be huge, the edge representation does not seem very useful. Fortunately, the following tidy result helps us out.

THEOREM 31.2 **(Caratheodory)** [11] *For any cone $\mathcal{K}$, every $\bar{x} \in \mathcal{K}$ can be expressed as the positive combination of at most d edge points, where d is the dimension of $\mathcal{K}$.*

[2]For the study of infinite systems of linear inequalities see Chapter 33 of this *Handbook*.

Conic Duality

The representation theory for convex polyhedral cones exhibits a remarkable duality relation. This duality relation is a central concept in the theory of linear inequalities and linear programming as we shall see later.

Let $\mathcal{K}$ be an arbitrary cone. The *dual* of $\mathcal{K}$ is given by

$$\mathcal{K}^* = \left\{ u : x^T u \leq 0, \quad \forall x \in \mathcal{K} \right\} .$$

THEOREM 31.3 *The representations of a cone and its dual are related by*
$\mathcal{K} = \{x : Ax \leq 0\} = \{x : x = E\mu, \quad \mu \geq 0\}$ *and*
$\mathcal{K}^* = \{u : E^T u \leq 0\} = \{u : u = A^T \lambda, \quad \lambda \geq 0\}$.

COROLLARY 31.1 $\mathcal{K}^*$ is a convex polyhedral cone and duality is involutory (that is $(\mathcal{K}^*)^*). = \mathcal{K}$.

As we shall see, there is not much to linear inequalities or linear programming, once we have understood convex polyhedral cones.

Convex Polyhedra

The transition from cones to polyhedra may be conceived of, algebraically, as a process of dehomogenization. This is to be expected, of course, since polyhedra are represented by systems of (possibly inhomogeneous) linear inequalities and cones by systems of *homogeneous* linear inequalities. Geometrically, this process of dehomogenization corresponds to realizing that a polyhedron is the Minkowski or set sum of a cone and a **polytope** (bounded polyhedron). But before we establish this identity, we need an algebraic characterization of polytopes. Just as cones in $\Re^n$ are generated by taking *positive* linear combinations of a finite set of points in $\Re^n$, polytopes are generated by taking *convex* linear combinations of a finite set of (generator) points.

DEFINITION 31.1 Given K points $\{x^1, x^2, \cdots, x^K\}$ in $\Re^n$ the *Convex Hull* of these points is given by

$$C.H.\left(\left\{x^i\right\}\right) = \left\{ \bar{x} : \bar{x} = \sum_{i=1}^{K} \alpha_i x^i, \quad \sum_{i=1}^{K} \alpha_i = 1, \quad \alpha \geq 0 \right\} ,$$

i.e., the convex hull of a set of points in $\Re^n$ is the object generated in $\Re^n$ by taking all convex linear combinations of the given set of points. Clearly, the convex hull of a finite list of points, is always bounded.

THEOREM 31.4 [80] *P is a polytope if and only if it is the convex hull of a finite set of points.*

DEFINITION 31.2 An **extreme point** of a convex set S is a point $x \in S$ satisfying

$$x = \alpha\bar{x} + (1-\alpha)\tilde{x}, \quad \bar{x}, \tilde{x} \in S, \quad \alpha \in (0,1) \ \rightarrow \ x = \bar{x} = \tilde{x}$$

Equivalently, an extreme point of a convex set S is one that cannot be expressed as a convex linear combination of some other points in S. When S is a polyhedron, extreme points of S correspond to the geometric notion of corner points. This correspondence is formalized in the corollary below.

COROLLARY 31.2 A polytope P is the convex hull of its extreme points.

Now we go on to discuss the representation of (possibly unbounded) convex polyhedra.

THEOREM 31.5 *Any convex polyhedron P represented by a linear inequality system* $\{y : yA \leq c\}$ *can be also represented as the set addition of a convex cone R and a convex polytope Q.*

$$\begin{aligned} P &= Q + R = \{x : x = \bar{x} + \bar{r},\ \ \bar{x} \in Q,\ \ \bar{r} \in R\} \\ Q &= \left\{ \bar{x} : \bar{x} = \sum_{i=1}^{K} \alpha_i x^i,\ \ \sum_{i=1}^{K} \alpha_i = 1,\ \ \alpha \geq 0 \right\} \\ R &= \left\{ \bar{r} : \bar{r} = \sum_{j=1}^{L} \mu_j r^j,\ \ \mu \geq 0 \right\} . \end{aligned}$$

It follows from the statement of the theorem that P is nonempty if and only if the polytope Q is nonempty. We proceed now to discuss the representations of R and Q, respectively.

The cone *R* associated with the polyhedron P is called the *recession or characteristic cone* of P. A hyperplane representation of R is also readily available. It is easy to show that

$$R = \{r : Ar \leq 0\} .$$

An obvious implication of Theorem 31.5 is that P equals the polytope Q if and only if $R = \{0\}$. In this form, the vectors $\{r^j\}$ are called the *extreme rays* of P.

The polytope *Q* associated with the polyhedron P is the convex hull of a finite collection $\{x^i\}$ of points in P. It is not difficult to see that the minimal set $\{x^i\}$ is precisely the set of extreme points of P. A nonempty pointed polyhedron P, it follows, must have at least one extreme point.

The **affine hull** of P is given by

$$\begin{aligned} A.H.\{P\} &= \left\{ x : x = \sum \alpha_i x^i \right\} \\ x^i &\in P \ \ \forall i, \ \text{ and } \sum \alpha_i = 1 . \end{aligned}$$

Clearly, the x^i can be restricted to the set of extreme points of P in the definition above. Furthermore, $A.H.\{P\}$ is the smallest affine set that contains P. A hyperplane representation of $A.H.\{P\}$ is also possible. First let us define the implicit linear equality system of P to be

$$\{A^{=}x = b^{=}\} = \{A_{i.}x = b_i \ \ \forall x \in P\} .$$

Let the remaining inequalities of P be defined as

$$A^{+}x \leq b^{+} .$$

It follows that P must contain at least one point $\bar{x}$ satisfying

$$A^{=}\bar{x} = b^{=} \text{ and } A^{+}\bar{x} < b^{+} .$$

LEMMA 31.1 $A.H.\{P\} = \{x : A^{=}x = b^{=}\}$.

The **dimension** of a polyhedron P in $\Re^n$ is defined to be the dimension of the affine hull of P, which equals the maximum number of affinely independent points, in $A.H.\{P\}$, minus one. P is said to be full-dimensional if its dimension equals n or, equivalently, if the affine hull of P is all of $\Re^n$.

A **supporting hyperplane** of the polyhedron P is a hyperplane H

$$H = \left\{ x : b^T x = z^* \right\} ,$$

satisfying

$$\begin{aligned} b^T x &\leq z^* \ \forall x \in P \\ b^T \hat{x} &= z^* \ for\ some\ \hat{x} \in P . \end{aligned}$$

A supporting hyperplane H of P is one that touches P such that all of P is contained in a halfspace of H. Note that a supporting plane can touch P at more than one point.

A **face** of a nonempty polyhedron P is a subset of P that is either P itself or is the intersection of P with a supporting hyperplane of P. It follows that a face of P is itself a nonempty polyhedron. A face of dimension, one less than the dimension of P, is called a **facet.** A face of dimension one is called an **edge** (note that extreme rays of P are also edges of P). A face of dimension zero is called a **vertex** of P (the vertices of P are precisely the extreme points of P). Two vertices of P are said to be adjacent if they are both contained in an edge of P. Two facets are said to be adjacent if they both contain a common face of dimension one less than that of a facet. Many interesting aspects of the facial structure of polyhedra can be derived from the following representation lemma.

LEMMA 31.2 F is a face of $P = \{x : Ax \leq b\}$ if and only if F is nonempty and $F = P \cap \{x : \tilde{A}x = \tilde{b}\}$, where $\tilde{A}x \leq \tilde{b}$ is a subsystem of $Ax \leq b$.

As a consequence of the lemma, we have an algebraic characterization of extreme points of polyhedra.

THEOREM 31.6 *Given a polyhedron P, defined by* $\{x : Ax \leq b\}$, x^i *is an extreme point of P if and only if it is a face of P satisfying* $A^i x^i = b^i$ *where* $((A^i), (b^i))$ *is a submatrix of* (A, b) *and the rank of* A^i *equals n.*

Now we come to Farkas Lemma, which says that a linear inequality system has a solution if and only if a related (polynomial size) linear inequality system has no solution. This lemma is representative of a large body of theorems in mathematical programming known as *theorems of the alternative.*

LEMMA 31.3 **(Farkas)** [27] Exactly one of the alternatives

$$I.\ \ \exists\, x\, :\, Ax \leq b \qquad II.\ \ \exists\, y \geq 0\, :\, A^T y = 0,\ b^T y < 0$$

is true for any given real matrices A, b.

Optimization and Dual Linear Programs

The two fundamental problems of linear programming (which are polynomially equivalent) are

- **Solvability:** This is the problem of checking if a system of linear constraints on real (rational) variables is solvable or not. Geometrically, we have to check if a polyhedron, defined by such constraints, is nonempty.
- **Optimization:** This is the problem (LP) of optimizing a linear objective function over a polyhedron described by a system of linear constraints.

Building on polarity in cones and polyhedra, duality in linear programming is a fundamental concept which is related to both the complexity of linear programming and to the design of algorithms for solvability and optimization. We will encounter the solvability version of duality (called Farkas' Lemma) while discussing the Fourier elimination technique below. Here we will state the main duality results for optimization. If we take the *primal* linear program to be

$$(P) \quad \min_{x \in \Re^n} \{cx : Ax \geq b\} ,$$

there is an associated *dual* linear program

$$(D) \quad \max_{y \in \Re^m} \left\{ b^T y : A^T y = c^T ,\ y \geq 0 \right\} ,$$

and the two problems satisfy

1. For any $\hat{x}$ and $\hat{y}$ feasible in (P) and (D) (i.e., they satisfy the respective constraints), we have $c\hat{x} \geq b^T \hat{y}$ (`weak duality`).
2. (P) has a finite optimal solution if and only if (D) does.
3. x^* and y^* are a pair of optimal solutions for (P) and (D), respectively, if and only if x^* and y^* are feasible in (P) and (D) (i.e., they satisfy the respective constraints) **and** $cx^* = b^T y^*$ (`strong duality`).
4. x^* and y^* are a pair of optimal solutions for (P) and (D), respectively, if and only if x^* and y^* are feasible in (P) and (D) (i.e., they satisfy the respective constraints) **and** $(Ax^* - b)^T y^* = 0$ (`complementary slackness`).

The strong duality condition above gives us a good stopping criterion for optimization algorithms. The complementary slackness condition, on the other hand gives us a constructive tool for moving from dual to primal solutions and vice-versa. The weak duality condition gives us a technique for obtaining lower bounds for minimization problems and upper bounds for maximization problems.

Note that the properties above have been stated for linear programs in a particular form. The reader should be able to check that if for example the primal is of the form

$$\left(P'\right) \quad \min_{x \in \Re^n} \{cx : Ax = b,\ x \geq 0\} ,$$

then the corresponding dual will have the form

$$\left(D'\right) \quad \max_{y \in \Re^m} \left\{ b^T y : A^T y \leq c^T \right\} .$$

The tricks needed for seeing this is that any equation can be written as two inequalities, an unrestricted variable can be substituted by the difference of two nonnegatively constrained variables, and an inequality can be treated as an equality by adding a nonnegatively constrained variable to the lesser side. Using these tricks, the reader could also check that dual construction in linear programming is involutory (i.e., the dual of the dual is the primal).

Complexity of Linear Equations and Inequalities

Complexity of Linear Algebra

Let us restate the fundamental problem of linear algebra as a decision problem.

$$\mathcal{CLS} = \left\{ (A, b) :\ \exists\, x \in \mathcal{Q}^n, Ax = b \right\} . \tag{31.1}$$

In order to solve the decision problem on $\mathcal{CLS}$ it is useful to recall *homogeneous* linear equations. A basic result in linear algebra is that any linear subspace of $\mathcal{Q}^n$ has two representations, one from hyperplanes and the other from a vector basis.

$\mathcal{L} = \{x \in \mathcal{Q}^n : Ax = 0\}$

$\mathcal{L} = \{x \in \mathcal{Q}^n : x = Cy, \quad y \in \mathcal{Q}^k\}$.

Corresponding to a linear subspace $\mathcal{L}$ there exists a dual (orthogonal complementary) subspace $\mathcal{L}^*$ with the roles of the hyperplanes and basis vectors of $\mathcal{L}$ exchanged.

$\mathcal{L}^* = \{z : Cz = 0\}$

$\mathcal{L}^* = \{z : z = Ax\}$

$dimension\mathcal{L} + dimension\mathcal{L}^* = n$.

Using these representation results it is quite easy to establish the *Fundamental Theorem of Linear Algebra.*

THEOREM 31.7 *Either $Ax = b$ for some x* or *$yA = 0$, $yb \neq 0$ for some y.*

Along with the basic theoretical constructs outlined above, let us also assume knowledge of the *Gaussian Elimination Method* for solving a system of linear equations. It is easily verified that on a system of size m by n, this method uses $O(m^2n)$ elementary arithmetic operations. However we also need some bound on the size of numbers handled by this method. By the size of a rational number we mean the length of binary string encoding the number. And similarly for a matrix of numbers.

LEMMA 31.4 For any square matrix S of rational numbers, the size of the determinant of S is polynomially related to the size of S itself.

Since all the numbers in a basic solution (i.e., basis-generated) of $Ax = b$ are bounded in size by subdeterminants of the input matrix (A, b) we can conclude that $\mathcal{CLS}$ is a member of $\mathcal{NP}$. The Fundamental Theorem of Linear Algebra further establishes that $\mathcal{CLS}$ is in $\mathcal{NP} \bigcap co\mathcal{NP}$. And finally the polynomiality of Gaussian Elimination establishes that $\mathcal{CLS}$ is in $\mathcal{P}$.

Complexity of Linear Inequalities

From our earlier discussion of polyhedra, we have the following algebraic characterization of extreme points of polyhedra.

THEOREM 31.8 *Given a polyhedron P, defined by $\{x : Ax \leq b\}$, x^i is an extreme point of P if and only if it is a face of P satisfying $A^i x^i = b^i$ where $((A^i), (b^i))$ is a submatrix of (A, b) and the rank of A^i equals n.*

COROLLARY 31.3 The decision problem of verifying the membership of an input string (A, b) in the language $\mathcal{L}_I = \{(A, b) : \exists\, x \; such \; that \; Ax \leq b\}$ belongs to $\mathcal{NP}$.

PROOF It follows from the theorem that every extreme point of the polyhedron $P = \{x : Ax \leq b\}$ is the solution of an $(n \times n)$ linear system whose coefficients come from (A, b). Therefore we can guess a polynomial length string representing an extreme point and check its membership in P in polynomial time.

A consequence of Farkas Lemma is that the decision problem of testing membership of input (A, b) in the language

$$\mathcal{L}_I = \{(A, b) : \exists\, x \;\text{ such that }\; Ax \leq b\}$$

is in $\mathcal{NP} \bigcap co\mathcal{NP}$. That $\mathcal{L}_I$ can be recognized in polynomial time, follows from algorithms for linear programming that we now discuss.

We are now ready for a tour of some algorithms for linear programming. We start with the classical technique of Fourier, which is interesting because of its simple syntactic specification. It leads to simple proofs of the duality principle of linear programming that was alluded to above. We will then review the simplex method of linear programming [19], a method that uses the vertex-edge structure of a convex polyhedron to execute an optimization march. The simplex method has been finely honed over almost five decades now. We will spend some time with the ellipsoid method and in particular with the polynomial equivalence of solvability (optimization) and **separation** problems. This aspect of the ellipsoid method [35] has had a major impact on the identification of many tractable classes of combinatorial optimization problems. We conclude the tour of the basic methods with a description of Karmarkars [47] breakthrough in 1984, which was an important landmark in the brief history of linear programming. A noteworthy role of interior point methods has been to make practical the theoretical demonstrations of tractability of various aspects of linear programming, including solvability and optimization, that were provided via the ellipsoid method.

In later sections we will review the more sophisticated (and naturally esoteric) aspects of linear programming algorithms. This will include **strongly polynomial** algorithms for special cases, randomized algorithms and specialized methods for large-scale linear programming. Some readers may notice that we do not have a special section devoted to the discussion of parallel computation in the context of linear programming. This is partly because we are not aware of a well developed framework for such a discussion. We have instead introduced discussion and remarks about the effects of parallelism in the appropriate sections of this chapter.

31.4 Fourier's Projection Method

Linear programming is at the starting point for variable elimination techniques on algebraic constraints [12], which in turn forms the core of algebraic and symbolic computation. Constraint systems of linear *inequalities* of the form $Ax \leq b$, where A is an $m \times n$ matrix of real numbers are widely used in mathematical models. Testing the solvability of such a system is equivalent to linear programming. We now describe the elegant syntactic variable elimination technique due to Fourier [30].

Suppose we wish to eliminate the first variable x_1 from the system $Ax \leq b$. Let us denote

$$I^+ = \{i : A_{i1} > 0\} \quad I^- = \{i : A_{i1} < 0\} \quad I^0 = \{i : A_{i1} = 0\} \ .$$

Our goal is to create an equivalent system of linear inequalities $\tilde{A}\tilde{x} \leq \tilde{b}$ defined on the variables $\tilde{x} = (x_2, x_3, \cdots, x_n)$.

- If I^+ is empty then we can simply delete all the inequalities with indices in I^-, since they can be trivially satisfied by choosing a large enough value for x_1. Similarly, if I^- is empty we can discard all inequalities in I^+.
- For each $k \in I^+$, $l \in I^-$ we add $-A_{l1}$ times the inequality $A_k x \leq b_k$ to A_{k1} times $A_l x \leq b_l$. In these new inequalities the coefficient of x_1 is wiped out, i.e., x_1 is eliminated. Add these new inequalities to those already in I^0.
- The inequalities $\{\tilde{A}_{i1}\tilde{x} \leq \tilde{b}_i\}$ for all $i \in I^0$ represent the equivalent system on the variables $\tilde{x} = (x_2, x_3, \cdots, x_n)$.

Repeat this construction with $\tilde{A}\tilde{x} \leq \tilde{b}$ to eliminate x_2 and so on until all variables are eliminated. If the resulting $\tilde{b}$ (after eliminating x_n) is nonnegative we declare the original (and intermediate) inequality

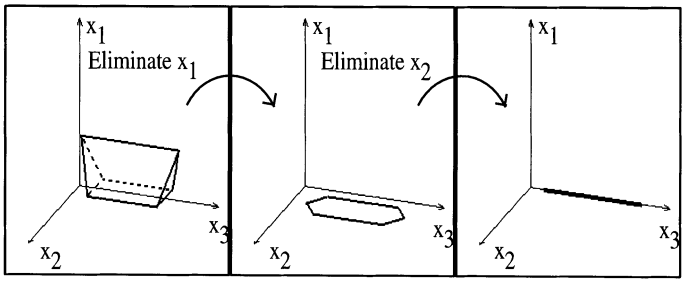

FIGURE 31.1 Variable elimination and projection.

systems as being consistent. Otherwise[3] $\tilde{b} \not\geq 0$ and we declare the system inconsistent.

As an illustration of the power of elimination as a tool for theorem proving, we show now that Farkas Lemma is a simple consequence of the correctness of Fourier elimination. The lemma gives a direct proof that solvability of linear inequalities is in $\mathcal{NP} \bigcap co\mathcal{NP}$.

Farkas Lemma Exactly one of the alternatives

$$I. \quad \exists\, x \in \Re^n \,:\, Ax \leq b \qquad II. \quad \exists\, y \in \Re^m_+ \,:\, y^t A = 0,\ y^t b < 0$$

is true for any given real matrices $A,\ b$.

PROOF Let us analyze the case when Fourier Elimination provides a proof of the inconsistency of a given linear inequality system $Ax \leq b$. The method clearly converts the given system into $RAx \leq Rb$ where RA is zero and Rb has at least one negative component. Therefore, there is some row of R, say r, such that $rA = 0$ and $rb < 0$. Thus $\neg I$ implies II. It is easy to see that I and II cannot both be true for fixed A, b.

In general, the Fourier elimination method is quite inefficient. Let k be any positive integer and n the number of variables be $2^k + k + 2$. If the input inequalities have left-hand sides of the form $\pm x_r \pm x_s \pm x_t$ for all possible $1 \leq r < s < t \leq n$, it is easy to prove by induction that after k variables are eliminated, by Fourier's method, we would have at least $2^{\frac{n}{2}}$ inequalities. The method is therefore exponential in the worst case and the explosion in the number of inequalities has been noted, in practice as well, on a wide variety of problems. We will discuss the central idea of minimal generators of the projection cone that results in a much improved elimination method [41].

First let us identify the set of variables to be eliminated. Let the input system be of the form

$$P = \left\{ (x, u) \in \Re^{n_1+n_2} \mid Ax + Bu \leq b \right\},$$

where u is the set to be eliminated. The projection of P onto x or equivalently the effect of eliminating the u variables is

$$P_x = \left\{ x \in \Re^{n_1} \mid \exists u \in \Re^{n_2} \text{ such that } Ax + Bu \leq b \right\}.$$

Now W, the *projection cone* of P, is given by

$$W = \left\{ w \in \Re^m \mid wB = 0,\ w \geq 0 \right\}.$$

[3]Note that the final $\tilde{b}$ may not be defined if all the inequalities are deleted by the monotone sign condition of the first step of the construction described above. In such a situation we declare the system $Ax \leq b$ *strongly consistent,* since it is consistent for any choice of b in $\Re^m$. In order to avoid making repeated references to this exceptional situation, let us simply assume that it does not occur. The reader is urged to verify that this assumption is indeed benign.

A simple application of Farkas Lemma yields a description of P_x in terms of W.

Projection Lemma Let G be any set of generators (e.g., the set of extreme rays) of the cone W. Then $P_x = \{ x \in \Re^{n_1} \mid (gA)x \leq gb \quad \forall\, g \in G \}$.

The lemma, sometimes attributed to Černikov [10], reduces the computation of P_x to enumerating the extreme rays of the cone W or equivalently the extreme points of the polytope $W \cap \{ w \in \Re^m \mid \Sigma_{i=1}^m w_i = 1 \}$.

31.5 The Simplex Method

Consider a polyhedron $\mathcal{K} = \{x \in \Re^n : \ Ax = b, \ x \geq 0\}$. Now $\mathcal{K}$ cannot contain an infinite (in both directions) line, since it is lying within the nonnegative orthant of $\Re^n$. Such a polyhedron is called a *pointed* polyhedron. Given a pointed polyhedron $\mathcal{K}$ we observe that

- If $\mathcal{K} \neq \emptyset$ then $\mathcal{K}$ has at least one extreme point.
- If $\min\{cx : \ Ax = b, \ x \geq 0\}$ has an optimal solution, then it has an optimal extreme point solution.

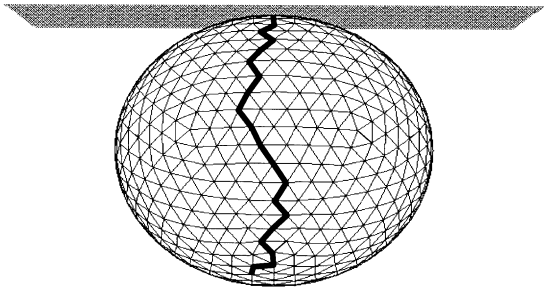

FIGURE 31.2 The simplex path.

These observations together are sometimes called the fundamental theorem of linear programming since they suggest simple finite tests for both solvability and optimization. To generate all extreme points of $\mathcal{K}$, in order to find an optimal solution, is an impractical idea. However, we may try to run a partial search of the space of extreme points for an optimal solution. A simple local improvement search strategy of moving from extreme point to adjacent extreme point until we get to a local optimum is nothing but the simplex method of linear programming [19, 20]. The local optimum also turns out to be a global optimum, because of the convexity of the polyhedron $\mathcal{K}$ and the objective function cx.

Procedure: **Primal Simplex**($\mathcal{K}$,c)

0. **Initialize:**
   - x_0 := an extreme point of $\mathcal{K}$
   - $k := 0$
1. **Iterative Step:**

   do

   If for all edge directions $\mathcal{D}_k$ at x_k, the objective function is

nondecreasing, i.e.,

$$cd \geq 0 \quad \forall\, d \in \mathcal{D}_k$$

then exit and return optimal x_k.

Else pick some d_k in $\mathcal{D}_k$ such that $cd_k < 0$.

If $d_k \geq 0$ **then** declare the linear program unbounded in objective value and exit.

Else $x_{k+1} := x_k + \theta_k * d_k$, where

$$\theta_k = \max\{\theta : x_k + \theta * d_k \geq 0\}$$

$k := k + 1$

od

2. **End**

Remarks:

1. In the initialization step we assumed that an extreme point x_0 of the polyhedron $\mathcal{K}$ is available. This also assumes that the solvability of the constraints defining $\mathcal{K}$ has been established. These assumptions are reasonable since we can formulate the solvability problem as an optimization problem, with a self-evident extreme point, whose optimal solution either establishes unsolvability of $Ax = b,\ x \geq 0$, or provides an extreme point of $\mathcal{K}$. Such an optimization problem is usually called a Phase I model. The point is, of course, that the simplex method as described above can be invoked on the Phase I model and if successful, can be invoked once again to carry out the intended minimization of cx. There are several different formulations of the Phase I model that have been advocated. Here is one.

$$\min\{v_0 : Ax + bv_0 = b,\ x \geq 0,\ v_0 \geq 0\}\ .$$

   The solution $(x, v_0)^T = (0, \cdots, 0, 1)$ is a self-evident extreme point, and $v_0 = 0$ at an optimal solution of this model is a necessary and sufficient condition for the solvability of $Ax = b,\ x \geq 0$.
2. The scheme for generating improving edge directions uses an algebraic representation of the extreme points as certain bases, called feasible bases, of the vector space generated by the columns of the matrix A. It is possible to have linear programs for which an extreme point is geometrically overdetermined (degenerate), i.e., there are more than d facets of $\mathcal{K}$ that contain the extreme point, where d is the dimension of $\mathcal{K}$. In such a situation, there would be several feasible bases corresponding to the same extreme point. When this happens, the linear program is said to be *primal degenerate.*
3. There are two sources of nondeterminism in the primal simplex procedure. The first involves the choice of edge direction d_k made in Step 1. At a typical iteration there may be many edge directions that are improving in the sense that $cd_k < 0$. Dantzig's Rule, Maximum Improvement Rule, and Steepest Descent Rule are some of the many rules that have been used to make the choice of edge direction in the simplex method. There is, unfortunately, no clearly dominant rule, and successful codes exploit the empirical and analytic insights that have been gained over the years to resolve the edge selection nondeterminism in the simplex method.
   The second source of nondeterminism arises from degeneracy. When there are multiple feasible bases corresponding to an extreme point, the simplex method has to pivot from basis to adjacent basis by picking an entering basic variable (a pseudo edge direction) and by dropping

one of the old ones. A wrong choice of the leaving variables may lead to cycling in the sequence of feasible bases generated at this extreme point. Cycling is a serious problem when linear programs are highly degenerate, as in the case of linear relaxations of many combinatorial optimization problems. The Lexicographic Rule (Perturbation Rule) for choice of leaving variables in the simplex method is a provably finite method (i.e., all cycles are broken).
A clever method proposed by Bland (cf. [71]) preorders the rows and columns of the matrix A. In case of nondeterminism in either entering or leaving variable choices, Bland's Rule just picks the lowest index candidate. All cycles are avoided by this rule also.

Implementation Issues: Basis Representations

The enormous success of the simplex method has been primarily due to its ability to solve large size problems that arise in practice. A distinguishing feature of many of the linear problems that are solved routinely in practice, is the sparsity of the constraint matrix. So from a computational point of view, it is desirable to take advantage of the sparseness of the constraint matrix. Another important consideration in the implementation of the simplex method is to control the accumulation of round off errors that arise because the arithmetic operations are performed with only a fixed number of digits and the simplex method is an iterative procedure.
An algebraic representation of the simplex method in matrix notation is as follows:

0: Find an initial feasible extreme point x^0, and the corresponding feasible basis B (of the vector space generated by the columns of the constraint matrix A). If no such x_0 exists, stop, there is no feasible solution. Otherwise, let $t = 0$, and go to Step 1.

1: Partition the matrix A as $A = (B, N)$, the solution vector x as $x = (x_B, x_N)$ and the objective function vector c as $c = (c_B, c_N)$, corresponding to the columns in B.

2: The extreme point x^t is given by $x^t = (x_B, 0)$, where $Bx_B = b$

3: Solve the system $\pi_B\ B = c_B$ and calculate $r = c_N - \pi_B\ N$. If $r \geq 0$, stop, the current solution $x^t = (x_B, 0)$ is optimal. Otherwise, let $r_k = \min_j\{r_j\}$, where r_j is the jth component of r (actually one may pick any $r_j < 0$ as r_k).

4: Let a_k denote the kth column of N corresponding to r_k. Find y_k such that $B\ y_k = a_k$

5: Find $x_B(p)/y_{pk} = \min_i\{x_B(i)/y_{ik} :\ y_{ik} > 0\}$ where $x_B(i)$ and y_{ik} denote the ith component of x_B and y_k, respectively.

6: The new basis $\hat{B}$ is obtained from B by replacing the pth column of B by the kth column of N. Let the new feasible basis $\hat{B}$ be denoted as B. Return to Step 1.

LU Factorization

At each iteration, the simplex method requires the solution of the following systems:
$Bx_B = b$; $\pi_B B = c_B$ and $By_k = a_k$.

After row interchanges, if necessary, any basis B can be factorized as $B = LU$ where L is a lower triangular matrix and U is an upper triangular matrix. So solving $LUx_B = b$ is equivalent to solving the triangular systems $Lv = b$ and $Ux_B = v$. Similarly, for $By_k = a_k$, we solve $Lw = a_k$ and $Uy_k = w$. Finally, for $\pi_B B = c_B$, we solve $\pi_B L = \lambda$ and $\lambda U = c_B$.

Let the current basis B and the updated basis $\hat{B}$ be represented as
$B = (a_1, a_2, \ldots, a_{p-1}, a_p, a_{p+1}, \ldots, a_m)$ and $\hat{B} = (a_1, a_2, \ldots, a_{p-1}, a_{p+1}, a_{p+2}, \ldots, a_m, a_k)$.

An efficient implementation of the simplex method requires the updating of the triangular matrices L and U as triangular matrices $\hat{L}$ and $\hat{U}$ where $B = LU$ and $\hat{B} = \hat{L}\hat{U}$. This is done by first obtaining $H = (u_1, u_2, \ldots, u_{p-1}, u_{p+1}, \ldots, u_m, w)$ where u_i is the ith column of U and $w = L^{-1}a_k$. The matrix H has zeros below the main diagonal in the first $p-1$ columns and zeros below the element immediately under the diagonal in the remaining columns. The matrix H can be reduced to an upper triangular matrix by Gaussian elimination which is equivalent to multiplying H on the left by matrices $M_i,\ i = p, p+1, \ldots, m-1$, where M_j differs from an identity matrix in column j which is given by $(0, \ldots, 0, 1, m_j, 0 \ldots 0)^T$, where m_j is in position $j+1$. Now $\hat{U}$ is given by $\hat{U} = M_{m-1}, M_{m-2}, \ldots, M_p H$ and $\hat{L}$ is given by $\hat{L} = LM_p^{-1}, \ldots, M_{m-1}^{-1}$. Note that M_j^{-1} is M_j with the sign of the off-diagonal term m_j reversed.

The LU factorization preserves the sparsity of the basis B, in that the number of non-zero entries in L and U is typically not much larger than the number of non-zero entries in B. Furthermore, this approach effectively controls the accumulation of round off errors and maintains good numerical accuracy. In practice, the LU factorization is periodically recomputed for the matrix $\hat{B}$ instead of updating the factorization available at the previous iteration. This computation of $\hat{B} = \hat{L}\hat{U}$ is achieved by Gaussian elimination to reduce $\hat{B}$ to an upper triangular matrix (for details, see for instance [37, 61, 62]). There are several variations of the basic idea of factorization of the basis matrix B, as described here, to preserve sparsity and control round off errors.

REMARK 31.1 The simplex method is not easily amenable to parallelization. However, some steps such as identification of the entering variable and periodic refactorization can be efficiently parallelized.

Geometry and Complexity of the Simplex Method

An elegant geometric interpretation of the simplex method can be obtained by using a *column space representation* [20], i.e., $\Re^{m+1}$ coordinatized by the rows of the $(m+1) \times n$ matrix $\begin{pmatrix} c \\ A \end{pmatrix}$. In fact it is this interpretation that explains why it is called the simplex method. The bases of A correspond to an arrangement of simplicial cones in this geometry, and the pivoting operation corresponds to a physical pivot from one cone to an adjacent one in the arrangement. An interesting insight that can be gained from the column space perspective is that Karmarkar's interior point method can be seen as a natural generalization of the simplex method [14, 77].

However, the geometry of linear programming, and of the simplex method, has been largely developed in the space of the x variables, i.e., in $\Re^n$. The simplex method walks along edge paths on the combinatorial graph structure defined by the boundary of convex polyhedra. These graphs are quite dense (Balinski's Theorem [83] states that the graph of d-dimensional polyhedron must be d-connected). A polyhedral graph can also have a huge number of vertices since the Upper Bound Theorem of McMullen, see [83], states that the number of vertices can be as large as $O(k^{\lfloor d/2 \rfloor})$ for a polytope in d dimensions defined by k constraints. Even a polynomial bound on the diameter of polyhedral graphs is not known. The best bound obtained to date is $O(k^{1+\log d})$ of a polytope in d dimensions defined by k constraints. Hence it is no surprise that there is no known variant of the simplex method with a worst-case polynomial guarantee on the number of iterations.

Klee and Minty [49] exploited the sensitivity of the original simplex method of Dantzig, to projective scaling of the data, and constructed exponential examples for it. These examples were simple projective distortions of the hypercube to embed long isotonic (improving objective value) paths in the graph. Scaling is used in the Klee–Minty construction, to trick the choice of entering variable (based on most negative reduced cost) in the simplex method and thus keep it on an exponential path. Later, several variants of the entering variable choice (best improvement, steepest descent, etc.) were all shown to be susceptible to similar constructions of exponential examples (cf. [71]).

Despite its worst-case behavior, the simplex method has been the veritable workhorse of linear programming for five decades now. This is because both empirical [7, 20] and probabilistic [9, 39] analyses indicate that the number of iterations of the simplex method is just slightly more than linear in the dimension of the primal polyhedron.

The ellipsoid method of Shor [76] was devised to overcome poor scaling in convex programming problems and therefore turned out to be the natural choice of an algorithm to first establish polynomial-time solvability of linear programming. Later Karmarkar [47] took care of both projection and scaling simultaneously and arrived at a superior algorithm.

31.6 The Ellipsoid Method

The Ellipsoid Algorithm of Shor [76] gained prominence in the late 1970s when Haćijan (pronounced Khachiyan) [38] showed that this convex programming method specializes to a polynomial-time algorithm for linear programming problems. This theoretical breakthrough naturally led to intense study of this method and its properties. The survey paper by Bland et al. [8] and the monograph by Akgül [2] attest to this fact. The direct theoretical consequences for combinatorial optimization problems was independently documented by Padberg and Rao [66], Karp and Papadimitriou [48], and Grötschel, Lovász and Schrijver [34]. The ability of this method to implicitly handle linear programs with an exponential list of constraints and maintain polynomial-time convergence is a characteristic that is the key to its applications in combinatorial optimization. For an elegant treatment of the many deep theoretical consequences of the ellipsoid algorithm, the reader is directed to the monograph by Lovász [51], and the book by Grötschel, Lovász and Schrijver [35].

Computational experience with the ellipsoid algorithm, however, showed a disappointing gap between the theoretical promise and practical efficiency of this method in the solution of linear programming problems. Dense matrix computations as well as the slow average-case convergence properties are the reasons most often cited for this behavior of the ellipsoid algorithm. On the positive side though, it has been noted (cf. Ecker and Kupferschmid [24]) that the ellipsoid method is competitive with the best known algorithms for (nonlinear) convex programming problems.

Let us consider the problem of testing if a polyhedron $\mathcal{Q} \in \Re^d$, defined by linear inequalities, is nonempty. For technical reasons let us assume that $\mathcal{Q}$ is rational, i.e., all extreme points and rays of $\mathcal{Q}$ are rational vectors or equivalently that all inequalities in some description of $\mathcal{Q}$ involve only rational coefficients. The ellipsoid method does not require the linear inequalities describing $\mathcal{Q}$ to be explicitly specified. It suffices to have an oracle representation of $\mathcal{Q}$. Several different types of oracles can be used in conjunction with the ellipsoid method [35, 48, 66]. We will use the *strong separation oracle* described below.

Oracle: **Strong Separation** $(\mathcal{Q}, y)$
`Given a vector` $y \in \Re^d$`, decide whether` $y \in \mathcal{Q}$`, and if not find a hyperplane that separates` y `from` $\mathcal{Q}$`; more precisely, find a vector` $c \in \Re^d$ `such that` $c^T y < \min\{c^T x : x \in \mathcal{Q}\}$.

The ellipsoid algorithm initially chooses an ellipsoid large enough to contain a part of the polyhedron $\mathcal{Q}$ if it is nonempty. This is easily accomplished because we know that if $\mathcal{Q}$ is nonempty then it has a rational solution whose (binary encoding) length is bounded by a polynomial function of the length of the largest coefficient in the linear program and the dimension of the space.

The center of the ellipsoid is a feasible point if the separation oracle tells us so. In this case, the algorithm terminates with the coordinates of the center as a solution. Otherwise, the separation oracle outputs an inequality that separates the center point of the ellipsoid from the polyhedron $\mathcal{Q}$. We translate the hyperplane defined by this inequality to the center point. The hyperplane slices the ellipsoid into two halves, one of which can be discarded. The algorithm now creates a new ellipsoid that is the minimum

volume ellipsoid containing the remaining half of the old one. The algorithm questions if the new center is feasible and so on. The key is that the new ellipsoid has substantially smaller volume than the previous one. When the volume of the current ellipsoid shrinks to a sufficiently small value, we are able to conclude that $\mathcal{Q}$ is empty. This fact is used to show the polynomial time convergence of the algorithm.

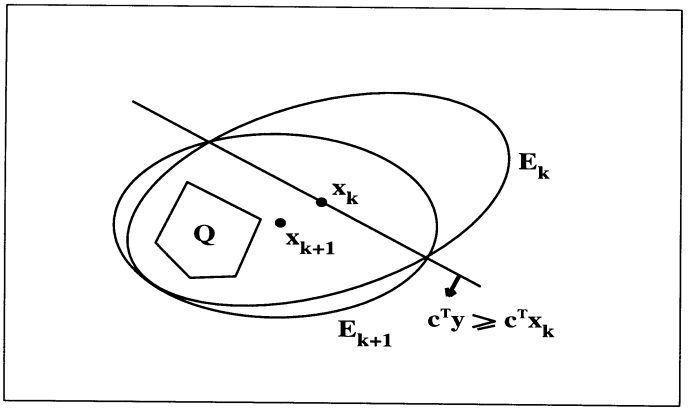

FIGURE 31.3 Shrinking ellipsoids.

Ellipsoids in $\Re^d$ are denoted as $E(A, y)$ where A is a $d \times d$ positive definite matrix and $y \in \Re^d$ is the center of the ellipsoid $E(A, y)$.

$$E(A, y) = \left\{ x \in \Re^d \;\middle|\; (x - y)^T A^{-1} (x - y) \leq 1 \right\}.$$

The ellipsoid algorithm is described on the iterated values, A_k and x^k, which specify the underlying ellipsoids $E_k(A_k, x^k)$.

Procedure: **Ellipsoid** $(\mathcal{Q})$

0. **Initialize:**
   - $N := N(\mathcal{Q})$ `(comment: iteration bound)`
   - $R := R(\mathcal{Q})$ `(comment: radius of the initial ellipsoid/sphere` E_0`)`
   - $A_0 := R^2 I$
   - $x_0 := 0$ `(comment: center of` E_0`)`
   - $k := 0$

1. **Iterative Step:**

   while $k < N$

   call `Strong Separation` $(\mathcal{Q}, x^k)$

   if $x^k \in \mathcal{Q}$ **halt**

   else `hyperplane` $\{x \in \Re^d \mid c^T x = c_0\}$ `separates` x^k `from` $\mathcal{Q}$

   Update

$$b := \frac{1}{\sqrt{c^T A_k c}} A_k c$$

$$x^{k+1} := x^k - \frac{1}{d+1} b$$

$$A_{k+1} := \frac{d^2}{d^2-1}(A_k - \frac{2}{d+1}bb^T)$$
$$k := k+1$$

endwhile

2. **Empty Polyhedron:**
   - **halt** `and` **declare** ``$\mathcal{Q}$ `is empty`''
3. **End**

The crux of the complexity analysis of the algorithm is on the a priori determination of the iteration bound. This in turn depends on three factors. The volume of the initial ellipsoid E_0, the rate of volume shrinkage ($\frac{vol(E_{k+1})}{vol(E_k)} < e^{-\frac{1}{(2d)}}$) and the volume threshold at which we can safely conclude that $\mathcal{Q}$ must be empty. The assumption of $\mathcal{Q}$ being a rational polyhedron is used to argue that $\mathcal{Q}$ can be modified into a full-dimensional polytope without affecting the decision question ("Is $\mathcal{Q}$ nonempty?"). After careful accounting for all these technical details and some others (e.g., compensating for the round-off errors caused by the square root computation in the algorithm), it is possible to establish the following fundamental result.

THEOREM 31.9 *There exists a polynomial $g(d, \phi)$ such that the* `ellipsoid method` *runs in time bounded by $T\ g(d, \phi)$ where ϕ is an upper bound on the size of linear inequalities in some description of $\mathcal{Q}$ and T is the maximum time required by the oracle* `Strong Separation`$(\mathcal{Q}, y)$ *on inputs y of size at most $g(d, \phi)$.*

The size of a linear inequality is just the length of the encoding of all the coefficients needed to describe the inequality. A direct implication of the theorem is that solvability of linear inequalities can be checked in polynomial time if strong separation can be solved in polynomial time. This implies that the standard linear programming solvability question has a polynomial-time algorithm (since separation can be effected by simply checking all the constraints). Happily, this approach provides polynomial-time algorithms for much more than just the standard case of linear programming solvability. The theorem can be extended to show that the optimization of a linear objective function over $\mathcal{Q}$ also reduces to a polynomial number of calls to the strong separation oracle on $\mathcal{Q}$. A converse to this theorem also holds, namely separation can be solved by a polynomial number of calls to a solvability/optimization oracle [35]. Thus, optimization and separation are polynomially equivalent. This provides a very powerful technique for identifying tractable classes of optimization problems. Semidefinite programming and submodular function minimization are two important classes of optimization problems that can be solved in polynomial time using this property of the ellipsoid method.

Semidefinite Programming

The following optimization problem, defined on symmetric $(n \times n)$ real matrices,

$$(SDP) \quad \min_{X \in \Re^{n \times n}} \left\{ \sum_{ij} C \bullet X : A \bullet X = B,\ X \succeq 0 \right\},$$

is called a semidefinite program. Note that $X \succeq 0$ denotes the requirement that X is a positive semidefinite matrix, and $F \bullet G$ for $n \times n$ matrices F and G denotes the product matrix $(F_{ij} * G_{ij})$. From the definition of positive semi-definite matrices, $X \succeq 0$ is equivalent to

$$q^T X q \ \geq\ 0 \quad \text{for every } \ q \in \Re^n\ .$$

Thus (SDP) is really a linear program on $O(n^2)$ variables with an (uncountably) infinite number of linear inequality constraints. Fortunately, the strong separation oracle is easily realized for these constraints. For a given symmetric X we use Cholesky factorization to identify the minimum eigenvalue λ_{min}. If λ_{min} is nonnegative then $X \succeq 0$ and if, on the other hand, λ_{min} is negative we have a separating inequality

$$\gamma_{min}^T X \gamma_{min} \geq 0 ,$$

where γ_{min} is the eigenvector corresponding to λ_{min}. Since the Cholesky factorization can be computed by an $O(n^3)$ algorithm, we have a polynomial-time separation oracle and an efficient algorithm for (SDP) via the Ellipsoid method. Alizadeh [3] has shown that interior point methods can also be adapted to solving (SDP) to within an additive error ϵ in time polynomial in the size of the input and $\log \frac{1}{\epsilon}$.

This result has been used to construct efficient approximation algorithms for maximum stable sets and cuts of graphs [33], Shannon capacity of graphs, minimum colorings of graphs. It has been used to define hierarchies of relaxations for integer linear programs that strictly improve on known exponential-size linear programming relaxations [52].

Minimizing Submodular Set Functions

The minimization of submodular set functions is a generic optimization problem that contains a large class of important optimization problems as special cases [26]. Here we will see why the ellipsoid algorithm provides a polynomial-time solution method for submodular minimization.

DEFINITION 31.3 Let N be a finite set. A real valued set function f defined on the subsets of N is

- submodular if $f(X \cup Y) + f(X \cap Y) \leq f(X) + f(Y)$ for $X, Y \subseteq N$.

EXAMPLE 31.1:

Let $G = (V, E)$ be an undirected graph with V as the node set and E as the edge set. Let $c_{ij} \geq 0$ be the weight or capacity associated with edge $(ij) \in E$. For $S \subseteq V$, define the cut function $c(S) = \Sigma_{i \in S,\, j \in V \setminus S} c_{ij}$. The cut function defined on the subsets of V is submodular since $c(X) + c(Y) - c(X \cup Y) - c(X \cap Y) = \Sigma_{i \in X \setminus Y,\, j \in Y \setminus X} 2c_{ij} \geq 0$.

The optimization problem of interest is

$$\min\{f(X) : X \subseteq N\} .$$

The following remarkable construction that connects submodular function minimization with convex function minimization is due to Lovász (cf. [35]).

DEFINITION 31.4 *The Lovász extension* $\hat{f}(.)$ of a submodular function $f(.)$ satisfies

- $\hat{f} : [0, 1]^N \rightarrow \Re$.
- $\hat{f}(x) = \Sigma_{I \in \mathcal{I}} \lambda_I f(x_I)$ where $x = \Sigma_{I \in \mathcal{I}} \lambda_I x_I$, $x \in [0, 1]^N$, x_I is the incidence vector of I for each $I \in \mathcal{I}$, $\lambda_I > 0$ for each I in $\mathcal{I}$, and $\mathcal{I} = \{I_1, I_2, \cdots, I_k\}$ with $\emptyset \neq I_1 \subset I_2 \subset \cdots \subset I_k \subseteq N\}$. Note that the representation $x = \Sigma_{I \in \mathcal{I}} \lambda_I x_I$ is unique given that the $\lambda_I > 0$ and that the sets in $\mathcal{I}$ are nested.

It is easy to check that $\hat{f}(.)$ is a convex function. Lovász also showed that the minimization of the submodular function $f(.)$ is a special case of convex programming by proving

$$\min\{f(X) : X \subseteq N\} = \min\left\{\hat{f}(x) : x \in [0, 1]^N\right\} .$$

Further, if x^* is an optimal solution to the convex program and

$$x^* = \sum_{I \in \mathcal{I}} \lambda_I x_I ,$$

then for each $\lambda_I > 0$, it can be shown that $I \in \mathcal{I}$ minimizes f. The ellipsoid method can be used to solve this convex program (and hence submodular minimization) using a polynomial number of calls to an oracle for f (this oracle returns the value of $f(X)$ when input X).

31.7 Interior Point Methods

The announcement of the polynomial solvability of linear programming followed by the probabilistic analyses of the simplex method in the early 1980s left researchers in linear programming with a dilemma. We had one method that was good in a theoretical sense but poor in practice and another that was good in practice (and on average) but poor in a theoretical worst-case sense. This left the door wide open for a method that was good in both senses. Narendra Karmarkar closed this gap with a breathtaking new projective scaling algorithm. In retrospect, the new algorithm has been identified with a class of nonlinear programming methods known as logarithmic barrier methods. Implementations of a primal-dual variant of the logarithmic barrier method have proven to be the best approach at present. The recent monogragh by S.J. Wright [81] is dedicated to primal-dual interior point methods. It is a variant of this method that we describe below.

It is well known that moving through the interior of the feasible region of linear program using the negative of the gradient of the objective function, as the movement direction, runs into trouble because of getting "jammed" into corners (in high dimensions, corners make up most of the interior of a polyhedron). This jamming can be overcome if the negative gradient is balanced with a "centering" direction. The centering direction in Karmarkar's algorithm is based on the **analytic center** y_c of a full dimensional polyhedron $\mathcal{D} = \{x : A^T y \leq c\}$ which is the unique optimal solution to

$$\max \left\{ \sum_{j=1}^{n} \ln(z_j) : A^T y + z = c \right\} .$$

Recall the primal and dual forms of a linear program may be taken as

$$\begin{aligned} (P) \quad & \min \{cx : Ax = b,\ x \geq 0\} \\ (D) \quad & \max \left\{ b^T y : A^T y \leq c \right\} . \end{aligned}$$

The logarithmic barrier formulation of the dual (D) is

$$(D_\mu) \quad \max \left\{ b^T y + \mu \sum_{j=1}^{n} \ln (z_j) : A^T y + z = c \right\} .$$

Notice that (D_μ) is equivalent to (D) as $\mu \to 0^+$. The optimality (Karush–Kuhn–Tucker) conditions for (D_μ) are given by

$$\begin{aligned} D_x D_z e &= \mu e \\ Ax &= b \\ A^T y + z &= c , \end{aligned}$$

where D_x and D_z denote $n \times n$ diagonal matrices whose diagonals are x and z, respectively. Notice that if we set μ to 0, the above conditions are precisely the primal-dual optimality conditions; complementary

slackness, primal and dual feasibility of a pair of optimal (P) and (D) solutions. The problem has been reduced to solving the above equations in x, y, z. The classical technique for solving equations is Newton's method which prescribes the directions

$$\begin{aligned} \Delta y &= -\left(AD_x D_z^{-1} A^T\right)^{-1} AD_z^{-1}(\mu e - D_x D_z e) \\ \Delta z &= -A^T \Delta y \\ \Delta x &= D_z^{-1}(\mu e - D_x D_z e) - D_x D_z^{-1} \Delta z\,. \end{aligned} \tag{31.2}$$

The strategy is to take one Newton step, reduce μ, and iterate until the optimization is complete. The criterion for stopping can be determined by checking for feasibility $(x, z \geq 0)$ and if the duality gap $(x^t z)$ is close enough to 0. We are now ready to describe the algorithm.

Procedure: **Primal-Dual Interior**

0. **Initialize:**
   - $x_0 > 0$, $y_0 \in \Re^m$, $z_0 > 0, \mu_0 > 0, \epsilon > 0, \rho > 0$
   - $k := 0$
1. **Iterative Step:**

   do

   Stop `if` $Ax_k = b$, $A^T y_k + z_k = c$ `and` $x_k^T z_k \leq \epsilon$.

   $x_{k+1} \leftarrow x_k + \alpha_k^P \Delta x_k$

   $y_{k+1} \leftarrow y_k + \alpha_k^D \Delta y_k$

   $z_{k+1} \leftarrow z_k + \alpha_k^D \Delta z_k$

   `/*` Δx_k, Δy_k, Δz_k `are the Newton directions from (31.2) */`

   $\mu_{k+1} \leftarrow \rho \mu_k$

   $k := k + 1$

   od
2. **End**

Remarks:

1. The primal-dual algorithm has been used in several large-scale implementations. For appropriate choice of parameters, it can be shown that the number of iterations in the worst-case is $O(\sqrt{n} \log(\epsilon_0/\epsilon))$ to reduce the duality gap from ϵ_0 to ϵ [69, 81]. While this is sufficient to show that the algorithm is polynomial time, it has been observed that the "average" number of iterations is more like $O(\log n \log(\epsilon_0/\epsilon))$. However, unlike the simplex method we do not have a satisfactory theoretical analysis to explain this observed behavior.
2. The stepsizes α_k^P and α_k^D are chosen to keep x_{k+1} and z_{k+1} strictly positive. The ability in the primal-dual scheme to choose separate stepsizes for the primal and dual variables is a major computational advantage that this method has over the pure primal or dual methods. Empirically this advantage translates to a significant reduction in the number of iterations.

3. The stopping condition essentially checks for primal and dual feasibility and near complementary slackness. Exact complementary slackness is not possible with interior solutions. It is possible to maintain primal and dual feasibility through the algorithm, but this would require a Phase I construction via artificial variables. Empirically, this feasible variant has not been found to be worthwhile. In any case, when the algorithm terminates with an interior solution, a post-processing step is usually invoked to obtain optimal extreme point solutions for the primal and dual. This is usually called the purification of solutions and is based on a clever scheme described by Megiddo [56].
4. Instead of using Newton steps to drive the solutions to satisfy the optimality conditions of (D_μ), Mehrotra [59] suggested a predictor-corrector approach based on power series approximations. This approach has the added advantage of providing a rational scheme for reducing the value of μ. It is the predictor-corrector based primal-dual interior method that is considered the current winner in interior point methods. The OB1 code of Lustig, Marsten and Shanno [53] is based on this scheme. CPLEX 4.0 [18], a general purpose linear (and integer) programming solver, also contains implementations of interior point methods.
   Saltzman [70] describes a parallelization of the OB1 method to run on shared-memory vector multiprocessor architectures. Recent computational studies of parallel implementations of simplex and interior point methods on the SGI Power Challenge (SGI R8000) platform indicate that on all but a few small linear programs in the NETLIB linear programming benchmark problem set, interior point methods dominate the simplex method in run times. New advances in handling Cholesky factorizations in parallel are apparently the reason for this exceptional performance of interior point methods.
   As in the case of the simplex method, there are a number of special structures in the matrix A that can be exploited by interior point methods to obtain improved efficiencies. Network flow constraints, generalized upper bounds (GUB), and variable upper bounds (VUB) are structures that often come up in practice and which can be useful in this context [15, 79].
5. Interior point methods, like ellipsoid methods, do not directly exploit the linearity in the problem description. Hence they generalize quite naturally to algorithms for semidefinite and convex programming problems. More details of these generalizations are given in Chapter 33 of this *Handbook.* Kamath and Karmarkar [46] have proposed an interior-point approach for integer programming problems. The main idea is to reformulate an integer program as the minimization of a quadratic energy function over linear constraints on continuous variables. Interior-point methods are applied to this formulation to find local optima.

31.8 Strongly Polynomial Methods

The number of iterations and hence the number of elementary arithmetic operations required for the ellipsoid method as well as the interior point method is bounded by a polynomial function of the number of bits required for the binary representation of the input data. Recall that the size of a rational number a/b is defined as the total number of bits required in the binary representation of a and b. The dimension of the input is the number of data items in the input. An algorithm is said to be *strongly polynomial* if it consists of only elementary arithmetic operations (performed on rationals of size bounded by a polynomial in the size of the input) and the number of such elementary arithmetic operations is bounded by a polynomial in the dimension of the input.

It is an open question as to whether there exists a strongly polynomial algorithm for the general linear programming problem. However, there are some interesting partial results:

- Tardos [78] has devised an algorithm for which the number of elementary arithmetic operations is bounded by a polynomial function of n, m and the number of bits required for the

binary representation of the elements of the constraint matrix A which is $m \times n$. The number of elementary operations does not depend upon the right-hand side or the cost coefficients.

- Megiddo [57] described a strongly polynomial algorithm for checking the solvability of linear constraints with at most two non-zero coefficients per inequality. Later, Hochbaum and Naor [40] showed that Fourier elimination can be specialized to provide a strongly polynomial algorithm for this class.
- Megiddo [58] and Dyer [22] have independently designed strongly polynomial (linear-time) algorithms for linear programming in fixed dimensions. The number of operations for these algorithms is linear in the number of constraints and independent of the coefficients but doubly exponential in the number of variables.

The rest of this section details these three results and some of their consequences.

Combinatorial Linear Programming

Consider the linear program, (LP) $Max\{cx : Ax = b,\ x \geq 0\}$, where A is a $m \times n$ integer matrix. The associated dual linear program is $Min\ \{yb\ :\ y\ A \geq c\}$. Let L be the maximum absolute value in the matrix and let $\Delta = (nL)^n$. We now describe Tardos' algorithm for solving (LP) which permits the number of elementary operations to be free of the magnitudes of the "rim" coefficients b and c.

The algorithm uses Procedure 1 to solve a system of linear inequalities. Procedure 1, in turn, calls Procedure 2 with any polynomial-time linear programming algorithm as the required subroutine. Procedure 2 finds the optimal objective function value of a linear program and a set of variables which are zero in some optimal solution, if the optimum is finite. Note that Procedure 2 only finds the optimal objective value and not an optimal solution. The main algorithm also calls Procedure 2 directly with Subroutine 1 as the required subroutine. For a given linear program, Subroutine 1 finds the optimal objective function value and a dual solution, if one exists. Subroutine 1, in turn, calls Procedure 2 along with any polynomial-time linear programming algorithm as the required subroutine. We omit the detailed descriptions of the Procedures 1 & 2 and Subroutine 1 and instead only give their input/output specifications.

Algorithm: **Tardos**

INPUT: A linear programming problem $\max\{cx : Ax = b,\ x \geq 0\}$

OUTPUT: An optimal solution, if it exists and the optimal objective function value.

1. Call Procedure 1 to test whether $\{Ax = b,\ x \geq 0\}$ is feasible. If the system is not feasible, the optimal objective function value $= -\infty$, stop.
2. Call Procedure 1, to test whether $\{yA \geq c\}$ is feasible. If the system is not feasible, the optimal objective function value $= +\infty$, stop.
3. Call Procedure 2 with the inputs as the linear program $Max\{cx : Ax = b,\ x \geq 0\}$ and Subroutine 1 as the required subroutine. Let $x_i = 0,\ i \in K$ be the set of equalities identified.
4. Call Procedure 1 to find a feasible solution x^* to $\{Ax = b,\ x \geq 0,\ x_i = 0,\ i \in K\}$. The solution x^* is optimal and the optimal objective function value is cx^*
5. **End**

Specification of Procedure 1:

INPUT: A linear system $A\,x \leq b$, where A is a $m \times n$ matrix .

OUTPUT: Either $Ax \leq b$ is infeasible or $\hat{x}$ is a feasible solution.

Specification of Procedure 2:

INPUT: Linear program $Max\{cx : Ax = b,\ x \geq 0\}$, which has a feasible solution and a subroutine which for a given integer vector $\bar{c}$ with $\| \bar{c}\|_\infty \leq n^2\ \Delta$ and a set K of indices, determines $\max\{\bar{c}x : Ax = b,\ x \geq 0,\ x_i = 0,\ i \in K\}$ and if the maximum is finite, finds an optimal dual solution.

OUTPUT: The maximum objective function value z^* of the input linear program $\max\{c\ x\ :\ A\ x = b,\ x \geq 0,\}$ and the set K of indices such $x_i = 0,\ i \in K$ for some optimum solution to the input linear program.

Specification of Subroutine 1:

INPUT: A Linear program $\max\{\bar{c}x : Ax = b,\ x \geq 0,\ x_i = 0,\ i \in K\}$, which is feasible and $\| \bar{c}\|_\infty \leq n^2\ \Delta$.

OUTPUT: The Optimal objective function value z^* and an optimal dual solution y^*, if it exists.

The validity of the algorithm and the analysis of the number of elementary arithmetic operations required are in the paper by Tardos [78]. This result may be viewed as an application of techniques from *diophantine approximation* to linear programming. A scholarly account of these connections is given in the book by Schrijver [71].

REMARK 31.2 Linear programs with $\{0,\ \pm\ 1\}$ elements in the constraint matrix A arise in many applications of polyhedral methods in combinatorial optimization. Network flow problems (shortest path, maximum flow, and transshipment) [1] are examples of problems in this class. Such linear programs, and more generally linear programs with the matrix A made up of integer coefficients of bounded magnitude, are known as *combinatorial linear programs.* The algorithm described shows that combinatorial linear programs can be solved by strongly polynomial methods.

Fourier Elimination and $LI(2)$:

We now describe a special case of the linear programming solvability problem for which Fourier elimination yields a very efficient (strongly polynomial) algorithm. This is the case $LI(2)$ of linear inequalities with at most two variables per inequality. Nelson [63] observed that Fourier elimination is subexponential in this case. He showed that the number of inequalities generated never exceeds $O(mn^{\lceil \log n \rceil} \log n)$. Later Aspvall & Shiloach [4] obtained the first polynomial-time algorithm for solving $LI(2)$ using a graph representation of the inequalities. We give a high-level description of the technique of Hochbaum & Naor [40] that combines Fourier elimination and a graph reasoning technique to obtain the best known sequential complexity bounds for $LI(2)$.

An interesting property of $LI(2)$ systems is that they are closed under Fourier elimination. Therefore, the projection of an $LI(2)$ system on to a subspace whose coordinates are a subset of the variables is also an $LI(2)$ system. Note that $LI(3)$ does not have this closure property. Indeed $LI(3)$ is unlikely to have any special property, since any system of linear inequalities can be reduced to an instance of $LI(3)$ with $0, \pm 1$ coefficients [43].

Given an instance of $LI(2)$ of the form $Ax \leq b$ with each row of A containing at most two nonzero coefficients we construct a graph $G(V,E)$ as follows. The vertices V are $x_0, x_1, \cdots, x_n$ corresponding

to the variables of the constraints (x_0 is an extra dummy variable). The edges E of G are composed of pairs (x_i, x_j) if x_i and x_j are two variables with nonzero coefficients of at least one inequality in the system. There are also edges of the form (x_0, x_k) if x_k is the only variable with a nonzero coefficient in some constraint. Let us also assume that each edge is labelled with all the inequalities associated with its existence.

Aspvall & Shiloach [4] describe a "grapevine algorithm" that takes as input a "rumour" $x_j = \alpha$ and checks its authenticity, i.e., checks if α is too small, too large, or within the range of feasible values of x_j. The idea is simply to start at node x_j and set $x_j = \alpha$. Obviously, each variable x_k that is a neighbor of x_j in G gets an implied lower bound or upper bound (or both), depending on the sign of the coefficient of x_k in the inequality shared with x_j. These bounds get propagated further to neighbors of the x_k and so on. If this propagation is carried out in a breadth-first fashion, it is not hard to argue that the implications of setting $x_j = \alpha$ are completely revealed in $3n - 2$ stages. Proofs of inconsistency can be traced back to delineate if α was either too high or too low a value for x_j.

The grapevine algorithm is similar to Bellman & Ford's classical shortest path algorithm for graphs which also takes $O(mn)$ effort. This subroutine provides the classification test for being able to execute binary search in choosing values for variables. The specialization of Fourier's algorithm for $LI(2)$ can be described now.

Algorithm Fourier $LI(2)$:

For $j = 1, 2, \cdots n$

1. The inequalities of each edge (x_j, x_k) define a convex polygon Q_{jk} in x_j, x_k-space. Compute J_k the sorted collection of x_j coordinates of the corner (extreme) points of Q_{jk}. Let J denote the sorted union (merge) of the J_k (x_k a neighbor of x_j in G).
2. Perform a binary search on the sequence J for a feasible value of x_j. If we succeed in finding a feasible value for x_j among the values in J we fix x_j at that value and contract vertex x_j with x_0. Move to the next variable $j \leftarrow j + 1$ and repeat.
3. Else we know that the sequence is too coarse and that all feasible values lie in the strict interior of some interval $[x_j^1, x_j^2]$ defined by consecutive values in J. In this latter case we prune all but the two essential inequalities, defining the edges of the polygon Q_{jk}, for each of the endpoints x_j^1 and x_j^2.
4. Eliminate x_j using standard Fourier elimination.

End

Notice that at most four new inequalities are created for each variable elimination. Also note that the size of J is always $O(m)$. The complexity is dominated by the search over J. Each search step requires a call to the "grapevine" procedure and there are at most $n \log m$ calls. Therefore the overall time-complexity is $O(mn^2 \log m)$, which is strongly polynomial in that it is polynomial and independent of the size of the input coefficients.

An open problem related to $LI(2)$ is the design of a strongly polynomial algorithm for optimization of an arbitrary linear function over $LI(2)$ constraints. This would imply, via duality, a strongly polynomial algorithm for generalized network flows (flows with gains and losses).

Fixed Dimensional LPs: Prune and Search

Consider the linear program $\max\{cx : Ax \leq b\}$ where A is a $m \times n$ matrix that includes the nonnegativity constraints. Clearly, for fixed dimension n, there is a polynomial-time algorithm because there are at most $\binom{m}{n}$ system of linear equations to be solved, to generate all extreme points of the feasible region. However, Megiddo [56] and Dyer [22] have shown that for the above linear program with fixed n, there is a linear-time algorithm that requires $O(m)$ elementary arithmetic operations on numbers of size bounded by a polynomial in the input data. The algorithm is highly recursive. Before we give an outline of the algorithm, some definitions are required.

DEFINITION 31.5 Given a linear program $\max\{cx : Ax \leq b\}$ and a linear equality $fx = q$,

(i) The inequality $fx < q$ is said to hold for the optimum if either

(a) We know that $Ax \leq b$ is feasible and
$\max\{cx : Ax \leq b, fx \leq q\} > \max\{cx : Ax \leq b, fx = q\}$

or

(b) We know a row vector $y \geq 0$ such that $yA = f$ and $yb < q$.

(ii) The inequality $fx > q$ is said to hold for the optimum if either

(a) We know that $Ax \leq b$ is feasible and
$\max\{cx : Ax \leq b, fx \geq q\} > \max\{cx : Ax \leq b, fx = q\}$

or

(b) We know a vector $y \geq 0$ such that $yA = -f$ and $yb < -q$.

DEFINITION 31.6 For a given linear program $\max\{cx : Ax \leq b\}$ and a given linear equation $fx = q$, the position of the optimum of the linear program relative to the linear equation is said to be known if either we know that $fx < q$ holds for an optimum or $fx > q$ holds for an optimum.

An outline of the algorithm is presented below. The algorithm requires an oracle, denoted as Procedure 1, with inputs as the linear program $\max\{cx : Ax \leq b\}$ where A is a $m \times n$ matrix and a system of p linear equations $Fx = d$ with the rank of F being r. The output of Procedure 1 is either a solution to the linear program (possibly unbounded or infeasible) or a set of $\lceil p/2^{2^{r-1}} \rceil$ equations in $Fx = d$ relative to each of which we know the position of the optimum of the linear program.

`Algorithm Sketch:` **Prune & Search**

`Call Procedure 1 with inputs as the linear program` $\max\{cx : Ax \leq b\}$ `and the system of` m `equations` $Ax = b$. `Procedure 1 either solves the linear program or identifies` $k = \lceil m/2^{2^{n-1}} \rceil$ `equations in` $Ax = b$ `relative to each of which we know the position of the optimum of the linear program. The identified equations are then omitted from the system` $Ax = b$. `The resulting subsystem,` $A_1x = b_1$ `has` $m_1 = m - k$ `equations. Procedure 1 is applied again with the original given linear program and the system of equations` $A_1x = b_1$ `as the inputs. This process is repeated until either the linear program is solved or we know the position of the optimum with respect to each of the equations in` $Ax = b$. `In the latter case the system` $Ax \leq b$ `is infeasible.`

We next describe the input/output specification of Procedure 1. The procedure is highly recursive and splits into a lot of cases. This procedure requires a linear-time algorithm for the identification of the median of a given set of rationals in linear time.

`Specification of Procedure 1:`

> INPUT: `Linear program` $\max\{cx : Ax \leq b\}$ `where` A `is a` $m \times n$ `matrix and a system of` p `equations` $Fx = d$ `where rank of` F `is` r.
>
> OUTPUT: `A solution to the linear program or a set of` $\lceil p/2^{2^{r-1}} \rceil$ `equations in` $Fx = d$ `relative to each of which we know the position of the optimum as in Definition 31.6.`

For fixed n, Procedure 1 requires $O(p + m)$ elementary arithmetic operations on numbers of size bounded by a polynomial in the size of the input data. Since at the outset $p = m$, algorithm `Prune & Search` solves linear programs with fixed n in linear time. Details of the validity of the algorithm as well as analysis of its linear time complexity for fixed n are given by Megiddo [56], Dyer [22], and in the book by Schrijver [71]. As might be expected, the linear-time solvability of linear programs in fixed dimension has important implications in the field of computational geometry which deals largely with two and three dimensional geometry. The book by Edelsbrunner [25] documents these connections.

The linear programming problem is known to be $\mathcal{P}$-complete and therefore we do not expect to find a parallel algorithm that achieves polylog run time. However, for fixed n, there are simple polylog algorithms [23]. In a recent paper, Sen [72] shows that linear programming in fixed dimension n can be solved in $O(\log \log^{n+1} m)$ steps using m processors in a *CRCW PRAM*.

31.9 Randomized Methods for Linear Programming

The advertising slogan for randomized algorithms has been "simplicity and speed" [60]. In the case of fixed-dimensional linear programming there appears to be some truth in the advertisement. In stark contrast with the very technical deterministic algorithm outlined in the last section, we will see that an almost trivial randomized algorithm will achieve comparable performance (but of course at the cost of determinism).

Consider a linear programming problem of the form

$$\min\{cx : Ax \leq b\},$$

with the following properties:

- The feasible region $\{x : Ax \leq b\}$ is nonempty and bounded.
- The objective function c has the form $(1, 0, \ldots, 0)$.
- The minimum to the linear program is unique and occurs at an extreme point of the feasible region.
- Each vertex of $\{x : Ax \leq b\}$ is defined by exactly n constraints where A is $m \times n$.

Note that none of these assumptions compromise the generality of the linear programming problem that we are considering.

Let $\mathcal{S}$ denote the constraints $Ax \leq b$. A feasible $B \subseteq \mathcal{S}$ is called optimal if it defines the uniquely optimal extreme point of the feasible region. The following randomized algorithm due to Sharir and Welzl [74] uses an incremental technique to obtain the optimal basis of the input linear program.

Algorithm: **ShW**

INPUT: The constraint set $\mathcal{S}$ and a feasible basis T.
OUTPUT: The optimal basis for the linear program.

1. If $\mathcal{S}$ equals T, return T;
2. Pick a random constraint $s \in \mathcal{S}$. Now define $\bar{T} = \mathbf{ShW}(\mathcal{S} \setminus \{s\}, T)$;
3. If the point defined by $\bar{T}$ satisfies s, output $\bar{T}$; Else output $\mathbf{ShW}(\mathcal{S}, \mathbf{opt}(\{s\} \cup \bar{T}))$
4. **End**

The subroutine **opt** when given an input of $n+1$ or less constraints $H \subseteq \mathcal{S}$ returns an optimal basis for the linear program with constraints defined by H (and objective function cx). It has been shown [55] that algorithm **ShW** has an expected running time of $O(\min\{mn \exp \sqrt[4]{n \ln (m+1)}, \quad n^4 2^n m\})$. Thus algorithm **ShW** is certainly linear expected time for fixed n but has a lower complexity than `Prune & Search` if n is allowed to vary.

31.10 Large-Scale Linear Programming

Linear programming problems with thousands of rows and columns are routinely solved either by variants of simplex method or by interior point methods. However, for several linear programs that arise in combinatorial optimization, the number of columns (or rows in the dual) are too numerous to be enumerated explicitly. The columns, however, often have a structure which is exploited to generate the columns as and when required in the simplex method. Such an approach, which is referred to as **column generation,** is illustrated next on the *cutting stock problem* (Gilmore and Gomory [32]), which is also known as the *bin packing problem* in the computer science literature.

Cutting Stock Problem

Rolls of sheet metal of standard length L are used to cut required lengths $l_i, i = 1, 2 \ldots, m$. The jth cutting pattern should be such that a_{ij}, the number of sheets length l_i cut from one roll of standard length L must satisfy $\Sigma_{i=1}^{m} a_{ij} l_i \leq L$. Suppose $n_i, i = 1, 2, \ldots, m$ sheets of length l_i are required. The problem is to find cutting patterns so as to minimize the number of rolls of standard length L that are used to meet the requirements. A linear programming formulation of the problem is as follows:

Let $x_j, \quad j = 1, 2, \ldots, n$ denote the number of times the jth cutting pattern is used. In general, $x_j, \quad j = 1, 2, \ldots, n$ should be an integer but in the formulation below the variables are permitted to be fractional.

$$\begin{array}{rll} (P1) & \min \sum_{j=1}^{n} x_j & \\ \text{Subject to} & \sum_{j=1}^{n} a_{ij} x_j \geq n_i & i = 1, 2, \ldots, m \\ & x_j \geq 0 & j = 1, 2, \ldots, n \\ \text{where} & \sum_{i=1}^{m} l_i a_{ij} \leq L & j = 1, 2, \ldots, n\,. \end{array}$$

The formulation can easily be extended to allow for the possibility of p standard lengths, L_k, $k = 1, 2, \ldots, p$ from which the n_i units of length $l_i, i = 1, 2, \ldots, m$ are to be cut.

The cutting stock problem can also be viewed as a bin packing problem. Several bins, each of standard capacity L are to be packed with n_i units of item i, each of which uses up capacity of l_i in a bin. The problem is to minimize the number of bins used.

Column Generation

In general, the number of columns in $(P1)$ is too large to enumerate all the columns explicitly. The simplex method, however, does not require all the columns to be explicitly written down. Given a basic feasible solution and the corresponding simplex multipliers $w_i, i = 1, 2, \ldots, m$, the column to enter the basis is determined by applying dynamic programming to solve the following knapsack problem:

$$
\begin{aligned}
(P2) \quad z = \max \quad & \sum_{i=1}^{m} w_i a_i \\
\text{Subject to} \quad & \sum_{i=1}^{m} l_i a_i \leq L \\
& a_i \geq 0 \text{ and integer } i = 1, 2, \ldots, m \, .
\end{aligned}
$$

Let $a_i^*, i = 1, 2, \ldots, m$ denote an optimal solution to $(P2)$. If $z > 1$, the kth column to enter the basis has coefficients $a_{ik} = a_i^*, i = 1, 2, \ldots, m$.

Using the identified columns, a new improved (in terms of the objective function value) basis is obtained and the column generation procedure is repeated. A major iteration is one in which $(P2)$ is solved to identify, if there is one, a column to enter the basis. Between two major iterations, several minor iterations may be performed to optimize the linear program using only the available (generated) columns.

If $z \leq 1$ the current basic feasible solution is optimal to $(P1)$. From a computational point of view, alternative strategies are possible. For instance, instead of solving $(P2)$ to optimality, a column to enter the basis can be identified as soon as a feasible solution to $(P2)$ with an objective function value greater than 1 has been found. Such an approach would reduce the time required to solve $(P2)$ but may increase the number of iterations required to solve $(P1)$.

A column, once generated may be retained, even if it comes out of the basis at a subsequent iteration, so as to avoid generating the same column again later on. However, at a particular iteration some columns that appear unattractive in terms of their reduced costs may be discarded in order to avoid having to store a large number of columns. Such columns can always be generated again subsequently, if necessary. The rationale for this approach is that such unattractive columns will rarely be required subsequently.

The dual of $(P1)$ has a large number of rows. Hence column generation may be viewed as row generation in the dual. In other words, in the dual we start with only a few constraints explicitly written down. Given an optimal solution w to the current dual problem (i.e., with only a few constraints which have been explicitly written down) find a constraint that is violated by w or conclude that no such constraint exists. The problem to be solved for identifying a violated constraint, if any, is exactly the separation problem that we encountered in Section 31.6.

Decomposition

Large-scale linear programming problems sometimes have a block diagonal structure. Consider for instance, the following linear program:

$$
\begin{aligned}
(P3) \quad & \max \sum_{j=1}^{p} c^j x^j && (31.3) \\
\text{Subject to} \quad & \sum_{j=1}^{p} A^j x^j = b && (31.4) \\
& D^j x^j = d^j \quad j = 2, 3, \ldots, p && (31.5) \\
& x^j \geq 0 \quad j = 1, 2, \ldots, p \, , && (31.6)
\end{aligned}
$$

where A^j is a $m \times n_j$ matrix; D^j is a $m_j \times n_j$ matrix; x_j is a $n_j \times 1$ column vector; c^j is a $1 \times n_j$ row vector; b is a $m \times 1$ column vector; d^j is a $m_j \times 1$ column vector.

The constraints (31.4) are referred to as the linking master constraints. The p sets of constraints (31.5) and (31.6) are referred to as subproblem constraints. Without the constraints (31.4), the problem decomposes into p separate problems which can be handled in parallel. The Dantzig–Wolfe [21] decomposition approach to solving $(P3)$ is described next.

Clearly, any feasible solution to $(P3)$ must satisfy constraints (31.5) and (31.6). Now consider the polyhedron P_j, $j = 2, 3, \ldots, p$ defined by the constraints (31.5) and (31.6). By the representation theorem of polyhedra (see Section 2) a point $x^j \in P_j$ can be written as

$$\begin{aligned} x^j &= \sum_{k=1}^{h_j} x^{jk}\rho_{jk} + \sum_{k=1}^{g_j} y^{jk}\mu_{jk} \\ \sum_{k=1}^{h_j} \rho_{jk} &= 1 \\ \rho_{jk} &\geq 0 \quad k = 1, 2, \ldots, h_j \\ \mu_{jk} &\geq 0 \quad k = 1, 2, \ldots, g_j \ , \end{aligned}$$

where x^{jk} $(k = 1, 2, \ldots, h_j)$ are the extreme points and y^{jk} $(k = 1, 2, \ldots, g_j)$ are the extreme rays of P_j.

Now substituting for x^j, $j = 2, 3, \ldots, p$ in (31.3) and (31.4), $(P3)$ is written as

$$(P4) \qquad \max \left\{ c^1x^1 + \sum_{j=2}^{p} \left[\sum_{k=1}^{h_j} \left(c^j x^{jk} \right) \rho_{jk} + \sum_{k=1}^{g_j} \left(c^j y^{jk} \right) \mu_{jk} \right] \right\}$$

$$\text{Subject to} \qquad A^1x^1 + \sum_{j=2}^{p} \left[\sum_{k=1}^{h_j} \left(A^j x^{jk} \right) \rho_{jk} + \sum_{k=1}^{g_j} \left(A^j y^{jk} \right) \mu_{jk} \right] = b \tag{31.7}$$

$$\sum_{k=1}^{h_j} \rho_{jk} = 1 \quad j = 2, 3, \ldots, p \tag{31.8}$$

$$\rho_{jk} \geq 0 \quad j = 2, 3, \ldots, p; \quad k = 1, 2, \ldots, h_j$$

$$\mu_{jk} \geq 0 \quad j = 2, 3, \ldots, p; \quad k = 1, 2, \ldots, g_j \ .$$

In general, the number of variables in $(P4)$ is an exponential function of the number of variables n_j, $j = 1, 2, \ldots, p$ in $(P3)$. However, if the simplex method is adapted to solve $(P4)$, the extreme points or the extreme rays of P_j, $j = 2, 3, \ldots, p$, and consequently the columns in $(P4)$ can be generated, as and when required, by solving the linear programs associated with the p subproblems. This column generation is described next.

Given a basic feasible solution to $(P4)$, let w and u be row vectors denoting the simplex multipliers associated with constraints (31.7) and (31.8), respectively. For $j = 2, \ldots, p$, solve the following linear programming subproblems:

$$\begin{aligned} (S_j) \qquad z_j &= \min \left(wA^j - c^j \right) x^j \\ D^j x^j &= d^j \\ x^j &\geq 0 \ . \end{aligned}$$

Suppose z_j is finite. An extreme point solution x^{jt} is then identified. If $z_j + u_j < 0$, a candidate column to enter the basis is given by $\begin{pmatrix} A^j x^{jt} \\ 1 \end{pmatrix}$. On the other hand if $z_j + u_j \geq 0$, there is no extreme point of P_j that gives a column to enter the basis at this iteration. Suppose the optimal solution to S_j is unbounded. An extreme ray y^{jt} of P_j is then identified and a candidate column to enter the basis is given by $\begin{pmatrix} A^j y^{jt} \\ 0 \end{pmatrix}$. If the simplex method is used to solve S_j, the extreme point or the extreme ray is identified automatically. If a column to enter the basis is identified from any of the subproblems, a new improved basis is obtained and the column generation procedure is repeated. If none of the subproblems identify a column to enter the basis, the current basic solution to $(P4)$ is optimal.

As in "Cutting Stock Problem," a major iteration is when the subproblems are solved. Instead of solving all the p subproblems at each major iteration, one option is to update the basis as soon as a column to enter the basis has been identified in any of the subproblems. If this option is used at each major iteration, the subproblems that are solved first are typically the ones that were not solved at the previous major iteration.

The decomposition approach is particularly appealing if the subproblems have a special structure that can be exploited. Note that only the objective functions for the subproblems change from one major iteration to another. Given the current state of the art, $(P4)$ can be solved in polynomial time (polynomial in the problem parameters of $(P3)$) by the ellipsoid method but not by the simplex method or interior point methods. However $(P3)$ can be solved in polynomial time by interior point methods.

It is interesting to note that the reverse of decomposition is also possible. In other words, suppose we start with a statement of a problem and an associated linear programming formulation with a large number columns (or rows in the dual). If the column generation (or row generation in the dual) can be accomplished by solving a "compact" linear program, then a "compact" formulation of the original problem can be obtained. Here "compact" refers to the number of rows and columns being bounded by a polynomial function of the parameters (not the number of the columns in the original linear programming formulation) in the statement of the original problem. This result due to Martin [54] enables one to solve the problem in the polynomial time by solving the compact formulation directly using interior point methods.

Compact Representation

Consider the following linear program:

$$\begin{aligned} (P5) \qquad & \min\ cx \\ \text{Subject to} \quad & Ax \geq b \\ & x \geq 0 \\ x \quad & \in \bigcap_{j=1}^{p} P_j\ , \end{aligned}$$

where A is a $m \times n$ matrix; x is a $n \times 1$ vector; c is a $1 \times n$ vector and b is a $m \times 1$ vector; $P_j,\ j = 1, 2, \ldots, p$ is a polyhedron and p is bounded by a polynomial in m and n.

Without loss of generality, it is assumed that $P_j,\ j = 1, 2, \ldots, p$ is nonempty and $(P5)$ is feasible. Given $\bar{x}$ such that $A\bar{x} \geq b$, the constraint identification or separation problem $S_j(\bar{x})$ with respect to P_j is to *either* (a) conclude that $\bar{x} \in P_j$, *or* (b) find a valid inequality $D_i^j x \leq d_i^j$ that is satisfied by $x \in P_j$ but $D_i^j \bar{x} > d_i^j$.

Suppose the separation problem $S_j(\bar{x})$ can be solved by the following linear program

$$\begin{aligned} S_j(\bar{x}) : z_j \quad &= \quad \max\ \left(\bar{x}^T G^j + g^j\right) y \\ F^j y \quad &\leq \quad f^j \\ y \quad &\geq \quad 0\ , \end{aligned}$$

where

G^j is an $n \times k$ matrix; F^j is a $r \times k$ matrix;

g^j is a $1 \times k$ vector; f^j is a $r \times 1$ vector;

y is a $k \times 1$ vector; r and k are bounded by a polynomial in m and n; and

$\bar{x} \in P_j \bigcap \{x : Ax \geq b\}$ if and only if $z_j \leq h^j \bar{x} + k_j$ where h^j is a $1 \times n$ vector and k_j is a scalar.

Now, if w^j denotes the dual variables associated with the $F^j y \leq f^j$ constraints in S_j, it follows from the duality theorem of linear programming that a **compact representation** of $(P5)$ is given by

$$\begin{array}{rcl} \min cx & & \\ \text{Subject to} \quad Ax & \geq & b \\ (F^j)^T w^j - (G^j)^T x & \geq & (g^j)^T \quad j = 1, 2, \ldots p \\ (f^j)^T w^j - h^j x & \leq & k_j \quad j = 1, 2, \ldots p \\ x & \geq & 0 \\ w^j & \geq & 0 \quad j = 1, 2, \ldots, p\,. \end{array}$$

Note that this approach to obtaining a compact formulation is predicated on being able to formulate the separation problem as a compact linear program. This may not always be possible. In fact, Yannakakis [82] shows that for a b-matching problem under a symmetry assumption, no compact formulation is possible. This despite the fact that b-matching can be solved in polynomial time using a polynomial-time separation oracle.

An Application: Neural Net Loading

The decision version of the Hopfield neural net loading problem (cf. [64]) is as follows.

Given y^i $(i = 1, 2, \ldots, p)$ where each y^i is an n-dimensional training vector whose components are $(+1, -1)$, construct a symmetric $n \times n$ synaptic weight matrix W, such that for every n-dimensional vector v whose components are $(+1, -1)$, the following holds:

$$\text{If } d\left(y^i, v\right) \leq k \text{ then } y^i = sgn(Wv) \text{ for } i = 1, 2, \ldots, p\,.$$

A feasible W would represent a Hopfield net with a radius of direct attraction of at least k around each training vector, i.e., a robust network of associative memory. Here k is specified and $d(y^i, v)$ is the Hamming distance between y^i and v. For $t = 1, 2, \ldots, p$, let $v^{tq}, q = 1, 2, \ldots, m_t$ be all the vectors whose components are $(+1, -1)$ and $d(y^t, v^{tq}) \leq k$. The Hopfield neural net loading problem is to find a matrix W such that

$$(P6) \quad \sum_{j=1}^{n} y_i^t w_{ij} v_j^{tq} \geq 1 \quad \text{for } i = 1, 2, \ldots, n;\ t = 1, 2, \ldots, p;\ \text{and } q = 1, 2, \ldots, m_t\,.$$

This is a linear program with the number of inequalities equal to $pn\binom{n}{k}$, which is huge. The synaptic weights have to be symmetric, so in addition to the inequalities given above, $(P6)$ would include the constraints $w_{ij} = w_{ji}$ for $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, n$.

Given the weights $\bar{w_{uv}}, u = 1, 2, \ldots, n, v = 1, 2, \ldots, n$, the separation problem, $S_{it}(\bar{w})$ for specified i and t, where $1 \leq i \leq n$ and $1 \leq t \leq p$, can be formulated as follows [13]:

Let

$$u_{ij}^{tq} = \begin{cases} 1 & \text{if } v_j^{tq} = -y_j^t \\ 0 & \text{if } v_j^{tq} = y_j^t\,. \end{cases}$$

Since $d(y^t, v^{tq}) \leq k$ it follows that

$$\sum_{j=1}^{n} u_{ij}^{tq} \leq k \quad q = 1, 2, \ldots, m_t\,.$$

Note that for specified i, t, and q, the inequality in $(P6)$ is equivalent to

$$\sum_{j=1}^{n} y_i^t \, w_{ij} \left[y_j^t \left(-u_{ij}^{tq} \right) + y_j^t \left(1 - u_{ij}^{tq} \right) \right] \geq 1 \, ,$$

which reduces to

$$-\sum_{j=1}^{n} 2 y_i^t \, y_j^t \, w_{ij} \, u_{ij}^{tq} + \sum_{j=1}^{n} y_i^t \, y_j^t \, w_{ij} \geq 1 \, .$$

Consequently, the separation problem after dropping the superscript q is

$$S_{it}\,(\bar{w}) : z_{it} = \max \sum_{j=1}^{n} 2 \, y_i^t \, y_j^t \, \bar{w}_{ij} \, u_{ij}^t$$

$$\text{Subject to} \quad \sum_{j=1}^{n} u_{ij}^t \leq k \tag{31.9}$$

$$0 \leq u_{ij}^t \leq 1 \quad j = 1, 2, \ldots, n \, . \tag{31.10}$$

Note that $S_{it}(\bar{w})$ is trivial to solve and always has a solution such that $u_{ij}^t = 0$ or 1. It follows that for given i and t, $\bar{w}$ satisfies the inequalities in $(P6)$ corresponding to $q = 1, 2, \ldots, m_t$ if and only if

$$z_{it} \leq \sum_{j=1}^{n} y_i^t \, y_j^t \, \bar{w}_{ij} - 1 \, .$$

Let θ_{it} and β_{ij}^t, $j = 1, 2, \ldots, n$ denote the dual variables associated with constraints (31.9) and (31.10), respectively. Now applying the compact representation result stated above, a compact formulation of the neural net loading problem $(P6)$ is as follows:

$$\begin{aligned}
\theta_{it} + \beta i j^t - 2 y_i^t y_j^t w_{ij} &\geq 0 \quad i = 1, 2, \ldots, n \quad t = 1, 2, \ldots, p \quad j = 1, 2, \ldots, n \\
k\,\theta_{it} + \sum_{j=1}^{n} \beta i j^t - \sum_{j=1}^{n} y_i^t y_j^t w_{ij} &\leq -1, \quad i = 1, 2, \ldots, n \quad t = 1, 2, \ldots, p \\
\theta_{it} &\geq 0 \quad i = 1, 2, \ldots, n; \quad t = 1, 2, \ldots, p \\
\beta_{ij}^t &\geq 0 \quad i = 1, 2, \ldots, n; \quad t = 1, 2, \ldots, p; \quad j = 1, 2, \ldots, n \, .
\end{aligned}$$

With the symmetry condition $w_{ij} = w_{ji}$ for $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, n$ added in, we now have a linear programming formulation of the Hopfield net loading problem that is compact in the size of the network $n \times n$ and the size of the training set $n \times p$.

31.11 Linear Programming: A User's Perspective

This chapter has been written for readers interested in learning about the algorithmics of linear programming. However, for someone who is primarily a user of linear programming software, there are a few important concerns that we address briefly here.

1. THE EXPRESSION OF LINEAR PROGRAMMING MODELS. The data sources from which the coefficients of a linear programming model are generated may be organized in a format that is incompatible with the linear programming software in use. Tools to facilitate this translation have come to be known as "matrix generators" [28]. Over the years such tools have evolved into more complete modeling languages (for example, AMPL [29]), and GAMS [6].

2. THE VIEWING, REPORTING, AND ANALYSIS OF RESULTS. This issue is similar to that of model expression. The results of a linear programming problem when presented as raw numerical output are often difficult for a user to digest. Report writers and modeling languages like the ones mentioned above usually provide useful features for processing the output into a user-friendly form. Because of the widespread use of linear programming in decision support, user interfaces based on spreadsheets have become popular with software vendors [73].
3. TOOLS FOR ERROR DIAGNOSIS AND MODEL CORRECTION. Many modeling exercises using linear programming involve a large amount of data and are prone to numerical as well as logical errors. Some sophisticated tools [36] are now available for helping users in this regard.
4. SOFTWARE SUPPORT FOR LINEAR PROGRAMMING MODEL MANAGEMENT. Proliferation of linear programming models can occur in practice because of several reasons. The first is that when a model is being developed, it is likely that several versions are iterated on before converging to a suitable model. Scenario analysis is the second type of source for model proliferation. Finally, iterative schemes such as those based on column generation or stochastic linear programming may require the user to develop a large number of models. The software support in optimization systems for helping users in all such situations have come to be known as tools for "model management" [28, 31].
5. THE CHOICE OF A LINEAR PROGRAMMING SOLUTION PROCEDURE. For linear programs with special structure (for example, network flows [1]) it pays to use specialized versions of linear programming algorithms. In the case of general linear optimization software, the user may be provided a choice of a solution method from a suite of algorithms. While the right choice of an algorithm is a difficult decision, we hope that insights gained from reading this chapter would help the user.

31.12 Defining Terms

Analytic center: The interior point of a polytope at which the product of the distances to the facets is uniquely maximized.

Column generation: A scheme for solving linear programs with a huge number of columns.

Compact representation: A polynomial size linear programming representation of an optimization problem.

Decomposition: A strategy of divide and conquer applied to large scale linear programs.

Duality: The relationship between a linear program and its dual.

Extreme point: A corner point of a polyhedron.

Linear program: Optimization of a linear function subject to linear equality and inequality constraints.

Matrix factorization: Representation of a matrix as a product of matrices of simple form.

Polyhedral cone: The set of solutions to a finite system of homogeneous linear inequalities on real-valued variables.

Polyhedron: The set of solutions to a finite system of linear inequalities on real-valued variables. Equivalently, the intersection of a finite number of linear half-spaces in $\Re^n$.

Polytope: A bounded polyhedron.

Relaxation: An enlargement of the feasible region of an optimization problem. Typically, the relaxation is considerably easier to solve than the original optimization problem.

Separation: Test if a given point belongs to a convex set and if it does not, identify a separating hyperplane.

Strongly polynomial: Polynomial algorithms with the number of elementary arithmetic operations bounded by a polynomial function of the dimensions of the linear program.

32.1 Abstract

Integer programming is an expressive framework for modeling and solving discrete optimization problems that arise in a variety of contexts in the engineering sciences. Integer programming representations work with implicit algebraic constraints (linear equations and inequalities on integer valued variables) to capture the feasible set of alternatives, and linear objective functions (to minimize or maximize over the feasible

[1] Readers unfamiliar with linear programming methodology are strongly encouraged to consult Chapter 31 on linear programming in this *Handbook*.

set) that specify the criterion for defining optimality. This algebraic approach permits certain natural extensions of the powerful methodologies of linear programming to be brought to bear on combinatorial optimization and on fundamental algorithmic questions in the geometry of numbers.

32.2 Introduction

In 1957 the Higgins lecturer of mathematics at Princeton, Ralph Gomory, announced that he would lecture on solving **linear programs** in integers. The immediate reaction he received was "But that's impossible!" This was his first indication that others had thought about the problem [57]. Gomory went on to work on the foundations of the subject of integer programming as a scientist at IBM from 1959 until 1970 (when he took over as Director for Research). From **cutting planes** and the polyhedral combinatorics of corner polyhedra to group knapsack **relaxations,** the approaches that Gomory developed remain striking to researchers even today.

There were other pioneers in integer programming who collectively played a similar role in developing techniques for linear programming in Boolean or 0-1 variables. These efforts were directed at combinatorial optimization problems such as routing, scheduling, layout, and network design. These are generic examples of combinatorial optimization problems that often arise in computer engineering and decision support.

Unfortunately, almost all interesting generic classes of integer programming problems are $\mathcal{NP}$-hard. The scale at which these problems arise in applications and the explosive exponential complexity of the search spaces preclude the use of simplistic enumeration and search techniques. Despite the worst-case intractability of integer programming, in practice we are able to solve many large problems and often enough with off-the-shelf software. Effective software for integer programming is usually problem specific and based on sophisticated algorithms that combine approximation methods with search schemes and that exploit mathematical (and not just syntactic) structure in the problem at hand.

An abstract formulation of combinatorial optimization is

$$(CO) \quad \min\{f(I) : I \in \mathcal{I}\}$$

where $\mathcal{I}$ is a collection of subsets of a finite ground set $E = \{e_1, e_2, \ldots, e_n\}$ and f is a criterion (objective) function that maps 2^E (the power set of E) to the reals. The most general form of an integer linear program is

$$(MILP) \quad \min_{\mathbf{x} \in \Re^n} \left\{ \mathbf{cx} : A\mathbf{x} \geq \mathbf{b},\ x_j \text{ integer } \forall\, j \in J \right\}$$

which seeks to minimize a linear function of the decision vector $\mathbf{x}$ subject to linear inequality constraints and the requirement that a subset of the decision variables are integer valued. This model captures many variants. If $J = \{1, 2, \ldots, n\}$, we say that the integer program is *pure,* and *mixed* otherwise. Linear equations and bounds on the variables can be easily accommodated in the inequality constraints. Notice that by adding in inequalities of the form $0 \leq x_j \leq 1$ for a $j \in J$ we have forced x_j to take value 0 or 1. It is such Boolean variables that help capture combinatorial optimization problems as special cases of (MILP).

The next section contains preliminaries on linear inequalities, polyhedra, linear programming, and an overview of the complexity of integer programming. These are the tools we will need to analyze and solve integer programs. Section 32.4 is the testimony on how integer programs model combinatorial optimization problems. In addition to working a number of examples of such integer programming formulations, we shall also review formal representation theories of (Boolean) **mixed integer linear programs.**

With any mixed integer program we associate a `linear programming relaxation` obtained by simply ignoring the integrality restrictions on the variables. The point being, of course, that we have polynomial-time (and practical) algorithms for solving linear programs (see Chapter 31 of this *Handbook*). Thus the linear programming relaxation of (MILP) is given by

$$(LP) \quad \min_{\mathbf{x} \in \Re^n} \{\mathbf{cx} : A\mathbf{x} \geq \mathbf{b}\}$$

The thesis underlying the integer linear programming approaches is that this linear programming relaxation retains enough of the structure of the combinatorial optimization problem to be a useful weak representation. In Section 32.5 we shall take a closer look at this thesis in that we shall encounter special structures for which this relaxation is "tight." For general integer programs, there are several alternate schemes for generating linear programming relaxations with varying qualities of approximation. A general technique for improving the quality of the linear programming relaxation is through the generation of valid inequalities or cutting planes.

The computational art of integer programming rests on useful interplays between search methodologies and algebraic relaxations. The paradigms of branch & bound and branch & cut are the two enormously effective partial enumeration schemes that have evolved at this interface. These will be discussed in Section 32.6. It may be noted that all general purpose integer programming software available today uses one or both of these paradigms.

A general principle, is that we often need to disaggregate integer formulations to obtain higher quality linear programming relaxations. To solve such huge linear programs we need specialized techniques of large-scale linear programming. These aspects are described in Chapter 31 in this *Handbook.* The reader should note that the focus in this chapter is on solving hard combinatorial optimization problems. We catalog several special structures in integer programs that lead to tight linear programming relaxations (Section 32.7) and hence to polynomial-time algorithms. These include structures such as network flows, matching, and matroid optimization problems. Many hard problems actually have pieces of these nice structures embedded in them. Successful implementations of combinatorial optimization have always used insights from special structures to devise strategies for hard problems.

The inherent complexity of integer linear programming has led to a long-standing research program in approximation methods for these problems. Linear programming relaxation and Lagrangean relaxation (Section 32.7) are two general approximation schemes that have been the real workhorses of computational practice. Primal-dual strategies and semidefinite relaxations (Section 32.8) are two recent entrants that appear to be very promising.

Pure integer programming with variables that take arbitrary integer values is a natural extension of diophantine equations in number theory. Such problems arise in the context of cryptography, dependence analysis in programs, the geometry of numbers and Presburgher arithmetic. Section 32.9 covers this aspect of integer programming.

We conclude the chapter with brief comments on future prospects in combinatorial optimization from the algebraic modeling perspective.

32.3 Preliminaries

Polyhedral Preliminaries

Polyhedral combinatorics is the study of embeddings of combinatorial structures in Euclidean space and their algebraic representations. We will make extensive use of some standard terminology from polyhedral theory. Definitions of terms not given in the brief review below can be found in [95, 124].

A (convex) **polyhedron** in $\Re^n$ can be algebraically defined in two ways. The first and more straightforward definition is the *implicit* representation of a polyhedron in $\Re^n$ as the solution set to a finite system of linear inequalities in n variables. A single linear inequality $\mathbf{ax} \leq a_0\,;\ a \neq 0$ defines a *half-space* of $\Re^n$. Therefore geometrically a polyhedron is the intersection set of a finite number of half-spaces.

A *polytope* is a bounded polyhedron. Every polytope is the convex closure of a finite set of points. Given a set of points whose convex combinations generate a polytope we have an explicit or *parametric* algebraic representation of it. A *polyhedral cone* is the solution set of a system of homogeneous linear inequalities. Every (polyhedral) cone is the conical or positive closure of a finite set of vectors. These generators of the cone provide a parametric representation of the cone. And finally a polyhedron can be alternately defined as the Minkowski sum of a polytope and a cone. Moving from one representation of any of these polyhedral

objects to another defines the essence of the computational burden of polyhedral combinatorics. This is particularly true if we are interested in "minimal" representations.

A set of points $\mathbf{x}^1, \ldots, \mathbf{x}^m$ is *affinely independent* if the unique solution of $\Sigma_{i=1}^m \lambda_i \mathbf{x}^i = \mathbf{0}$, $\Sigma_{i=1}^m \lambda_i = 0$ is $\lambda_i = 0$ for $i = 1, \ldots, m$. Note that the maximum number of affinely independent points in $\Re^n$ is $n+1$. A polyhedron P is of *dimension* k, $\dim P = k$, if the maximum number of affinely independent points in P is $k+1$. A polyhedron $P \subseteq \Re^n$ of dimension n is called *full-dimensional*.

An inequality $\mathbf{ax} \leq a_0$ is called *valid* for a polyhedron P if it is satisfied by all $\mathbf{x}$ in P. It is called *supporting* if in addition there is an $\tilde{\mathbf{x}}$ in P that satisfies $\mathbf{a}\tilde{\mathbf{x}} = a_0$. A *face* of the polyhedron is the set of all $\mathbf{x}$ in P that also satisfy a valid inequality as an equality. In general, many valid inequalities might represent the same face. Faces other than P itself are called *proper*. A *facet* of P is a maximal nonempty and proper face. A facet is then a face of P with a dimension of $\dim P - 1$. A face of dimension zero, i.e., a point $\mathbf{v}$ in P that is a face by itself, is called an **extreme point** of P. The extreme points are the elements of P that cannot be expressed as a strict convex combination of two distinct points in P. For a full-dimensional polyhedron, the valid inequality representing a facet is unique up to multiplication by a positive scalar, and facet-inducing inequalities give a minimal implicit representation of the polyhedron. Extreme points, on the other hand, give rise to minimal parametric representations of polytopes.

The two fundamental problems of linear programming (which are polynomially equivalent) are

- **Solvability.** This is the problem of checking if a system of linear constraints on real (rational) variables is solvable or not. Geometrically, we have to check if a polyhedron, defined by such constraints, is nonempty.
- **Optimization.** This is the problem (LP) of optimizing a linear objective function over a polyhedron described by a system of linear constraints.

Building on polarity in cones and polyhedra, duality in linear programming is a fundamental concept which is related to both the complexity of linear programming and to the design of algorithms for solvability and optimization. Here we will state the main duality results for optimization. If we take the *primal* linear program to be

$$(P) \quad \min_{\mathbf{x} \in \Re^n} \{\mathbf{cx} : A\mathbf{x} \geq \mathbf{b}\}$$

there is an associated *dual* linear program

$$(D) \quad \max_{\mathbf{y} \in \Re^m} \left\{\mathbf{b}^T\mathbf{y} : A^T y = \mathbf{c}^T,\ \mathbf{y} \geq \mathbf{0}\right\}$$

and the two problems satisfy the following:

1. For any $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ feasible in (P) and (D) (i.e., they satisfy the respective constraints), we have $\mathbf{c}\hat{\mathbf{x}} \geq \mathbf{b}^T\hat{\mathbf{y}}$ (**weak duality**). Consequently, (P) has a finite optimal solution if and only if (D) does.
2. $\mathbf{x}^*$ and $\mathbf{y}^*$ are a pair of optimal solutions for (P) and (D), respectively, if and only if $\mathbf{x}^*$ and $\mathbf{y}^*$ are feasible in (P) and (D) (i.e., they satisfy the respective constraints) **and** $\mathbf{cx}^* = \mathbf{b}^T\mathbf{y}^*$ (**strong duality**).
3. $\mathbf{x}^*$ and $\mathbf{y}^*$ are a pair of optimal solutions for (P) and (D), respectively, if and only if $\mathbf{x}^*$ and $\mathbf{y}^*$ are feasible in (P) and (D) (i.e., they satisfy the respective constraints) **and** $(A\mathbf{x}^* - \mathbf{b})^T\mathbf{y}^* = 0$ (**complementary slackness**).

The strong duality condition gives us a good stopping criterion for optimization algorithms. The complementary slackness condition, on the other hand gives us a constructive tool for moving from dual to primal solutions and vice-versa. The weak duality condition gives us a technique for obtaining lower bounds for minimization problems and upper bounds for maximization problems.

Note that the properties above have been stated for linear programs in a particular form. The reader should be able to check, that if for example the primal is of the form

$$(P') \quad \min_{\mathbf{x}\in\Re^n} \{\mathbf{cx} : A\mathbf{x} = \mathbf{b},\ \mathbf{x} \geq 0\}$$

then the corresponding dual will have the form

$$(D') \quad \max_{\mathbf{y}\in\Re^m} \left\{\mathbf{b}^T\mathbf{y} : A^T\mathbf{y} \leq \mathbf{c}^T\right\}$$

The tricks needed for seeing this is that any equation can be written as two inequalities, an unrestricted variable can be substituted by the difference of two nonnegatively constrained variables and an inequality can be treated as an equality by adding a nonnegatively constrained variable to the lesser side. Using these tricks, the reader could also check that duality in linear programming is involutory (i.e., the dual of the dual is the primal).

Linear Diophantine Systems

Let us first examine the simple case of solving a single equation with integer (rational) coefficients and integer variables.

$$a_1x_1 + a_2x_2 + \cdots + a_nx_n \ = \ b \tag{32.1}$$

A classical technique is to use the Euclidean algorithm to eliminate variables. Consider the first iteration in which we compute a_{12}, and the integers δ_1 and δ_2 where

$$a_{12} \ = \ gcd\,(a_1, a_2) \ = \ \delta_1 a_1 \ + \ \delta_2 a_2$$

Now we have a reduced equation that is equivalent to Eq. (32.1).

$$a_{12}x_{12} + a_3x_3 + \cdots + a_nx_n \ = \ b \tag{32.2}$$

It is apparent that integer solutions to Eq. (32.2) are linear projections of integer solutions to Eq. (32.1). However, it is not a simple elimination of a variable as happens in the case of equations over reals. It is a projection to a space whose dimension is one less than the dimension we began with. The solution scheme reduces the equation to a univariate equation and then inverts the projection maps. All of this can be accomplished in polynomial time since the Euclidean algorithm is "good."

Solving a system of linear diophantine equations $A\mathbf{x} = \mathbf{b},\ \mathbf{x} \in Z^n$ now only requires a matrix version of the simple scheme described above. An integer matrix, of full row rank, is said to be in *Hermite normal form* if it has the appearance $[L|0]$ where L is nonsingular and lower triangular with nonnegative entries satisfying the condition that the largest entry of each row is on the main diagonal. A classical result (cf. [113]) is that any integer matrix A with full row rank has a *unique* Hermite normal form HNF$(A) = AK = [L|0]$ where K is a square unimodular matrix (an integer matrix with determinant ± 1).

The matrix K encodes the composite effect of the elementary column operations on the matrix A needed to bring it to normal form. The elementary operations are largely defined by repeated invocation of the Euclidean algorithm in addition to column swaps and subtractions. Polynomial-time computability of Hermite normal forms of integer matrices was first proved by Kannan and Bachem [75] using delicate and complicated analysis of the problems of intermediate swell. Subsequently, a much easier argument based on modulo arithmetic was given by Domich, Kannan and Trotter [36]. As consequences, we have that

- *Linear Diophantine systems can be solved in polynomial time. Assuming A has been preprocessed to have full row rank, to solve $A\mathbf{x} = b, \mathbf{x} \in Z^n$ we first obtain HNF(A) = AK = [L|0]. The*

input system has a solution if and only if $L^{-1}\mathbf{b}$ *is integral and if so, a solution is given by* $\mathbf{x} = K\begin{pmatrix} L^{-1}\mathbf{b} \\ \mathbf{0} \end{pmatrix}$.

- KRONECKER: (cf. [113]) $A\mathbf{x} = \mathbf{b}, \mathbf{x} \in Z^n$ *has no solution if and only if there exists a* $\mathbf{y} \in \Re^m$ *such that* $\mathbf{y}^t A$ *is integral and* $\mathbf{y}^t\mathbf{b}$ *is not. A certificate of unsolvability is always available from the construction described above.*
- *The solutions to a linear Diophantine system are finitely generated. In fact, a set of generators can be found in polynomial time.* $\{\mathbf{x} \in Z^n | A\mathbf{x} = \mathbf{b}\} = \{\mathbf{x}^0 + \Sigma_{i=1}^m \lambda_j \mathbf{x}^j | \lambda_j \in Z\}$, $\mathbf{x}^0 = K\begin{pmatrix} L^{-1}\mathbf{b} \\ \mathbf{0} \end{pmatrix}$ *and* $[\mathbf{x}^1, \mathbf{x}^2, \cdots, \mathbf{x}^m] = K(0, I)^t$.

In summary, linear Diophantine systems are a lot like linear systems over the reals (rationals). The basic theory and complexity results for variable elimination in both constraint domains are similar. This comfortable situation changes when we move on to linear *inequalities* over the integers or equivalently to nonnegative solutions to linear Diophantine systems.

Computational Complexity of Integer Programming

Any algorithm for integer programming is a universal polynomial-time decision procedure on a nondeterministic Turing machine. This statement is credible not only because the solvable systems of linear inequalities (with rational coefficients) over integer-valued variables describe an $\mathcal{NP}$-complete language but also because integer programs are expressive enough to capture most decision problems in $\mathcal{NP}$ via straightforward reductions. This expressiveness derives from our ability to embed sentential inference and combinatorial structures with equal ease in integer programs. We will see ample demonstration of this expressiveness in the next section. This relationship of integer programming with $\mathcal{NP}$ is akin to the relationship of linear programming with $\mathcal{P}$.

Complexity of Linear Inequalities

From our earlier discussion of polyhedra, we have the following algebraic characterization of extreme points of polyhedra.

THEOREM 32.1 *Given a polyhedron P, defined by* $\{\mathbf{x} : A\mathbf{x} \leq \mathbf{b}\}$, *where A is* $m \times n$, $\mathbf{x}^i$ *is an extreme point of P if and only if it is a face of P satisfying* $A^i\mathbf{x}^i = \mathbf{b}^i$ *where* $((A^i), (\mathbf{b}^i))$ *is a submatrix of* $(A, \mathbf{b})$ *and the rank of* A^i *equals n.*

COROLLARY 32.1 The decision problem of verifying the membership of an input string $(A, \mathbf{b})$ in the language $\mathcal{L}_I = \{(A, \mathbf{b}) : \exists\, \mathbf{x}$ *such that* $A\mathbf{x} \leq \mathbf{b}\}$ belongs to $\mathcal{NP}$.

PROOF It follows from the theorem that every extreme point of the polyhedron $Q = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{b}\}$ is the solution of an $(n \times n)$ linear system whose coefficients come from $(A, \mathbf{b})$. Therefore we can guess a polynomial length string representing an extreme point and check its membership in Q in polynomial time.

A consequence of Farkas Lemma [45] (duality in linear programming) is that the decision problem of testing membership of input $(A, \mathbf{b})$ in the language

$$\mathcal{L}_I = \{(A, \mathbf{b}) : \exists\, \mathbf{x} \text{ such that } A\mathbf{x} \leq \mathbf{b}\}$$

is in $\mathcal{NP} \bigcap co\mathcal{NP}$. That $\mathcal{L}_I \in \mathcal{P}$, follows from algorithms for linear programming [77, 81]. This is as

far down the polynomial hierarchy that we can go, since $\mathcal{L}_I$ is known to be $\mathcal{P}$-complete (that is, complete for $\mathcal{P}$ with respect to log-space reductions).

Complexity of Linear Inequalities in Integer Variables

The complexity of integer programming is polynomially equivalent to the complexity of the language

$$\mathcal{L}_{IP} = \{(A, \mathbf{b}) : \exists \mathbf{x} \in Z^n \text{ such that } A\mathbf{x} \leq \mathbf{b}\}$$

We are assuming that the input coefficients in $A, \mathbf{b}$ are integers (rationals). It is very easy to encode Boolean satisfiability as a special case of $\mathcal{L}_{IP}$ with appropriate choice of $A, \mathbf{b}$ as we shall see in the next section. Hence $\mathcal{L}_{IP}$ is $\mathcal{NP}$-hard.

It remains to argue that the decision problem of verifying the membership of an input string $(A, \mathbf{b})$ in the language $\mathcal{L}_{IP}$ belongs to $\mathcal{NP}$. We will have to work a little harder since integer programs may have solutions involving numbers that are large in magnitude. Unlike the case of linear programming there is no extreme point characterization for integer programs. However, since linear diophantine systems are well behaved, we are able to salvage the following technical result that plays a similar role. Let α denote the largest integer in the integer matrices $A, \mathbf{b}$ and let $q = \max\{m, n\}$ where A is $m \times n$.

Finite Precision Lemma [103] If B is an $r \times n$ submatrix of A with rank $B < n$ then $\exists$ a nonzero integral vector $\mathbf{z} = (z_1, z_2, \cdots z_n)$ in the null space of B such that $|z_j| \leq (\alpha q)^{q+1}\ \forall j$.

Repeated use of this lemma shows that if $\{\mathbf{x} \in Z^n : A\mathbf{x} \leq \mathbf{b}\}$ is solvable then there is a polynomial size certificate of solvability and hence that $\mathcal{L}_{IP}$ belongs to $\mathcal{NP}$.

As with any $\mathcal{NP}$-hard problem, researchers have looked for special cases that are polynomial-time solvable. Table 32.1 is a summary of the important complexity classification results in integer programming that have been obtained to date.

32.4 Integer Programming Representations

We will first discuss several examples of combinatorial optimization problems and their formulation as integer programs. Then we will review a general representation theory for integer programs that gives a formal measure of the expressiveness of this algebraic approach. We conclude this section with a representation theorem due to Benders [10] that has been very useful in solving certain large-scale combinatorial optimization problems in practice.

Formulations

Formulating decision problems as integer or mixed integer programs is often considered an art form. However, there are a few basic principles which can be used by a novice to get started. As in all art forms though, principles can be violated to creative effect. We list below a number of example formulations, the first few of which may be viewed as principles for translating logical conditions into models.

1. Discrete Choice:

CONDITION	MODEL
$X \in \{s_1, s_2, \ldots, s_p\}$	$X = \sum_{j=1}^{p} s_j\ \delta_j$ $\sum_{j=1}^{p} \delta_j = 1,\ \delta_j = 0 \text{ or } 1\ \forall j$

TABLE 32.1 Summary of Complexity Results

	Input Data	Generic Problem	Complexity
	`Solvability`	`Does ∃ an x satisfying:`	
1.	$n, m, A, \mathbf{b}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	NP-complete [16, 54, 79]
2.	$n, m, A, \mathbf{b}$	$A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \in \{0, 1\}^n$	NP-complete [79, 110]
3.	$n, m, A, \mathbf{b}, d(> 0)$	$A\mathbf{x} \equiv \mathbf{b} \pmod{d}; \mathbf{x} \geq \mathbf{0}$, integer	P [6, 50]
4.	$n, m, A, \mathbf{b}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x}$ integer	P [6, 50]
5.	$n, m, A, \mathbf{b}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$	P [77, 81]
6.	$n, (m = 1), (A \geq 0), (\mathbf{b} \geq \mathbf{0})$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	NP-complete [110]
7.	$n, (m = 2), (A \geq 0), (\mathbf{b} \geq \mathbf{0})$	$a^1\mathbf{x} \geq b_1; a^2\mathbf{x} \leq b_2; \mathbf{x} \geq \mathbf{0}$, integer	NP-complete [76]
8.	$(n = k), m, A, \mathbf{b}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	P [87]
9.	$n, (m = k), A, \mathbf{b}$	$A\mathbf{x} \leq \mathbf{b}; \mathbf{x}$ integer	P [87]
	`Optimization`	`Find an x that maximizes cx subject to:`	
10.	$n, m, A, \mathbf{b}, \mathbf{c}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	NP-hard [54, 79]
11.	$n, m, A, \mathbf{b}, \mathbf{c}$	$A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \in \{0, 1\}^n$	NP-hard [79, 110]
12.	$n, (m = 1), (A \geq 0), (\mathbf{b} \geq \mathbf{0}), \mathbf{c}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	NP-hard [110]
13.	$n, (m = 1), (A \geq 0), (\mathbf{b} \geq \mathbf{0}), \mathbf{c}$	$A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \in \{0, 1\}^n$	NP-hard [110]
14.	$n, m, A, \mathbf{b}, \mathbf{c}, (d_i \geq 2 \forall i)$	$A\mathbf{x} \equiv \mathbf{b} \pmod{\mathbf{d}}; \mathbf{x} \geq \mathbf{0}$, integer	NP-hard [20]
15.	$(n = k), m, A, \mathbf{b}, \mathbf{c}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$, integer	P [87]
16.	$n, (m = k), A, \mathbf{b}, \mathbf{c}$	$A\mathbf{x} \leq \mathbf{b}; \mathbf{x}$ integer	P [87]
17.	$n, m, A, \mathbf{b}, \mathbf{c}$	$A\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}$	P [77, 81]
18.	$n, m,$ (A is graphic)[a], $\mathbf{b}_1, \mathbf{b}_2, \mathbf{d}_1, \mathbf{d}_2$	$\mathbf{d}_1 \leq \mathbf{x} \leq \mathbf{d}_2, \mathbf{b}_1 \leq A\mathbf{x} \leq \mathbf{b}_2, \mathbf{x} \in Z^n$	P [44, 101]

[a] A is a graphic matrix if it has entries from $\{0, \pm 1, \pm 2\}$ such that the sum of absolute values of the entries in any column is at most 2.

2. DICHOTOMY:

CONDITION	MODEL	
$g(\mathbf{x}) \geq 0$	$g(\mathbf{x}) \geq \delta\, \underline{g}$	$\underline{g}$ and $\underline{h}$ are
or		finite lower
$h(\mathbf{x}) \geq 0$	$h(\mathbf{x}) \geq (1 - \delta)\, \underline{h}$	bounds on g, h,
or both	$\delta = 0$ or 1	respectively.

3. K-FOLD ALTERNATIVES:

condition	model
at least k of	$g_i(\mathbf{x}) \geq \delta_i\, \underline{g}_i \quad i = 1, \ldots, m$
$g_i(\mathbf{x}) \geq 0, i = 1, \ldots, m$	$\sum_{i=1}^{m} \delta_i \leq m - k$
must hold	$\delta_i = 0$ or 1

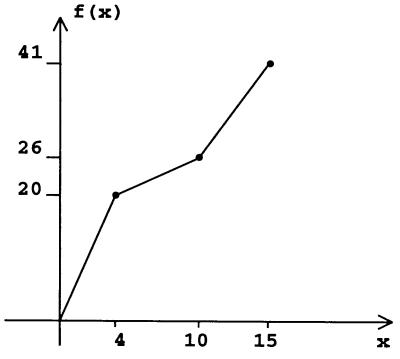
4. CONDITIONAL CONSTRAINTS:

condition	model	
$(f(\mathbf{x}) > 0 \Rightarrow g(\mathbf{x}) \geq 0)$	$g(\mathbf{x}) \geq \delta \underline{g}$	$\bar{f}/\underline{g}$ is an
$\Updownarrow$	$f(\mathbf{x}) \leq (1 - \delta)\, \bar{f}$	upper/lower bound
$(f(\mathbf{x}) \leq 0$ or $g(\mathbf{x}) \geq 0$ or *both* $)$	$\delta = 0$ or 1	on f/g

5. FIXED CHARGE MODELS:

condition	model	
$f(x) = 0$ if $x = 0$	$f(x) = Ky + cx$	
$f(x) = K + cx$ if $x > 0$	$x \le Uy$	U an upper bound
	$x \ge 0$	on x
	$y = 0$ or 1	

6. PIECEWISE LINEAR MODELS:



condition	model	
	$f(x) =$	$5\delta_1 + \delta_2 + 3\delta_3$
$\delta_2 > 0 \Rightarrow \delta_1 = 4$		$4W_1 \le \delta_1 \le 4$
$\delta_3 > 0 \Rightarrow \delta_2 = 6$		$6W_2 \le \delta_2 \le 6W_1$
		$0 \le \delta_3 \le 5W_2$
		$W_1, W_2 = 0$ or 1

FIGURE 32.1 A polyline.

7. CAPACITATED PLANT LOCATION MODEL:

$i =$	$\{1, 2, \ldots, m\}$	possible locations for plants
$j =$	$\{1, 2, \ldots, n\}$	demand sites
$k_i =$	capacity of plant i, if opened	
$f_i =$	fixed cost of opening plant i	
$c_{ij} =$	per unit production cost at i plus transportion cost from i to j	
$d_j =$	demand at location j	

Choose plant locations so as to minimize total cost and meet all demands.
Formulation:

$$\begin{aligned} \min \textstyle\sum_i \sum_j c_{ij}\, x_{ij} \quad &+ \quad \sum_i f_i\, y_i \\ s.t. \ \textstyle\sum_i x_{ij} \quad &\ge \quad d_j \ \forall j \\ \textstyle\sum_j x_{ij} \quad &\le \quad k_i\, y_i \ \forall i \\ x_{ij} \quad &\ge \quad 0 \quad \forall\, i,\ j \\ y_i \quad &= \quad 0 \text{ or } 1 \ \forall i \end{aligned}$$

If the demand d_j is less than the capacity k_i for some ij combination, it is useful to add the constraint $x_{ij} \le d_j y_i$ to improve the quality of the linear programming relaxation.

8. TRAVELING SALESMAN PROBLEM (ALTERNATE FORMULATIONS): A recurring theme in integer programming is that the same decision problem can be formulated in several different ways. Principles for sorting out the better ones have been the subject of some discourse [121]. We now illustrate this with the well-known traveling salesman problem. Given a complete directed graph D(N,A) with distance c_{ij} of arc (i, j), we are to find the minimum length tour beginning at node 1 and visiting each node of D(N,A) exactly once before returning to the start node 1.

Formulation 1:

$$\begin{aligned} \min \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}\, x_{ij} & & & \\ s.t.\ \sum_{j=1}^{n} x_{ij} &= 1 \ \forall i \\ \sum_{i=1}^{n} x_{ij} &= 1 \ \forall j \\ \sum_{i\in\phi} \sum_{j\notin\phi} x_{ij} &\geq 1 \ \forall\, \phi \subset N \\ x_{ij} &= 0 \text{ or } 1 \quad \forall\, i\ j \end{aligned}$$

Formulation 2:

$$\begin{aligned} \min \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}\, x_{ij} & & & \\ s.t.\ \sum_{j=1}^{n} x_{ij} &= 1 \ \forall i \\ \sum_{i=1}^{n} x_{ij} &= 1 \ \forall j \\ \sum_{j=1}^{n} y_{ji} - \sum_{j=2}^{n} y_{ij} &= 1 \ \forall i \neq 1 \\ y_{ij} &\leq (n-1)\, x_{ij} \quad i = 1, 2, \ldots, n \\ & \qquad\qquad j = 2, \ldots, n \\ x_{ij} &= 0 \text{ or } 1 \quad \forall ij \\ y_{ij} &\geq 0 \quad \forall ij \end{aligned}$$

9. NONLINEAR FORMULATIONS: If we allow arbitrary nonlinear objective and constraint functions the general integer programming problem is closely related to Hilbert's tenth problem and is undecidable [69]. However, when the integer variables are restricted to $0-1$, the problem is of the form

$$(NIP) \quad \min \left\{ f(\mathbf{x}) \mid g_i(\mathbf{x}) \leq 0,\ i = 1, \ldots m,\ \mathbf{x} \in \{0,1\}^n \right\}$$

and we can capture a rich variety of decision problems (modular design, cluster analysis, capital budgeting under uncertainty, and production planning in flexible manufacturing systems, to name a few). Restricting the constraints to linear assignment constraints while allowing quadratic cost functions yields the quadratic assignment problem (QAP)

$$\begin{aligned} \min \sum_{i\neq j} \sum_{k\neq l} c_{ijkl}\, x_{ik}\, x_{jl} & & & \\ s.t.\ \sum_{i} x_{ik} &= 1 \ \forall k \\ \sum_{k} x_{ik} &= 1 \ \forall i \\ x_{ik} &= 0 \text{ or } 1 \ \forall ik \end{aligned}$$

which includes the travelling salesman problem and plant location problems as special cases. Karmarkar [78] has advocated solving integer programs, by first formulating them as minimizing an indefinite quadratic function over a polyhedral region, and then solving the continuous model using interior point methods.
The other side of the coin is that these problems are extremely hard to solve, and the most successful strategies to date for these problems are via linearization techniques and semidefinite relaxations.

10. COVERING AND PACKING PROBLEMS: A wide variety of location and scheduling problems can be formulated as set covering or set packing or set partitioning problems. The three different types of covering and packing problems can be succinctly stated as follows: Given

    (a) A finite set of elements $\mathcal{M} = \{1, 2, \ldots, m\}$, and

    (b) A family F of subsets of $\mathcal{M}$ with each member $F_j,\ j = 1, 2, \ldots, n$ having a profit (or cost) c_j associated with it,

    find a collection, S, of the members of F that maximizes the profit (or minimizes the cost) while ensuring that every element of $\mathcal{M}$ is in

(P1): at most one member of S (set packing problem)

(P2): at least one member of S (set covering problem)

(P3): exactly one member of S (set partitioning problem)

The three problems (P1), (P2), and (P3) can be formulated as integer linear programs as follows:
Let A denote the $m \times n$ matrix where

$$A_{ij} = \begin{cases} 1 & \text{if element } i \in F_j \\ 0 & \text{otherwise} \end{cases}$$

The decision variables are $x_j,\ \ j = 1, 2, \ldots, n$ where

$$x_j = \begin{cases} 1 & \text{if } F_j \text{ is chosen} \\ 0 & \text{otherwise} \end{cases}$$

The set packing problem is

$$\begin{array}{lll} \text{(P1)} & \text{Max} & c\mathbf{x} \\ & \text{Subject to} & A\mathbf{x} \leq \mathbf{e}_m \\ & & x_j = 0 \text{ or } 1, \quad j = 1, 2, \ldots, n \end{array}$$

where $\mathbf{e}_m$ is an m-dimensional column vector of 1s.
The set covering problem (P2) is (P1) with less than or equal to constraints replaced by greater than or equal to constraints and the objective is to minimize rather than maximize. The set partitioning problem (P3) is (P1) with the constraints written as equalities. The set partitioning problem can be converted to a set packing problem or a set covering problem (see [98]) using standard transformations. If the right-hand side vector e_m is replaced by a nonnegative integer vector b, (P1) is referred to as the generalized set packing problem.
The airline crew scheduling problem is a classic example of the set partitioning or the set covering problem. Each element of $\mathcal{M}$ corresponds to a flight segment. Each subset F_j corresponds to an acceptable set of flight segments of a crew. The problem is to cover, at minimum cost, each flight segment exactly once. This is a set partitioning problem. If *dead heading* of crew is permitted, we have the set covering problem.

11. PACKING AND COVERING PROBLEMS IN A GRAPH: Suppose A is the node-edge incidence matrix of a graph. Now, (P1) is a weighted matching problem. If in addition, the right-hand side vector e_m is replaced by a nonnegative integer vector b, (P1) is referred to as a weighted b-matching problem. In this case, each variable x_j that is restricted to be an integer may have a positive upper bound of u_j. Problem (P2) is now referred to as the weighted edge covering problem. Note that by substituting for $x_j = 1 - y_j$, where $y_j = 0 \text{ or } 1$, the weighted edge covering problem is transformed to a weighted b-matching problem in which the variables are restricted to be 0 or 1.
Suppose A is the edge-node incidence matrix of a graph. Now, (P1) is referred to as the weighted vertex packing problem and (P2) is referred to as the weighted vertex covering problem. It is easy to see that the weighted vertex packing problem and the weighted vertex covering problem are equivalent in the sense that the complement of an optimal solution to one problem defines an optimal solution to the other. The *set packing* problem can be transformed to a weighted vertex packing problem in a graph G as follows:

G contains a node for each x_j and an edge between nodes j and k exists if and only if the columns $A_{.j}$ and $A_{.k}$ are not orthogonal. G is called the *intersection graph* of A. Given G, the complement graph $\bar{G}$ has the same node set as G, and there is an edge between nodes j and k in $\bar{G}$ if and only if there is no such corresponding edge in G. A clique in a graph is a subset, k, of nodes of G such that the subgraph induced by k is complete. Clearly, the weighted vertex packing problem in G is equivalent to finding a maximum weighted clique in $\bar{G}$.

12. SATISFIABILITY AND INFERENCE PROBLEMS: In propositional logic, a truth assignment is an assignment of "true" or "false" to each atomic proposition $x_1, x_2, \ldots, x_n$. A literal is an atomic proposition x_j or its negation $\neg x_j$. For propositions in conjunctive normal form, a clause is a disjunction of literals and the proposition is a conjunction of clauses. A clause is obviously satisfied by a given truth assignment if at least one of its literals is true. The satisfiability problem consists of determining whether there exists a truth assignment to atomic propositions such that a set S of clauses is satisfied.
Let T_i denote the set of atomic propositions such that if any one of them is assigned "true," the clause $i \in S$ is satisfied. Similarly let F_i denote the set of atomic propositions such that if any one of them is assigned "false," the clause $i \in S$ is satisfied.
The decision variables are

$$x_j = \begin{cases} 1 & \text{if atomic proposition } j \text{ is assigned true} \\ 0 & \text{if atomic proposition } j \text{ is assigned false} \end{cases}$$

The satisfiability problem is to find a feasible solution to

$$(P4) \quad \sum_{j \in T_i} x_j - \sum_{j \in F_i} x_j \geq 1 - |\, F_i \,| \;\; i \in S$$
$$x_j = 0 \text{ or } 1 \;\text{ for } j = 1, 2, \ldots, n$$

By substituting $x_j = 1 - y_j$, where $y_j = 0$ or 1, for $j \in F_i$, (P4) is equivalent to the set covering problem

$$\begin{aligned} (P5) \qquad \text{Min} \quad & \sum_{j=1}^{n} (x_j + y_j) \\ \text{subject to} \quad & \sum_{j \in T_i} x_j + \sum_{j \in F_i} y_j \geq 1 \;\; i \in S \\ & x_j + y_j \geq 1 \;\; j = 1, 2, \ldots, n \\ & x_j, y_j = 0 \text{ or } 1 \;\; j = 1, 2, \ldots, n \end{aligned}$$

Clearly (P4) is feasible if and only if (P5) has an optimal objective function value equal to n.
Given a set S of clauses and an additional clause $k \notin S$, the logical inference problem is to find out whether every truth assignment that satisfies all the clauses in S also satisfies the clause k. The logical inference problem is

$$
\begin{aligned}
(P6) \qquad \text{Min} \quad & \sum_{j \in T_k} x_j - \sum_{j \in F_k} x_j \\
\text{subject to} \quad & \sum_{j \in T_i} x_j - \sum_{j \in F_i} x_j \geq 1 - \mid F_i \mid \; i \in S \\
& x_j = 0 \text{ or } 1 \quad j = 1, 2, \ldots, n
\end{aligned}
$$

The clause k is implied by the set of clauses S, if and only if (P6) has an optimal objective function value greater than $-\mid F_k \mid$. It is also straightforward to express the MAX-SAT problem (i.e., find a truth assignment that maximizes the number of satisfied clauses in a given set S) as an integer linear program.

13. MULTI-PROCESSOR SCHEDULING: Given n jobs and m processors, the problem is to allocate each job to one and only one of the processors so as to minimize the make span time, i.e., minimize the completion time of all the jobs. The processors may not be identical and hence job j if allocated to processor i requires p_{ij} units of time. The multi-processor scheduling problem is

$$
\begin{aligned}
(P7) \quad \text{Min} \quad & T \\
\text{subject to} \quad & \sum_{i=1}^{m} x_{ij} = 1 \quad j = 1, 2, \ldots, n \\
& \sum_{j=1}^{n} p_{ij} x_{ij} - T \leq 0 \quad i = 1, 2, \ldots, m \\
& x_{ij} = 0 \text{ or } 1 \quad \forall\, i\ j
\end{aligned}
$$

Note that if all p_{ij} are integers, the optimal solution will be such that T is an integer.

Jeroslow's Representability Theorem

R. Jeroslow [70], building on joint work with J.K. Lowe [71], characterized subsets of n-space that can be represented as the feasible region of a mixed integer (Boolean) program. They proved that a set is the feasible region of some mixed integer/linear programming problem (MILP) if and only if it is the union of finitely many polyhedra having the same recession cone (defined below). Although this result is not widely known, it might well be regarded as the fundamental theorem of mixed integer modeling.

The basic idea of Jeroslow's results is that any set that can be represented in a mixed integer model can be represented in a disjunctive programming problem (i.e., a problem with either/or constraints). A *recession direction* for a set S in n-space is a vector $\mathbf{x}$ such that $\mathbf{s} + \alpha\mathbf{x} \in S$ for all $\mathbf{s} \in S$ and all $\alpha \geq 0$. The set of recession directions is denoted $rec(S)$. Consider the general mixed integer constraint set below.

$$
\begin{aligned}
& f(\mathbf{x}, \mathbf{y}, \lambda) \leq \mathbf{b} \\
& \mathbf{x} \in \Re^n, \quad \mathbf{y} \in \Re^p \\
& \lambda = (\lambda_1, \ldots, \lambda_k), \quad \text{with } \lambda_j \in \{0, 1\} \text{ for } j = 1, \ldots, k
\end{aligned}
\tag{32.3}
$$

Here $\mathbf{f}$ is vector-valued function, so that $\mathbf{f}(\mathbf{x}, \mathbf{y}, \lambda) \leq \mathbf{b}$ represents a set of constraints. We say that a set $S \subset \Re^n$ is *represented* by (32.3) if

$$
\mathbf{x} \in S \text{ if and only if } (\mathbf{x}, \mathbf{y}, \lambda) \text{ satisfies (32.3) for some } \mathbf{y}, \lambda\ .
$$

If **f** is a linear transformation, so that (32.3) is a MILP constraint set, we will say that S is *MILP representable.* The main result can now be stated.

THEOREM 32.2 **Jeroslow, Lowe [70, 71]** *A set in n-space is MILP representable if and only if it is the union of finitely many polyhedra having the same set of recession directions.*

Benders Representation

Any mixed integer linear program (MILP) can be reformulated so that there is only one continuous variable. This reformulation, due to Benders [10], will in general have an exponential number of constraints. Benders representation suggests an algorithm for mixed integer programming (known as Benders Decomposition in the literature because of its similarity to Dantzig–Wolfe Decomposition, cf. [95]) that uses dynamic activation of these rows (constraints) as and when required.

Consider the (MILP)

$$\max\{\mathbf{cx} + \mathbf{dy} :\ A\mathbf{x} + G\mathbf{y} \ \leq\ \mathbf{b},\ \mathbf{x} \geq \mathbf{0},\ y \geq \mathbf{0} \text{ and integer}\}$$

Suppose the integer variables **y** are fixed at some values, then the associated linear program is

$$(LP)\quad \max\{\mathbf{cx} : \mathbf{x} \in \mathcal{P} = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{b} - G\mathbf{y},\ \mathbf{x} \geq \mathbf{0}\}\}$$

and its dual is

$$(DLP)\quad \min\{\mathbf{w}(\mathbf{b} - G\mathbf{y}) :\ \mathbf{w} \in Q = \{\mathbf{w} : \mathbf{w}A \geq \mathbf{c},\ \mathbf{w} \geq 0\}\}$$

Let $\{\mathbf{w}^k\}$, $k = 1, 2, \ldots, K$ be the extreme points of Q and $\{\mathbf{u}^j\}$, $j = 1, 2, \ldots, J$ be the extreme rays of the recession cone of Q, $C_Q = \{\mathbf{u} : \mathbf{u}A \geq \mathbf{0},\ \mathbf{u} \geq \mathbf{0}\}$. Note that if Q is nonempty, the $\{\mathbf{u}^j\}$ are all the extreme rays of Q.

From linear programming duality, we know that if Q is empty and $\mathbf{u}^j(\mathbf{b} - G\mathbf{y}) \geq 0$, $j = 1, 2, \ldots, J$ for some $\mathbf{y} \geq \mathbf{0}$ and integer then (LP) and consequently $(MILP)$ has an unbounded solution. If Q is nonempty and $\mathbf{u}^j(\mathbf{b} - G\mathbf{y}) \geq 0$, $j = 1, 2, \ldots, J$ for some $\mathbf{y} \geq \mathbf{0}$ and integer, then (LP) has a finite optimum given by

$$\min_k \left\{\mathbf{w}^k(\mathbf{b} - G\mathbf{y})\right\}$$

Hence, an equivalent formulation of $(MILP)$ is

$$\begin{array}{rcl}
\max\ \alpha & & \\
\alpha & \leq & \mathbf{dy} + \mathbf{w}^k(\mathbf{b} - G\mathbf{y}),\quad k = 1, 2, \cdots, K \\
\mathbf{u}^j(\mathbf{b} - G\mathbf{y}) & \geq & 0,\quad j = 1, 2, \cdots, J \\
\mathbf{y} & \geq & \mathbf{0} \text{ and integer} \\
\alpha & & \text{unrestricted}
\end{array}$$

which has only one continuous variable α as promised.

Aggregation

An integer linear programming problem with only one constraint, other than upper bounds on the variables, is referred to as a **knapsack problem.** An integer linear programming problem with m constraints can be represented as a knapsack problem. In this section, we show this representation for an integer linear program with bounded variables [53, 96]. We show how two constraints can be aggregated into a single constraint. By repeated application of this aggregation, an integer linear program with m constraints can be represented as a knapsack problem.

Consider the feasible set S defined by two constraints with integer coefficients and m nonnegative integer variables with upper bounds, i.e.,

$$S = \left\{ \mathbf{x} : \sum_{j=1}^{n} a_j x_j = d_1; \quad \sum_{j=1}^{n} b_j x_j = d_2; \quad 0 \le x_j \le u_j \text{ and } x_j \text{ integer} \right\}$$

Consider now the problem

$$(P) \quad z = \max \left\{ \left| \sum_{j=1}^{n} a_j x_j - d_1 \right| \; : \; 0 \le x_j \le u_j \text{ and } x_j \text{ integer}, \; j = 1, 2, \ldots, n \right\}$$

This problem is easily solved by considering two solutions, one in which the variables x_j with positive coefficients are set to u_j while the other variables are set to zero and the other in which the variables x_j with negative coefficients are set to u_j while the other variables are set to zero.

Let α be an integer greater than z, the maximum objective value of (P).

It is easy to show that S is equivalent to

$$K = \left\{ \mathbf{x} : \sum_{j=1}^{n} \left(a_j + \alpha b_j\right) x_j = d_1 + \alpha d_2; \; 0 \le x_j \le u_j \text{ and } x_j \text{ integer} \right\}$$

Note that if $\mathbf{x}^* \in S$, then clearly $\mathbf{x}^* \in K$. Suppose $\mathbf{x}^* \in K$. Now we show that $\Sigma_{j=1}^{n} b_j x_j^* = d_2$. Suppose not and that

$$\sum_{j=1}^{n} b_j x_j^* = d_2 + k \tag{32.4}$$

where k is some arbitrary integer, positive or negative. Now multiplying (32.4) by α, and subtracting it from the equality constraint defining K, we have $\Sigma_{j=1}^{n} a_j x_j^* = d_1 - \alpha k$. But since $|\Sigma_{j=1}^{n} a_j x_j^* - d_1| < \alpha$, it follows that $k = 0$ and $\mathbf{x}^* \in S$.

32.5 Polyhedral Combinatorics

One of the main purposes of writing down an algebraic formulation of a combinatorial optimization problem as an integer program is to then examine the linear programming relaxation and understand how well it represents the discrete integer program [107]. There are somewhat special but rich classes of such formulations for which the linear programming relaxation is sharp or tight. These special structures are presented next.

Special Structures and Integral Polyhedra

A natural question of interest is whether the LP associated with an ILP has only integral extreme points. For instance, the linear programs associated with matching and edge covering polytopes in a bipartite graph have only integral vertices. Clearly, in such a situation, the ILP can be solved as LP. A polyhedron or a polytope is referred to as being integral if it is either empty or has only integral vertices.

DEFINITION 32.1 A 0, ± 1 matrix is totally unimodular if the determinant of every square submatrix is 0 or ± 1.

THEOREM 32.3 Hoffman and Kruskal [64] *Let* $A = \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}$ *be a* $0, \pm 1$ *matrix and* $\mathbf{b} = \begin{pmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \\ \mathbf{b}_3 \end{pmatrix}$ *be a vector of appropriate dimensions. Then A is totally unimodular if and only if the polyhedron*

$$P(A, \mathbf{b}) = \{\mathbf{x} \,:\, A_1\mathbf{x} \leq \mathbf{b}_1;\, A_2\mathbf{x} \geq \mathbf{b}_2;\, A_3\mathbf{x} = \mathbf{b}_3;\, \mathbf{x} \geq \mathbf{0}\}$$

is integral for all integral vectors **b**.

The constraint matrix associated with a network flow problem (see for instance [1]) is totally unimodular. Note that for a given integral **b**, $P(A, \mathbf{b})$ may be integral even if A is not totally unimodular.

DEFINITION 32.2 A polyhedron defined by a system of linear constraints is totally dual integral (TDI) if for each objective function with integral coefficients, the dual linear program has an integral optimal solution whenever an optimal solution exists.

THEOREM 32.4 Edmonds and Giles [43]
If $P(A) = \{\mathbf{x} \,:\, A\mathbf{x} \leq \mathbf{b}\}$ *is TDI and* **b** *is integral, then* $P(A)$ *is integral.*

Hoffman and Kruskal [64] have in fact shown that the polyhedron $P(A, \mathbf{b})$ defined in Theorem 32.3 is TDI. This follows from Theorem 32.3 and the fact that A is totally unimodular if and only if A^T is totally unimodular.

Balanced matrices, first introduced by Berge [13] have important implications for **packing and covering** problems (see also [14]).

DEFINITION 32.3 A 0, 1 matrix is balanced if it does not contain a square submatrix of odd order with two ones per row and column.

THEOREM 32.5 Berge [13], Fulkerson, Hoffman and Oppenheim [52]
Let A be a balanced 0, 1 *matrix. Then the set packing, set covering, and set partitioning polytopes associated with A are integral, i.e., the polytopes*
$P(A) = \{\mathbf{x} \,:\, \mathbf{x} \geq \mathbf{0}; A\mathbf{x} \leq \mathbf{1}\}$
$Q(A) = \{\mathbf{x} \,:\, \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}; A\mathbf{x} \geq \mathbf{1}\}$ *and*
$R(A) = \{\mathbf{x} \,:\, \mathbf{x} \geq \mathbf{0}; A\mathbf{x} = \mathbf{1}\}$
are integral.

Let $A = \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}$ be a balanced 0, 1 matrix. Fulkerson, Hoffman and Oppenheim [52] have shown that the polytope $P(A) = \{\mathbf{x} :\, A_1\mathbf{x} \leq \mathbf{1}; A_2\mathbf{x} \geq \mathbf{1}; A_3\mathbf{x} = \mathbf{1}; \mathbf{x} \geq \mathbf{0}\}$ is TDI and by the theorem of Edmonds and Giles [43] it follows that $P(A)$ is integral.

Truemper [119] has extended the definition of balanced matrices to include $0, \pm 1$ matrices.

DEFINITION 32.4 A $0, \pm 1$ matrix is balanced if for every square submatrix with exactly two nonzero entries in each row and each column, the sum of the entries is a multiple of 4.

THEOREM 32.6 Conforti and Cornuejols [26]
Suppose A is a balanced $0, \pm 1$ *matrix. Let* $\mathbf{n}(A)$ *denote the column vector whose ith component is the number of* -1*s in the ith row of A. Then the polytopes*
$P(A) = \{\mathbf{x} \,:\, A\mathbf{x} \leq \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$

$Q(A) = \{\mathbf{x} : A\mathbf{x} \geq \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$
$R(A) = \{\mathbf{x} : A\mathbf{x} = \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$
are integral.

Note that a $0, \pm 1$ matrix A is balanced if and only if A^T is balanced. Moreover A is balanced (totally unimodular) if and only if every submatrix of A is balanced (totally unimodular). Thus if A is balanced (totally unimodular) it follows that Theorem 32.6 (Theorem 32.3) holds for every submatrix of A.

Totally unimodular matrices constitute a subclass of balanced matrices, i.e., a totally unimodular $0, \pm 1$ matrix is always balanced. This follows from a theorem of Camion [17], which states that a $0, \pm 1$ is totally unimodular if and only if for every square submatrix with an even number of nonzeros entries in each row and in each column, the sum of the entries equals a multiple of 4. The 4×4 matrix in Fig. 32.2 illustrates the fact that a balanced matrix is not necessarily totally unimodular. Balanced $0, \pm 1$ matrices have implications for solving the satisfiability problem. If the given set of clauses defines a balanced $0, \pm 1$ matrix, then as shown by Conforti and Cornuejols [26], the satisfiability problem is trivial to solve and the associated MAXSAT problem is solvable in polynomial time by linear programming. A survey of balanced matrices is in Conforti et al. [29].

$$A = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix} \qquad A = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

FIGURE 32.2 A balanced matrix and a perfect matrix.

DEFINITION 32.5 A $0, 1$ matrix A is perfect if the set packing polytope $P(A) = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{1}; \mathbf{x} \geq \mathbf{0}\}$ is integral.

The chromatic number of a graph is the minimum number of colors required to color the vertices of the graph so that no two vertices with the same color have an edge incident between them. A graph G is perfect if for every node induced subgraph H, the chromatic number of H equals the number of nodes in the maximum clique of H. The connections between the integrality of the set packing polytope and the notion of a perfect graph, as defined by Berge [11, 12], are given in Fulkerson [51], Lovász [89], Padberg [97], and Chvátal [25].

THEOREM 32.7 Fulkerson [51], Lovasz [89], Chvátal [25]

Let A be $0, 1$ matrix whose columns correspond to the nodes of a graph G and whose rows are the incidence vectors of the maximal cliques of G. The graph G is perfect if and only if A is perfect.

Let G_A denote the intersection graph associated with a given $0, 1$ matrix A (see Section "Formulations"). Clearly, a row of A is the incidence vector of a clique in G_A. In order for A to be perfect, every maximal clique of G_A must be represented as a row of A because inequalities defined by maximal cliques are facet defining. Thus by Theorem 32.7, it follows that a $0, 1$ matrix A is perfect if and only if the undominated (a row of A is dominated if its support is contained in the support of another row of A) rows of A form the clique-node incidence matrix of a perfect graph.

Balanced matrices with 0, 1 entries, constitute a subclass of 0, 1 perfect matrices, i.e., if a 0, 1 matrix A is balanced, then A is perfect. The 4×3 matrix in Fig. 32.2 is an example of a matrix that is perfect but not balanced.

DEFINITION 32.6 A 0, 1 matrix A is ideal if the set covering polytope

$$Q(A) = \{\mathbf{x} \ : \ A\mathbf{x} \geq \mathbf{1}; \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$$

is integral.

Properties of ideal matrices are described by Lehman [85], Padberg [99] and Cornuejols and Novick [32]. The notion of a 0, 1 perfect (ideal) matrix has a natural extension to a 0, ± 1 perfect (ideal) matrix. Some results pertaining to 0, ± 1 ideal matrices are contained in Hooker [65], while some results pertaining to 0, ± 1 perfect matrices are given in Conforti, Cornuejols and De Francesco [27].

An interesting combinatorial problem is to check whether a given 0, ± 1 matrix is totally unimodular, balanced, or perfect. Seymour's [116] characterization of totally unimodular matrices provides a polynomial time algorithm to test whether a given matrix 0, 1 matrix is totally unimodular. Conforti, Cornuejols and Rao [30] give a polynomial time algorithm to check whether a 0, 1 matrix is balanced. This has been extended by Conforti et al. [28] to check in polynomial time whether a 0, ± 1 matrix is balanced. An open problem is that of checking in polynomial time whether a 0, 1 matrix is perfect. For linear matrices (a matrix is linear if it does not contain a 2×2 submatrix of all ones), this problem has been solved by Fonlupt and Zemirline [47] and Conforti and Rao [31].

Matroids

Matroids and submodular functions have been studied extensively, especially from the point of view of combinatorial optimization (see for instance Nemhauser & Wolsey [95]). Matroids have nice properties that lead to efficient algorithms for the associated optimization problems. One of the interesting examples of matroid optimization is the problem of finding a maximum or minimum weight spanning tree in a graph. Two different but equivalent definitions of a matroid are given first. A greedy algorithm to solve a linear optimization problem over a matroid is presented. The matroid intersection problem is then discussed briefly.

DEFINITION 32.7 Let $N = \{1, 2, \cdot, n\}$ be a finite set and let $\mathcal{F}$ be a set of subsets of N. Then $I = (N, \mathcal{F})$ is an independence system if $S_1 \in \mathcal{F}$ implies that $S_2 \in \mathcal{F}$ for all $S_2 \subseteq S_1$. Elements of $\mathcal{F}$ are called independent sets. A set $S \in \mathcal{F}$ is a maximal independent set if $S \cup \{j\} \notin \mathcal{F}$ for all $j \in N \backslash S$. A maximal independent set T is a maximum if $|T| \geq |S|$ for all $S \in \mathcal{F}$.

DEFINITION 32.8 The rank $r(Y)$ of a subset $Y \subseteq N$ is the cardinality of the maximum independent subset $X \subseteq Y$. Note that $r(\phi) = 0$, $r(X) \leq |X|$ for $X \subseteq N$ and the rank function is non-decreasing, i.e., $r(X) \leq r(Y)$ for $X \subseteq Y \subseteq N$.

DEFINITION 32.9 A matroid $M = (N, \mathcal{F})$ is an independence system in which every maximal independent set is a maximum.

EXAMPLE 32.1:

Let $G = (V, E)$ be an undirected connected graph with V as the node set and E as the edge set.

(i) Let $I = (E, \mathcal{F})$ where $F \in \mathcal{F}$ if $F \subseteq E$ is such that at most one edge in F is incident to each node of V, i.e., $F \in \mathcal{F}$ if F is a matching in G. Then $I = (E, \mathcal{F})$ is an independence system but not a matroid.

(ii) Let $M = (E, \mathcal{F})$ where $F \in \mathcal{F}$ if $F \subseteq E$ is such that $G_F = (V, F)$ is a forest, i.e., G_F contains no cycles. Then $M = (E, \mathcal{F})$ is a matroid and maximal independent sets of M are spanning trees.

An alternate but equivalent definition of matroids is in terms of submodular functions.

DEFINITION 32.10 Let N be a finite set. A real valued set function f defined on the subsets of N is submodular if $f(X \cup Y) + f(X \cap Y) \leq f(X) + f(Y)$ for $X, Y \subseteq N$.

EXAMPLE 32.2:

Let $G = (V, E)$ be an undirected graph with V as the node set and E as the edge set. Let $c_{ij} \geq 0$ be the weight or capacity associated with edge $(ij) \in E$. For $S \subseteq V$, define the cut function $c(S) = \Sigma_{i \in S,\, j \in V \setminus S} c_{ij}$. The cut function defined on the subsets of V is submodular since $c(X) + c(Y) - c(X \cup Y) - c(X \cap Y) = \Sigma_{i \in X \setminus Y,\, j \in Y \setminus X} 2c_{ij} \geq 0$.

DEFINITION 32.11 A nondecreasing integer valued submodular function r defined on the subsets of N is called a matroid rank function if $r(\phi) = 0$ and $r(\{j\}) \leq 1$ for $j \in N$. The pair (N, r) is called a matroid.

DEFINITION 32.12 A nondecreasing, integer-valued, submodular function f defined on the subsets of N is called a polymatroid function if $f(\phi) = 0$. The pair (N, r) is called a polymatroid.

Matroid Optimization

In order to decide whether an optimization problem over a matroid is polynomially solvable or not, we need to first address the issue of representation of a matroid. If the matroid is given either by listing the independent sets or by its rank function, many of the associated linear optimization problems are trivial to solve. However, matroids associated with graphs are completely described by the graph and the condition for independence. For instance, the matroid in which the maximal independent sets are spanning trees, the graph $G = (V, E)$ and the independence condition of no cycles describes the matroid.

Most of the algorithms for matroid optimization problems require a test to determine whether a specified subset is independent or not. We assume the existence of an oracle or subroutine to do this checking in running time which is a polynomial function of $|N| = n$.

Maximum Weight Independent Set Given a matroid $M = (N, \mathcal{F})$ and weights w_j for $j \in N$, the problem of finding a maximum weight independent set is $\max_{F \in \mathcal{F}} \left\{ \Sigma_{j \in F} w_j \right\}$. The greedy algorithm to solve this problem is as follows:

Procedure: **Greedy**

0. **Initialize:** Order the elements of N so that $w_i \geq w_{i+1}$, $i = 1, 2, \cdots, n-1$. Let $T = \phi$, $i = 1$.
1. **If** $w_i \leq 0$ or $i > n$, **stop** T is optimal, i.e., $x_j = 1$ for $j \in T$ and $x_j = 0$ for $j \notin T$. If $w_i > 0$ and $T \cup \{i\} \in \mathcal{F}$, add element i to T.
2. **Increment** i by 1 and return to Step 1.

Edmonds [40, 41] derived a complete description of the *matroid polytope,* the convex hull of the characteristic vectors of independent sets of a matroid. While this description has a large (exponential) number of constraints, it permits the treatment of linear optimization problems on independent sets of matroids as linear programs. Cunningham [35] describes a polynomial algorithm to solve the *separation problem*[2] for the matroid polytope. The matroid polytope and the associated greedy algorithm have been extended to polymatroids [40, 93].

The separation problem for a polymatroid is equivalent to the problem of minimizing a submodular function defined over the subsets of N, see Nemhauser and Wolsey [95]. A class of submodular functions that have some additional properties can be minimized in polynomial time by solving a maximum flow problem (Rhys [109], Picard and Ratliff [106]). The general submodular function can be minimized in polynomial time by the ellipsoid algorithm (Grötschel, Lovász and Schrijver [60]).

The uncapacitated plant location problem (see "LP Relaxation") can be reduced to maximizing a submodular function. Hence it follows that maximizing a submodular function is NP-hard.

Matroid Intersection

A matroid intersection problem involves finding an independent set contained in two or more matroids defined on the same set of elements.

Let $G = (V_1, V_2, E)$ be a bipartite graph. Let $M_i = (E, \mathcal{F}_i)$, $i = 1, 2$ where $F \in \mathcal{F}_i$ if $F \subseteq E$ is such that no more than one edge of F is incident to each node in V_i. The set of matchings in G constitute the intersection of the two matroids M_i, $i = 1, 2$. The problem of finding a maximum weight independent set in the intersection of two matroids can be solved in polynomial time (Lawler [84], Edmonds [40, 42], Frank [49]). The two (poly) matroid intersection polytope has been studied by Edmonds [42].

The problem of testing whether a graph contains a Hamiltonian path is NP-complete. Since this problem can be reduced to the problem of finding a maximum cardinality independent set in the intersection of three matroids, it follows that the matroid intersection problem involving three or more matroids is NP-hard.

Valid Inequalities, Facets and Cutting Plane Methods

In "Special Structures and Integral Polyhedra," we were concerned with conditions under which the packing and covering polytopes are integral. But in general these polytopes are not integral and additional inequalities are required to have a complete linear description of the convex hull of integer solutions. The existence of finitely many such linear inequalities is guaranteed by Weyl's Theorem [120].

Consider the feasible region of an ILP given by

$$P_I = \{\mathbf{x} \ : \ A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \geq \mathbf{0} \text{ and integer}\} \tag{32.5}$$

Recall that an inequality $\mathbf{fx} \leq f_0$ is referred to as a valid inequality for P_I if $\mathbf{fx}^* \leq f_0$ for all $\mathbf{x}^* \in P_I$. A valid linear inequality for $P_I(A, \mathbf{b})$ is said to be facet defining if it intersects $P_I(A, \mathbf{b})$ in a face of dimension one less than the dimension of $P_I(A, \mathbf{b})$. In the example shown in Fig. 32.3, the inequality $x_2 + x_3 \leq 1$ is a facet defining inequality of the integer hull.

[2]The separation problem for a convex body K is to test if an input point $\mathbf{x}$ belongs to K and if it does not to produce a linear halfspace that separates $\mathbf{x}$ from K. It is known [60, 80, 100] that linear optimization over K is polynomially equivalent to separation from K.

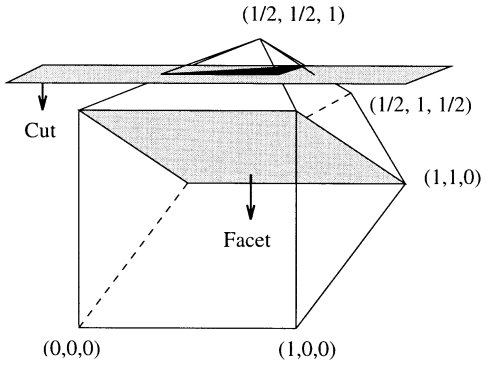


FIGURE 32.3 Relaxation, cuts and facets.

The Relaxation

$$\begin{aligned} x_1 + x_2 + x_3 &\leq 2 \\ x_1 - x_2 - x_3 &\geq -1 \\ 0 \leq x_1, x_2, x_3 &\leq 1 \end{aligned}$$

The Integer Hull

$$\begin{aligned} x_1 + x_2 + x_3 &\leq 2 \\ x_1 - x_2 - x_3 &\geq -1 \\ x_2 + x_3 &\leq 1 \\ 0 \leq x_1, x_2, x_3 &\leq 1 \end{aligned}$$

Let $\mathbf{u} \geq 0$ be a row vector of appropriate size. Clearly $\mathbf{u}A\mathbf{x} \leq \mathbf{ub}$ holds for every $\mathbf{x}$ in P_I. Let $(\mathbf{u}A)_j$ denote the jth component of the row vector $\mathbf{u}A$ and $\lfloor(\mathbf{u}A)_j\rfloor$ denote the largest integer less than or equal to $(\mathbf{u}A)_j$. Now, since $\mathbf{x} \in P_I$ is a vector of nonnegative integers, it follows that $\Sigma_j \lfloor(\mathbf{u}A)_j\rfloor x_j \leq \lfloor\mathbf{ub}\rfloor$ is a valid inequality for P_I. This scheme can be used to generate many valid inequalities by using different $\mathbf{u} \geq 0$. Any set of generated valid inequalities may be added to the constraints in (32.5) and the process of generating them may be repeated with the enhanced set of inequalities. This iterative procedure of generating valid inequalities is called Gomory–Chvátal (GC) rounding. It is remarkable that this simple scheme is complete, i.e., every valid inequality of P_I can be generated by finite application of GC rounding [24, 113].

The number of inequalities needed to describe the convex hull of P_I is usually exponential in the size of A. But to solve an optimization problem on P_I, one is only interested in obtaining a partial description of P_I that facilitates the identification of an integer solution and prove its optimality. This is the underlying basis of any cutting plane approach to combinatorial problems.

The Cutting Plane Method

Consider the optimization problem

$$\max\{\mathbf{cx} : \mathbf{x} \in P_I\{\mathbf{x} : A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \geq \mathbf{0} \text{ and integer}\}\}$$

The generic cutting plane method as applied to this formulation is given below.

Procedure: **Cutting Plane**

1. Initialize $A' \leftarrow A$ and $\mathbf{b}' \leftarrow \mathbf{b}$.
2. Find an optimal solution $\bar{\mathbf{x}}$ to the linear program

$$\max\{\mathbf{cx} : A'\mathbf{x} \leq \mathbf{b}'; \mathbf{x} \geq \mathbf{0}\}$$

   If $\bar{\mathbf{x}} \in P_I$, stop and return $\bar{\mathbf{x}}$.
3. Generate a valid inequality $\mathbf{fx} \leq f_0$ for P_I such that $f\bar{\mathbf{x}} > f_0$ (the inequality ''cuts'' $\bar{\mathbf{x}}$).
4. Add the inequality to the constraint system, update

$$A' \leftarrow \begin{pmatrix} A' \\ \mathbf{f} \end{pmatrix}, \quad \mathbf{b}' \leftarrow \begin{pmatrix} \mathbf{b}' \\ f_0 \end{pmatrix}$$

   Go to Step 2.

In Step 3 of the cutting plane method, we require a suitable application of the GC rounding scheme (or some alternate method of identifying a cutting plane). Notice that while the GC rounding scheme will generate valid inequalities, the identification of one that cuts off the current solution to the linear programming relaxation is all that is needed. Gomory [56] provided just such a specialization of the rounding scheme that generates a cutting plane. While this met the theoretical challenge of designing a sound and complete cutting plane method for integer linear programming, it turned out to be a weak method in practice. Successful cutting plane methods, in use today, use considerable additional insights into the structure of facet-defining cutting planes. Using facet cuts makes a huge difference in the speed of convergence of these methods. Also, the idea of combining cutting plane methods with search methods has been found to have a lot of merit. These branch and cut methods will be discussed in the next section.

The b-Matching Problem

Consider the **b**-matching problem:

$$\max\{\mathbf{cx} : \ A\mathbf{x} \leq \mathbf{b}, \ \mathbf{x} \geq \mathbf{0} \ \text{ and } \ \text{integer}\} \tag{32.6}$$

where A is the node-edge incidence matrix of an undirected graph and $\mathbf{b}$ is a vector of positive integers. Let G be the undirected graph whose node-edge incidence matrix is given by A and let $W \subseteq V$ be any subset of nodes of G (i.e., subset of rows of A) such that $\mathbf{b}(W) = \Sigma_{i \in W} b_i$ is odd. Then the inequality

$$\mathbf{x}(W) = \sum_{e \in E(W)} x_e \leq \frac{1}{2}(\mathbf{b}(W) - 1) \tag{32.7}$$

is a valid inequality for integer solutions to (32.6) where $E(W) \subseteq E$ is the set of edges of G having both ends in W. Edmonds [39] has shown that the inequalities (32.6) and (32.7) define the integral **b**-matching polytope (see also [44]). Note that the number of inequalities (32.7) is exponential in the number of nodes of G. An instance of the successful application of the idea of using only a partial description of P_I is in the blossom algorithm for the matching problem, due to Edmonds [39].

An implication of the ellipsoid method for linear programming is that the linear program over P_I can be solved in polynomial time if and only if the associated separation problem can be solved in polynomial time (see Grotschel, Lovász and Schrijver [60], Karp and Papadimitriou [80], and Padberg and Rao [100]). The separation problem for the **b**-matching problem with or without upper bounds was shown by Padberg and Rao [101], to be solvable in polynomial time. The procedure involves a minor modification of the algorithm of Gomory and Hu [59] for multiterminal networks. However, no polynomial (in the number of nodes of the graph) linear programming formulation of this separation problem is known. Martin [92] has shown that if the separation problem can be expressed as a compact linear program then so can the optimization problem. Hence an unresolved issue is whether there exists a polynomial size (compact) formulation for the **b**-matching problem. Yannakakis [123] has shown that, under a symmetry assumption, such a formulation is impossible.

Other Combinatorial Problems

Besides the matching problem several other combinatorial problems and their associated polytopes have been well studied and some families of facet defining inequalities have been identified. For instance the set packing, graph partitioning, plant location, maximum cut, traveling salesman and Steiner tree problems have been extensively studied from a polyhedral point of view (see for instance Nemhauser and Wolsey [95]).

These combinatorial problems belong to the class of NP-complete problems. In terms of a worst-case analysis, no polynomial time algorithms are known for these problems. Nevertheless, using a cutting plane approach with branch and bound or branch and cut (see Section 32.6), large instances of these problems

have been successfully solved, see Crowder, Johnson and Padberg [34], for general $0-1$ problems, Barahona et al. [7] for the maximum cut problem, Padberg and Rinaldi [102] for the traveling salesman problem and Chopra, Gorres and Rao [23] for the Steiner tree problem.

32.6 Partial Enumeration Methods

In many instances, to find an optimal solution to an integer linear programing problems (ILP), the structure of the problem is exploited together with some sort of partial enumeration. In this section, we review the branch and bound (B & B) and branch and cut (B & C) methods for solving an ILP.

Branch and Bound

The branch and bound (B & B) method is a systematic scheme for implicitly enumerating the finitely many feasible solutions to an ILP. Although, theoretically the size of the enumeration tree is exponential in the problem parameters, in most cases, the method eliminates a large number of feasible solutions. The key features of branch and bound method are

(i) **Selection/Removal** of one or more problems from a candidate list of problems.

(ii) **Relaxation** of the selected problem so as to obtain a lower bound (on a minimization problem) on the optimal objective function value for the selected problem.

(iii) **Fathoming,** if possible, of the selected problem.

(iv) **Branching Strategy:** If the selected problem is not fathomed, branching creates subproblems which are added to the candidate list of problems.

The above four steps are repeated until the candidate list is empty. The B & B method sequentially examines problems that are added and removed from a candidate list of problems.

Initialization Initially the candidate list contains only the original ILP which is denoted as

$$(P) \qquad \min\{\mathbf{cx} : A\mathbf{x} \leq \mathbf{b},\ \mathbf{x} \geq \mathbf{0} \text{ and integer}\}$$

Let $F(P)$ denote the feasible region of (P) and $z(P)$ denote the optimal objective function value of (P). For any $\bar{\mathbf{x}}$ in $F(P)$, let $z_P(\bar{\mathbf{x}}) = \mathbf{c}\bar{\mathbf{x}}$.

Frequently, heuristic procedures are first applied to get a good feasible solution to (P). The best solution known for (P) is referred to as the current incumbent solution. The corresponding objective function value is denoted as z_I. In most instances, the initial heuristic solution is not either optimal or at least not immediately certified to be optimal. So further analysis is required to ensure that an optimal solution to (P) is obtained. If no feasible solution to (P) is known, z_I is set to ∞.

Selection/Removal In each iterative step of B & B, a problem is selected and removed from the candidate list for further analysis. The selected problem is henceforth referred to as the candidate problem (CP). The algorithm terminates if there is no problem to select from the candidate list. Initially there is no issue of selection since the candidate list contains only the problem (P). However, as the algorithm proceeds, there would be many problems on the candidate list and a selection rule is required. Appropriate selection rules, also referred to as branching strategies, are discussed later. Conceptually, several problems may be simultaneously selected and removed from the candidate list. However, most sequential implementations of B & B select only one problem from the candidate list and this is assumed henceforth. Parallel aspects of B & B on $0-1$ integer linear programs are discussed in Cannon and Hoffman [18] and for the case of traveling salesman problems in [4].

The computational time required for the B & B algorithm depends crucially on the order in which the problems in the candidate list are examined. A number of clever heuristic rules may be employed in devising such strategies. Two general purpose selection strategies that are commonly used are

(A) Choose the problem that was added last to the candidate list. This last-in-first-out rule (LIFO) is also called depth first search (DFS), since the selected candidate problem increases the depth of the active enumeration tree.

(B) Choose the problem on the candidate list that has the least lower bound. Ties may be broken by choosing the problem that was added last to the candidate list. This rule would require that a lower bound be obtained for each of the problems on the candidate list. In other words, when a problem is added to the candidate list, an associated lower bound should also be stored. This may be accomplished by using ad-hoc rules or by solving a relaxation of each problem before it is added to the candidate list.

Rule (A) is known to empirically dominate the rule (B) when storage requirements for candidate list and computation time to solve (P) are taken into account. However, some analysis indicates that rule (B) can be shown to be superior if minimizing the number of candidate problems to be solved is the criterion (see Parker and Rardin [105]).

Relaxation In order to analyze the selected candidate problem, (CP), a relaxation (CP_R) of (CP) is solved to obtain a lower bound $z(CP_R) \leq z(CP)$. (CP_R) is a relaxation of (CP) if

(i) $F(CP) \subseteq F(CP_R)$,

(ii) for $\bar{\mathbf{x}} \in F(CP)$, $z_{CP_R}(\bar{\mathbf{x}}) \leq z_{CP}(\bar{\mathbf{x}})$ and

(iii) for $\bar{\mathbf{x}}, \hat{\mathbf{x}} \in F(CP)$, $z_{CP_R}(\bar{\mathbf{x}}) \leq z_{CP_R}(\hat{\mathbf{x}})$ implies that $z_{CP}(\bar{\mathbf{x}}) \leq z_{CP}(\hat{\mathbf{x}})$.

Relaxations are needed because the candidate problems are typically hard to solve. The relaxations used most often are either linear programming or Lagrangean relaxations of (CP); see Section 32.7 for details. Sometimes, instead of solving a relaxation of (CP), a lower bound is obtained by using some ad-hoc rules such as penalty functions.

Fathoming A candidate problem is fathomed if

(FC1) analysis of (CP_R) reveals that (CP) is infeasible. For instance if $F(CP_R) = \phi$, then $F(CP) = \phi$.

(FC2) analysis of (CP_R) reveals that (CP) has no feasible solution better than the current incumbent solution. For instance if $z(CP_R) \geq z_I$, then $z(CP) \geq z(CP_R) \geq z_I$.

(FC3) analysis of (CP_R) reveals an optimal solution of (CP). For instance, if $\mathbf{x}_R$ is optimal for (CP_R) and is feasible in (CP), then $(\mathbf{x}_R)$ is an optimal solution to (CP) and $z(CP) = z_{CP}(\mathbf{x}_R)$.

(FC4) analysis of (CP_R) reveals that (CP) is dominated by some other problem, say CP^*, in the candidate list. For instance if it can shown that $z(CP^*) \leq z(CP)$, then there is no need to analyze (CP) further.

If a candidate problem (CP) is fathomed using any of the criteria above, then further examination of (CP) or its descendants (subproblems) obtained by separation is not required. If (FC3) holds, and $z(CP) < z_I$, the incumbent is updated as $\mathbf{x}_R$ and z_I is updated as $z(CP)$.

Separation/Branching If the candidate problem (CP) is not fathomed, then CP is separated into several problems, say $(CP_1), (CP_2), \ldots, (CP_q)$ where $\bigcup_{t=1}^{q} F(CP_t) = F(CP)$ and typically

$$F(CP_i) \cap F(CP_j) = \phi \quad \forall i \neq j \ .$$

For instance a separation of (CP) into $(CP_i), i = 1, 2, \ldots, q$ is obtained by fixing a single variable, say x_j, to one of the q possible values of x_j in an optimal solution to (CP). The choice of the variable to fix depends upon the separation strategy which is also part of the branching strategy. After separation, the subproblems are added to the candidate list. Each subproblem (CP_t) is a restriction of (CP) since $F(CP_t) \subseteq F(CP)$. Consequently $z(CP) \leq z(CP_t)$ and $z(CP) = \min_t z(CP_t)$.

The various steps in the B & B algorithm are outlined below.

Procedure: **B & B**

0. **Initialize:** Given the problem (P), the incumbent value z_I is obtained by applying some heuristic (if a feasible solution to (P) is not available, set $z_I = +\infty$). Initialize the candidate list $C \leftarrow \{(P)\}$.
1. **Optimality:** If $C = \emptyset$ and $z_I = +\infty$, then (P) is infeasible, stop. Stop also if $C = \emptyset$ and $z_I < +\infty$, the incumbent is an optimal solution to (P).
2. **Selection:** Using some candidate selection rule, select and remove a problem $(CP) \in C$.
3. **Bound:** Obtain a lower bound for (CP) by either solving a relaxation (CP_R) of (CP) or by applying some ad-hoc rules. If (CP_R) is infeasible, return to Step 1. Else, let $\mathbf{x}_R$ be an optimal solution of (CP_R).
4. **Fathom:** If $z(CP_R) \geq z_I$, return to Step 1. Else if $\mathbf{x}_R$ is feasible in (CP) and $z(CP) < z_I$, set $z_I \leftarrow z(CP)$, update the incumbent as $\mathbf{x}_R$ and return to Step 1. Finally, if $\mathbf{x}_R$ is feasible in (CP) but $z(CP) \geq z_I$, return to Step 1.
5. **Separation:** Using some separation or branching rule, separate (CP) into $(CP_i), i = 1, 2, \cdots, q$ and set $C \leftarrow C \cup \{CP_1), (CP_2), \cdots, (CP_q)\}$ and return to Step 1.
6. **End Procedure.**

Although the B & B method is easy to understand, the implementation of this scheme for a particular ILP is a nontrivial task requiring

(A) A relaxation strategy with efficient procedures for solving these relaxations,
(B) Efficient data-structures for handling the rather complicated book-keeping of the candidate list,
(C) Clever strategies for selecting promising candidate problems, and
(D) Separation or branching strategies that could effectively prune the enumeration tree.

A key problem is that of devising a relaxation strategy (A), i.e., to find "good relaxations" which are significantly easier to solve than the original problems and tend to give sharp lower bounds. Since these two are conflicting, one has to find a reasonable trade-off.

Branch and Cut

In the last few years, the branch and cut (B & C) method has become popular for solving combinatorial optimization problems. As the name suggests, the B & C method incorporates the features of both the branch and bound method presented above and the cutting plane method presented in the previous section. The main difference between the B & C method and the general B & B scheme is in the bound step (Step 3).

A distinguishing feature of the B & C method is that the relaxation (CP_R) of the candidate problem (CP) is a linear programming problem and instead of merely solving (CP_R), an attempt is made to solve (CP) by using cutting planes to tighten the relaxation. If (CP_R) contains inequalities that are valid for (CP) but not for the given ILP, then the GC rounding procedure may generate inequalities that are valid for (CP) but not for the ILP. In the B & C method, the inequalities that are generated are always valid for the ILP, and hence can be used globally in the enumeration tree.

Another feature of the B & C method is that often heuristic methods are used to convert some of the fractional solutions, encountered during the cutting plane phase, into feasible solutions of the (CP) or more generally of the given ILP. Such feasible solutions naturally provide upper bounds for the ILP. Some of these upper bounds may be better than the previously identified best upper bound and if so, the current incumbent is updated accordingly.

We thus obtain the B & C method by replacing the bound step (Step 3) of the B & B method by Steps 3(a) and 3(b), and also by replacing the fathom step (Step 4) by Steps 4(a) and 4(b) given below.

3(a) **Bound:** Let (CP_R) be the LP relaxation of (CP). Attempt to solve (CP) by a cutting plane method which generates valid inequalities for (P). Update the constraint System of (P) and the incumbent as appropriate.

Let $F\mathbf{x} \leq \mathbf{f}$ denote all the valid inequalities generated during this phase. Update the constraint system of (P) to include all the generated inequalities, i.e., set $A^T \leftarrow (A^T, F^T)$ and $\mathbf{b}^T \leftarrow (\mathbf{b}^T, \mathbf{f}^T)$. The constraints for all the problems in the candidate list are also to be updated.

During the cutting plane phase, apply heuristic methods to convert some of the identified fractional solutions into feasible solutions to (P). If a feasible solution, $\bar{\mathbf{x}}$, to (P), is obtained such that $\mathbf{c}\bar{\mathbf{x}} < z_I$, update the incumbent to $\bar{\mathbf{x}}$ and z_I to $c\bar{\mathbf{x}}$. Hence the remaining changes to B & B are as follows:

3(b) **If** (CP) is solved go to Step 4(a). **Else,** let $\hat{\mathbf{x}}$ be the solution obtained when the cutting plane phase is terminated (we are unable to identify a valid inequality of (P) that is violated by $\hat{\mathbf{x}}$.) go to Step 4(b).

4(a) **Fathom by Optimality:** Let $\mathbf{x}^*$ be an optimal solution to (CP). If $z(CP) < z_I$, set $\mathbf{x}_I \leftarrow z(CP)$ and update the incumbent as $\mathbf{x}^*$. Return to Step 1.

4(b) **Fathom by Bound:** If $\mathbf{c}\hat{\mathbf{x}} \geq z_I$, return to Step 1. Else go to Step 5.

The incorporation of a cutting plane phase into the B & B scheme involves several technicalities which require careful design and implementation of the B & C algorithm. Details of the state of the art in cutting plane algorithms including the B & C algorithm are reviewed in Jünger, Reinelt and Thienel [72].

32.7 Relaxations

The effectiveness of a partial enumeration strategy such as branch and bound is closely related to the quality of the relaxations used to generate the bounds and incumbents. We describe four general relaxation methods that together cover the most successful computational techniques for bound evaluation in the practice of partial enumeration for integer programming. These are linear programming relaxation, Lagrangean relaxation, group relaxation, and semidefinite relaxation methods.

LP Relaxation

A linear programming relaxation is derived from an integer programming formulation by relaxing the integrality constraints. When there are alternate integer programming formulations, modeling the same decision problem, it becomes necessary to have some criteria for selecting from among the candidate relaxations. We illustrate these ideas on the plant location model, a prototypical integer programming example.

Plant Location Problems

Given a set of customer locations $N = \{1, 2, \ldots, n\}$ and a set of potential sites for plants $M = \{1, 2, \ldots, m\}$, the plant location problem is to identify the sites where the plants are to be located so that the customers are served at a minimum cost. There is a fixed cost f_i of locating the plant at site i and the cost of serving customer j from site i is c_{ij}. The decision variables are

y_i is set to 1 if a plant is located at site i and to 0 otherwise.

x_{ij} is set to 1 if site i serves customer j and to 0 otherwise.

A formulation of the problem is

$$
\begin{aligned}
(P8) \quad \text{Min} \quad & \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}x_{ij} \quad + \sum_{i=1}^{m} f_i y_i \\
\text{subject to} \quad & \sum_{i=1}^{m} x_{ij} = 1 \qquad j = 1, 2, \ldots, n \\
& x_{ij} - y_i \leq 0 \qquad i = 1, 2, \ldots, m; \;\; j = 1, 2, \ldots, n \\
& y_i = 0 \text{ or } 1 \qquad i = 1, 2, \ldots, m \\
& x_{ij} = 0 \text{ or } 1 \qquad i = 1, 2, \ldots, m; \;\; j = 1, 2, \ldots, n
\end{aligned}
$$

Note that the constraints $x_{ij} - y_i \leq 0$ are required to ensure that customer j may be served from site i only if a plant is located at site i. Note that the constraints $y_i = 0$ or 1, force an optimal solution in which $x_{ij} = 0$ or 1. Consequently the $x_{ij} = 0$ or 1 constraints may be replaced by non-negativity constraints $x_{ij} \geq 0$.

The linear programming relaxation associated with (P8) is obtained by replacing constraints $y_i = 0$ or 1, and $x_{ij} = 0$ or 1 by nonnegativity constraints on x_{ij} and y_i. The upper bound constraints on y_i are not required provided $f_i \geq 0, \;\; i = 1, 2, \ldots, m$. The upper bound constraints on x_{ij} are not required in view of constraints $\Sigma_{i=1}^{m} x_{ij} = 1$.

Remark: It is frequently possible to formulate the same combinatorial problem as two or more different ILPs. Suppose we have two ILP formulations (F1) and (F2) of the given combinatorial problem with both (F1) and (F2) being minimizing problems. Formulation (F1) is said to be stronger than (F2) if (LP1), the linear programming relaxation of (F1), always has an optimal objective function value which is greater than or equal to the optimal objective function value of (LP2) which is the linear programming relaxation of (F2).

It is possible to reduce the number of constraints in (P8) by replacing the constraints $x_{ij} - y_i \leq 0$ by an aggregate:

$$\sum_{j=1}^{n} x_{ij} - ny_i \leq 0 \;\; i = 1, 2, \ldots, m$$

However, the disaggregated (P8) is a stronger formulation than the formulation obtained by aggregrating the constraints as above. By using standard transformations, (P8) can also be converted into a set packing problem.

Lagrangean Relaxation

This approach has been widely used for about two decades now in many practical applications. Lagrangean relaxation, like linear programming relaxation, provides bounds on the combinatorial optimization problem being relaxed (i.e., lower bounds for minimization problems).

Lagrangean relaxation has been so successful because of a couple of distinctive features. As was noted earlier, in many hard combinatorial optimization problems, we usually have some "nice" tractable embedded subproblems which admit efficient algorithms. Lagrangean relaxation gives us a framework to

"jerry-rig" an approximation scheme that uses these efficient algorithms for the subproblems as subroutines. A second observation is that it has been empirically observed that well-chosen Lagrangean relaxation strategies usually provide very tight bounds on the optimal objective value of integer programs. This is often used to great advantage within partial enumeration schemes to get very effective pruning tests for the search trees.

Practitioners also have found considerable success with designing heuristics for combinatorial optimization by starting with solutions from Lagrangean relaxations and constructing good feasible solutions via so-called dual ascent strategies. This may be thought of as the analogue of rounding strategies for linear programming relaxations (but with no performance guarantees—other than empirical ones).

Consider a representation of our combinatorial optimization problem in the form

$$(P) \quad z = \min \left\{ \mathbf{cx} : A\mathbf{x} \geq \mathbf{b},\ \mathbf{x} \in X \subseteq \Re^n \right\}$$

Implicit in this representation is the assumption that the explicit constraints ($A\mathbf{x} \geq \mathbf{b}$) are *"small"* in number. For convenience let us also assume that X can be replaced by a finite list $\{\mathbf{x}^1, \mathbf{x}^2, \ldots, \mathbf{x}^T\}$.

The following definitions are with respect to (P):

- `Lagrangean` $L(\mathbf{u},\mathbf{x}) = \mathbf{u}(A\mathbf{x} - \mathbf{b}) + \mathbf{cx}$ where $\mathbf{u}$ are the Lagrange multipliers.
- `Lagrangean Subproblem` $\min_{\mathbf{x}\in X}\{L(\mathbf{u},\mathbf{x})\}$
- `Lagrangean-Dual Function` $\mathcal{L}(\mathbf{u}) = \min_{\mathbf{x}\in X}\{L(\mathbf{u},\mathbf{x})\}$
- `Lagrangean-Dual Problem` (D) $d = \max_{\mathbf{u}\geq\mathbf{0}}\{\mathcal{L}(\mathbf{u})\}$

It is easily shown that (D) satisfies a weak duality relationship with respect to (P), i.e., $z \geq d$. The discreteness of X also implies that $\mathcal{L}(\mathbf{u})$ is a piecewise linear and concave function (see Shapiro [115]). In practice, the constraints X are chosen such that the evaluation of the Lagrangean dual function $\mathcal{L}(\mathbf{u})$ is easily made.

An Example: `Traveling Salesman Problem (TSP)`

For an undirected graph G, with costs on each edge, the TSP is to find a minimum cost set H of edges of G such that it forms a Hamiltonian cycle of the graph. H is a Hamiltonian cycle of G if it is a simple cycle that spans all the vertices of G. Alternately H must satisfy

1. Exactly two edges of H are adjacent to each node, and
2. H forms a connected, spanning subgraph of G.

Held and Karp [63] used these observations to formulate a Lagrangean relaxation approach for TSP, that relaxes the degree constraints (condition 1 above) Notice that the resulting subproblems are minimum spanning tree problems that can be easily solved.

The most commonly used general method of finding the optimal multipliers in Lagrangean relaxation is subgradient optimization (cf. Held et al. [62]). Subgradient optimization is the non-differentiable counterpart of steepest descent methods. Given a dual vector $\mathbf{u}^k$, the iterative rule for creating a sequence of solutions is given by

$$\mathbf{u}^{k+1} = \mathbf{u}^k + t_k\, \gamma\left(\mathbf{u}^k\right)$$

where t_k is an appropriately chosen step size, and $\gamma(\mathbf{u}^k)$ is a subgradient of the dual function $\mathcal{L}$ at $\mathbf{u}^k$. Such a subgradient is easily generated by

$$\gamma\left(\mathbf{u}^k\right) = A\mathbf{x}^k - \mathbf{b}$$

where $\mathbf{x}^k$ is an optimal solution of $\min_{\mathbf{x}\in X}\{L(\mathbf{u}^k, \mathbf{x})\}$.

Subgradient optimization has proven effective in practice for a variety of problems. It is possible to choose the step sizes $\{t_k\}$ to guarantee convergence to the optimal solution. Unfortunately, the method is not finite, in that the optimal solution is attained only in the limit. Further, it is not a pure descent method. In practice, the method is heuristically terminated and the best solution in the generated sequence is recorded. In the context of nondifferentiable optimization, the ellipsoid algorithm was devised by Shor [118] to overcome precisely some of these difficulties with the subgradient method.

The ellipsoid algorithm may be viewed as a scaled subgradient method in much the same way as variable metric methods may be viewed as scaled steepest descent methods (cf. [2]). And if we use the ellipsoid method to solve the Lagrangean dual problem, we obtain the following as a consequence of the polynomial-time equivalence of optimization and separation.

THEOREM 32.8 *The Lagrangean dual problem is polynomial-time solvable if and only if the Lagrangean subproblem is. Consequently, the Lagrangean dual problem is $\mathcal{NP}$-hard if and only if the Lagrangean subproblem is.*

The theorem suggests that in practice, if we set up the Lagrangean relaxation so that the subproblem is tractable, then the search for optimal Lagrangean multipliers is also tractable.

Group Relaxations

A relaxation of the integer programming problem is obtained by dropping the nonnegativity restrictions on some variables. Consider the integer linear program

$$(ILP) \quad \max\{\mathbf{cx} \ : \ A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0} \text{ and integer}\}$$

where the elements of A, b are integral.

Suppose the linear programming relaxation of (ILP) has a finite optimum, then an extreme-point optimal solution $\mathbf{x}^* = \begin{pmatrix} B^{-1}\mathbf{b} \\ \mathbf{0} \end{pmatrix}$ where B is a nonsingular submatrix of A. Let $A = (B, N)$, $\mathbf{x} = \begin{pmatrix} \mathbf{x}_B \\ \mathbf{x}_N \end{pmatrix}$, and $\mathbf{c} = (\mathbf{c}_B, \mathbf{c}_N)$. By dropping the nonnegativity constraint on $\mathbf{x}_B$, substituting $\mathbf{x}_B = B^{-1}(\mathbf{b} - N\mathbf{x}_N)$, ignoring the constant term $\mathbf{c}_B B^{-1} b$ in the objective function, and changing the objective function from maximize to minimize, we obtain the following relaxation of (ILP).

$$(ILP_B) \quad \min \left\{ \left(\mathbf{c}_B B^{-1} N - \mathbf{c}_N \right) \mathbf{x}_N \ : \ \mathbf{x}_B = B^{-1} (\mathbf{b} - N\mathbf{x}_N) , \ \mathbf{x}_B \text{ integer}, \ \mathbf{x}_N \geq \mathbf{0} \text{ and integer} \right\}$$

Now $\mathbf{x}_B = B^{-1}(\mathbf{b} - N\mathbf{x}_N)$ and $\mathbf{x}_B$ integer is equivalent to requiring

$$B^{-1} N \mathbf{x}_N \equiv B^{-1}\mathbf{b} (mod \ \mathbf{1})$$

where the congruence is with respect to each element of the vector $B^{-1}\mathbf{b}$ taken modulo 1.

Hence, (ILP_B) can be written as

$$(ILP_G) \quad \min \left\{ \left(\mathbf{c}_B B^{-1} N - \mathbf{c}_N \right) \mathbf{x}_N \ : \ B^{-1} N \mathbf{x}_N \equiv B^{-1}\mathbf{b} (mod \ \mathbf{1}), \ \mathbf{x}_N \geq \mathbf{0} \text{ and integer} \right\}$$

Since A and $\mathbf{b}$ are integer matrices, the fractional parts of elements of $B^{-1}N$ and $B^{-1}\mathbf{b}$ are of the form $\left(\frac{\text{k}}{\text{detB}}\right)$ where $k \in \{0, 1, \ldots, |det B| - 1\}$. The congruences in (ILP_G) are equivalent to working in a product of cyclic groups. The structure of the product group is revealed by the Hermite normal form of B (see "Linear Diophantine Systems"). Hence, (ILP_G) is referred to as a group (knapsack) problem and is solved by a dynamic programming algorithm [58].

Semidefinite Relaxation

Semidefinite programs are linear optimization problems defined over a cone of positive semidefinite matrices. These are models that generalize linear programs and are specializations of convex programming models. There are theoretical and "practical" algorithms for solving semidefinite programs in polynomial time [3]. Lovász and Schrijver [91] suggest a general relaxation strategy for $0-1$ integer programming problems that obtains semidefinite relaxations. The first step is to consider a homogenized version of a $0-1$ integer program (solvability version).

$$F_I = \left\{ \mathbf{x} \in \Re^{n+1} \,:\, A\mathbf{x} \geq 0,\ x_0 = 1,\ x_i \in \{0,1\} \text{ for } i = 1, 2, \cdots, n \right\}$$

The problem is to check if F_I is nonempty. Note that any $0-1$ integer program can be put in this form by absorbing a general right-hand side b as the negative of x_0 column of A. Now a linear programming relaxation of this integer program is given by:

$$\left\{ \mathbf{x} \in \Re^{n+1} \,:\, A\mathbf{x} \geq 0,\ x_0 = 1,\ 0 \leq x_i \leq x_0 \text{ for } i = 1, 2, \cdots, n \right\}$$

Next, we define two polyhedral cones.

$$\begin{aligned} \mathcal{K} &= \left\{ \mathbf{x} \in \Re^{n+1} \,:\, A\mathbf{x} \geq 0,\ 0 \leq x_i \leq x_0 \text{ for } i = 0, 1, \cdots, n \right\} \\ \mathcal{K}_I &= \text{Cone generated by } 0-1 \text{ vectors in } P_I \end{aligned}$$

Lovász and Schrijver [91] show how we might construct a family of convex cones $\{\mathcal{C}\}$ such that $\mathcal{K}_I \subseteq \mathcal{C} \subseteq \mathcal{K}$ for each $\mathcal{C}$.

(i) Partition the cone constraints of $\mathcal{K}$ into $T_1 = \{A_1\mathbf{x} \geq 0\}$ and $T_2 = \{A_2\mathbf{x} \geq 0\}$, with the constraints $\{0 \leq x_i \leq x_0 \text{ for } i = 0, 1, \cdots, n\}$ repeated in both (the overlap can be larger).

(ii) Multiply each constraint in T_1 with each constraint in T_2 to obtain a quadratic homogeneous constraint.

(iii) Replace each occurrence of a quadratic term $x_i x_j$ by a new variable X_{ij}. The quadratic constraints are now linear homogeneous constraints in X_{ij}.

(iv) Add the requirement that the $(n+1) \times (n+1)$ matrix X is symmetric and positive semidefinite.

(v) Add the constraints $X_{0i} = X_{ii}$ for $i = 1, 2, \ldots, n$.

The system of constraints on the X_{ij} constructed in steps (iii), (iv), and (v) above define a cone $M_+(T_1, T_2)$ parametrized by the partition T_1, T_2. We finally project the cone $M_+(T_1, T_2)$ to $\Re^{n+1}$ as follows.

$$\mathcal{C}_+(T_1, T_2) = \text{Diagonals of matrices in } M_+(T_1, T_2)$$

These resulting cones $\{\mathcal{C}_+(T_1, T_2)\}$ satisfy

$$\mathcal{K}_I \subseteq \mathcal{C}_+(T_1, T_2) \subseteq \mathcal{K}$$

where the X_{ii} in $\mathcal{C}_+(T_1, T_2)$ are interpreted as the original x_i in $\mathcal{K}$ and $\mathcal{K}_I$.

One semidefinite relaxation of the $0-1$ integer program F_I is just $\mathcal{C}_+(T_1, T_2)$ along with the normalizing constraint $X_{00} = x_0 = 1$. For optimization versions of integer programming, we simply carry over the objective function. An amazing result obtained by Lovász and Schrijver [91] is that this relaxation when applied to the vertex packing polytope (see "Aggregation") is at least as good as one obtained by adding "clique, odd hole, odd antihole and odd wheel" valid inequalities (see [61] for the definitions) to the linear programming relaxation of the set packing formulation. This illustrates the power of this approach to reveal structure and yet obtain a tractable relaxation. In particular, it also implies a polynomial-time algorithm

for the vertex packing problem on perfect graphs (cf. [61]). Another remarkable success that semidefinite relaxations have registered is the recent result on finding an approximately maximum weight edge cutset of a graph. This result of Goemans and Williamson [55] will be described in the next section. While the jury is still out on the efficacy of semidefinite relaxation as a general strategy for integer programming, there is little doubt that it provides an exciting new weapon in the arsenal of integer programming methodologies.

32.8 Approximation with Performance Guarantees

The relaxation techniques we encountered in the previous section are designed with the intent of obtaining a "good" lower (upper) bound on the optimum objective value for a minimization (maximization) problem. If in addition, we are able to construct a "good" feasible solution using a heuristic (possibly based on a relaxation technique) we can use the bound to quantify the suboptimality of the incumbent and hence the "quality of the approximation."

In the past few years, there has been significant progress in our understanding of performance guarantees for approximation of $\mathcal{NP}$-hard combinatorial optimization problems (cf. [117]). A ρ-approximate algorithm for an optimization problem is an approximation algorithm that delivers a feasible solution with objective value within a factor of ρ of optimal (think of minimization problems and $\rho \geq 1$). For some combinatorial optimization problems, it is possible to *efficiently* find solutions that are arbitrarily close to optimal even though finding the true optimal is hard. If this were true of most of the problems of interest we would be in good shape. However, the recent results of Arora et al. [5] indicate exactly the opposite conclusion.

A PTAS or polynomial-time approximation scheme for an optimization problem is a family of algorithms A_ρ, such that for each $\rho > 1$, A_ρ is a polynomial-time ρ-approximate algorithm. Despite concentrated effort spanning about two decades, the situation in the early 1990s was that for many combinatorial optimization problems, we had no PTAS and no evidence to suggest the nonexistence of such schemes either. This led Papadimitriou and Yannakakis [104] to define a new complexity class (using reductions that preserve approximate solutions) called MAXSNP and they identified several complete languages in this class. The work of Arora and colleagues completed this agenda by showing that, assuming $\mathcal{P} \neq \mathcal{NP}$, there is no PTAS for a MAXSNP-complete problem.

An implication of these theoretical developments is that for most combinatorial optimization problems, we have to be quite satisfied with performance guarantee factors $\rho \geq 1$ that are of some small fixed value. (There are problems, like the general traveling salesman problem, for which there are no ρ-approximate algorithms for any finite value of ρ—of course assuming $\mathcal{P} \neq \mathcal{NP}$). Thus one avenue of research is to go problem by problem and knock ρ down to its smallest possible value.

A different approach would be to look for other notions of "good approximations" based on probabilistic guarantees or empirical validation. A good example of the benefit to be gained from randomization is the problem of computing the volume of a convex body. Dyer and Frieze [37] have shown that this problem is $\#\mathcal{P}$-hard. Barany and Furedi [8] provide evidence that no polynomial-time deterministic approximation method with relative error less than $(cn)^{\frac{n}{2}}$, where c is a constant, is likely to exist. However, Dyer et al. [38] have designed a fully polynomial randomized approximation scheme (FPRAS) for this problem. The FPRAS of Dyer et al. [38] uses techniques from integer programming and the geometry of numbers (see Section 32.9).

LP Relaxation and Rounding

Consider the well-known problem of finding the *smallest weight vertex cover* in a graph (see "Formulations"). So we are given a graph $G(V, E)$ and a nonnegative weight $w(v)$ for each vertex $v \in V$. We want to find the smallest total weight subset of vertices S such that each edge of G has at least one end in S (this problem is known to be MAXSNP-hard). An integer programming formulation of this problem is given

by

$$\min \left\{ \sum_{v \in V} w(v)x(v) : x(u) + x(v) \geq 1, \ \forall (u, v) \in E, \quad x(v) \in \{0, 1\} \ \forall v \in V \right\}$$

To obtain the linear programming relaxation we substitute the $x(v) \in \{0, 1\}$ constraint with $x(v) \geq 0$ for each $v \in V$. Let $\mathbf{x}^*$ denote an optimal solution to this relaxation. Now let us round the fractional parts of $\mathbf{x}^*$ in the usual way, that is, values of 0.5 and up are rounded to 1 and smaller values to 0. Let $\hat{\mathbf{x}}$ be the 0–1 solution obtained. First note that $\hat{x}(v) \leq 2x^*(v)$ for each $v \in V$. Also, for each $(u, v) \in E$, since $x^*(u) + x^*(v) \geq 1$, at least one of $x(\hat{u})$ and $x(\hat{v})$ must be set to 1. Hence $\hat{\mathbf{x}}$ is the incidence vector of a vertex cover of G whose total weight is within twice the total weight of the linear programming relaxation (which is a lower bound on the weight of the optimal vertex cover). Thus we have a 2-approximate algorithm for this problem which solves a linear programming relaxation and uses rounding to obtain a feasible solution.

The deterministic rounding of the fractional solution worked quite well for the vertex cover problem. One gets a lot more power from this approach by adding in randomization to the rounding step. Raghavan and Thompson [108] proposed the following obvious randomized rounding scheme. Given a $0 - 1$ integer program, solve its linear programming relaxation to obtain an optimal $\mathbf{x}^*$. Treat the $x_j{}^* \in [0, 1]$ as probabilities, i.e., let Probability$\{x_j = 1\} = x_j{}^*$, to randomly round the fractional solution to a $0 - 1$ solution. Using Chernoff bounds on the tails of the binomial distribution, they were able to show, for specific problems, that with high probability, this scheme produces integer solutions which are close to optimal. In certain problems, this rounding method may not always produce a feasible solution. In such cases, the expected values have to be computed as conditioned on feasible solutions produced by rounding. More complex (nonlinear) randomized rounding schemes have been recently studied and have been found to be extremely effective. We will see an example of nonlinear rounding in the context of semidefinite relaxations of the max-cut problem below.

Primal Dual Approximation

The linear programming relaxation of the vertex cover problem, we saw above, is given by

$$(P_{VC}) \quad \min \left\{ \sum_{v \in V} w(v)x(v) : x(u) + x(v) \geq 1, \ \forall (u, v) \in E, \quad x(v) \geq 0 \ \forall v \in V \right\}$$

and its dual is

$$(D_{VC}) \quad \max \left\{ \sum_{(u,v) \in E} y(u, v) : \sum_{u | (u,v) \in E} y(u, v) \leq w(v), \ \forall v \in V, \quad y(u, v) \geq 0 \ \forall (u, v) \in E \right\}$$

The primal-dual approximation approach would first obtain an optimal solution y^* to the dual problem (D_{VC}). Let $\hat{V} \subseteq V$ denote the set of vertices for which the dual constraints are tight, i.e.,

$$\hat{V} = \left\{ v \in V : \sum_{u | (u,v) \in E} y^*(u, v) = w(v) \right\}$$

The approximate vertex cover is taken to be $\hat{V}$. It follows from complementary slackness that $\hat{V}$ is a vertex cover. Using the fact that each edge (u, v) is in the star of at most two vertices (u and v), it also follows that $\hat{V}$ is a 2-approximate solution to the minimum weight vertex cover problem.

In general, the primal-dual approximation strategy is to use a dual solution, to the linear programming relaxation, along with complementary slackness conditions as a heuristic to generate an integer (primal) feasible solution which for many problems turns out to be a good approximation of the optimal solution to the original integer program.

It is a remarkable property of the vertex covering (and packing) problem that all extreme points of the linear programming relaxation have values 0, $\frac{1}{2}$ or 1 [94]. It follows that the deterministic rounding of the linear programming solution to (P_{VC}) constructs exactly the same approximate vertex cover as the primal-dual scheme described above. However, this is not true in general.

Semidefinite Relaxation and Rounding

The idea of using semidefinite programming to approximately solve combinatorial optimization problems appears to have originated in the work of Lovász [90] on the Shannon capacity of graphs. Grötschel, Lovász and Schrijver [61] later used the same technique to compute a maximum stable set of vertices in perfect graphs via the ellipsoid method. As we saw in "Semidefinite Relaxation," Lovasz and Schrijver [91] have devised a general technique of semidefinite relaxations for general $0-1$ integer linear programs. We will present a lovely application of this methodology to approximate the maximum weight cut of a graph (the maximum sum of weights of edges connecting across all strict partitions of the vertex set). This application of semidefinite relaxation for approximating MAXCUT is due to Goemans and Williamson [55].

We begin with a quadratic Boolean formulation of MAXCUT

$$\max \left\{ \frac{1}{2} \sum_{(u,v)\in E} w(u,v)(1 - x(u)x(v)) : \quad x(v) \in \{-1, 1\} \ \forall \ v \in V \right\}$$

where $G(V, E)$ is the graph and $w(u, v)$ is the nonnegative weight on edge (u, v). Any $\{-1, 1\}$ vector of $\mathbf{x}$ values provides a bipartition of the vertex set of G. The expression $(1 - x(u)x(v))$ evaluates to 0 if u and v are on the same side of the bipartition and 2 otherwise. Thus, the optimization problem does indeed represent exactly the MAXCUT problem.

Next we reformulate the problem in the following way.

- We square the number of variables by allowing each $\mathbf{x}(v)$ to denote an n-vector of variables (where n is the number of vertices of the graph).
- The quadratic term $x(u)x(v)$ is replaced by $\mathbf{x}(u) \cdot \mathbf{x}(v)$, which is the inner product of the vectors.
- Instead of the $\{-1, 1\}$ restriction on the $x(v)$, we use the Euclidean normalization $\|\mathbf{x}(v)\| = 1$ on the $\mathbf{x}(v)$.

So we now have a problem

$$\max \left\{ \frac{1}{2} \sum_{(u,v)\in E} w(u,v)(1 - \mathbf{x}(u) \cdot \mathbf{x}(v)) : \quad \|\mathbf{x}(v)\| = 1 \ \forall \ v \in V \right\}$$

which is a relaxation of the MAXCUT problem (note that if we force only the first component of the $\mathbf{x}(v)$'s to have nonzero value, we would just have the old formulation as a special case).

The final step is in noting that this reformulation is nothing but a semidefinite program. To see this we introduce $n \times n$ Gram matrix Y of the unit vectors $\mathbf{x}(v)$. So $Y = X^T X$ where $X = (\mathbf{x}(v) : \ v \in V)$. So the relaxation of MAXCUT can now be stated as a semidefinite program.

$$\max \left\{ \frac{1}{2} \sum_{(u,v)\in E} w(u,v)(1 - Y_{(u,v)}) : \quad Y \succeq 0, \quad Y_{(v,v)} = 1 \ \forall \ v \in V \right\}$$

Note that we are able to solve such semidefinite programs to an additive error ϵ in time polynomial in the input length and $\log \frac{1}{\epsilon}$ using either the ellipsoid method or interior point method (see [3] and Chapters 31 and 34 of this *Handbook*).

Let $\mathbf{x}^*$ denote the near optimal solution to the semidefinite programming relaxation of MAXCUT (convince yourself that $\mathbf{x}^*$ can be reconstructed from an optimal Y^* solution). Now we encounter the final trick of Goemans and Williamson. The approximate maximum weight cut is extracted from $\mathbf{x}^*$ by randomized rounding. We simply pick a random hyperplane H passing through the origin. All the $v \in V$ lying to one side of H get assigned to one side of the cut and the rest to the other. Goemans and Williamson observed the following inequality.

LEMMA 32.1 For $\mathbf{x}_1$ and $\mathbf{x}_2$, two random n-vectors of unit norm, let $x(1)$ and $x(2)$ be ± 1 values with opposing sign if H separates the two vectors and with same signs otherwise. Then $\tilde{E}(1 - \mathbf{x}_1{}^T \mathbf{x}_2) \leq 1.1393 \cdot \tilde{E}(1 - x(1)x(2))$ where $\tilde{E}$ denotes the expected value.

By linearity of expectation, the lemma implies that the expected value of the cut produced by the rounding is at least 0.878 times the expected value of the semidefinite program. Using standard conditional probability techniques for derandomizing, Goemans and Williamson show that a deterministic polynomial-time approximation algorithm with the same margin of approximation can be realized. Hence we have a cut with value at least 0.878 of the maximum value.

32.9 Geometry of Numbers and Integer Programming

Given an integer program with a fixed number of variables (k) we seek a polynomial-time algorithm for solving them. Note that the complexity is allowed to be exponential in k, which is independent of the input length. Clearly if the integer program has all (0, 1) integer variables this is a trivial task, since complete enumeration works. However if we are given an "unbounded" integer program to begin with, the problem is no longer trivial.

Lattices, Short Vectors and Reduced Bases

Euclidean **lattices** are a simple generalization of the regular integer lattice $\mathcal{Z}^n$. A (point) *lattice* is specified by $\{\mathbf{b}_1, \cdots, \mathbf{b}_n\}$ a *basis* (where $\mathbf{b}_i$ are linearly independent n-dimensional rational vectors). The lattice L is given by

$$L = \left\{ \mathbf{x} : \mathbf{x} = \sum_{i=1}^{n} z_i \mathbf{b}_i; \quad z_i \in Z \ \forall i \right\}$$

$$B = \left(\mathbf{b}_1 \vdots \mathbf{b}_2 \vdots \cdots \vdots \mathbf{b}_n \right) \text{ a basis matrix of } L$$

THEOREM 32.9 *$|det\, B|$ is an invariant property of the lattice L (i.e., for every basis matrix B_i of L we have invariant $d(L) = |det\, B_i|$).*

Note that

$$d(L) = \Pi_{i=1}^{n} |\mathbf{b}_i| \text{ where } |\mathbf{b}_i| \text{ denotes the Euclidean length of } \mathbf{b}_i$$

if and only if the basis vectors $\{\mathbf{b}_i\}$ are mutually orthogonal. A "sufficiently orthogonal" basis B (called a **reduced basis**) is one that satisfies a weaker relation

$$d(L) \leq c_n \Pi_{i=1}^{n} \left| \mathbf{b_i} \right| \text{ where } c_n \text{ is a constant that depends only on } n$$

One important use (from our perspective) of a reduced basis is that one of the basis vectors has to be "short." Note that there is substantive evidence that finding the shortest lattice vector is $\mathcal{NP}$-hard [61].

Minkowski proved that in every lattice L there exists a vector of length no larger than $c\sqrt{n}\sqrt[n]{d(L)}$ (with c no larger than 0.32). This follows from the celebrated Minkowski's Convex Body Theorem which forms the centerpiece of the geometry of numbers [19].

THEOREM 32.10 **(Minkowski's Convex Body Theorem)** *If $K \subseteq \Re^n$ is a convex body that is centrally symmetric with respect to the origin, and $L \subseteq \Re^n$ is a lattice such that $vol(K) \geq 2^n d(L)$ then K contains a lattice point different from the origin.*

However, no one has been successful thus far in designing an efficient algorithm (polynomial-time) for constructing the short lattice vector guaranteed by Minkowski. This is where the concept of a reduced basis comes to the rescue. We are able to construct a reduced basis in polynomial time and extract a short vector from it. To illustrate the concepts we will now discuss an algorithm due to Gauss (cf. [6]) that proves the theorem for the special case of planar lattices ($n = 2$). It is called the 60^o algorithm because it produces a reduced basis $\{\mathbf{b_1}, \mathbf{b_2}\}$ such that the acute angle between the two basis vectors is at least 60°.

Procedure: 60^o **Algorithm**

Input: `Basis vectors` $\mathbf{b}_1$ `and` $\mathbf{b}_2$ `with` $|\mathbf{b}_1| \geq |\mathbf{b}_2|$.

Output: `A reduced basis` $\{\mathbf{b}_1, \mathbf{b}_2\}$ `with at least` 60° `angle between the basis vectors.`

0. `repeat until` $|\mathbf{b}_1| < |\mathbf{b}_2|$
1. `swap` $\mathbf{b}_1$ `and` $\mathbf{b}_2$
2. $\mathbf{b}_2 \leftarrow (\mathbf{b}_2 - m\mathbf{b}_1)$ `and` $m = \left[\frac{\mathbf{b}_2^T \mathbf{b}_1}{\mathbf{b}_1^T \mathbf{b}_1}\right] \in Z$.
   `Here` $[\alpha]$ `denotes the integer nearest to` α.
3. `end`

Remarks:

(i) In each iteration the projection of $(\mathbf{b}_2 - m\mathbf{b}_1)$ onto the direction of $\mathbf{b}_1$ is of length atmost $|\mathbf{b}_1|/2$.

(ii) When the algorithm stops $\mathbf{b}_2$ must lie in one of the shaded areas at the top or at the bottom of Fig. 32.4 (since $|\mathbf{b}_2| > |\mathbf{b}_1|$ and since the projection of $\mathbf{b}_2$ must fall within the two vertical lines about $\mathbf{b}_1$).

(iii) The length of $\mathbf{b}_1$ strictly decreases in each iteration. Hence the algorithm is finite. That it is polynomial time takes a little more argument [82].

(iv) The short vector $\mathbf{b}_1$ produced by the algorithm satisfies $|\mathbf{b}_1| \leq (1.075)(d(L))^{\frac{1}{2}}$).

The only known polynomial-time algorithm for constructing a reduced basis in an arbitrary dimensional lattice [86] is not much more complicated than the 60° algorithm. However, the proof of polynomiality is quite technical (see [6] for an exposition).

Lattice Points in a Triangle

Consider a triangle T in the Euclidean plane defined by the inequalities

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 &\leq d_1 \\ a_{21}x_1 + a_{22}x_2 &\leq d_2 \\ a_{31}x_1 + a_{32}x_2 &\leq d_3 \end{aligned}$$

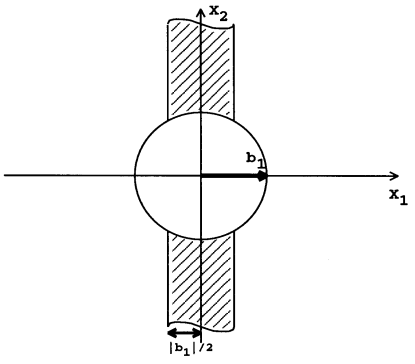

FIGURE 32.4 A reduced basis.

The problem is to check if there is a lattice point $(x_1, x_2) \in Z^2$ satisfying the three inequalities. The reader should verify that checking all possible lattice points within some bounding box of T leads to an exponential algorithm for skinny and long triangles. There are many ways of realizing a polynomial-time search algorithm [46, 73] for two-variable integer programs. Following Lenstra [88] we describe one that is a specialization of his [87] powerful algorithm for integer programming (searching for a lattice point in a polyhedron).

First we use a nonsingular linear transform τ that makes T equilateral (round). The transform sends the integer lattice Z^2 to a generic two-dimensional lattice L. Next we construct a reduced basis $\{\mathbf{b}_1, \mathbf{b}_2\}$ for L using the 60° algorithm. Let β_1 denote the length of the short vector $\mathbf{b}_1$. If l denotes the length of a side of the equilateral triangle $\tau(T)$ we can conclude that T is guaranteed to contain a lattice point if $\frac{l}{\beta_1} \geq \sqrt{6}$. Else $l < \sqrt{6}\beta_1$ and we can argue that just a few (no more than 3) of the lattice lines $\{\text{Affine Hull}\{\mathbf{b_1}\} + \mathbf{kb_2}\}_{\mathbf{k}\in\mathbf{Z}}$ can intersect T. We recurse to the lower dimensional segments (lattice lines intersecting with T) and search each segment for a lattice point. Hence this scheme provides a simple polynomial-time algorithm for searching for a lattice point in a triangle.

Lattice Points in Polyhedra

In 1979, H.W. Lenstra, Jr., announced that he had a polynomial-time algorithm for integer programming problems with a fixed number of variables. The final published version [87] of his algorithm resembles the procedure described above for the case of a triangle and a planar lattice. As we have noted before, integer programming is equivalent to searching a polyhedron specified by a system of linear inequalities for an integer lattice point. Lenstra's algorithm then proceeds as follows.

- First "round" the polyhedron using a linear transformation. This step can be executed in polynomial time (even for varying n) using any polynomial-time algorithm for linear programming.
- Find a reduced basis of the transformed lattice. This again can be done in polynomial time even for varying n.
- Use the reduced basis to conclude that a lattice point must lie inside or recurse to several lower dimensional integer programs by slicing up the polyhedron using a "long" vector of the basis to ensure that the number of slices depends only on n.

A slightly different approach based on Minkowski's convex body theorem was designed by Kannan [74] to obtain an $O(n^{\frac{9n}{2}}L)$ algorithm for integer programming (where L is the length of the input). The following two theorems are straightforward consequences of these polynomial-time algorithms for integer programming with a fixed number of variables.

THEOREM 32.11 **(Fixed Number of Constraints)** *Checking the solvability of*

$$A\mathbf{x} \leq \mathbf{b};\ \mathbf{x} \in Z^n$$

where A is $(m \times n)$ *is solvable in polynomial time if* m *is held fixed.*

THEOREM 32.12 **(Mixed Integer Programming)** *Checking the solvability of*

$$A\mathbf{x} \leq \mathbf{b};\ x_j \in Z \text{ for } j = 1, \cdots, k;\ x_j \in \Re \text{ for } j = k+1, \cdots, n$$

where A is $(m \times n)$ *is solvable in polynomial time if* $\min\{m, k\}$ *is held fixed.*

A related but more difficult question is that of counting the number of feasible solutions to an integer program or equivalently counting the number of lattice points in a polytope. Building on results described above, Barvinok [9] was able to show the following.

THEOREM 32.13 **(Counting Lattice Points)** *Counting the size of the set*

$$\left\{\mathbf{x} \in Z^k\ :\ A\mathbf{x} \leq \mathbf{b}\right\}$$

is solvable in polynomial time if k *is held fixed.*

An Application in Cryptography

In 1982, Adi Shamir [114] pointed out that Lenstra's algorithm could be used to devise a polynomial-time algorithm for cracking the basic Merkle–Hellman Cryptosystem (a knapsack-based public-key cryptosystem). In such a cryptosystem the message to be sent is a (0-1) string $\bar{\mathbf{x}} \in \{0, 1\}^n$. The message is sent as an instance of the (0,1) knapsack problem, which asks for an $\mathbf{x} \in \{0, 1\}^n$ satisfying $\Sigma_{i=1}^n a_i x_i = a_0$. The knapsack problem is an $\mathcal{NP}$-hard optimization problem (we saw in Section "Aggregation" that any integer program can be aggregated to a knapsack). However, if $\{a_i\}$ form a super-increasing sequence, i.e., $a_i > \Sigma_{j=1}^{i-1} a_j\ \forall i$, the knapsack problem can be solved in time $O(n)$ by a simple algorithm:

Procedure: **Best-Fit**

0. $i \leftarrow n$
1. **If** $a_i \leq a_0,\ \overline{x}_i \leftarrow 1,\ a_0 \leftarrow a_0 - a_i$
2. $i \leftarrow (i-1)$
3. `If` $a_0 = 0$ **stop** `and` **return** `the solution` $\mathbf{x}$
4. `If` $i = 1$ **stop** `the knapsack is infeasible.`
5. `repeat 1.`

However, an eavesdropper could solve this problem as well and hence the $\{a_i\}$ have to be encrypted. The disguise is chosen through two "secret" numbers M and U such that $M > \Sigma_{i=1}^n a_i$ and U is relatively prime to M (i.e., $gcd(U, M) = 1$). Instead of $\{a_i\}$, the sequence $\{\tilde{a}_i = Ua_i (\text{mod } M)\}_{i=1,2,\cdots,n}$ is published and $\tilde{a}_0 = Ua_0 (\text{mod } M)$ is transmitted.

Any receiver who "*knows*" U and M can easily reconvert $\{\tilde{a}_i\}$ to $\{a_i\}$ and apply the best fit algorithm to obtain the message $\bar{\mathbf{x}}$. To find a_i given $\tilde{a}_i$, U and M, he runs the Euclidean algorithm on (U, M) to obtain $1 = PU + QM$. Hence, P is the inverse multiplier of U since $PU \equiv 1 (\text{mod } M)$. Using the identity $a_i \equiv P\tilde{a}_i (\text{mod } M)\ \ \forall i = 0, 1, \ldots, n$, the intended receiver can now use the best fit method to

decode the message. An eavesdropper knows only the $\{\tilde{a}_i\}$ and is therefore supposedly unable to decrypt the message.

The objective of Shamir's cryptanalyst (code breaker) is to find a $\hat{P}$ and in $\hat{M}$ (positive integer) such that

$$(*) \qquad \begin{array}{l} \hat{a}_i \equiv \hat{P}\tilde{a}_i \bmod \hat{M} \ \forall i = 0, 1, \cdots, n \\ \{\hat{a}_i\}_{i=1,\cdots,n} \text{ is a super increasing sequence.} \\ \sum_{i=1}^{n} \hat{a}_i < \hat{M} \end{array}$$

It can be shown that for all pairs $(\hat{P}, \hat{M})$ such that $(\hat{P}/\hat{M})$ is "sufficiently"close to (P/M) will satisfy $(*)$. Using standard techniques from diophantine approximation it would be possible to guess P and M from the estimate $(\hat{P}/\hat{M})$. However, the first problem is to get the estimate of (P/M). This is where integer programming helps.

Since $a_i \equiv P\tilde{a}_i \pmod{M}$ for $i = 1, 2, \ldots, n$ we have $a_i P\tilde{a}_i - y_i M$ for some integers $y_1, y_2, \ldots, y_n$. Dividing by $\tilde{a}_i M$ we have $\left(\frac{a_i}{\tilde{a}_i M}\right) = \frac{P}{M} - \frac{y_i}{\tilde{a}_i}$ for $i = 1, 2, \ldots, n$. For small $i(1, 2, 3, \ldots, t)$ the LHS $\approx$ 0 since $\Sigma_{i=1}^{n} a_i < M$ and the $\{a_i\}_{i=1,\cdots,n}$ are super-increasing. Thus $(y_1/\tilde{a}_1), (y_2/\tilde{a}_2), \ldots, (y_t/\tilde{a}_t)$ are "close to" (P/M) and hence to each other. Therefore a natural approach to estimating (P/M) would be to solve the integer program:

$$(IP) \qquad \begin{array}{l} \text{Find } y_1, y_2, \cdots, y_t \in \mathcal{Z} \text{ such that :} \\ \underline{\epsilon_i} \leq \tilde{a}_i y_1 - \tilde{a}_1 y_i \leq \overline{\epsilon_i} \text{ for } i = 2, 3, \cdots, t \\ 0 < y_i < \tilde{a}_i \text{ for } i = 1, 2, \cdots, t \end{array}$$

This t variable integer program provides an estimate of (P/M), whence Diophantine approximation methods can be used to find $\hat{P}$ and $\hat{M}$. If we denote by d a density parameter of the instance where, $d = \frac{\log a_o}{n \log 2}$, the above scheme works correctly (with probability one as $n \to \infty$) if t is chosen to be $(\lfloor d \rfloor + 2)$ [83, 114]. Moreover, the scheme is polynomial-time in n for fixed d. The probabilistic performance is not a handicap, since as Shamir points out, "... a cryptosystem becomes useless when most of its keys can be efficiently cryptanalyzed" [114].

32.10 Prospects in Integer Programming

The current emphasis in software design for integer programming is in the development of shells (for example CPLEX [33], MINTO [111], and OSL [68]) wherein a general purpose solver like Branch & Cut is the driving engine. Problem specific code for generation of cuts and facets can be easily interfaced with the engine. We believe that this trend will eventually lead to the creation of general purpose problem solving languages for combinatorial optimization akin to AMPL [48] for linear and nonlinear programming.

A promising line of research is the development of an empirical science of algorithms for combinatorial optimization [66]. Computational testing has always been an important aspect of research on the efficiency of algorithms for integer programming. However, the standards of test designs and empirical analysis have not been uniformly applied. We believe that there will be important strides in this aspect of integer programming, and more generally of algorithms of all kinds. It may be useful to stop looking at algorithmics as purely a deductive science, and start looking for advances through repeated application of "hypothesize and test" paradigms [67], i.e., through empirical science.

The integration of logic-based methodologies and mathematical programming approaches is evidenced in the recent emergence of constraint logic programming (CLP) systems [15, 112] and logico-mathematical programming [21, 70]. In CLP, we see a structure of Prolog-like programming language in which some of the predicates are constraint predicates whose truth values are determined by the solvability of constraints in a wide range of algebraic and combinatorial settings. The solution scheme is simply a clever orchestration

of constraint solvers in these various domains and the role of conductor is played by SLD-resolution. The clean semantics of logic programming is preserved in CLP. A bonus is that the output language is symbolic and expressive. An orthogonal approach to CLP is to use constraint programming methods to solve inference problems in logic. Imbeddings of logics in mixed integer programming sets were proposed by Williams [122] and Jeroslow [70]. Efficient algorithms have been developed for inference problems in many types and fragments of logic, ranging from Boolean to predicate to belief logics [22].

A persistent theme in the integer programming approach to combinatorial optimization, as we have seen, is that the representation (formulation), of the problem, deeply affects the efficacy of the solution methodology. A proper choice of formulation can therefore make the difference between a successful solution of an optimization problem and the more common perception that the problem is insoluble and one must be satisfied with the best that heuristics can provide. Formulation of integer programs has been treated more as an art form than a science by the mathematical programming community (exceptions are Jeroslow [70] and Williams [121]). We believe that progress in representation theory can have an important influence on future of integer programming as a broad-based problem solving methodology.

32.11 Defining Terms

ρ-Approximation: An approximation method that delivers a feasible solution with objective value within a factor ρ of the optimal value of a combinatorial optimization problem.

Cutting plane: A valid inequality for an **integer polyhedron** that separates the polyhedron from a given point outside it.

Extreme point: A corner point of a polyhedron.

Fathoming: Pruning a search tree.

Integer polyhedron: A polyhedron, all of whose extreme points are integer valued.

Knapsack problem: An integer linear program with a single linear constraint other than the trivial bounds and integrality constraints on the variables.

Lattice: A point lattice generated by taking integer linear combinations of a set of basis vectors.

Linear program: Optimization of a linear function subject to linear equality and inequality constraints.

Mixed integer linear program: A linear program with the added constraint that some of the decision variables are integer valued.

Packing and covering: Given a finite collection of subsets of a finite ground set, to find an optimal subcollection that are pairwise disjoint (packing) or whose union covers the ground set (covering).

Polyhedron: The set of solutions to a finite system of linear inequalities on real-valued variables. Equivalently, the intersection of a finite number of linear half-spaces in $\Re^n$.

Reduced basis: A basis for a lattice that is nearly orthogonal.

Relaxation: An enlargement of the feasible region of an optimization problem. Typically, the relaxation is considerably easier to solve than the original optimization problem.

Further Information

Research publications in integer programming are dispersed over a large range of journals. The following is a partial list which emphasize the algorithmic aspects: *Mathematical Programming, Mathematics of Operations Research, Operations Research, Discrete Mathematics, Discrete Applied Mathematics, Journal of Combinatorial Theory (Series B), INFORMS Journal on Computing, Operations Research Letters, SIAM Journal on Computing, SIAM Journal on Discrete Mathematics, Journal of Algorithms, Algorithmica, Combinatorica.*

Integer programming professionals frequently use the following newsletters to communicate with each other:

- *INFORMS Today* (earlier *OR/MS Today*) published by The Institute for Operations Research and Management Science (INFORMS).
- *INFORMS CSTS Newsletter* published by the INFORMS computer science technical section.
- *Optima* published by the Mathematical Programming Society.

The International Symposium on Mathematical Programming (ISMP) is held once every three years and is sponsored by the Mathematical Programming Society. The most recent ISMP was held in August 1997 in Lausanne, Switzerland. A conference on Integer Programming and Combinatorial Optimization (IPCO) is held on years when the symposium is not held. Some important results in integer programming are also announced in the general conferences on algorithms and complexity (for example, SODA (SIAM), STOC (ACM), and FOCS (IEEE)). The annual meeting of the Computer Science Technical Section (CSTS) of the INFORMS held each January (partial proceedings published by Kluwer Press) is an important source for recent results in the computational aspects of integer programming.

33

Convex Optimization

Stephen A. Vavasis
Cornell University

33.1 Introduction

Nonlinear constrained **optimization** refers to the problem of minimizing $f(\mathbf{x})$ subject to $\mathbf{x} \in D$, where D is a subset of $\mathbf{R}^n$ and f is a continuous function from D to $\mathbf{R}$. Thus, an input instance is a specification of D, called the **feasible set,** and f, called the **objective function.** The output from an optimization algorithm is either a point $\mathbf{x}^* \in D$, called an **optimizer** or **global optimizer,** such that $f(\mathbf{x}^*) \leq f(\mathbf{x})$ for all $\mathbf{x} \in D$, or else a statement (preferably accompanied by a certificate) that no such $\mathbf{x}^*$ exists. The terms "**minimizer**" and "global minimizer" are also used.

Stated in this manner, nonlinear optimization encompasses a huge range of scientific and engineering problems. In fact, this statement of the problem is too general: there are undecidable problems that can naturally fit into the framework of the last paragraph. Thus, most optimization algorithms are limited to some subclass of the general case. Furthermore, most algorithms compute something easier to find than a true global minimizer, like a local minimizer.

This chapter focuses on **convex programming,** the subclass of nonlinear optimization in which the set D is convex and the function f is also convex. The term "convex" is defined in the next section. Convex programming is interesting for three reasons: (a) convex problems arise in many applications, some of which are described in subsequent sections, (b) mathematicians have developed a rich body of theory on the topic of convexity, and (c) there are powerful algorithms for efficiently solving convex problems, which is the topic of most of this chapter. The development of "**self-concordant barrier functions**" by Nesterov and Nemirovskii [37] has led to much new research in the field. The purpose of this chapter is to describe

some of the fundamentals of convex optimization and sketch some of the recent developments based on self-concordance. At the end of the chapter, some issues concerning general (nonconvex) nonlinear optimization are raised. This chapter does not cover "low dimensional" convex programming in which the number of unknowns is very small, e.g., less than 10. Such problems arise in computational geometry and are covered in that chapter.

The remainder of this chapter is organized as follows. In the next section we cover general definitions and principles of convex optimization. In Section 33.3 we cover the **ellipsoid method** for convex optimization. In Section 33.4 and Section 33.5 we describe an **interior-point method** for convex programming, based on self-concordant barrier functions. In Section 33.6 the interior-point method is specialized to **semidefinite programming** and in Section 33.7 further specialized to **linear programming.** In Section 33.8 we discuss some Turing-machine complexity issues for convex optimization. Finally, in Section 33.9 we make some brief remarks on applications to nonconvex optimization.

33.2 Underlying Principles

Convexity

The main theme of this chapter is convexity. A set $D \subset \mathbf{R}^n$ is said to be **convex** if, for any $\mathbf{x},\mathbf{y} \in D$, and for any $\lambda \in [0, 1]$, $\lambda\mathbf{x} + (1-\lambda)\mathbf{y} \in D$. In other words, for any $\mathbf{x},\mathbf{y} \in D$, the segment joining $\mathbf{x},\mathbf{y}$ also lies in D. Some useful properties of **convex sets** are as follows:

- A convex set is connected.
- The intersection of two convex sets is convex. In fact, an infinite intersection of convex sets is convex.
- An affine transformation applied to a convex set yields a convex set. An **affine transformation** from $\mathbf{R}^n$ to $\mathbf{R}^m$ is a mapping of the form $\mathbf{x} \mapsto A\mathbf{x} + \mathbf{b}$, where A is an $m \times n$ matrix and $\mathbf{b}$ is an m-vector.

Let D be a convex subset of $\mathbf{R}^n$. A function $f : D \to \mathbf{R}$ is said to be **convex** if for all $\mathbf{x},\mathbf{y} \in D$, and for all $\lambda \in [0, 1]$,

$$f(\lambda\mathbf{x} + (1-\lambda)\mathbf{y}) \leq \lambda f(\mathbf{x}) + (1-\lambda) f(\mathbf{y}) \,. \tag{33.1}$$

This definition may be stated geometrically as follows. If $\mathbf{x},\mathbf{y} \in D$, then the segment in $\mathbf{R}^{n+1}$ joining $(\mathbf{x}, f(\mathbf{x}))$ to $(\mathbf{y}, f(\mathbf{y}))$ lies above the graph of f. Some useful properties of **convex functions** are as follows:

- A convex function composed with an affine transformation is convex.
- The pointwise maximum of two convex functions is convex.
- If f, g are convex functions, so is $\alpha f + \beta g$ for any nonnegative scalars α and β.
- If f is a convex function on D, then the set $\{\mathbf{x} \in D : f(\mathbf{x}) \leq \alpha\}$ is convex for any choice of $\alpha \in \mathbf{R}$.

Some examples of convex functions are as follows:

- A **linear function** $f(\mathbf{x}) = \mathbf{a}^T\mathbf{x} + c$, where $\mathbf{a} \in \mathbf{R}^n$ and $c \in \mathbf{R}$ are given. (A constant function is a special case of a linear function.)
- More generally, a **positive semidefinite** quadratic function. Recall that a quadratic function has the form $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^T H\mathbf{x} + \mathbf{a}^T\mathbf{x} + c$, where H is a given $n \times n$ **symmetric matrix, a** is a given vector, and c a given scalar. Recall that an $n \times n$ real matrix H is **symmetric** if $H^T = H$, where superscript ^{T} denotes matrix transpose. This function is convex provided that H is a positive semidefinite matrix. Recall that a real symmetric matrix H is said to be **positive semidefinite** if either of the following two equivalent conditions holds:
  1. For every $\mathbf{w} \in \mathbf{R}^n$, $\mathbf{w}^T H\mathbf{w} \geq 0$.

2. Every eigenvalue of H is nonnegative.

If every eigenvalue of H is positive (or, equivalently, if $\mathbf{w}^T H\mathbf{w} > 0$ for every nonzero vector $\mathbf{w}$), we say H is **positive definite.**

- The function $f(x) = -\ln x$ defined on the positive real numbers.

Feasible sets D for optimization problems are typically defined as the set of points $\mathbf{x}$ satisfying a list of **equality constraints,** that is, **constraints** of the form $g(\mathbf{x}) = 0$ where g is a real-valued function, and **inequality constraints,** that is, constraints of the form $h(\mathbf{x}) \leq 0$, where h is a real-valued function. The entries of $\mathbf{x}$ are called the **variables** or **decision variables** or **unknowns** of the optimization problem. Some commonly occurring constraints are as follows.

- A linear equation $\mathbf{a}^T\mathbf{x} = b$, where $\mathbf{a}$ is a fixed vector in $\mathbf{R}^n$ and b is a scalar.
- A linear inequality $\mathbf{a}^T\mathbf{x} \leq b$.
- A p-norm constraint of the form $\|\mathbf{x} - \mathbf{x}_0\|_p \leq r$ where $\mathbf{x}_0 \in \mathbf{R}^n$, $p \geq 1$ and $r \geq 0$ are given.
- A constraint that X must be symmetric and positive semidefinite, where X is a matrix whose entries are variables.
  The constraint that X is symmetric amounts to $n(n-1)/2$ linear equality constraints among off-diagonal elements of X. The **semidefinite constraint** can be written in the form $-\pi(X) \leq 0$ where
  $$\pi(X) = \min_{\|\mathbf{w}\|_2=1} \mathbf{w}^T X\mathbf{w} .$$
  The function $-\pi$ is a convex function of matrices. In the case that X is symmetric, $\pi(X)$ is the minimum eigenvalue of X.

A **convex constraint** is defined to be either a linear equality or inequality constraint, or is a constraint of the form $h(\mathbf{x}) \leq \mathbf{0}$ where h is a convex function. In fact, all of the above constraints are convex constraints. Because the intersection of convex sets is convex, any arbitrary conjunction of constraints of any type chosen from the above list, or affine transformations of these constraints, yields a convex set.

A convex set defined by linear constraints (that is, constraints of the first two types in the above list) is said to be a **polyhedron.**

Finally, we come to the definition of the main topic of this chapter. A **convex optimization** or **convex programming** instance is an optimization instance in which the feasible set D is defined by convex constraints, and the objective function f is also convex.

An alternative (more general) definition is that convex programming means minimizing a convex function $f(\mathbf{x})$ over a convex set D. The distinction (compared to the definition in the last paragraph) is that a convex set D is sometimes represented by means other than convex constraints. For example, the set $D = \{(x, y) \in \mathbf{R}^2 : x \geq 0, xy \geq 1\}$ is convex even though $xy \geq 1$ is not a convex constraint. The interior-point method described below can sometimes be applied in this more general setting.

Some special cases of convex programming problems include the following:

1. **Linear programming** (LP) refers to optimization problems in which $f(\mathbf{x})$ is a linear function of $\mathbf{x}$ and D is a polyhedron, i.e., it is defined by the conjunction of linear constraints.
2. **Quadratic programming** (QP) refers to optimization problems in which $f(\mathbf{x})$ is a quadratic function and D is a polyhedron. Such problems will be convex if the matrix in the quadratic function is positive semidefinite.
3. **Semidefinite programming** (SDP) refers to optimization problems in which $f(\mathbf{x})$ is a linear function and D is defined by linear and semidefinite constraints.

The word "programming" in these contexts is not directly related to "programming" a computer in the usual sense. This terminology arises for historical reasons.

One reason to be interested in convex optimization is that these classes of problems occur in many applications. Linear programming [6] is the problem that launched optimization as a discipline of study and is widely used for scheduling and planning problems. Quadratic programming arises in applications in which the objective function involves distance or energy (which are typically quadratic functions). Quadratic programming also arises as a subproblem of more general optimization algorithms; see, e.g., [35].

Finally, semidefinite programming is more general than both linear and convex programming, and arises in a number of unexpected contexts. The recent survey [55] presents many applications in which, at first glance, the optimization problem seemingly has nothing to do with positive semidefinite matrices. One recently discovered interesting class of applications is approximation algorithms for combinatorial problems. See the chapter on approximation algorithms.

Derivatives

Derivatives play a crucial role in optimization for two related reasons: necessary conditions for optimality usually involve derivatives, and most optimization algorithms involve derivatives. Both of these points are developed in more detail below. For a function $f : \mathbf{R}^n \to \mathbf{R}$, we denote its first derivative (the **gradient**) by ∇f and its second derivative (the **Hessian** matrix) as $\nabla^2 f$. Recall that, under the assumption that f is C^2, the Hessian matrix is always symmetric.

A convex function is not necessarily differentiable: for example, the convex function $f(x) = |x|$ is not differentiable at the origin. Convex functions, however, have the special property that even when they fail to be differentiable, they possess a **subdifferential,** which is a useful generalization of derivative. Let D be a nonempty convex subset of $\mathbf{R}^n$. Let f be a convex function on a convex set D, and let $\mathbf{x}$ be a point in the interior of D. This definition can also be generalized to the case when D has no interior, i.e., its affine hull has dimension less than n. (The **affine hull** of a set X is the minimal affine set containing X. An **affine set** is a subset of $\mathbf{R}^n$ of the form $\{A\mathbf{x} + \mathbf{b} : \mathbf{x} \in \mathbf{R}^p\}$ where A is an $n \times p$ matrix and $\mathbf{b}$ is an n-vector.) The **subdifferential** of f at $\mathbf{x}$ is defined to be the set of vectors $\mathbf{v} \in \mathbf{R}^n$ such that $f(\mathbf{y}) \geq f(\mathbf{x}) + \mathbf{v}^T(\mathbf{y} - \mathbf{x})$ for all $\mathbf{y} \in D$. For example, the subdifferential of the function $f(x) = |x|$ at $x = 0$ is the closed interval $[-1, 1]$. Some useful properties of the subdifferential are

- The subdifferential is a nonempty, closed, convex set.
- When f is differentiable at a point $\mathbf{x}$ in the interior of D, the subdifferential is a singleton set whose unique member is the ordinary derivative $\nabla f(\mathbf{x})$.

An element of the subdifferential is called a **subgradient** of f.

Since a convex function is not necessarily differentiable, *a fortiori* it is not necessarily twice-differentiable. When f is twice-continuously differentiable, there is a simple characterization of convexity. Let f be a C^2 function defined on a convex set D with a nonempty interior. Then f is convex if and only if the second derivative of f, that is, its Hessian matrix $\nabla^2 f(\mathbf{x})$, is positive semidefinite for all $\mathbf{x} \in D$.

Optimality Conditions

Recall that $\mathbf{x}^* \in D$ is the optimizer if $f(\mathbf{x}^*) \leq f(\mathbf{x})$ for all $\mathbf{x} \in D$. Verifying optimality thus apparently requires global knowledge of the function f. Given a feasible point $\mathbf{x}^*$, it is desirable to be able to check whether $\mathbf{x}^*$ is an optimizer using information about D and f only in a small neighborhood of $\mathbf{x}^*$. For general optimization problems, such a local characterization is not possible because general optimization problems can have local minimizers that are not globally optimal. We define this term as follows: $\mathbf{x}^* \in D$ is a **local minimizer** of f if there exists an open set $N \subset \mathbf{R}^n$ containing $\mathbf{x}^*$ such that $f(\mathbf{x}) \geq f(\mathbf{x}^*)$ for all $\mathbf{x} \in N \cap D$.

In the case of convex optimization, local minimizers are always global minimizers; we state this as a theorem.

THEOREM 33.1 *Let f be a convex function defined on a convex domain D. Let $\mathbf{x}^* \in D$ be a local minimizer of f. Then $\mathbf{x}^*$ is a global minimizer of f.*

PROOF Suppose $\mathbf{x}^*$ is a local minimizer, and let $\mathbf{x}$ be any other feasible point. Consider the sequence of points $\mathbf{x}_1, \mathbf{x}_2, \ldots$ converging to $\mathbf{x}^*$ given by $\mathbf{x}_i = (1 - 1/i)\mathbf{x}^* + (1/i)\mathbf{x}$; clearly these points lie in D since D is convex. By the convexity of f, $f(\mathbf{x}_i) \leq (1 - 1/i) f(\mathbf{x}^*) + (1/i) f(\mathbf{x})$. On the other hand, by the local minimality of $\mathbf{x}^*$, there is an i sufficiently large such that $f(\mathbf{x}_i) \geq f(\mathbf{x}^*)$. Combining these inequalities, we have $f(\mathbf{x}^*) \leq (1 - 1/i) f(\mathbf{x}^*) + (1/i) f(\mathbf{x})$, which simplifies to $f(\mathbf{x}^*) \leq f(\mathbf{x})$.

For general optimization problems, **local optimizers** have local characterizations in terms of derivatives. Usually derivative characterizations are either necessary or sufficient for local minimality, but rarely is there a single condition that is both necessary *and* sufficient. In the case of convex optimization, there exist derivative conditions that are both necessary and sufficient for *global* optimality, provided that a certain "**constraint qualification**" holds, and provided that the functions in question are differentiable.

To set the stage, let us first consider the general nonconvex case. Given a point $\mathbf{x}^* \in D$, we will say that a nonzero vector $\mathbf{v}$ is a **feasible direction** at $\mathbf{x}^*$ if there exists a sequence of points $\mathbf{x}_1, \mathbf{x}_2, \ldots \in D$ converging to $\mathbf{x}^*$ and a sequence of positive scalars $\alpha_1, \alpha_2, \ldots$ converging to zero such that $\mathbf{x}_k - \mathbf{x}^* = \alpha_k \mathbf{v} + o(\alpha_k)$. Assuming the objective function f is differentiable at $\mathbf{x}^*$, it is easily seen that a necessary condition for local minimality is that $\nabla f(\mathbf{x}^*)^T \mathbf{v} \geq 0$ for any feasible direction $\mathbf{v}$.

In order to apply the condition in the previous paragraph, one must be able to determine the set of feasible directions at $\mathbf{x}^*$. Assume that D is defined via a sequence of equality constraints $g_1(\mathbf{x}) = \cdots = g_p(\mathbf{x}) = 0$ and inequality constraints $h_1(\mathbf{x}) \leq 0, \ldots, h_q(\mathbf{x}) \leq 0$ with $g_1, \ldots, g_p$ and $h_1, \ldots, h_q$ continuous. We say that an inequality constraint is **active** at $\mathbf{x}^*$ if it is satisfied as an equality. Clearly the inactive constraints can be ignored in determining local optimality: if $h_i(\mathbf{x}^*) < 0$, then by continuity, $h_i(\mathbf{x}) < 0$ for all $\mathbf{x}$ sufficiently close to $\mathbf{x}^*$ and hence this constraint has no effect on the problem locally. Thus, the feasible directions at $\mathbf{x}^*$ are determined by equality and active inequality constraints. Let $A \subset \{1, \ldots, q\}$ index the inequality constraints that are active at $\mathbf{x}^*$, i.e., $h_i(\mathbf{x}^*) = 0$ for all $i \in A$. For uniform terminology, we will regard equality constraints as always being active.

Assume further that all active constraints at $\mathbf{x}^*$ are C^1 in a neighborhood of $\mathbf{x}^*$. Consider replacing the active constraints locally at $\mathbf{x}^*$ by **linearizations.** For an equality constraint, say $g_i(\mathbf{x}) = 0$, we know that $g_i(\mathbf{x}^* + \mathbf{v}) = g_i(\mathbf{x}^*) + \mathbf{v}^T \nabla g_i(\mathbf{x}^*) + o(\|\mathbf{v}\|) = \mathbf{v}^T \nabla g_i(\mathbf{x}^*) + o(\|\mathbf{v}\|)$. This means that a feasible direction $\mathbf{v}$ for this one constraint in isolation must satisfy $\mathbf{v}^T \nabla g_i(\mathbf{x}^*) = 0$. Similarly a feasible direction $\mathbf{v}$ for an inequality constraint $h_i(\mathbf{x}) \leq 0$ active at $\mathbf{x}^*$ must satisfy $\mathbf{v}^T \nabla h_i(\mathbf{x}^*) \leq 0$. This leads to the following definition: a nonzero vector $\mathbf{v}$ is said to be a **linearized feasible direction** at $\mathbf{x}^*$ if $\mathbf{v}^T \nabla g_i(\mathbf{x}^*) = 0$ for all $i = 1, \ldots, p$, and $\mathbf{v}^T \nabla h_i(\mathbf{x}^*) \leq 0$ for all $i \in A$. Observe that the linearized feasible directions at $\mathbf{x}^*$ form a polyhedral cone, and assuming we have reasonably explicit representations of the constraints, membership in this cone is easy to check.

Under the assumption of differentiability, the set of feasible directions is a subset of the linearized feasible directions, but in general, it could be a proper subset. A **constraint qualification** is a condition on the constraints that guarantees that every linearized feasible direction is also a feasible direction. There are many constraint qualifications proposed in the literature. Two simple ones are as follows: (1) All the active constraints are linear, and (2) all the constraints are C^1 and their gradient vectors are linearly independent. If either (1) or (2) holds at a feasible point $\mathbf{x}^*$, then every linearized feasible direction is a feasible direction.

Assuming a constraint qualification holds, we can now state necessary conditions for local minimality, known as the **Karush–Kuhn–Tucker** (KKT) conditions. The conditions state that (1) $\mathbf{x}^*$ must be feasible and (2) for every linearized feasible direction $\mathbf{v}$ at $\mathbf{x}^*$, $\mathbf{v}^T \nabla f(\mathbf{x}^*) \geq 0$.

Using Farkas' lemma (a result that is equivalent to linear programming duality; see, e.g., [38]), we can reformulate condition (2) as the following equivalent statement: The gradient $\nabla f(\mathbf{x}^*)$ can be written in the form

$$\nabla f\left(\mathbf{x}^*\right) = \sum_{i=1}^{p} \lambda_i \nabla g_i\left(\mathbf{x}^*\right) - \sum_{i \in A} \mu_i \nabla h_i\left(\mathbf{x}^*\right) \tag{33.2}$$

where $\mu_i \geq 0$ for each $i \in A$. The variables λ_i, μ_i are called **multipliers.** In the case of equality

constraints only, we have only the first summation present on the right-hand side. In this special case the KKT conditions are called the "Lagrange multiplier" conditions.

The third (and final) way to write the KKT conditions is as follows. We introduce multipliers μ_i for constraints in $\{1, \ldots, q\} - A$ and force them to be zero. This allows us to write the conditions without explicit reference to A. We state this as a theorem.

THEOREM 33.2 *Consider minimizing $f(\mathbf{x})$ over a domain D, where*

$$D = \left\{ \mathbf{x} \in \mathbf{R}^n : g_1(\mathbf{x}) = \cdots = g_p(\mathbf{x}) = 0; h_1(\mathbf{x}) \leq 0, \ldots, h_q(\mathbf{x}) \leq 0 \right\} . \tag{33.3}$$

Let $\mathbf{x}^* \in D$ be a local minimizer of f, and assume that a constraint qualification holds at $\mathbf{x}^*$. Assume that $g_1, \ldots, g_p, h_1, \ldots, h_q$, f are all C^1 in a neighborhood of $\mathbf{x}^*$. Then there exist parameters $\lambda_1, \ldots, \lambda_p$ and $\mu_1, \ldots, \mu_q$ satisfying

$$\begin{aligned} \nabla f\left(\mathbf{x}^*\right) &= \sum_{i=1}^{p} \lambda_i \nabla g_i\left(\mathbf{x}^*\right) - \sum_{i=1}^{q} \mu_i \nabla h_i\left(\mathbf{x}^*\right) , \\ h_i\left(\mathbf{x}^*\right) \mu_i &= 0 \quad \textit{for } i = 1, \ldots, q , \\ \mu_i &\geq 0 \quad \textit{for } i = 1, \ldots, q , \\ g_i(\mathbf{x}^*) &= 0 \quad \textit{for } i = 1, \ldots, p , \\ h_i(\mathbf{x}^*) &\leq 0 \quad \textit{for } i = 1, \ldots, q . \end{aligned} \tag{33.4}$$

The first condition is the same as before, except we have inserted dummy multipliers for inactive inequality constraints. The second condition expresses the fact that μ_i must be zero for every inactive constraint. This condition is known as the **complementarity** condition. The last two relations express feasibility of $\mathbf{x}^*$.

A point that satisfies all of these conditions is said to be a **KKT point** or **stationary point.** In general, the KKT conditions are not sufficient for local minimality. To see this, consider the case of an unconstrained problem, in which case the KKT conditions reduce to the single requirement that $\nabla f(\mathbf{x}^*) = \mathbf{0}$. This condition is satisfied at local maxima as well as local minima! To address this shortcoming, the KKT conditions are often accompanied by second-order conditions about the second derivative of the objective function. We omit second-order conditions from this discussion.

Let us now specialize this discussion to convex programming, where everything becomes simpler. Assuming a constraint qualification, the KKT conditions are necessary for local and hence global minimality. It turns out that they are also *sufficient* for local (and hence global) minimality, provided that the constraints are convex and differentiable. (The differentiability assumption can be dropped because one can use subgradients in place of derivatives in the KKT conditions.) Thus, the second-order optimality conditions are extraneous in the case of convex programming.

Unfortunately, the constraint qualification cannot be discarded for convex programming. For example, the convex optimization problem of minimizing $x + y$ subject to $x^2 + y^2 \leq 1$ and $x \geq 1$ has a single feasible point $(1, 0)$ and hence trivially this point is optimal. However, $(1, 0)$ is not a KKT point; the failure of the KKT conditions at $(1, 0)$ arises from the fact that the linearized feasible directions are not feasible directions. (There are no feasible directions!) In the case of convex programming, there is a specialized constraint qualification called the "**Slater condition,**" which applies to **feasible regions** defined by convex constraints. The condition is: there exists a point $\mathbf{x} \in D$ such that all the nonlinear constraints (i.e., all the h_i that are not linear functions) are inactive at $\mathbf{x}$. Note that the existence of a *single* such point means that the linearized feasible directions are the same as the feasible directions at *every* point in the domain.

33.3 The Ellipsoid Algorithm

There are many general purpose algorithms in the literature for nonlinear optimization. There is nothing to prevent such algorithms from being applied to convex problems. In this case, convergence to a KKT point means convergence to a global minimizer, so convexity already buys us something even with an algorithm that knows nothing about convexity. Rather than covering general nonlinear optimization algorithms, we will cover two specific algorithms for convex programming in this chapter: the ellipsoid method and an interior-point method. The ellipsoid method is easier to understand and is easier to set up than interior-point methods, but it can inefficient in practice. Interior-point methods have come to be the preferred approach for convex programming.

The ellipsoid method is due to Yudin and Nemirovskii [68], although some of the ideas appeared earlier in Shor [46]. The treatment that follows is based on a section of the book by Nemirovskii and Yudin [36]. In that book, the ellipsoid method is called the "modified method of centers of gravity." It is a variant of a method called "method of centers of gravity" also described in [36]. The method of centers of gravity requires at each step the computation of the centroid of a region defined by convex constraints. The method of centers of gravity is optimal in an information-theoretic sense (i.e., compared to other convex optimization methods, it uses the fewest number of function evaluations to compute an approximate optimizer within a prespecified tolerance of optimal) but is computationally intractable because there is no known efficient way to compute the required center of gravity.

For this section we are considering the convex programming problem

$$\begin{array}{ll} \text{minimize} & f(\mathbf{x}) \\ \text{subject to} & h_1(\mathbf{x}) \leq 0 \\ & \vdots \\ & h_q(\mathbf{x}) \leq 0 \end{array} \tag{33.5}$$

where $f, h_1, \ldots, h_q$ are convex. In other words, any linear equality constraints have been removed by solving for some of the variables and reducing to a lower dimension.

Recall that an ellipsoid is a subset of $\mathbf{R}^n$ defined as follows. Let B be a symmetric positive definite $n \times n$ matrix. Let $\mathbf{c}$ be an n-vector. Then the set

$$E = \left\{ \mathbf{x} \in \mathbf{R}^n : (\mathbf{x} - \mathbf{c})^T B^{-1} (\mathbf{x} - \mathbf{c}) \leq 1 \right\} \tag{33.6}$$

is said to be an **ellipsoid.** Point $\mathbf{c}$ is said to be the **center** of the ellipsoid. An ellipsoid is easily seen to be a convex set because it is the image of the unit ball $\{\mathbf{x} \in \mathbf{R}^n : \|\mathbf{x}\| \leq 1\}$ under an affine transformation. From now on, $\|\cdot\|$ denotes the ordinary Euclidean norm unless otherwise noted.

In order to explain the ellipsoid method, we need the following preliminary result.

THEOREM 33.3 *Let D be a convex subset of $\mathbf{R}^n$, and let f be a convex function from $\mathbf{R}^n$ to $\mathbf{R}$. Suppose f is differentiable at a point $\mathbf{x} \in D$. Let $\mathbf{y} \in D$ be another point. If $f(\mathbf{y}) \leq f(\mathbf{x})$, then*

$$\nabla f(\mathbf{x})^T (\mathbf{y} - \mathbf{x}) \leq 0 \,. \tag{33.7}$$

We omit the proof of this result, which follows from the definition of derivative and standard convexity arguments. In the case when f is not differentiable at $\mathbf{x}$, a similar result holds, where in place $\nabla f(\mathbf{x})$ we can use any subgradient of f at $\mathbf{x}$.

The ellipsoid method is initialized with an ellipsoid E_0 containing the optimal solution $\mathbf{x}^*$. There is no general-purpose method for computing E_0; it must come from some additional knowledge about the convex programming problem. In Section 33.8 we discuss the issue of determining E_0 for the special case of linear programming.

The method now constructs a sequence of ellipsoids $E_1, E_2, \ldots$ with the following two properties: each E_i contains the optimal solution $\mathbf{x}^*$, and the volume of the E_i's decreases at a fixed rate. The algorithm terminates when it determines that, for some p, E_p is sufficiently small so that its center is a good approximation to the optimizer.

The procedure for obtaining E_{i+1} from E_i is as follows. We first check whether $\mathbf{c}_i$, the center of E_i, is feasible. Case 1 is that it is infeasible. Then we select a violated constraint, say h_j such that $h_j(\mathbf{c}_i) > 0$. Let H_i be the halfspace defined by the single linear inequality

$$H_i = \left\{ \mathbf{y} : \nabla h_j(\mathbf{c}_i)^T (\mathbf{y} - \mathbf{c}_i) \leq 0 \right\} . \tag{33.8}$$

(When h_j is not differentiable at $\mathbf{c}_i$, we instead use any subgradient.) Note that the boundary of this halfspace passes through $\mathbf{c}_i$. Observe now that the entire feasible region is contained in H_i. The reason is that for any feasible point $\mathbf{x}$, we have $h_j(\mathbf{x}) \leq 0 \leq h_j(\mathbf{c}_i)$, hence $\mathbf{x} \in H_i$ by (33.7). In particular, the optimizer is in H_i.

We must also rule out the degenerate case when $\nabla h_j(\mathbf{c}_i) = \mathbf{0}$, because in this case (33.8) does not specify a halfspace. In this case, $\mathbf{c}_i$ is the global minimizer of h_j by the KKT conditions. Since $h_j(\mathbf{c}_i) > 0$ and $\mathbf{c}_i$ is a global minimizer, there does not exist an $\mathbf{x}$ such that $h_j(\mathbf{x}) \leq 0$. This means that the feasible region is empty and the problem has no solution.

Case 2 is that the center $\mathbf{c}_i$ of E_i is feasible. In this case, the ellipsoid algorithm takes H_i to be the halfspace

$$H_i = \left\{ \mathbf{y} : \nabla f\,(\mathbf{c}_i)^T \left(\mathbf{y} - \mathbf{c}_i\right) \leq 0 \right\} . \tag{33.9}$$

(When f is not differentiable at $\mathbf{c}_i$, we instead use a subgradient. When $\nabla f(\mathbf{c}_i) = \mathbf{0}$, we are done, i.e., the ellipsoid method has found the exact optimizer.) Observe that by (33.7), every point $\mathbf{x}$ with a lower objective function value than $\mathbf{c}_i$ (and in particular, the optimizer) lies in H_i.

Thus, in both cases, we compute a halfspace H_i whose boundary passes through $\mathbf{c}_i$ such that the optimizer is guaranteed to lie in H_i. By induction, the optimizer also lies in E_i. The ellipsoid algorithm now computes a new ellipsoid E_{i+1} that is a superset of $E_i \cap H_i$. By induction, we know that the optimizer must thus lie in E_{i+1}.

The formulas for E_{i+1} are as follows. Let us suppose $E_i = \{\mathbf{x} : (\mathbf{x} - \mathbf{c}_i)^T B_i^{-1} (\mathbf{x} - \mathbf{c}_i) \leq 1\}$ and $H_i = \{\mathbf{a}_i^T (\mathbf{x} - \mathbf{c}_i) \leq 0\}$ where $\mathbf{a}_i$ is a gradient/subgradient of either a constraint or the objective function. We define

$$E_{i+1} = \left\{ \mathbf{x} : \left(\mathbf{x} - \mathbf{c}_{i+1}\right)^T B_{i+1}^{-1} \left(\mathbf{x} - \mathbf{c}_{i+1}\right) \leq 1 \right\} \tag{33.10}$$

where

$$B_{i+1} = \frac{n^2}{n^2 - 1} \cdot \left(B_i - \frac{2 B_i \mathbf{a}_i \mathbf{a}_i^T B_i}{(n+1) \mathbf{a}_i^T B_i \mathbf{a}_i} \right) \tag{33.11}$$

and

$$\mathbf{c}_{i+1} = \mathbf{c}_i - \frac{B_i \mathbf{a}_i}{(n+1)\sqrt{\mathbf{a}_i^T B_i \mathbf{a}_i}} . \tag{33.12}$$

Properties of these formulas are summarized in the following theorem.

THEOREM 33.4 *With B_{i+1} defined by (33.11), $\mathbf{c}_{i+1}$ defined by (33.12), and E_{i+1} defined by (33.10), we have the following properties:*

- *Matrix B_{i+1} is symmetric and positive definite.*
- $E_i \cap H_i \subset E_{i+1}$.
- *If we let* vol *denote volume, then*

$$\frac{vol\left(E_{i+1}\right)}{vol\left(E_i\right)} = \frac{n}{n+1}\left(\frac{n^2}{n^2-1}\right)^{(n-1)/2}. \tag{33.13}$$

Each of these properties is verified by substituting definitions and then algebraically simplifying. See, e.g., [4].

Using the standard inequality $1 + x \leq e^x$, one can show that the volume decrease factor on the right-hand side of (33.13) is bounded above by $\exp(-1/(2n+2))$. Thus, the volumes of the ellipsoids form a decreasing geometric sequence.

The algorithm is terminated at an ellipsoid E_p that is judged to be sufficiently small. Once E_p is reached, the ellipsoid algorithm returns as an approximate optimizer a point $\mathbf{c}^*$, where $\mathbf{c}^*$ is the center of one of $E_0, \ldots, E_p$, and is chosen as follows. Among all of $\{\mathbf{c}_0, \ldots, \mathbf{c}_p\}$, consider the subset of feasible $\mathbf{c}_i$'s, i.e., consider the set $\{\mathbf{c}_0, \ldots, \mathbf{c}_p\} \cap D$. Choose $\mathbf{c}^*$ from this subset to have the smallest objective function value. This is the approximate minimizer. If $\{\mathbf{c}_0, \ldots, \mathbf{c}_p\} \cap D$ is empty, then one of the following is true: either E_0 was chosen incorrectly, p has not been chosen sufficiently large, or $\text{vol}(D) = 0$.

Thus, the ellipsoid method is summarized as follows.

Ellipsoid Algorithm for (33.5)
Choose E_0 centered at $\mathbf{c}_0$ so that $\mathbf{x}^* \in E_0$.
$i := 0$.
while $\text{vol}(E_i)$ too large do
  if $\mathbf{c}_i \notin D$
    choose a j such that $h_j(\mathbf{c}_i) > 0$.
    $\mathbf{a}_i := \nabla h_j(\mathbf{c}_i)$.
  else
    $\mathbf{a}_i := \nabla f(\mathbf{c}_i)$.
  end if
  define $E_{i+1}, \mathbf{c}_{i+1}$ by (33.10)–(33.12).
  $i := i + 1$.
end while
Let $\mathbf{c}^*$ minimize f over $\{\mathbf{c}_0, \ldots \mathbf{c}_i\} \cap D$.

We now analyze the relationship between the number of steps p and the degree to which $\mathbf{c}^*$ approximates the optimizer. This complexity analysis requires some additional assumptions. Let the volume of the feasible region D be v_D. We assume that v_D is a positive real number. There are two cases when this assumption fails. The first case is that $v_D = \infty$. In this case, there is no difficulty with the ellipsoid method itself, but the upcoming complexity analysis no longer holds. The assumption also fails if $v_D = 0$. This happens when the dimension of the affine hull of D is less than n, including the case when $D = \emptyset$.

Since v_D is finite and positive, there is an ellipsoid that contains D. Let us assume that in fact E_0 contains D. There is no way to detect whether E_0 contains D or that $0 < \mathbf{v}_D < \infty$ within the framework of the ellipsoid algorithm itself; instead, this must be discerned from additional information about the problem. There are special classes of convex programming problems, notably linear and quadratic programming, in which it is possible to initialize and terminate the ellipsoid algorithm without prior information (other than the specification of the problem) even when $v_D = \infty$ or $v_D = 0$.

Under the assumption that v_D is finite and positive and that E_0 contains D, let us now analyze the running time of the ellipsoid algorithm, following the analysis in [36]. Let us assume that the last iteration of the algorithm is the pth and generates an ellipsoid E_p whose volume is less than $v_D\gamma^n$, where $\gamma \in (0, 1)$ will be defined below. Define the bijective affine map $\phi : \mathbf{R}^n \to \mathbf{R}^n$ by the formula $\phi(\mathbf{x}) = (1-\gamma)\mathbf{x}^* + \gamma\mathbf{x}$. Note that this mapping shrinks $\mathbf{R}^n$ toward $\mathbf{x}^*$. Let $D' = \phi(D)$. Observe that D' contains $\mathbf{x}^*$, and by convexity, $D' \subset D$. Finally, observe that $\text{vol}(D') = v_D\gamma^n$. Since $\text{vol}(E_p) < v_D\gamma^n$, there exists at least

one point $\mathbf{y}' \in D'$ that is not in E_p. Since $\mathbf{y} \in D' \subset D \subset E_0$ and $\mathbf{y}' \notin E_p$, there must have been an iteration, say m, such that $\mathbf{y}' \notin E_m$ but $\mathbf{y}' \in E_{m-1}$. This means that $\mathbf{y}' \notin H_{m-1}$. Recall that H_{m-1} was chosen according to one of two rules depending on whether $\mathbf{c}_{m-1}$ was feasible or not. For the step under consideration, $\mathbf{c}_{m-1}$ cannot be infeasible as the following argument shows. Recall that when $\mathbf{c}_i$ is infeasible for some i, H_i contains the entire feasible region. Since $\mathbf{y}'$ is feasible and not in H_{m-1}, this means that $\mathbf{c}_{m-1}$ must have been feasible. In particular, this means that the ellipsoid method will be able to return a feasible $\mathbf{c}^*$.

Furthermore, we can use the existence of $\mathbf{c}_{m-1}$ to get bounds on the distance to optimality of $\mathbf{c}^*$. Recall that, because step $m-1$ falls into case 2, halfspace H_{m-1} contains all feasible points whose objective function value is less than $\mathbf{c}_{m-1}$. Thus, $f(\mathbf{y}') \geq f(\mathbf{c}_{m-1})$. Further, $f(\mathbf{c}_{m-1}) \geq f(\mathbf{c}^*)$. Let $\mathbf{y} = \phi^{-1}(\mathbf{y}')$, i.e., $\mathbf{y}' = (1-\gamma)\mathbf{x}^* + \gamma\mathbf{y}$. Observe that $\mathbf{y} \in D$ since $\mathbf{y}' \in D'$. By convexity, $f(\mathbf{y}') \leq (1-\gamma)f(\mathbf{x}^*) + \gamma f(\mathbf{y})$, i.e.,

$$f\left(\mathbf{y}'\right) - f\left(\mathbf{x}^*\right) \leq \gamma\left(f(\mathbf{y}) - f\left(\mathbf{x}^*\right)\right) \tag{33.14}$$

so

$$f\left(\mathbf{c}^*\right) - f\left(\mathbf{x}^*\right) \leq \gamma\left(f(\mathbf{y}) - f\left(\mathbf{x}^*\right)\right) . \tag{33.15}$$

Let us say that a feasible point $\mathbf{x}$ is an ϵ-**approximate** optimizer if

$$\frac{f(\mathbf{x}) - f\left(\mathbf{x}^*\right)}{f\left(\mathbf{x}^{\#}\right) - f\left(\mathbf{x}^*\right)} \leq \epsilon \tag{33.16}$$

where $\mathbf{x}^{\#}$ is the feasible point with the worst objective function value. Thus, assuming f is bounded, a 0-approximate optimizer is the true optimizer, and every feasible point is a 1-approximate optimizer. We see from (33.15) that the ellipsoid method computes a γ-approximate optimizer.

Recall we defined $\gamma \in (0, 1)$ as a free parameter. Thus, the ellipsoid method can return arbitrarily good approximate optima. The price paid for a better approximation is a higher running time. Let the volume of the initial ellipsoid be denoted v_0. Recall that we run the method until $\text{vol}(E_p) < v_D\gamma^n$. Recall also that the ellipsoids decrease by a multiplicative factor less than $\exp(-1/(2n+2))$ per step. Thus, we must pick p sufficiently large so that $\exp(-p/(2n+2))v_0 < v_D\gamma^n$, i.e.,

$$p > (2n+2)\left(n\ln(1/\gamma) + \ln v_0 - \ln v_D\right) . \tag{33.17}$$

Thus, we see that the running time depends logarithmically on the desired degree of accuracy. The running time also grows in the case when E_0 is much larger than D.

This raises the question: is there a case when $\ln v_0$ would have to be much larger than $\ln v_D$? The answer is no: for any convex set D satisfying $0 < \text{vol}(D) < \infty$, there exists an ellipsoid E such that $D \subset E$ and such that $\text{vol}(E) \leq n^n\text{vol}(D)$. Thus, if we had complete information about D, we could ensure that the term $\ln v_0 - \ln v_D$ in (33.17) is never more than $n \ln n$.

33.4 A Primal Interior-Point Method

Interior-point methods for linear programming were introduced by Karmarkar [25]. It was discovered later that Karmarkar's interior-point method is related to log-barrier methods introduced earlier in the literature (see, e.g., [11]) and also to an affine scaling method due to Dikin [7]. Soon after Karmarkar's method was published, several papers, e.g., Kapoor and Vaidya [24] and Ye and Tse [67] extended the method to quadratic programming. A further extension of interior-point methods to some classes of nonlinear constraints came in the work of Jarre [19, 20] and Mehrotra and Sun [32]. An extension to the general case of convex programming came later with the landmark monograph by Nesterov and Nemirovskii [37] and the introduction of self-concordant functions. In this chapter, we reverse the historical development by first presenting the general convex programming case, and then specializing to linear programming. (It

should be pointed out that lecture notes containing the main ideas of self-concordance had circulated for some years previous to publication of the monograph in 1994. In addition, many of the journal citations in this chapter have dates three or four years after the initial circulation of the result via preprints.)

Interior-point methods are generally believed to be the best approach for large-scaled structured linear programming and more general convex programming. As for complexity theory, interior-point methods represent only a slight improvement on the ellipsoid method. The difference is that interior-point methods work extremely well in practice (much better than their known worst-case bounds), whereas the running time of the ellipsoid method tends to be equal to its worst-case bound.

Interior-point methods are generally classified into three categories: path-following, potential reduction, and projective. Karmarkar's original method was a projective method, but projective methods have faded in importance since 1984. Both of the remaining two classes are used in practice, though at the time of this writing, path-following methods seem to be preferred. Because of space limitations, we cover only path-following methods in this section. Potential reduction is briefly described in the context of semidefinite programming in Section 33.6.

A second way of classifying interior-point methods is whether they are primal or primal-dual. The algorithm presented in this section is a "primal" algorithm. When we specialize to semidefinite and linear programming in upcoming sections, we present primal-dual algorithms, which are generally considered to be superior to primal algorithms.

In this section we closely follow the treatment of self-concordance due to Jarre [21, 22] rather than [37]. The foundation of all interior-point methods is Newton's method. Let $g : \mathbf{R}^n \to \mathbf{R}$ be a three-times differentiable function, and suppose we want to minimize g over $\mathbf{R}^n$ (no constraints). Suppose we have a current point $\mathbf{x}_c$, called an **iterate,** and we would like to compute a better point $\mathbf{x}^+$. Newton's method for optimization is based on expanding g as a Taylor series around $\mathbf{x}_c$:

$$\begin{aligned} g(\mathbf{x}) &= g(\mathbf{x}_c) + \nabla g(\mathbf{x}_c)^T (\mathbf{x} - \mathbf{x}_c) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_c)^T \nabla^2 g(\mathbf{x}_c) (\mathbf{x} - \mathbf{x}_c) \\ &\quad + O\left(\|\mathbf{x} - \mathbf{x}_c\|^3 \right) . \end{aligned} \tag{33.18}$$

A reasonable approach to minimizing g might be to minimize $q(\mathbf{x})$, where $q(\mathbf{x})$ is the quadratic function that arises from dropping high-order terms from (33.18):

$$q(\mathbf{x}) = g(\mathbf{x}_c) + \nabla g(\mathbf{x}_c)^T (\mathbf{x} - \mathbf{x}_c) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_c)^T \nabla^2 g(\mathbf{x}_c) (\mathbf{x} - \mathbf{x}_c) . \tag{33.19}$$

This function $q(\mathbf{x})$ is called a "quadratic model." In the case when $\nabla^2 g(\mathbf{x}_c)$ is a positive definite matrix, a standard linear algebra result tells us that the minimizer of $q(\mathbf{x})$ is

$$\mathbf{x}^+ = \mathbf{x}_c - \left(\nabla^2 g(\mathbf{x}_c) \right)^{-1} \nabla g(\mathbf{x}_c) \tag{33.20}$$

where the exponent '-1' denotes matrix inversion. In a pure Newton's method, $\mathbf{x}^+$ would be taken as the next iterate, and a new quadratic model would be formed. In the case when $\nabla^2 g(\mathbf{x}_c)$ is not positive definite, the pure Newton's method has to be modified in some manner.

In the case of convex programming, however, we have already seen that $\nabla^2 g(\mathbf{x}_c)$ is always at least positive semidefinite, so indefiniteness is not as severe a difficulty as in the general case. Suppose in fact that g is C^2 and that $\nabla^2 g(\mathbf{x})$ is positive definite for all $\mathbf{x}$; then the Newton step is always well-defined. This assumption of positive definiteness implies that g is strictly convex. A function $g(\mathbf{x})$ is said to be **strictly convex** if for all points $\mathbf{x}$,$\mathbf{y}$ in the domain such that $\mathbf{x} \neq \mathbf{y}$, and for all $\lambda \in (0, 1)$,

$$g(\lambda \mathbf{x} + (1 - \lambda)\mathbf{y}) < \lambda g(\mathbf{x}) + (1 - \lambda) g(\mathbf{y}) . \tag{33.21}$$

Strict convexity has the following useful consequence. A strictly convex function defined on a convex domain D has at most one point satisfying the KKT conditions, and hence at most one minimizer. (But a strictly convex function need not have a minimizer: consider the function $g(x) = e^x$.)

One interesting feature of Newton's method is its invariance under affine transformation. In particular, for any fixed nonsingular square matrix A and fixed vector $\mathbf{b}$, Newton's method applied to $g(\mathbf{x})$ starting at $\mathbf{x}_c$ is equivalent to Newton's method applied to $h(\mathbf{x}) = g(A\mathbf{x} + \mathbf{b})$ starting at a point $\mathbf{x}'_c$ defined by $A\mathbf{x}'_c + \mathbf{b} = \mathbf{x}_c$. (Note that other classical methods for optimization, such as steepest descent, do not have this desirable property.) Suppose we want to measure progress in Newton's method, i.e., determine whether the current iterate $\mathbf{x}$ is near the minimizer $\mathbf{x}^*$. The obvious distance measure $\|\mathbf{x} - \mathbf{x}^*\|$ is not useful, since $\mathbf{x}^*$ is not known *a priori;* the measure $g(\mathbf{x}) - g(\mathbf{x}^*)$ suffers from the same flaw. The gradient norm $\|\nabla g(\mathbf{x})\|$ seems like a better choice since we know that $\nabla g(\mathbf{x}^*) = \mathbf{0}$ at optimum, except that this measure of nearness is not preserved under affine transformation. Nesterov and Nemirovskii propose the metric $\left(\nabla g(\mathbf{x})(\nabla^2 g(\mathbf{x}))^{-1}\nabla g(\mathbf{x})\right)^{1/2}$ to measure the degree of optimality. This measure has the advantage of invariance under affine transformation.

Newton's method as described so far does not handle constraints. A classical approach to incorporating constraints into Newton's method is a barrier-function approach. Assume from now on that D is a convex, closed set with an interior point.

Let $F(\mathbf{x})$ be a function defined on the interior of D with the following two properties:

- F is strictly convex, and
- Let $\mathbf{x}$ be an arbitrary point on the boundary of D, and let $\mathbf{x}_1, \mathbf{x}_2, \ldots$ be a sequence of interior points converging to $\mathbf{x}$. Then $F(\mathbf{x}_k) \to \infty$ as $k \to \infty$.

In this case, F is said to be a **barrier function** for D. For example, the function $F(x) = -\ln x$ is a barrier function for the nonnegative real numbers $\{x \in \mathbf{R} : x \geq 0\}$. Note that a set D admits many different barrier functions. Barrier functions are a classical technique in optimization—see for instance [11]—although their prominence in the literature had waned during the 1970s and 1980s until the advent of interior-point methods.

For the rest of this section we will make the assumption that the objective function is a linear function $\mathbf{c}^T\mathbf{x}$. Thus, our problem is written:

$$\begin{array}{ll} \text{minimize} & \mathbf{c}^T\mathbf{x} \\ \text{subject to} & h_1(\mathbf{x}) \leq 0\,, \\ & \vdots \\ & h_q(\mathbf{x}) \leq 0\,. \end{array} \tag{33.22}$$

This assumption is without loss of generality for the following reason. Given a general convex programming problem with a nonlinear objective function of the form (33.5), we can introduce a new variable z and a new constraint $f(\mathbf{x}) \leq z$ (which is convex, since $f(\mathbf{x}) - z$ is a convex function), and then we replace the objective function with "minimize z."

The barrier-function method for minimizing $\mathbf{c}^T\mathbf{x}$ on D is as follows. We choose a sequence of positive parameters $\mu_0, \mu_1, \mu_2, \ldots$ strictly decreasing to zero. On the kth iteration of the barrier-function method, we minimize $\mathbf{c}^T\mathbf{x} + \mu_k F(\mathbf{x})$ on the interior of D using Newton's method. The starting point for Newton's method is taken to be the (approximately-computed) minimizer of $\mathbf{c}^T\mathbf{x} + \mu_{k-1}F(\mathbf{x})$ from the previous iteration. The kth iteration continues until a sufficiently good approximate minimizer of $\mathbf{c}^T\mathbf{x} + \mu_k F(\mathbf{x})$ is found, at which point we move to iteration $k+1$. Since $\mu_k \to 0$ as $k \to \infty$, in the limit we are minimizing the original objective function $\mathbf{c}^T\mathbf{x}$.

The reason this method makes progress is as follows. Because the barrier function blows up near the boundaries of D, the minimizer of the sum $\mathbf{c}^T\mathbf{x} + \mu_k F(\mathbf{x})$ will be bounded away from the boundaries of D. As we let μ_k approach zero, the importance of the barrier function is diminished, and the original optimization problem dominates. The intuition behind the barrier function method is as follows. Newton's method works very well in the unconstrained case, but has no notion of inequality constraints. The barrier function has information about the constraints encoded in its Hessian in a way that is useful for Newton's

method. In particular, the barrier term prevents Newton's method from coming close to the boundary too soon.

Consider $\mu > 0$ fixed for a moment. Because of the assumption that F is strictly convex, the objective function $\mathbf{c}^T\mathbf{x} + \mu F(\mathbf{x})$ has at most one minimizer. Let this minimizer be denoted $\mathbf{x}(\mu)$. By the KKT conditions, $\mathbf{c} + \mu\nabla F(\mathbf{x}(\mu)) = \mathbf{0}$. The **central path** is defined to be the collection of points $\{\mathbf{x}(\mu) : 0 < \mu < \infty\}$. The case when $\mathbf{c}^T\mathbf{x} + \mu F(\mathbf{x})$ has no minimizer at all can occur if the domain D is unbounded and $\mathbf{c}^T\mathbf{x}$ has no lower bound over the domain. We do not consider that case here. An example of the central path is presented in Fig. 33.1.

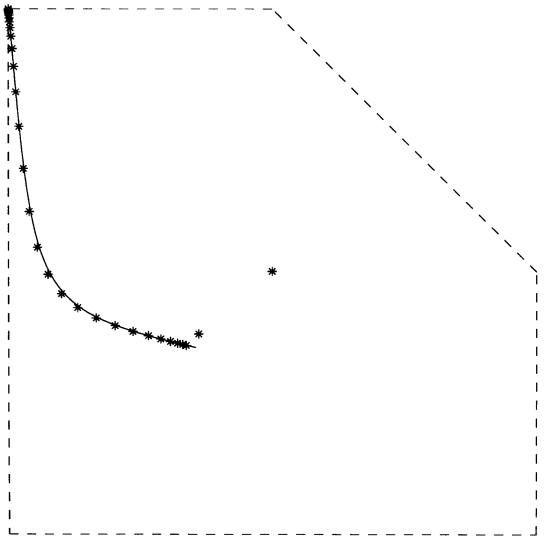

FIGURE 33.1 The central path, which is the solid trajectory, and iterates in a small-step path-following interior-point method, which are asterisks. The dashed segments indicate the boundary of the feasible region. The example problem is linear programming with two variables and five constraints. The iterates lie close to but not exactly on the central path, and their spacing decreases geometrically.

Everything presented so far concerning barrier function methods was known in the 1960s. The important recent progress has been the discovery of the self-concordance conditions, due to Nesterov and Nemirovskii. The following conditions are called the **finite-difference self-concordance conditions.** Let int(D) denote the interior of the feasible region D. Suppose $\mathbf{x} \in \text{int}(D)$ and let E be the open ellipsoid

$$E = \left\{\mathbf{y} : (\mathbf{y} - \mathbf{x})^T \nabla^2 F(\mathbf{x})(\mathbf{y} - \mathbf{x}) < 1\right\} . \tag{33.23}$$

The first finite-difference self-concordance condition is that

$$E \subset \text{int}(D) . \tag{33.24}$$

Next, suppose $\mathbf{y} \in E$ and let

$$r = \left((\mathbf{y} - \mathbf{x})^T \nabla^2 F(\mathbf{x})(\mathbf{y} - \mathbf{x})\right)^{1/2} \tag{33.25}$$

[so that, by assumption, $r < 1$ and $\mathbf{y} \in \text{int}(D)$]. The second condition is that for all $\mathbf{h} \in \mathbf{R}^n$,

$$(1 - r)^2 \mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h} \le \mathbf{h}^T \nabla^2 F(\mathbf{y})\mathbf{h} \le \frac{1}{(1 - r)^2} \mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h} . \tag{33.26}$$

We assume from now on that F satisfies (33.24) and (33.26). The finite-difference self-concordance conditions are the easiest to use in the analysis of interior-point methods, but they are difficult to verify because of multitude of free parameters in (33.26). In the next section we will state the differential self-concordance condition, which implies (33.24) and (33.26) but is easier to verify analytically.

The rationale behind (33.26) is as follows. The condition that $r < 1$ means that $\mathbf{y}$ lies in an ellipsoidal open set around $\mathbf{x}$, where the ellipsoid is defined by the symmetric positive definite matrix $\nabla^2 F(\mathbf{x})$. It is very natural to define a neighborhood in this manner, because other simpler definitions of a neighborhood around $\mathbf{x}$ would not be invariant under affine transformations. An ellipsoid like (33.23) is sometimes known as a **Dikin ellipsoid.** Condition (33.26) says that the Hessian of F does not vary too much over this natural neighborhood. Thus, we see the significance of the term "self-concordant:" variation in the Hessian of F is small with respect to the neighborhood defined by the Hessian itself. Subtracting $\mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h}$ from all three quantities of (33.26) and simplifying yields

$$\left|\mathbf{h}^T \left(\nabla^2 F(\mathbf{y}) - \nabla^2 F(\mathbf{x})\right) \mathbf{h}\right| \leq \left(\frac{1}{(1-r)^2} - 1\right) \mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h} \,. \tag{33.27}$$

The self-concordance condition is not sufficient by itself to yield a good algorithm. The difficulty is that the minimizer of F could be very close to a boundary of F, causing a very steep gradient in a small neighborhood and slowing down convergence. An example of this undesirable behavior, due to Jarre, is the self-concordant barrier function $-(\ln x)/\epsilon - \ln(1-x)$ for the interval $[0, 1]$ where $\epsilon > 0$ is small. This barrier function has its minimizer arbitrarily close to 1, and very large derivatives near the minimizer. To prevent this behavior, we impose a second condition, called the "self-limiting" condition by Jarre, that for all $\mathbf{x} \in \text{int}(D)$,

$$\nabla F(\mathbf{x})^T (\nabla^2 F(\mathbf{x}))^{-1} \nabla F(\mathbf{x}) \leq \theta \tag{33.28}$$

where $\theta \geq 1$ is a parameter that measures the quality of the self-concordant function. This parameter θ is called the **self-concordance parameter.** One way to interpret (33.28) is that it is the simplest possible upper bound on the first derivative of F that is invariant under affine transformations.

The parameter θ plays a crucial role in the analysis of interior-point methods. Thus, the question arises, what are typical values for θ? In subsequent sections we present specific classes of self-concordant barrier functions arising in applications, along with their accompanying values of θ. For this section the reader should imagine that $\theta = O(q)$, where q is the number of inequality constraints.

One kind of path-following chooses the parameter sequence $\mu_0, \mu_1, \mu_2, \ldots$ according to the rule

$$\mu_k = (1-\sigma)\mu_{k-1} \,, \tag{33.29}$$

where σ is a problem-dependent scalar that is constant across all iterations. This is known as "small-step" path-following in the literature, and is the easiest rule to analyze, though not very efficient in practice. Because of the small changes in μ per step, there is a need for only one Newton step at each iteration.

Let us fix the iteration number k and cease to write it as a subscript. Note that $\nabla^2 g = \mu \nabla^2 F$ since the second derivative of the linear term is zero. From iterate $\mathbf{x}$ the next iterate $\mathbf{x}^+$ is computed by applying one step of Newton's method to g, i.e.,

$$\mathbf{x}^+ := \mathbf{x} - \mu^{-1} \left(\nabla^2 F(\mathbf{x})\right)^{-1} (\mathbf{c} + \mu \nabla F(\mathbf{x})) \tag{33.30}$$

where we have used the fact that $\nabla g(\mathbf{x}) = \mathbf{c} + \mu \nabla F(\mathbf{x})$. Now we define $\mu^+ = (1-\sigma)\mu$ by (33.29) and repeat the iteration.

In order to carry out a complexity analysis, we would like to claim that if the current iterate $\mathbf{x}$ is close to the central path for parameter μ, then the next iterate $\mathbf{x}^+$ is also close to the central path for parameter μ^+. This requires a notion of proximity to the central path. Here we use the metric mentioned above. For each $(\mathbf{y}, \mu)$, we let

$$\lambda(\mathbf{y}, \mu) = \mu^{-1} \left[\left(\mathbf{c} + \mu \nabla F(\mathbf{y})\right)^T \left(\nabla^2 F(\mathbf{y})\right)^{-1} (\mathbf{c} + \mu \nabla F(\mathbf{y})) \right]^{1/2} . \tag{33.31}$$

Observe that if $\mathbf{y}$ is the point on the central path for parameter μ, then $\lambda(\mathbf{y},\mu) = 0$.

Returning to our complexity analysis, we claim that if $\lambda(\mathbf{x},\mu) \leq 1/5$, then $\lambda(\mathbf{x}^+, \mu^+) \leq 1/5$. This claim will require the correct choice of σ in (33.29). To prove this claim, we first analyze the intermediate quantity $\lambda(\mathbf{x}^+, \mu)$. In other words, we would like to know how much progress is made during one step of Newton's method applied to g. To preserve generality, let us state this as a theorem.

THEOREM 33.5 *Let $\mu > 0$ and $\mathbf{x} \in int(D)$ be given. Let λ denote $\lambda(\mathbf{x},\mu)$, and suppose $\lambda < 1$. Let $\mathbf{x}^+$ be chosen by (33.30). Then*

$$\lambda\left(\mathbf{x}^+, \mu\right) \leq \frac{\lambda^2}{(1-\lambda)^2} \,. \tag{33.32}$$

PROOF Let $\mathbf{v} = -\mu^{-1}(\nabla^2 F(\mathbf{x}))^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{x}))$, which is the update in (33.30), and let $\mathbf{y} = \mathbf{x} + s\mathbf{v}$ for some $s \in [0, 1]$ to be chosen later. Note that if $s = 1$, then $\mathbf{y} = \mathbf{x}^+$. We see from the definition (33.31) of $\lambda(\cdot, \cdot)$ that r in (33.25) is λs and hence satisfies $r < 1$ by assumption. Therefore, by (33.27), for any $\mathbf{h} \in \mathbf{R}^n$,

$$\left|\mathbf{h}^T \left(\nabla^2 F(\mathbf{x}) - \nabla^2 F(\mathbf{y})\right) \mathbf{h}\right| \leq \left(\frac{1}{(1-s\lambda)^2} - 1\right) \mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h} \,. \tag{33.33}$$

We now apply the "generalized Cauchy–Schwarz" inequality from Jarre [22], which is the following. Let A, M be two symmetric matrices such that A is positive definite and such that $|\mathbf{z}^T M \mathbf{z}| \leq \mathbf{z}^T A \mathbf{z}$ for all vectors $\mathbf{z}$. Then for all $\mathbf{a}, \mathbf{b}$, $(\mathbf{a}^T M \mathbf{b})^2 \leq (\mathbf{a}^T A \mathbf{a})(\mathbf{b}^T A \mathbf{b})$. We omit the proof here. Observe that if we define $A = \gamma \nabla^2 F(\mathbf{x})$, where γ is the scalar on the right-hand side of (33.33), and $M = \nabla^2 F(\mathbf{x}) - \nabla^2 F(\mathbf{y})$, then the hypothesis of the generalized Cauchy–Schwarz inequality holds by (33.33). Therefore, we can apply the conclusion, with "$\mathbf{a}$" taken to be an indeterminate vector $\mathbf{h}$ and "$\mathbf{b}$" taken to be $\mathbf{v}$ to obtain

$$\begin{aligned} \left|\mathbf{v}^T \left(\nabla^2 F(\mathbf{x}) - \nabla^2 F(\mathbf{y})\right) \mathbf{h}\right| &\leq \left(\frac{1}{(1-s\lambda)^2} - 1\right) \\ &\quad \sqrt{\mathbf{v}^T \nabla^2 F(\mathbf{x}) \mathbf{v}} \sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h}} \qquad (33.34) \\ &= \left(\frac{1}{(1-s\lambda)^2} - 1\right) \lambda \sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h}} \,. \qquad (33.35) \end{aligned}$$

Let us now come up with new expressions for the two terms on the left-hand side of (33.34). Recall by choice of $\mathbf{v}$ that the first term $\mathbf{v}^T \nabla^2 F(\mathbf{x}) \mathbf{h}$ evaluates to $-(\mathbf{c}/\mu + \nabla F(\mathbf{x}))^T \mathbf{h}$. For the second term, recall that $\mathbf{y} = \mathbf{x} + s\mathbf{v}$. Thinking of $\mathbf{y}$ as a function of s, observe that $\nabla^2 F(\mathbf{y})\mathbf{v} = \nabla^2 F(\mathbf{x} + s\mathbf{v})\mathbf{v} = d(\nabla F(\mathbf{x} + s\mathbf{v}))/ds = d(\mathbf{c}/\mu + \nabla F(\mathbf{x} + s\mathbf{v}))/ds$. Thus, we have

$$\begin{aligned} \left|-(\mathbf{c}/\mu + \nabla F(\mathbf{x}))^T \mathbf{h} - \frac{d(\mathbf{c}/\mu + \nabla F(\mathbf{x} + s\mathbf{v}))^T}{ds} \mathbf{h}\right| &\leq \left(\frac{1}{(1-s\lambda)^2} - 1\right) \\ &\quad \lambda \sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h}} \,. \qquad (33.36) \end{aligned}$$

Let us define

$$p(s) = (1-s)(\mathbf{c}/\mu + \nabla F(\mathbf{x}))^T \mathbf{h} - (\mathbf{c}/\mu + \nabla F(\mathbf{x} + s\mathbf{v}))^T \mathbf{h} \,. \tag{33.37}$$

Observe that $p(0) = 0$ because the two terms cancel. Observe also that (33.36) is equivalent to

$$\left|p'(s)\right| \leq \left(\frac{1}{(1-s\lambda)^2} - 1\right) \lambda \sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h}} \,. \tag{33.38}$$

Therefore, by integrating both sides of (33.38) for s from 0 to 1, we conclude that

$$|p(1)| \leq \frac{\lambda^2}{1-\lambda} \sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}) \mathbf{h}} \,. \tag{33.39}$$

On the other hand, directly from (33.37) we have $p(1) = -(\mathbf{c}/\mu + \nabla F(\mathbf{x}+\mathbf{v}))^T \mathbf{h}$. We combine this with (33.39), using the fact that $\mathbf{x}+\mathbf{v} = \mathbf{x}^+$, to obtain

$$\left|\left(\mathbf{c}/\mu + \nabla F\left(\mathbf{x}^+\right)\right)^T \mathbf{h}\right| \leq \frac{\lambda^2}{1-\lambda}\sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h}}\,. \tag{33.40}$$

We can now put an upper bound on the right-hand side of (33.40) using self-concordance to obtain

$$\left|\left(\mathbf{c}/\mu + \nabla F\left(\mathbf{x}^+\right)\right)^T \mathbf{h}\right| \leq \frac{\lambda^2}{(1-\lambda)^2}\sqrt{\mathbf{h}^T \nabla^2 F(\mathbf{x}^+)\mathbf{h}}\,. \tag{33.41}$$

Now finally we will define the hitherto indeterminate $\mathbf{h}$ to be $\mathbf{h} = (\nabla^2 F(\mathbf{x}^+))^{-1}(\mathbf{c}/\mu + \nabla F(\mathbf{x}^+))$. If we substitute this into (33.41) and use the definition of $\lambda(\cdot,\cdot)$, we obtain

$$\lambda\left(\mathbf{x}^+, \mu\right)^2 \leq \frac{\lambda^2}{(1-\lambda)^2}\lambda\left(\mathbf{x}^+, \mu\right)\,. \tag{33.42}$$

Dividing both sides by $\lambda(\mathbf{x}^+, \mu)$ proves (33.32).

In the specific case $\lambda \leq 1/5$, we see that $\lambda(\mathbf{x}^+, \mu) \leq 1/16$. Next, we want to show that $\lambda(\mathbf{x}^+, \mu^+) \leq 1/5$. Observe that the function $\mathbf{y} \mapsto (\mathbf{y}^T \nabla^2 F(\mathbf{x}^+)^{-1}\mathbf{y})^{1/2}$ is a norm on $\mathbf{R}^n$, and hence obeys the triangle inequality. Thus, we can apply this triangle inequality to $\mu^+\lambda(\mathbf{x}^+, \mu^+) - \mu\lambda(\mathbf{x}^+, \mu)$ [plugging in (33.31)] to obtain

$$\begin{aligned}
\mu^+\lambda\left(\mathbf{x}^+, \mu^+\right) - \mu\lambda\left(\mathbf{x}^+, \mu\right) &\leq \left|\mu - \mu^+\right| \\
&\quad \cdot \left[\nabla F\left(\mathbf{x}^+\right)^T \left(\nabla^2 F\left(\mathbf{x}^+\right)\right)^{-1} \nabla F\left(\mathbf{x}^+\right)\right]^{1/2} \qquad (33.43)\\
&\leq \left|\mu - \mu^+\right| \cdot \sqrt{\theta} \qquad (33.44)
\end{aligned}$$

where recall that θ was defined in (33.28). If we substitute (33.29) for μ^+ and simplify, we obtain

$$\lambda\left(\mathbf{x}^+, \mu^+\right) \leq \frac{\sigma\sqrt{\theta} + \lambda\left(\mathbf{x}^+, \mu\right)}{1-\sigma}\,. \tag{33.45}$$

If we choose

$$\sigma = \frac{1}{9\sqrt{\theta}} \tag{33.46}$$

and use the inequality $\lambda(\mathbf{x}^+, \mu) \leq 1/16$, we conclude finally that $\lambda(\mathbf{x}^+, \mu^+) \leq 25/128 < 1/5$.

Observe that (33.46) controls how fast μ can decrease in (33.29). Thus, the rate of convergence of the interior-point method is determined by the value of the self-concordance parameter.

The next step in our analysis is to show that as μ is driven to zero, the interior-point method converges to the true minimizer of (33.22). Let $(\mathbf{x}, \mu)$ be an iterate of the above algorithm, so that $\lambda(\mathbf{x}, \mu) \leq 1/5$. Let $\mathbf{x}^*$ denote the global minimizer for the original problem (33.22). We now show that $\mathbf{c}^T\mathbf{x} - \mathbf{c}^T\mathbf{x}^* \leq O(\mu)$, so the difference of the iterates from optimality tends to zero. This argument is broken up as two separate theorems. First, we show that $c^T\mathbf{x} \leq \mathbf{c}^T\hat{\mathbf{x}} + O(\mu)$, where $\hat{\mathbf{x}}$ is the point on the central path for μ. Second, we show $\mathbf{c}^T\hat{\mathbf{x}} \leq \mathbf{c}^T\mathbf{x}^* + O(\mu)$.

THEOREM 33.6 *Let $\mathbf{x} \in int(D)$ and $\mu > 0$ satisfy $\lambda(\mathbf{x}, \mu) \leq 1/5$. Let $\hat{\mathbf{x}} \in D$ be the central path point for μ, i.e., $\mathbf{c} + \mu\nabla F(\hat{\mathbf{x}}) = \mathbf{0}$. Then*

$$c^T\mathbf{x} \leq \mathbf{c}^T\hat{\mathbf{x}} + \mu\left(0.27\sqrt{\theta} + 0.044\right)\,. \tag{33.47}$$

PROOF Let us consider applying Newton's method for minimizing $\mathbf{c}^T\mathbf{x} + \mu F(\mathbf{x})$ starting from $\mathbf{x}$, keeping μ fixed. Observe that (33.32) says that Newton's method converges quadratically, and it must converge to $\hat{\mathbf{x}}$. Let the Newton iterates be $\mathbf{y}^{(0)}(=\mathbf{x}), \mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \ldots$ and sequence of proximities be denoted $\lambda_0, \lambda_1, \ldots$, so $\lambda_0 \leq 1/5$ by assumption. Let us consider two consecutive iterates in this sequence $\mathbf{y}^{(k)}, \mathbf{y}^{(k+1)}$ that we denote $\mathbf{y}$ and $\mathbf{y}^+$. By the definition of Newton's method, we have

$$\mathbf{y}^+ - \mathbf{y} = -\mu^{-1}\left(\nabla^2 F(\mathbf{y})\right)^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{y})) \tag{33.48}$$

so

$$\begin{aligned}
\mu \cdot \left|\mathbf{c}^T\mathbf{y}^+ - \mathbf{c}^T\mathbf{y}\right| &= \left|\mathbf{c}^T\left(\nabla^2 F(\mathbf{y}))^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{y})\right)\right| && (33.49)\\
&= \Big|(\mathbf{c} + \mu\nabla F(\mathbf{y}))^T\left(\nabla^2 F(\mathbf{y}))^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{y})\right) - \\
&\qquad \mu\nabla F(\mathbf{y})^T\left(\nabla^2 F(\mathbf{y}))^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{y})\right)\Big| && (33.50)\\
&\leq t + \mu t^{1/2} s^{1/2} && (33.51)
\end{aligned}$$

where

$$t = (\mathbf{c} + \mu\nabla F(\mathbf{y}))^T\left(\nabla^2 F(\mathbf{y})\right)^{-1}(\mathbf{c} + \mu\nabla F(\mathbf{y})) \tag{33.52}$$

and

$$s = \nabla F(\mathbf{y})^T\left(\nabla^2 F(\mathbf{y})\right)^{-1}\nabla F(\mathbf{y})\,. \tag{33.53}$$

We obtained (33.51) by applying first the triangle inequality to split up the two terms of (33.50), and then the Cauchy–Schwarz inequality to the second term. Observe that $t = (\lambda_k\mu)^2$ by definition of λ_k. Also, observe that $s \leq \theta$ by (33.28). Substituting these bounds into (33.51) and dividing by μ yields

$$\left|\mathbf{c}^T\mathbf{y}^+ - \mathbf{c}^T\mathbf{y}\right| \leq \mu\left(\lambda_k^2 + \lambda_k\sqrt{\theta}\right)\,. \tag{33.54}$$

Thus,

$$\left|\mathbf{c}^T\hat{\mathbf{x}} - \mathbf{c}^T\mathbf{x}\right| \leq \mu\sum_{k=0}^{\infty}\left(\lambda_k^2 + \lambda_k\sqrt{\theta}\right)\,. \tag{33.55}$$

Now we use the fact that the λ's are a decreasing quadratic series starting from $1/5$ and bounded by (33.32) to find that the sum of the λ_k's is at most 0.27 and the sum of λ_k^2 is at most 0.044. This proves (33.47).

THEOREM 33.7 *Let $(\hat{\mathbf{x}}, \mu)$ be a point on the central path. Let $\mathbf{x}^*$ be the optimal solution. Then*

$$\mathbf{c}^T\hat{\mathbf{x}} \leq \mathbf{c}^T\mathbf{x}^* + \mu\theta\,. \tag{33.56}$$

PROOF Let $\mathbf{h} = \mathbf{x}^* - \hat{\mathbf{x}}$. Then $\mathbf{c}^T\hat{\mathbf{x}} - \mathbf{c}^T\mathbf{x}^* = -\mathbf{c}^T\mathbf{h}$. To prove the theorem, we must show that $-\mathbf{c}^T\mathbf{h} \leq \mu\theta$. If $\mathbf{c}^T\mathbf{h} \geq 0$ then this result is trivial, so suppose $\mathbf{c}^T\mathbf{h} < 0$. Let $\psi(t) = F(\hat{\mathbf{x}} + t\mathbf{h})$. Observe that ψ is a convex function of t satisfying $\psi'(t) = \nabla F(\hat{\mathbf{x}} + t\mathbf{h})^T\mathbf{h}$ and $\psi''(t) = \mathbf{h}^T\nabla^2 F(\hat{\mathbf{x}} + t\mathbf{h})\mathbf{h}$. Observe that

$$\begin{aligned}
\left|\psi'(t)\right| &= \left|\nabla F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)^T\mathbf{h}\right| && (33.57)\\
&= \left|\nabla F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)^T\left(\nabla^2 F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)\right)^{-1/2}\left(\nabla^2 F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)\right)^{1/2}\mathbf{h}\right| && (33.58)\\
&\leq \left(\nabla F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)^T\left(\nabla^2 F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)\right)^{-1}\nabla F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)\right)^{1/2}
\end{aligned}$$

$$\left(\mathbf{h}^T \nabla^2 F\left(\hat{\mathbf{x}} + t\mathbf{h}\right)\mathbf{h}\right)^{1/2} \tag{33.59}$$

$$\leq \quad \theta^{1/2}\psi''(t)^{1/2} \tag{33.60}$$

where (33.59) follows from (33.58) by the Cauchy–Schwarz inequality, and (33.60) follows from (33.28). Thus, $\psi''(t) \geq \psi'(t)^2/\theta$. Observe also that $\psi'(0) = \nabla F(\hat{\mathbf{x}})^T\mathbf{h} = -\mathbf{c}^T\mathbf{h}/\mu$ since $\mathbf{c} + \mu\nabla F(\hat{\mathbf{x}}) = \mathbf{0}$ (by the optimality of $\hat{\mathbf{x}}$).

Now, consider the function χ defined by $\chi(t) = (-\mu/(\mathbf{c}^T\mathbf{h}) - t/\theta)^{-1}$. Observe that $\chi(0) = -\mathbf{c}^T\mathbf{h}/\mu$, so $\chi(0) = \psi'(0)$. Also, note that $\chi'(t) = \theta^{-1}(-\mu/(\mathbf{c}^T\mathbf{h}) - t/\theta)^{-2} = \chi(t)^2/\theta$.

Thus, χ is the solution to the initial value problem $u(0) = -\mathbf{c}^T\mathbf{h}/\mu$, $u'(t) = u(t)^2/\theta$. On the other hand, ψ' is a solution to the differential inequality $u(0) = -\mathbf{c}^T\mathbf{h}/\mu$, $u'(t) \geq u(t)^2/\theta$. Since u^2/θ is an increasing function of u for positive u, a theorem about differential inequalities tells us that ψ' must dominate χ for $t \geq 0$. But notice that χ blows up to ∞ at $t = -\mu\theta/(\mathbf{c}^T\mathbf{h})$ (recall we are assuming $\mathbf{c}^T\mathbf{h} < 0$). Thus, ψ' must blow up at some t_0 satisfying $t_0 \leq -\mu\theta/(\mathbf{c}^T\mathbf{h})$. On the other hand, we already know that ψ does not blow up on $[0, 1)$ because by convexity $\hat{\mathbf{x}} + t\mathbf{h} \in \text{int}(D)$ for $t < 1$. Thus, $-\mu\theta/(\mathbf{c}^T\mathbf{h}) \geq 1$, i.e., $-\mathbf{c}^T\mathbf{h} \leq \mu\theta$. This proves (33.56).

We can now summarize the interior-point method presented in this section.

Interior-point algorithm for (33.22)
Start with $\mu_0 > 0$ and $\mathbf{x}_0 \in \text{int}(D)$ satisfying $\lambda(\mathbf{x}_0, \mu_0) \leq 1/5$.
$i := 0$.
while $\mu_i(\theta + 0.27\sqrt{\theta} + 0.044) > \epsilon$
  $\mathbf{x}_{i+1} := \mathbf{x}_i - \mu_i^{-1}(\nabla^2 F(\mathbf{x}_i))^{-1}(\mathbf{c} + \mu_i \nabla F(\mathbf{x}_i))$.
  $\mu_{i+1} := (1 - 1/(9\sqrt{\theta}))\mu_i$.
  $i := i + 1$.
end while
return $\mathbf{x}_i$.

The preceding algorithm lacks an initialization procedure, i.e., a method to construct μ_0 and $\mathbf{x}_0$. In many situations it is easy to find $\mathbf{x}_0 \in \text{int}(D)$, but not so easy to find an $\mathbf{x}_0$ that is close to the central path (i.e., that satisfies $\lambda(\mathbf{x}_0, \mu_0) \leq 1/5$ for some μ_0). In this case, there is a general-purpose iterative procedure that starts at interior point $\mathbf{x}_0$ and eventually produces a point near the central path. This iterative procedure is based on the following observation. For any $\mathbf{x}_0 \in \text{int}(D)$, $\mathbf{x}_0$ is the minimizer of the artificial objective function $g(\mathbf{x}) = \mathbf{c}_0^T\mathbf{x} + \mu_0 F(\mathbf{x})$, where $\mathbf{c}_0 = -\nabla F(\mathbf{x}_0)$ and $\mu_0 = 1$: this claim is easily verified by checking that $\nabla g(\mathbf{x}_0) = \mathbf{0}$. Therefore, we can use a path-following method on the sequence of objective functions $\mathbf{c}_0^T\mathbf{x} + \mu F(\mathbf{x})$ and try to drive μ toward ∞ instead of 0. Once μ is sufficiently large, the first term of the objective function no longer matters, and can be replaced by $\mathbf{c}^T\mathbf{x}$ where $\mathbf{c}$ is the actual gradient of the linear functional that is under consideration. We omit the details.

The running time of this initialization procedure is determined by how close $\mathbf{x}_0$ is to the boundary of D. If $\mathbf{x}_0$ is close to the boundary, then $\nabla F(\mathbf{x}_0)$ is large, and the initialization procedure requires more steps to make μ sufficiently large. Thus, a good starting point for an interior-point method would be near the **analytic center** of D. The analytic center is the point $\mathbf{x}_a$ that minimizes the barrier function $F(\mathbf{x})$, i.e., the point satisfying $\nabla F(\mathbf{x}_a) = \mathbf{0}$. The analytic center is the limit of the central path as $\mu \to \infty$.

This approach to initializing an interior-point method, in which one works with an artificial objective function first and then the actual objective function, is commonly called "phase I—phase II" in the literature. Similar approaches have also been used for initializing the simplex method; see, e.g., [6].

If no interior feasible point is known, then there is no general-purpose procedure to initialize the interior-point algorithm, and an initial point must be constructed from additional information about the

problem. In the special cases of linear, quadratic and semidefinite programming, there are initialization techniques that do not need any other additional *a priori* information.

We would like to compare the complexity of the ellipsoid method with the interior-point method. A complete comparison is not possible because of the incompatible assumptions made concerning the initialization procedure. Therefore, we compare only the rates of convergence. Recall that the ellipsoid method guarantees error tolerance of γ after $O(n^2 \log(1/\gamma))$ iterations. Each iteration requires a rank-one update to an $n \times n$ matrix given by (33.11), which requires $O(n^2)$ operations.

The convergence rate of the interior-point method is determined as follows. Convergence to tolerance ϵ is achieved after $\mu \leq O(\epsilon/\theta)$ as seen from the algorithm. On each step μ is decreased by a factor of $1 - \text{const} \cdot \theta^{-1/2}$. Thus, the number of steps p to reduce the error tolerance to ϵ must satisfy $(1 - \text{const} \cdot \theta^{-1/2})^p \leq \epsilon/\theta$. By taking logarithms, using the approximation $\ln(1+\delta) \approx \delta$, and dropping the low-order term, we conclude that the number of iterations is $O(\sqrt{\theta}\log(1/\epsilon))$. Each iteration requires the solution of a system of $n \times n$ linear equations given by (33.30), which takes $O(n^3)$ operations.

Let us assume for now that $\theta = O(n)$, where n is the dimension of the problem. Actual values for barrier parameters are provided in the next section. In this case, we conclude that the interior-point method improves on the number of iterations over the ellipsoid method by a factor of $n^{1.5}$. On the other hand, an interior-point iteration is a factor of $O(n)$ more expensive than an ellipsoid iteration, so the total savings comes out to a factor of $O(\sqrt{n})$. Karmarkar [25] showed how to save another factor of $\sqrt{n}$ in an interior-point algorithm for LP by approximately solving the linear systems using information from the previous iteration. The amortized cost of this technique is $O(n^{2.5})$ per iteration rather than $O(n^3)$, but this technique is not often used in practice.

In fact, as mentioned in the introduction, interior-point methods in practice are far more efficient than the ellipsoid method. The reason for the improvement in practice is not so much the theoretical factor of $O(\sqrt{n})$ or $O(n)$ mentioned in the last paragraph. Rather, interior-point methods are efficient in practice because the number of iterations is usually much less than $O(\sqrt{\theta}\log(1/\epsilon))$: in particular, usually it is possible to decrease μ at a much faster rate than (33.29) and still maintain approximate centrality. In such an algorithm, the decrease in μ is chosen adaptively rather than according to a fixed formula like (33.29). Nonetheless, even for these algorithms, there is no known upper bound better than $O(\sqrt{\theta}\log(1/\epsilon))$ iterations. The reason for the mismatch between the upper bound and practical behavior is not completely understood. Todd and Ye [53] showed a lower bound of $\Omega(n^{1/3}\log(1/\epsilon))$ for linear programming (where $n = \theta$) that holds for a large variety of interior-point methods.

A second reason why interior-point methods outperform the ellipsoid method is that the linear system given by (33.30) in practice is often sparse, meaning that most entries of $\nabla^2 F(\mathbf{x})$ are zeros. Many special methods have been developed for solving sparse systems of linear equations [15]; the running time for solving sparse equations can be much better than the worst-case estimate of $O(n^3)$. Sparsity considerations are the primary reason that the amortized $O(n^{2.5})$ linear system solver mentioned above is not used in practice. The ellipsoid method as presented in Section 33.3 is not able to take advantage of sparsity because (33.11) implies that B_{i+1} in general will be a completely dense $n \times n$ matrix. On the other hand, Todd [50] and Burrell and Todd [5] show that a different way of representing B_{i+1} leads to better preservation of sparsity in the ellipsoid method, in which case the sparsity properties of the two algorithms may be comparable.

33.5 Additional Remarks on Self-Concordance

In this section we give some additional theoretical background on self-concordance and an example.

The first question is, for what convex sets do self-concordant barrier functions exist? It turns out that *every* closed, convex subset D of $\mathbf{R}^n$ with a nonempty interior has a self-concordant barrier function with

parameter $\theta = O(n)$. Given such a set D, Nesterov and Nemirovskii prove that the function

$$F(\mathbf{x}) = \text{const} \cdot \ln \text{vol}\left(\left\{\mathbf{a} \in \mathbf{R}^n : \mathbf{a}^T(\mathbf{y} - \mathbf{x}) \leq 1 \quad \forall \mathbf{y} \in D\right\}\right) \tag{33.61}$$

is self-concordant with parameter $O(n)$. This function is called the **universal** barrier. This barrier is not useful in practice because there is evidently no algorithm to evaluate (33.61), let alone its derivatives, for general convex sets. In practice, one constructs self-concordant barrier functions for certain special cases of commonly occurring forms of constraints.

Another question is, what is the best possible value of θ? In the last paragraph it was claimed that it is theoretically possible to always choose $\theta \leq \text{const} \cdot n$. On the other hand, it can be proved that $\theta \geq 1$ in all cases. This lower bound of 1 is tight. The barrier function

$$F(\mathbf{x}) = \ln\left(1 - x_1^2 - \cdots - x_n^2\right) \tag{33.62}$$

when D is the unit ball in $\mathbf{R}^n$ has self-concordance parameter 1. This result generalizes to any ellipsoidal constraint, since self-concordance is preserved by affine transformations.

How does one verify that (33.62) is indeed self-concordant? The two conditions (33.24) and (33.26) in the last section appear nontrivial to check, even for a simple function written down in closed form like (33.62).

It turns out that there is a simpler definition of self-concordance, which is as follows. A function F is **self-concordant** if for all $\mathbf{x} \in \text{int}(D)$ and for all $\mathbf{h} \in \mathbf{R}^n$

$$\left|\nabla^3 F(\mathbf{x})[\mathbf{h}, \mathbf{h}, \mathbf{h}]\right| \leq 2\left(\mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h}\right)^{3/2} . \tag{33.63}$$

The notation on the left-hand side means the application of the trilinear form $\nabla^3 F(\mathbf{x})$ to the three vectors $\mathbf{h}, \mathbf{h}, \mathbf{h}$. (We could have used analogous notation for the right-hand side: $2(\nabla^2 F(\mathbf{x})[\mathbf{h}, \mathbf{h}])^{3/2}$.) It should be apparent at an intuitive level why (33.63) and (33.26) are related: a bound on the third derivative in terms of the second means that the second derivative cannot vary too much over a neighborhood defined in terms of the second derivative.

The proof that (33.63) implies (33.26) is based on such an argument. The trickiest part of the proof is an inequality involving trilinear forms and related to the generalized Cauchy–Schwarz inequality above. The trilinear inequality is proved in [37] and has been simplified by Jarre [22]. Furthermore, under an assumption of sufficient differentiability, the other direction holds: (33.26) implies (33.63) as noted by Todd [51].

We now present one particularly simple barrier function, easily analyzed by (33.63). We consider the following barrier function for the positive orthant $O_n = \{\mathbf{x} \in \mathbf{R}^n : x_1 \geq 0, \ldots, x_n \geq 0\}$:

$$F(\mathbf{x}) = -\sum_{i=1}^{n} \ln x_i . \tag{33.64}$$

This barrier is the key to linear programming. The gradient $\nabla F(\mathbf{x})$ is seen to be $(-1/x_1, \ldots, -1/x_n)$ and the Hessian $\text{diag}(1/x_1^2, \ldots, 1/x_n^2)$, where $\text{diag}(\cdot)$ denotes a diagonal matrix with the specified entries. This matrix is positive definite so we see that (33.64) is indeed a strictly convex function that tends to ∞ at the boundaries of the orthant. The third derivative is $\text{diag}(-2/x_1^3, \ldots, -2/x_n^3)$, where "diag" denotes a diagonal tensor. Thus,

$$\nabla^3 F(\mathbf{x})[\mathbf{h}, \mathbf{h}, \mathbf{h}] = -2h_1^3/x_1^3 - \cdots - 2h_n^3/x_n^3 \tag{33.65}$$

compared to

$$\mathbf{h}^T \nabla^2 F(\mathbf{x})\mathbf{h} = h_1^2/x_1^2 + \cdots + h_n^2/x_n^2 . \tag{33.66}$$

It is now obvious that (33.63) holds. Furthermore, (33.28) is also easily checked; one finds that $\theta = n$ for this barrier. Nesterov and Nemirovskii show that n is also a lower bound for the barrier parameter on the positive orthant, and hence this barrier is optimal.

33.6 Semidefinite Programming and Primal-Dual Methods

In this section we specialize the interior-point framework to semidefinite programming. Interior-point methods for semidefinite programming were developed independently by Nesterov and Nemirovskii [37] and Alizadeh [1]. In this section we follow Alizadeh's treatment.

The following optimization problem is said to be primal standard form **semidefinite programming** (SDP):

$$\begin{array}{ll} \text{minimize} & C \bullet X \\ \text{subject to} & A_1 \bullet X = b_1 \ , \\ & \vdots \\ & A_m \bullet X = b_m \ , \\ & X \succeq 0 \ . \end{array} \tag{33.67}$$

The notation here is as follows. All of $C, A_1, \ldots, A_m, X$ are symmetric $n \times n$ matrices. Matrices $A_1, \ldots, A_m$ and C are given as data, as are scalars $b_1, \ldots, b_m$. Matrix X is the unknown. The notation $Y \bullet Z$ means elementwise inner product, i.e., $Y \bullet Z = \Sigma_{i,j} y_{ij} z_{ij}$. This is equal to trace XY if X, Y are symmetric. The constraint $X \succeq 0$ means that X is positive semidefinite. More generally, the notation $X \succeq Y$ means $X - Y$ is positive semidefinite. This order is known as the **Löwner partial order.**

The set S of symmetric positive semidefinite matrices is convex as noted in Section 33.2. Furthermore, the function $F(X) = -\ln \det(X)$ is a self-concordant barrier function on S whose parameter of self-concordance is n. We omit the proof; see [37]. This barrier is optimal for S in the sense that there is no self-concordant barrier on S with parameter less than n. (A set like the feasible region of (33.67), which is defined as the conjunction of a semidefinite constraint and equality constraints, may admit a better barrier. See remarks on this issue in the next section.)

Given this specification of the barrier, it is now straightforward to set up the interior-point method of Section 33.4 and solve (33.67). The only difficulty is the inclusion of linear equality constraints. This is handled by regarding the barrier function F as restricted to the affine set given by $\{X : A_i \bullet X = b_i \text{ for each } i\}$. Restricting $F(X)$ to this affine set means that the Newton step (33.30) now must be modified with linear projections on the Hessian and gradient. An example of a projected Newton step for LP is presented in the next section.

In this section we introduce **primal-dual** interior-point methods. In practice, primal-dual methods are preferred for SDP and LP over the primal method of Section 33.4. The framework of self-concordant barrier functions can be extended to primal-dual interior-point methods at a fairly general level [37], but we treat only the two special cases of primal-dual SDP and LP.

The dual problem for a convex optimization can be obtained from the KKT conditions (33.4): the multipliers in the KKT conditions turn out to be the solution to another convex optimization problem called the dual. An alternative way to derive the dual is by considering the KKT conditions of the barrier problem rather than the original problem. The SDP barrier problem is to minimize $C \bullet X - \mu \ln \det(X)$ subject to $X \succ 0$, $A_i \bullet X = b_i$ for $i = 1, \ldots, m$. The notation $X \succ 0$ means X is positive definite. Consider the KKT conditions for this barrier problem. Observe that the relation $X \succ 0$ drops out of the KKT conditions because it is inactive at the optimizer (because the barrier function blows up at the boundary of the feasible region, since $\det X = 0$ if X is semidefinite but not positive definite). Note also that the gradient of $\ln \det(X)$ is the function $X \mapsto X^{-1}$. Therefore, the KKT condition for the barrier problem is

$$C - \mu X^{-1} = y_1 A_1 + \cdots + y_m A_m \tag{33.68}$$

plus feasibility:

$$A_1 \bullet X = b_1, \ldots, A_m \bullet X = b_m \ . \tag{33.69}$$

Here, $y_1, \ldots, y_m$, are unconstrained Lagrange multipliers.

We claim that these are also the KKT conditions for another SDP barrier problem. Consider the SDP

$$\begin{array}{ll} \text{maximize} & b_1 y_1 + \cdots + b_m y_m \\ \text{subject to} & C - S = y_1 A_1 + \cdots + y_m A_m \ , \\ & S \succeq 0 \ , \end{array} \tag{33.70}$$

where $S, y_1, \ldots, y_m$ are the variables. Attaching a barrier changes the objective to maximizing $b_1 y_1 + \cdots + b_m y_m + \mu \ln \det(S)$. The KKT optimality condition is that $b_1 = A_1 \bullet X, \ldots, b_m = A_m \bullet X$, and $X = \mu S^{-1}$. Here X is a multiplier for the equality constraint of (33.70). But notice that the identification $X = \mu S^{-1}$ means that (33.68) and (33.69) are satisfied! Thus, the two barrier problems have the same KKT conditions. We say that (33.70) is the **dual** to (33.67). One can check that the dual of the dual, after some simplification, is again the primal.

Let us assume that a constraint qualification such as the Slater condition holds. Then the KKT conditions are necessary and sufficient for both primal and dual optimality. Furthermore, the primal and dual barrier objective function optimal values satisfy the following relation:

$$\begin{aligned} C \bullet X &= (S + y_1 A_1 + \cdots + y_m A_m) \bullet X && (33.71) \\ &= S \bullet X + y_1 A_1 \bullet X + \cdots + y_m A_m \bullet X && (33.72) \\ &= S \bullet X + b_1 y_1 + \cdots + b_m y_m && (33.73) \\ &= n\mu + b_1 y_1 + \cdots + b_m y_m \ . && (33.74) \end{aligned}$$

The last line was obtained by noting that since $SX = \mu I$, $S \bullet X = n\mu$. This follows because $S \bullet X = \text{trace } SX = \text{trace } \mu I$.

Thus, we see that for the barrier optimizers, the original primal function minimum value is exactly $n\mu$ greater than the dual objective function maximum value. Since we drive μ to zero in an interior-point method, we conclude that the two SDP's (33.67) and (33.70) have the same optimum value. Because of relationship (33.74), the parameter μ in an interior-point method is sometimes called the **duality gap.**

A **primal-dual interior-point method** for (33.67) and (33.70) is a method that simultaneously updates the primal and dual iterates, attempting to shrink the duality gap to zero. Alizadeh proposes a potential-reduction primal-dual algorithm for SDP, which is a generalization of Ye's [63] potential-reduction algorithm for linear programming. We define $q = n + \sqrt{n}$ and define

$$\psi(X, S) = q \ln(X \bullet S) - \ln \det(XS) \ . \tag{33.75}$$

The motivation for this definition is as follows. The first term decreases to $-\infty$ as the duality gap tends to 0. On the other hand, the second term is a penalty for loss of centrality. Unlike the method of Section 33.4, a potential-reduction method does not explicitly maintain proximity to the central path. Each iteration reduces the potential by a fixed constant amount, thus driving the potential to $-\infty$. The step taken is related to Newton's method for decreasing the potential function. To gain further insight, consider the case when X, S are on the central path, so that $XS = \mu I$: then the value of the potential function is $q \ln n + \sqrt{n} \ln \mu$, which tends to $-\infty$ as $\mu \to 0$. This algorithm has the same theoretical running time as the algorithm in Section 33.4, namely $O(\sqrt{n} \log(1/\epsilon))$ iterations to reduce the duality gap to $O(\epsilon)$.

We conclude this section with some applications of SDP, drawn from Vandenberghe and Boyd [55]. The most direct application is to eigenvalue optimization problems. For instance suppose we want to minimize the maximum eigenvalue of an unknown symmetric matrix A that is parameterized by n free variables $x_1, \ldots, x_n$ according to the formula $A = A_0 + x_1 A_1 + \cdots + x_n A_n$, where $A_0, \ldots, A_n$ are given symmetric matrices. This can be stated as the following semidefinite program: find the minimum t such that $tI - A_0 - x_1 A_1 - \cdots - x_n A_n \succeq 0$. Some applications and further references for eigenvalue optimization are in [55]. Another application is quadratically constrained quadratic programming, which is minimizing a convex quadratic function subject to ellipsoidal and linear constraints. An ellipsoidal

constraint $(\mathbf{x}-\mathbf{c})^T A(\mathbf{x}-\mathbf{c}) \leq 1$ can be transformed into an SDP constraint of the form:

$$\begin{bmatrix} I & R(\mathbf{x}-\mathbf{c}) \\ (\mathbf{x}-\mathbf{c})^T R^T & 1 \end{bmatrix} \succeq 0 \tag{33.76}$$

where R is a matrix such that $R^T R = A$ (e.g., the Cholesky factor of A). Note that a collection of SDP constraints can be concatenated along the diagonal to make a single large SDP constraint in order to put the problem in standard form. (These transformations do not necessarily lead to the most efficient algorithm for ellipsoidal constraints.) Another geometric problem that can be transformed to SDP is finding the smallest ellipsoid that contains the union of a set of given ellipsoids. See [55]. There are also applications of SDP to combinatorial optimization and control theory described in [1] and [55]. It should be noted that some of the combinatorial implications of semidefinite programming were observed before the advent of interior-point methods because the ellipsoid method can also solve semidefinite problems. See Grötschel, Lovász, and Schrijver [17, 18].

33.7 Linear Programming

A special case of SDP is linear programming. If we suppose that each matrix A_i is diagonal and C is diagonal, then one can show that the solution X is also diagonal without loss of generality. In this case, the inequality $X \succeq 0$ means that each diagonal entry of X is nonnegative. Thus, if we let $\mathbf{x}$ be the vector of diagonal entries of X, and similarly for S, A_i's and C, then we obtain the primal and dual forms of linear programming:

$$\begin{array}{ll} \text{minimize} & \mathbf{c}^T\mathbf{x} \\ \text{subject to} & A\mathbf{x} = \mathbf{b}\,, \\ & \mathbf{x} \geq \mathbf{0} \end{array} \tag{33.77}$$

and

$$\begin{array}{ll} \text{maximize} & \mathbf{b}^T\mathbf{y} \\ \text{subject to} & A^T\mathbf{y} + \mathbf{s} = \mathbf{c}\,, \\ & \mathbf{s} \geq \mathbf{0}\,. \end{array} \tag{33.78}$$

In these equations, A, $\mathbf{b}$,$\mathbf{c}$ are given: A is an $m \times n$ matrix assumed to have rank m (and hence $m \leq n$), $\mathbf{b}$ is an m-vector, and $\mathbf{c}$ is an n-vector. The variables are $\mathbf{x}$ for the primal and $(\mathbf{y},\mathbf{s})$ for the dual.

The barrier function for linear programming is the specialization of the SDP barrier to the case of diagonal matrices, which turns out to be the barrier for the positive orthant (33.64). Recall that this barrier has parameter n. Although this barrier is optimal for the orthant, it is not necessarily optimal for the orthant in conjunction with the linear constraints. The combination of the two types of constraints means that the feasible region is actually a polytope of dimension $n-m$ in the primal case, and m in the dual case. Since the noncomputable universal barrier has parameter $O(n-m)$ in the one case and $O(m)$ in the other case, the question arises whether there is a computable barrier with a better parameter than n for linear programming. Partial progress on this was made by Vaidya and is described in [37]: Vaidya's barrier has parameter $O(\sqrt{mn})$ for the dual problem.

Using the standard barrier (33.64), we can write down LP with the barrier functions and derive the KKT conditions. This yields the following system of equations that describe the central path for both the primal and dual. These equations are a special case of (33.68)–(33.69) for SDP derived in the previous section.

$$A\mathbf{x} = \mathbf{b}\,, \tag{33.79}$$

$$A^T\mathbf{y} + \mathbf{s} = \mathbf{c}\,, \tag{33.80}$$

$$x_i s_i = \mu \quad \text{for } i = 1, \ldots, n, \tag{33.81}$$

$$x_i, s_i > 0 \quad \text{for } i = 1, \ldots, n\,. \tag{33.82}$$

We have introduced the LP central path as a special case of SDP, which is in turn a special case of general convex programming, but in fact, the LP central path was discovered and analyzed before the others. This discovery is usually credited to [2, 29, 31, 47], and several of these authors considered algorithms that follow this path. The first interior-point method for LP was Karmarkar's [25] projective method, which requires $O(n \log(1/\epsilon))$ iterations. Gill et al. [16] spotted the connection between Newton's method and Karmarkar's interior-point method. Renegar [41] also related interior-point methods to Newton's method and used this analysis to reduce the running time to $O(\sqrt{n} \log(1/\epsilon))$ iterations. Note that the $\sqrt{n}$ factor is the specialization of the $\sqrt{\theta}$ factor from the general convex case since $\theta = n$ for (33.64).

Kojima, Mizuno and Yoshise [28] and Monteiro and Adler [33] introduced a primal-dual path-following method for (33.79)–(33.82). The idea is similar to what we have seen before: an iterate is a solution to (33.79)–(33.82), except (33.81) is satisfied only approximately. We then decrease μ and take a step of Newton's method to regain centrality. The iteration bound is also $O(\sqrt{n} \log(1/\epsilon))$. Because of the simple form, we can write down Newton's method explicitly. First, we need a measure of proximity to the central path. It turns out that the standard proximity measure $\lambda(\cdot, \cdot)$ for the primal or dual alone, after some manipulation and substitution of primal-dual approximations, has the form $\|XS\mathbf{e}/\mu - \mathbf{e}\|$, where $X = \text{diag}(\mathbf{x})$, $S = \text{diag}(\mathbf{s})$, and $\mathbf{e}$ is the vector of all 1's.

Assuming we have a primal-dual point $(\mathbf{x}, \mathbf{y}, \mathbf{s})$ satisfying (33.79), (33.80) and (33.82), and a parameter μ such that $\|XS\mathbf{e}/\mu - \mathbf{e}\| \leq \lambda_0$ (where $\lambda_0 = 1/5$ for example), we can take a step to solve (33.79)–(33.82) for a smaller value of μ, say $\bar{\mu}$. The Newton step $(\Delta\mathbf{x}, \Delta\mathbf{y}, \Delta\mathbf{s})$ linearizes (33.81) and is defined by

$$A\Delta\mathbf{x} = \mathbf{0}, \tag{33.83}$$

$$A^T\Delta\mathbf{y} + \Delta\mathbf{s} = \mathbf{0}, \tag{33.84}$$

$$X\Delta\mathbf{s} + S\Delta\mathbf{x} = -XS\mathbf{e} + \bar{\mu}\mathbf{e}. \tag{33.85}$$

Many of the best current interior-point methods are based on (33.83)–(33.85). Observe that (33.83)–(33.85) define a square system of linear equations with special structure; currently there is significant research on how to solve these equations efficiently and accurately. See [62].

It should be pointed out that Newton's method for solving (33.79)–(33.82) as a system of nonlinear equations, which is the way (33.83)–(33.85) were obtained, is not the same as Newton's method for minimizing the barrier in either the primal or dual. Newton's method for minimizing the barrier in the primal is equivalent to Newton's method for solving a system of nonlinear equations similar to (33.79)–(33.82) except with the third equation replaced by $s_i = \mu/x_i$. The equation $s_i = \mu/x_i$ is of course equivalent to $x_i s_i = \mu$, but these two equations induce different Newton steps. See El-Bakry et al. [10] for more information on this matter.

33.8 Complexity of Convex Programming

In this section we consider complexity issues for linear, semidefinite and convex programming. "Complexity" means establishing bounds on the asymptotic running time for large problems. An immediate issue we must confront is the problem of modeling the numerical computations in the ellipsoid and interior-point method. Actual computers have floating-point arithmetic, which provides a fixed number of significant digits (about 16 decimal digits in IEEE standard double precision) for arithmetic. Restricting arithmetic to a fixed number of digits precludes the solution of poorly conditioned problems, and hence is not desirable for a complexity theory.

One way of modeling the notion that the precision of arithmetic should not have an *a priori* limit is the Turing machine model of computation, covered in detail in another chapter. For the purpose of numerical algorithms, the Turing machine model can be regarded as a computational device that carries out operations on arbitrary-precision rational numbers, and the running time of a rational operation is polynomially dependent on the number of bits in the numerators and denominators. The Turing machine model is also called the "bit complexity" model in the literature.

In this model, the data for a linear programming instance is presented as a triple $(A, \mathbf{b}, \mathbf{c})$ where the entries of these items must be rational numbers. In fact, without loss of generality, let us assume the data is integral since we can clear common denominators in a rational representation, causing at most a polynomial increase in the size of the problem.

Let L be the total number of bits to write this data. We assume that L is at least $mn + m + n$, i.e., each coordinate entry of $(A, \mathbf{b}, \mathbf{c})$ requires at least one bit.

Khachiyan [26] showed that if an LP instance has a feasible solution, then it must have a feasible solution lying in a ball of radius $O(2^{cL})$ of the origin, where c is a universal constant. This ball can thus be used as the initial ellipsoid for the ellipsoid method. Furthermore, when the solution is known to accuracy $O(2^{-dL})$, then a rounding procedure can determine the exact answer.

A word is needed here concerning "the exact answer." For a linear programming problem, it can be shown that the exact answer is the solution to a square system of linear equations whose coefficients are all rational and are derived from the initial data $(A, \mathbf{b}, \mathbf{c})$. This is because the optimal solution in a linear programming problem is always attained at a vertex (provided the feasible region has a vertex). Vertices of a polytope are determined by which constraints are active at that vertex. Solving a system of equations over the rationals can be done exactly with only a polynomial increase in bit-length, a result due to Edmonds [9].

Thus, in the case of linear programming with integer data, it is possible to deduce from the problem data itself valid initialization and termination procedures without additional knowledge. These procedures are also guaranteed to correctly diagnose problems with no feasible points, feasible sets with volume 0, and problems with an unbounded objective function. Khachiyan's analysis shows that the number of arithmetic operations for the ellipsoid method is bounded by $O(n^4 L)$. (The actual Turing machine running time is higher by a factor of L^c to account for the time to do each arithmetic operation.) This bound is a polynomial in the length of the input, which is L. Thus, Khachiyan's linear programming algorithm is polynomial time. This result generalizes to quadratic programming.

A similar analysis can be carried out for interior-point methods; see, e.g.,[57] for the details. One reaches the conclusion that Karmarkar's method requires $O(nL)$ iterations to find the optimal solution, whereas Renegar's requires $O(\sqrt{n}L)$ iterations, where each iteration involves solving a system of equations. In the Turing-machine polynomial-time analysis of both the ellipsoid and interior-point methods, it is necessary to truncate the numerical data after each major iteration to $O(L)$ digits (else the number of digits grows exponentially). This truncation requires additional analysis to make sure that the invariants of the two algorithms are not violated.

Until 1979, the question of polynomiality of LP was a well-known open question. The reason is that the dominant algorithm in practice for solving LP problems until recently has been the simplex method of Dantzig [6]. The simplex method has many variants because many rules are possible for the selection of the "pivot column." Klee and Minty [27] showed that some common variants of the simplex method are exponential time in the worst case, even though they are observed to run in polynomial time in practice. "Exponential" means that the running time could be as large as $\Omega(2^n)$ operations. Kalai [23] proposed a variant of simplex that has worst-case running time lower than exponential but still far above polynomial. There is no known variant of simplex that is polynomial-time, but on the other hand, there is also no proof that such a variant does not exist.

The ellipsoid algorithm, while settling the question of polynomiality, is not completely satisfactory for the following reason. Observe that the number of arithmetic operations of the simplex method depends on the dimensions of the relevant matrices and vectors but not on the data in the matrix. This is common for other numerical computations that have finite algorithms, such as solving systems of equations, finding maximum flows, and so on. An algorithm whose number of arithmetic operations is polynomial in the dimension of the problem, and whose intermediate numerical data require a polynomially-bounded number of bits, is said to be **strongly polynomial time.** Notice that the ellipsoid method is not strongly polynomial time because the number of arithmetic operations depends on the number of bits L in the data rather than on n.

The question of whether there is a strongly polynomial time algorithm for LP remains open. Some partial progress was made by Megiddo [30], who showed that linear programming in a low, fixed dimension is strongly polynomial. Low dimensional linear programming arises in computational geometry. Partial progress in another direction was made by Tardos [49], who proposed an LP algorithm based on the ellipsoid method such that the number of arithmetic operations depends only on the number of bits in A, and is independent of the number of bits in **b** and **c**. This algorithm uses "rounding" to the nearest integer as a main operation. Tardos's result is important because many network optimization problems can be posed as LP instances in which the entries of A have all small integer data, but **b** and **c** have complicated numerical data. Tardos's result was generalized by Vavasis and Ye as described below.

We should add a word on how interior-point methods are initialized and terminated in practice. Three common techniques for initialization are phase I–phase II methods, big-M methods, and infeasible methods. Phase I–phase II methods were described at the end of Section 33.4. A big-M method appends a dummy variable to the LP instance, whose entry in the objective function vector is some very large number M. Because of the new variable, a feasible interior point is easily found. Because of the large weight on the new variable, it is driven to zero at optimum. A final class of initialization methods are "infeasible" interior-point methods. In these methods, an iterate satisfying (33.82) and approximately satisfying (33.81) is maintained, but the iterate does not necessarily satisfy (33.79) or (33.80). A trajectory is followed that simultaneously achieves feasibility and optimality in the limit.

All three initialization methods are guaranteed to work correctly and in polynomial time if the parameters are chosen correctly. For instance, M in the big-M method should be at least 2^{cL} for a theoretical guarantee. Infeasible interior-point methods are currently the best in practice but are the most difficult to analyze. See Wright [62].

As for termination, many practical interior-point methods simply stop when μ is sufficiently small and output the iterate at that step as the optimizer. Khachiyan's solution for termination at an exact optimizer is generally not used in practiced. Ye [65] proposed a termination procedure based on projection that also gives the exact solution, but possibly at a much earlier stage than the theoretical worst-case $\sqrt{n}L$ iterations.

Finally, we mention a recent LP interior-point algorithm by Vavasis and Ye [59] that is based on decomposing the system of Eqs. (33.83)–(33.85) into "layers." This algorithm has the property that its running time bound to find the exact optimizer is polynomial in a function of A that does not depend on **b** and **c**. If A contains integer data, then the bound by Vavasis and Ye depends polynomially on the number of bits in A. Thus, the layered algorithm gives a new proof of Tardos's result, but it is more general because no integrality assumption is made. In the case of generic real data, the running time of the algorithm depends on a parameter $\bar{\chi}_A$ that was discovered independently by a number of authors including Stewart [48] and Todd [54]. The earliest discoverer of the parameter is apparently Dikin [8].

Vavasis and Ye use a big-M initialization, but they show that the running time is independent of how big M is (i.e., the running time bound does not degrade if M is chosen too large). Furthermore, finite termination to an exact optimizer is built into the layered algorithm. Another consequence of the algorithm is a characterization of the LP central path as being composed of at most $O(n^2)$ alternating straight and curved segments such that the straight segments can be followed with a line search in a single step. There are still some obstacles preventing this algorithm from being completely practical; in particular, it is not known how to efficiently estimate the parameter $\bar{\chi}_A$ in a practical setting. Also, it is not known whether the approach generalizes beyond linear programming since there is no longer a direct relation between the layered step of [59] and Newton's method.

The complexity results in this section are not known to carry over to SDP. Consider the following SDP feasibility question: Given $A_1, \ldots, A_m$, each a symmetric $n \times n$ matrix with integer entries, and given m integer scalars $b_1, \ldots, b_m$, does there exist a real symmetric $n \times n$ matrix X satisfying $A_1 \bullet X = b_1, \ldots, A_m \bullet X = b_m$, $X \succeq 0$? This problem is not known to be solvable in polynomial time; in fact, it is not known even to lie in NP. The best Turing machine complexity bound, due to Porkolab and Khachiyan [40], is $O(mL2^{p(n)})$ operations, where $p(n)$ is a polynomial function of n, and L is the number of bits to write $A_1, \ldots, A_m, b_1, \ldots, b_m$. The technique uses a decision procedure for problems over the reals due to

Renegar [42]. Note that the Turing machine is not required to compute such an X, but merely produce a yes/no answer. Such a problem is called a "decision problem" or "language recognition problem."

There are two hurdles to generalizing Khachiyan's LP analysis to this SDP decision problem. The first is that the exact solution to an SDP is irrational even if the original problem data is all integral. This hurdle by itself is apparently not such a significant difficulty. For instance, in [60] it is shown that a certain optimization problem (the trust-region problem) with an irrational optimizer nonetheless has an associated decision problem solvable in polynomial time. The trust-region problem is much simpler than SDP, but the arguments of [60] might generalize to SDP.

The second hurdle, apparently more daunting, is that points in the feasible region of an SDP problem may be double-exponentially large in the size of the data (as opposed to LP, where they are at most single-exponentially large). For instance, consider example of minimizing x_n subject to $x_0 \geq 2$, and $x_1 \geq x_0^2$, $x_2 \geq x_1^2, \ldots, x_n \geq x_{n-1}^2$. (Recall that, as shown at the end of Section 33.6, convex quadratic constraints can be expressed in the SDP framework.) Clearly any feasible point satisfies $x_n \geq 2^{2^n}$. Note that even writing down 2^{2^n} as a binary number requires an exponential number of digits. This example is from Alizadeh [1], who attributes it to M. Ramana.

Since problems beyond linear and quadratic programming do not have rational solutions even when the data is rational, many researchers have abandoned the Turing machine model of complexity and adopted a real-number model of computation, in which the algorithm manipulates real numbers with unit cost per arithmetic operation. The preceding complexity bounds for the simplex method and layered-step method are both valid in the real number model. Other LP algorithms, as well as interior-point and ellipsoid algorithms for more general convex problems, need some new notion to replace the factor L. Several recent papers, e.g., [13, 43, 64], have defined a "condition number" for convex programming problems and have bounded the complexity in terms of this condition number.

33.9 Nonconvex Optimization

The powerful techniques of convex programming can sometimes carry over to nonconvex problems, although generally none of the accompanying theory carries over to the nonconvex setting. For instance, the barrier function method was originally invented for general inequality-constrained nonconvex optimization—see, e.g., Wright [61]—although it is does not necessarily converge to a global or even local optimizer in that setting. More recently, El-Bakry et al. [10] have looked at following the primal-dual central path for nonconvex optimization (which, as noted above, is not the same as following the barrier trajectory). In this section we will briefly summarize some known complexity results and approaches to nonconvex problems.

Perhaps the simplest class of nonconvex continuous optimization problems is nonconvex quadratic programming, that is, minimizing $\mathbf{x}^T H\mathbf{x}/2 + \mathbf{c}^T\mathbf{x}$ subject to linear constraints, where H is a symmetric but not positive semidefinite matrix. This problem is NP-hard [45], and NP-complete when posed as a decision problem [56]. Even when H has only one negative eigenvalue, the problem is still NP-hard [39]. Testing whether a point is a *local* minimizer is NP-hard [34]. If a polynomial time algorithm existed for computing an approximate answer guaranteed to be within a constant factor of optimal, this would imply that $\tilde{P} = \tilde{NP}$, where $\tilde{P}$ and $\tilde{NP}$ are complexity classes believed to be unequal [3].

In spite of all these negative results, some positive results are possible for nonconvex optimization. First, there are classes of nonconvex problems that can be transformed to SDP by nonlinear changes of variables; see [55] for examples. Sometimes the transformation from nonconvex to convex is not an exact transformation. For instance, if the feasible region is strictly enlarged, then the convex problem is said to be a **relaxation** of the nonconvex problem. The relaxed problem, while not equivalent to the original nonconvex problem, nonetheless yields a lower bound on the optimum value which may be useful for other purposes. See [55] for examples of semidefinite relaxations of nonconvex problems.

Another approach is to use convex optimization as a "subroutine" for nonconvex optimization. There are many examples of this in the nonlinear optimization literature; see [35]. Sometimes this can be done in a way that gives provable complexity bounds for nonconvex problems, such as the result by Vavasis [58] for nonconvex quadratic programming.

Finally, sometimes interior-point techniques, while not yielding global minima or approximations to global minima, can still deliver interesting results in polynomial time. For instance, Ye [66] shows that a primal-dual potential reduction algorithm applied to nonconvex quadratic programming can approximate a KKT point in polynomial time.

33.10 Research Issues and Summary

We have shown that convex optimization can be solved via two efficient algorithms, the ellipsoid method and interior-point methods. These methods can be derived in the general setting of convex programming and can also be specialized to semidefinite and linear programming. Perhaps the most outstanding research issue in the field is a better understanding of the complexity of semidefinite programming. Is this problem solvable in polynomial time? Is there a guaranteed efficient method for finding a starting point, and for determining whether a feasible region is empty? Another topic of great interest recently is to understand primal-dual path-following methods for SDP. The difficulty is that there are several different, inequivalent ways to generalize the Eqs. (33.83)–(33.85) (which define the primal-dual path-following step for linear programming) to semidefinite programming, and it is not clear which generalization to prefer. See Todd [52] for more information. Another issue not completely understood for SDP is the correct handling of sparsity, since the matrices $A_1, \ldots, A_m$ are often sparse [14].

Linear programming is known to be polynomial time but not known to be strongly polynomial time. This is another notorious open problem.

33.11 Defining Terms

Barrier function: Let D be a convex feasible region whose interior is nonempty. A barrier function $F : \text{int}(D) \to \mathbf{R}$ is a strictly convex function that tends to infinity as the boundary of D is approached.

Central path: Given a convex programming problem, the central path point for some $\mu > 0$ is the minimizer of $f(\mathbf{x}) + \mu F(\mathbf{x})$, where $f(\mathbf{x})$ is the objective function and $F(\mathbf{x})$ is a barrier function for D. The central path is the trajectory of all such points as μ varies from 0 to ∞. This curve joins the analytic center ($\mu = \infty$) of the region to the optimizer ($\mu = 0$). Many interior-point methods select iterates that are close to the central path according to a proximity measure.

Constraint: A feasible region $D \subset \mathbf{R}^n$ in an optimization problem is often represented as the set of points $\mathbf{x}$ satisfying a sequence of constraints involving $\mathbf{x}$. There are two main kinds of constraints: equality constraints, which have the form $g(\mathbf{x}) = 0$, and inequality constraints, which have the form $h(\mathbf{x}) \leq 0$.

Some specific types of constraints are as follows: A linear equality constraint has the form $\mathbf{a}^T\mathbf{x} = b$, where $\mathbf{a} \in \mathbf{R}^n$, $b \in \mathbf{R}$ are specified. A linear inequality constraint has the form $\mathbf{a}^T\mathbf{x} \leq b$. An ellipsoidal constraint has the form $(\mathbf{x} - \mathbf{c})^T A(\mathbf{x} - \mathbf{c}) \leq 1$, where $\mathbf{c}$ is a vector and A is a symmetric $n \times n$ positive definite matrix. A semidefinite constraint has the form

$$X \text{ is symmetric positive semidefinite}$$

where X is a matrix composed of variables.

For a point $\mathbf{x}_1 \in D$, an inequality constraint $h(\mathbf{x}) \leq 0$ is active at $\mathbf{x}_1$ if $h(\mathbf{x}_1) = 0$, else the constraint is inactive. Equality constraints by default are always active.

A convex constraint is either a linear equality constraint defined above, or is an inequality constraint $h(\mathbf{x}) \leq 0$, where h is a convex function. The feasible region defined by one or more convex constraints is convex.

Constraint qualification: A constraint qualification is a condition imposed on the constraints at some feasible point that ensures that every linearized feasible direction is also a feasible direction.

Convex function: Let f be a real-valued function defined on a convex set D. This function is convex if for all $\mathbf{x},\mathbf{y} \in D$ and for all $\lambda \in [0, 1]$, $f(\lambda\mathbf{x} + (1 - \lambda)\mathbf{y}) \geq \lambda f(\mathbf{x}) + (1 - \lambda) f(\mathbf{y})$. This function is strictly convex if the preceding inequality is strict whenever $\mathbf{x} \neq \mathbf{y}$ and $\lambda \in (0, 1)$.

Convex programming: An optimization problem in which the objective function is convex and the feasible region is specified via a sequence of convex constraints is called convex programming.

Convex set: A set $D \subset \mathbf{R}^n$ is convex if for any $\mathbf{x},\mathbf{y} \in D$ and for any $\lambda \in [0, 1]$, $\lambda\mathbf{x} + (1 - \lambda)\mathbf{y} \in D$.

Ellipsoid: Let A be an $n \times n$ symmetric positive definite matrix and let $\mathbf{c}$ be an n-vector. The set $E = \{\mathbf{x} \in \mathbf{R}^n : (\mathbf{x} - \mathbf{c})^T A(\mathbf{x} - \mathbf{c}) \leq 1\}$ is an ellipsoid.

Ellipsoid method: The ellipsoid method, due to Yudin and Nemirovskii [68], is a general-purpose algorithm for solving convex programming problems. It constructs a sequence of ellipsoids with shrinking volume each of which contains the optimizer. See Section 33.3.

Feasible direction: Let $D \subset \mathbf{R}^n$ be a feasible region and say $\mathbf{x} \in D$. A nonzero vector $\mathbf{v}$ is a feasible direction at $\mathbf{x}$ if there exists a sequence of points $\mathbf{x}_1, \mathbf{x}_2, \ldots$ all in D converging to $\mathbf{x}$ and a sequence of positive scalars $\alpha_1, \alpha_2, \ldots$ converging to zero such that $\mathbf{x}_k - \mathbf{x} = \alpha_k\mathbf{v} + o(\alpha_k)$.

Feasible region or feasible set: Defined under *optimization.*

Global optimizer: See *optimizer.*

Gradient: The gradient of a function $f : \mathbf{R}^n \to \mathbf{R}$ is its first derivative and is denoted ∇f. Note that $\nabla f(\mathbf{x})$ is an n-vector.

Hessian: The Hessian of a function $f : \mathbf{R}^n \to \mathbf{R}$ is its second derivative and is denoted $\nabla^2 f$. The Hessian is an $n \times n$ matrix which, under the assumption that f is C^2, is symmetric.

Interior-point method: An interior-point method for convex programming is an algorithm that constructs iterates interior to the feasible region and approaching the optimizer along some trajectory (usually the central path). See Section 33.4 to Section 33.7.

Karush–Kuhn–Tucker (KKT) conditions: Consider the optimization problem $\min\{f(\mathbf{x}) : \mathbf{x} \in D\}$ in which D is specified by equality and inequality constraints and f is differentiable. A point $\mathbf{x}$ satisfies the KKT conditions if $\mathbf{x}$ is feasible and if for every linearized feasible direction $\mathbf{v}$ at $\mathbf{x}$, $\mathbf{v}^T \nabla f(\mathbf{x}) \geq 0$. If $\mathbf{x}$ is a local optimizer and a constraint qualification holds at $\mathbf{x}$, then $\mathbf{x}$ must satisfy the KKT conditions. The standard form of the KKT conditions is given by (33.4) above.

Linear function: The function $\mathbf{x} \mapsto \mathbf{a}^T\mathbf{x} + b$, where $\mathbf{a},b$ are given, is linear.

Linear programming: Linear programming is an optimization problem in which $f(\mathbf{x})$ is a linear function and D is a polyhedron. The standard primal-dual format for linear programming is (33.77) and (33.78).

Linearized feasible direction: Let $D \subset \mathbf{R}^n$ be a feasible region specified as sequence of p equality constraints $g_1(\mathbf{x}) = \cdots = g_p(\mathbf{x}) = 0$ and q inequality constraints $h_1(\mathbf{x}) \leq 0, \ldots, h_q(\mathbf{x}) \leq 0$. Say $\mathbf{x} \in D$, and let $A \subset \{1, \ldots, q\}$ be the constraints active at D. Assume all these constraints are C^1 in a neighborhood of $\mathbf{x}$. A nonzero vector $\mathbf{v}$ is a linearized feasible direction at $\mathbf{x}$ if $\mathbf{v}^T \nabla g_i(\mathbf{x}) = 0$ for all $i = 1, \ldots, p$ and $\mathbf{v}^T \nabla h_i(\mathbf{x}) \leq 0$ for all $i \in A$.

Local optimizer: For the optimization problem $\min\{f(\mathbf{x}) : \mathbf{x} \in D\}$, $D \subset \mathbf{R}^n$, a local optimizer or local minimizer is a point $\mathbf{x}^* \in D$ such that there exists an open set $N \subset \mathbf{R}^n$ containing $\mathbf{x}^*$

such that $f(\mathbf{x}) \geq f(\mathbf{x}^*)$ for all $\mathbf{x} \in D \cap N$. In the case of convex programming problems, a local optimizer is also a global optimizer.

Minimizer: See *optimizer.*

Objective function: Defined under *optimization.*

Optimization: Optimization refers to solving problems of the form: $\min\{f(\mathbf{x}) : \mathbf{x} \in D\}$ where D (the feasible region) is a subset of $\mathbf{R}^n$ and f (the objective function) is a real-valued function. The vector $\mathbf{x}$ is called the vector of variables or decision variables or unknowns. Set D is often described via constraints.

Optimizer: For the optimization problem of minimizing $f(\mathbf{x})$ subject to $\mathbf{x} \in D$, the optimizer or minimizer is the point $\mathbf{x}^* \in D$ such that $f(\mathbf{x}^*) \leq f(\mathbf{x})$ for all $\mathbf{x} \in D$. Also called "global optimizer." Some authors use the term "optimizer" to mean "local optimizer."

Polyhedron: A polyhedron is the set defined by a sequence of linear constraints.

Positive definite: A square matrix A is positive definite if $\mathbf{x}^T A\mathbf{x} > 0$ for all nonzero vectors $\mathbf{x}$. This term is applied mainly to symmetric matrices.

Positive semidefinite: A square matrix A is positive semidefinite if $\mathbf{x}^T A\mathbf{x} \geq 0$ for all vectors $\mathbf{x}$. This term is applied mainly to symmetric matrices.

Quadratic programming: Quadratic programming is the optimization problem of minimizing a quadratic function $f(\mathbf{x}) = \mathbf{x}^T H\mathbf{x}/2 + \mathbf{c}^T\mathbf{x}$ subject to $\mathbf{x} \in D$, where D is a polyhedron.

Self-concordant barrier function: A barrier function F is said to be self-concordant if it satisfies (33.63) for all $\mathbf{x} \in \text{int}(D)$ and all $\mathbf{h} \in \mathbf{R}^n$. The parameter of self-concordance is the smallest θ such that F satisfies (33.28) for all $\mathbf{x} \in \text{int}(D)$.

Semidefinite programming: Semidefinite programming is the problem of minimizing a linear function subject to linear and semidefinite constraints. The standard primal-dual form for SDP is given by (33.67) and (33.70).

Slater condition: The Slater condition is a constraint qualification for convex programming. Let D be a convex feasible region specified by convex constraints. The Slater condition is that there exists a point $\mathbf{x}_0 \in D$ such that all the nonlinear constraints are inactive at $\mathbf{x}_0$. This condition serves as a constraint qualification for all of D, i.e., it implies that for every point $\mathbf{x} \in D$, the linearized feasible directions at $\mathbf{x}$ coincide with the feasible directions at $\mathbf{x}$.

Stationary point: For an optimization problem, a stationary point is a point satisfying the KKT conditions.

Subdifferential: For a convex function f defined on a convex set D, the subdifferential of f at $\mathbf{x}$ is defined to be the set of vectors $\mathbf{v} \in \mathbf{R}^n$ such that $f(\mathbf{y}) \geq f(\mathbf{x}) + \mathbf{v}^T(\mathbf{y} - \mathbf{x})$ for all $\mathbf{y} \in D$. The subdifferential is a nonempty closed convex set that coincides with the ordinary derivative in the case that f is differentiable at $\mathbf{x}$ and $\mathbf{x}$ is in the interior of D.

Subgradient: A subgradient of f at $\mathbf{x}$ is an element of the subdifferential.

Symmetric matrix: A square matrix A is symmetric if $A = A^T$, where the superscript ^{T} indicates matrix transpose.

Acknowledgments

The author received helpful comments on this chapter from Florian Jarre, Michael Todd, and the anonymous referee. This work has been supported in part by NSF grant CCR-9619489. Further Information

Interior-point methods for linear programming are covered in-depth by Wright [62]. Interior-point methods for semidefinite programming are the topic of the review article by Vandenberghe and Boyd [55]. Interior-point methods for general convex programming were introduced by Nesterov and Nemirovskii [37]. General theory of convexity is covered by Rockafellar [44]. General theory and algorithms for nonlinear optimization is covered by Fletcher [12] and Nash and Sofer [35]. Vavasis's book [57] covers complexity issues in optimization. The web page http://www.mcs.anl.gov/otc/ surveys optimization algorithms and software and includes the archive of interior-point preprints.

Approximation Algorithms for NP-Hard Optimization Problems

Philip N. Klein
Brown University

Neal E. Young
Dartmouth College

34.1 Introduction

In this chapter, we discuss **approximation algorithms** for **optimization problems.** An *optimization problem* consists in finding the best (cheapest, heaviest, etc.) element in a large set $\mathcal{P}$, called the **feasible region** and usually specified implicitly, where the quality of elements of the set are evaluated using a function $f(x)$, the **objective function,** usually something fairly simple. The element that minimizes (or maximizes) this function is said to be an **optimal solution** and the value of the objective function at this element is the **optimal value.**

$$\text{optimal value} = \min\{f(x) \mid x \in \mathcal{P}\} \tag{34.1}$$

An example of an optimization problem familiar to computer scientists is that of finding a minimum-cost spanning tree of a graph with edge costs. For this problem, the feasible region $\mathcal{P}$, the set over which

we optimize, consists of *spanning trees;* recall that a spanning tree is a set of edges that connect all the vertices but forms no cycles. The value $f(T)$ of the objective function applied to a spanning tree T is the sum of the costs of the edges in the spanning tree.

The minimum-cost spanning tree problem is familiar to computer scientists because there are several good algorithms for solving it — procedures that, for a given graph, quickly determine the minimum-cost spanning tree. No matter what graph is provided as input, the time required for each of these algorithms is guaranteed to be no more than a slowly growing function of the number of vertices n and edges m (e.g., $O(m \log n)$).

For most optimization problems, in contrast to the minimum-cost spanning tree problem, there is no known algorithm that solves all instances quickly in this sense. Furthermore, there is not likely to be such an algorithm ever discovered, for many of these problems are NP-hard, and such an algorithm would imply that every problem in NP could be solved quickly (i.e., P = NP), which is considered unlikely.[1] One option in such a case is to seek an *approximation algorithm*—an algorithm that is guaranteed to run quickly (in time polynomial in the input size) and to produce a solution for which the value of the objective function is quantifiably close to the optimal value.

Considerable progress has been made towards understanding which combinatorial-optimization problems can be approximately solved, and to what accuracy. The theory of NP-completeness can provide evidence not only that a problem is hard to solve precisely but also that it is hard to approximate to within a particular accuracy. Furthermore, for many natural NP-hard optimization problems, approximation algorithms have been developed whose accuracy nearly matches the best achievable according to the theory of NP-completeness. Thus optimization problems can be categorized according to the best accuracy achievable by a polynomial-time approximation algorithm for each problem.

This chapter, which focuses on discrete (rather than continuous) NP-hard optimization problems, is organized according to these categories; for each category, we describe a representative problem, an algorithm for the problem, and the analysis of the algorithm. Along the way we demonstrate some of the ideas and methods common to many approximation algorithms. Also, to illustrate the diversity of the problems that have been studied, we briefly mention a few additional problems as we go. We provide a sampling, rather than a compendium, of the field—many important results, and even areas, are not presented. In "Further Information," we mention some of the areas that we do not cover, and we direct the interested reader to more comprehensive and technically detailed sources, such as the excellent recent book [7]. Because of limits on space for references, we do not cite the original sources for algorithms covered in [7].

34.2 Underlying Principles

Our focus is on *combinatorial* optimization problems, problems where the feasible region $\mathcal{P}$ is finite (though typically huge). Furthermore, we focus primarily on optimization problems that are NP-hard. As our main organizing principle, we restrict our attention to algorithms that are provably good in the following sense: for *any* input, the algorithm runs in time polynomial in the length of the input and returns a solution (i.e., a member of the feasible region) whose value (i.e., objective function value) is guaranteed to be near-optimal in some well-defined sense.[2] Such a guarantee is called the **performance guarantee.** Performance guarantees may be *absolute,* meaning that the additive difference between the optimal value and the value found by the algorithm is bounded. More commonly, performance guarantees are *relative,* meaning that the value found by the algorithm is within a multiplicative factor of the optimal value.

[1] For those unfamiliar with the theory of NP-completeness, see Chapters 27 and 28 or [5].

[2] An alternative to this *worst-case* analysis is *average-case* analysis. See Chapter 14.

When an algorithm with a performance guarantee returns a solution, it has implicitly discovered a bound on the exact optimal value for the problem. Obtaining such bounds is perhaps the most basic challenge in designing approximation algorithms. If one can't compute the optimal value, how can one expect to prove that the output of an algorithm is near it? Three common techniques are what which we shall call **witnesses, relaxation,** and **coarsening.**

Intuitively, a *witness* encodes a short, easily verified proof that the optimal value is at least, or at most, a certain value. Witnesses provide a dual role to **feasible solutions** to a problem. For example, for a maximization problem, where any feasible solution provides a *lower* bound to the optimal value, a witness would provide an *upper* bound on the optimal value. Typically, an approximation algorithm will produce not only a feasible solution, but also a witness. The performance guarantee is typically proven with respect to the two bounds—the upper bound provided by the witness and the lower bound provided by the feasible solution. Since the optimal value is between the two bounds, the performance guarantee also holds with respect to the optimal value.

Relaxation is another way to obtain a lower bound on the minimum value (or an upper bound in the case of a maximization problem). One formulates a new optimization problem, called a relaxation of the original problem, using the same objective function but a larger feasible region $\mathcal{P}'$ that includes $\mathcal{P}$ as a subset. Because $\mathcal{P}'$ contains $\mathcal{P}$, any $x \in \mathcal{P}$ (including the optimal element x) belongs to $\mathcal{P}'$ as well. Hence the optimal value of the relaxation, $\min\{f(x) \mid x \in \mathcal{P}'\}$, is less than or equal to the optimal value of the original optimization problem. The intent is that the optimal value of the relaxation should be easy to calculate and should be reasonably close to the optimal value of the original problem.

Linear programming can provide both witnesses and relaxations, and is therefore an important technique in the design and analysis of approximation algorithms. **Randomized rounding** is a general approach, based on the probabilistic method, for converting a solution to a relaxed problem into an approximate solution to the original problem.

To *coarsen* a problem instance is to alter it, typically restricting to a less complex feasible region or objective function, so that the result problem can be efficiently solved, typically by dynamic programming. For coarsening to be useful, the coarsened problem must approximate the original problem, in that there is a rough correspondence between *feasible solutions* of the two problems, a correspondence that approximately preserves cost. We use the term *coarsening* rather loosely to describe a wide variety of algorithms that work in this spirit.

34.3 Approximation Algorithms with Small Additive Error

Minimum-Degree Spanning Tree

For our first example, consider a slight variant on the minimum-cost spanning tree problem, the *minimum-degree spanning tree problem.* As before, the feasible region $\mathcal{P}$ consists of spanning trees of the input graph, but this time the objective is to find a spanning tree whose *degree* is minimum. The degree of a vertex of a spanning tree (or, indeed, of any graph), is the number of edges incident to that vertex, and the degree of the spanning tree is the maximum of the degrees of its vertices. Thus minimizing the degree of a spanning tree amounts to finding a smallest integer k for which there exists a spanning tree in which each vertex has at most k incident edges.

Any procedure for finding a minimum-degree spanning tree in a graph could be used to find a Hamiltonian path in any graph that has one, for a Hamiltonian path is a degree-two spanning tree. (A Hamiltonian path of a graph is a path through that graph that visits each vertex of the graph exactly once.) Since it is NP-hard even to determine whether a graph has a Hamiltonian path, even determining whether the minimum-degree spanning tree has degree two is presumed to be computationally difficult.

An Approximation Algorithm for Minimum-Degree Spanning Tree

Nonetheless, the minimum-degree spanning-tree problem has a remarkably good approximation algorithm [7, Ch. 7]. For an input graph with m edges and n vertices, the algorithm requires time slightly more than the product of m and n. The output is a spanning tree whose degree is guaranteed to be at most *one more* than the minimum degree. For example, if the graph has a Hamiltonian path, the output is either such a path or a spanning tree of degree three.

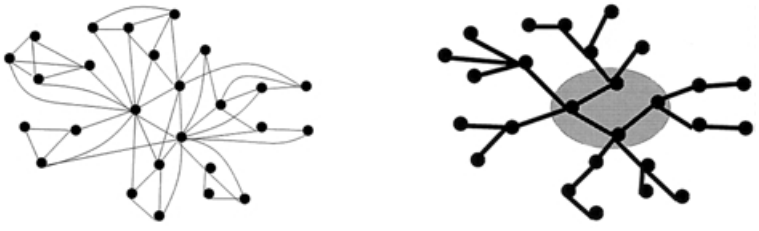

FIGURE 34.1 On the left is an example input graph G. On the right is a spanning tree T that might be found by the approximation algorithm. The shaded circle indicates the nodes in the witness set S.

Given a graph G, the algorithm naturally finds the desired spanning tree T of G. The algorithm also finds a witness—in this case, a set S of vertices proving that T's degree is nearly optimal. Namely, let k denote the degree of T, and let $T_1, T_2, \ldots, T_r$ be the subtrees that would result from T if the vertices of S were deleted. The following two properties are enough to show that T's degree is nearly optimal.

1. There are no edges of the graph G between distinct trees T_i, and
2. The number r of trees T_i is at least $|S|(k-1) - 2(|S|-1)$.

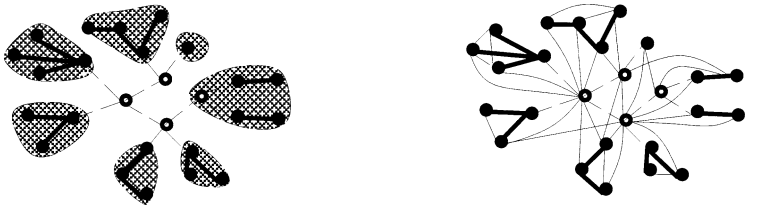

FIGURE 34.2 The figure on the left shows the r trees $T_1, \ldots, T_r$ obtained from T by deleting the nodes of S. Each tree is indicated by a shaded region. The figure on the right shows that no edges of the input graph G connect different trees T_i.

To show that T's degree is nearly optimal, let V_i denote the set of vertices comprising subtree T_i ($i = 1, \ldots, r$). Any spanning tree T^* at all must connect up the sets $V_1, V_2, \ldots, V_r$ and the vertices $y_1, y_2, \ldots, y_{|S|} \in S$, and must use at least $r + |S| - 1$ edges to do so. Furthermore, since no edges go between distinct sets V_i, all these edges must be incident to the vertices of S.

Hence we obtain

$$\begin{aligned} \sum \left\{ \deg_{T^*}(y) \;\middle|\; y \in S \right\} &\geq r + |S| - 1 \\ &\geq |S|(k-1) - 2(|S|-1) + |S| - 1 \\ &= |S|(k-1) - (|S|-1) \end{aligned} \tag{34.2}$$

where $\deg_{T^*}(y)$ denotes the degree of y in the tree T^*. Thus the average of the degrees of vertices in S is at least $\frac{|S|(k-1)-(|S|-1)}{|S|}$, which is strictly greater than $k-2$. Since the average of the degrees of vertices in S is greater than $k-2$, it follows that at least one vertex has degree at least $k-1$.

FIGURE 34.3 The figure on the left shows an arbitrary spanning tree T^* for the same input graph G. The figure on the right has r shaded regions, one for each subset V_i of nodes corresponding to a tree T_i in Fig.34.2. The proof of the algorithm's performance guarantee is based on the observation that at least $r + |S| - 1$ edges are needed to connect up the V_i's and the nodes in S.

We have shown that for every spanning tree T^*, there is at least one vertex with degree at least $k-1$. Hence the minimum degree is at least $k-1$.

We have not explained how the algorithm obtains both the spanning tree T and the set S of vertices, only how the set S shows that the spanning tree is nearly optimal. The basic idea is as follows. Start with any spanning tree T, and let d denote its degree. Let S be the set of vertices having degree d or $d-1$ in the current spanning tree. Let $T_1, \ldots, T_r$ be the subtrees comprising $T - S$. If there are no edges between these subtrees, the set S satisfies property 1 and one can show it also satisfies property 2; in this case the algorithm terminates. If on the other hand there is an edge between two distinct subtrees T_i and T_j, inserting this edge in T and removing another edge from T results in a spanning tree with fewer vertices having degree at least $d-1$. Repeat this process on the new spanning tree; in subsequent iterations the improvement steps are somewhat more complicated but follow the same lines. One can prove that the number of iterations is $O(n \log n)$.

We summarize our brief sketch of the algorithm as follows: either the current set S is a witness to the near-optimality of the current spanning tree T, or there is a slight modification to the set and the spanning tree that improve them. The algorithm terminates after a relatively small number of improvements.

This algorithm is remarkable not only for its simplicity and elegance but also for the quality of the approximation achieved. As we shall see, for most NP-hard optimization problems, we must settle for approximation algorithms that have much weaker guarantees.

Other Problems Having Small-Additive-Error Algorithms

There are a few other natural combinatorial-optimization problems for which approximation algorithms with similar performance guarantees are known. Here are two examples:

Edge Coloring

Given a graph, color its edges with a minimum number of colors so that, for each vertex, the edges incident to that vertex are all different colors. For this problem, it is easy to find a witness. For any graph G, let v be the vertex of highest degree in G. Clearly one needs to assign at least $\deg_G(v)$ colors to the edges of G, for otherwise there would be two edges with the same color incident to v. For any graph G, there is an edge coloring using a number of colors equal to one plus the degree of G. The proof of this fact

translates into a polynomial-time algorithm that approximates the minimum edge-coloring to within an additive error of 1.

Bin Packing

The input consists of a set of positive numbers less than 1. A solution is a partition of the numbers into sets summing to no more than 1. The goal is to minimize the number of sets in the partition. There are approximation algorithms for bin packing that have very good performance guarantees. For example, the performance guarantee for one such algorithm is as follows: for any input set I of item weights, it finds a packing that uses at most $\mathrm{OPT}(I) + O(\log^2 \mathrm{OPT}(I))$ bins, where $\mathrm{OPT}(I)$ is the number of bins used by the best packing, i.e., the optimal value.

34.4 Randomized Rounding and Linear Programming

A *linear programming* problem is any optimization problem in which the feasible region corresponds to assignments of values to variables meeting a set of linear inequalities and in which the objective function is a linear function. An instance is determined by specifying the set of variables, the objective function, and the set of inequalities. **Linear programs** are capable of representing a large variety of problems and have been studied for decades in combinatorial optimization and have a tremendous literature (see e.g., Chapters 31 and 32 of this book). Any linear program can be solved—that is, a point in the feasible region maximizing or minimizing the objective function can be found—in time bounded by a polynomial in the size of the input.

A *(mixed) integer linear programming problem* is a linear programming problem augmented with additional constraints specifying that (some of) the variables must take on integer values. Such constraints make integer linear programming even more general than linear programming—in general, solving **integer linear programs** is NP-hard.

For example, consider the following *balanced matching problem:* The input is a bipartite graph $G = (V, W, E)$. The goal is to choose an edge incident to each vertex in V ($|V|$ edges in total), while minimizing the maximum *load* of (number of chosen edges adjacent to) any vertex in W. The vertices in V might represent tasks, the vertices in W might represent people, while the presence of edge $\{v, w\}$ indicates that person w is competent to perform task v. The problem is then to assign each task to a person competent to perform it, while minimizing the maximum number of tasks assigned to any person.[3]

This balanced matching problem can be formulated as the following integer linear program:

$$\text{minimize } \Delta$$
$$\text{subject to } \begin{cases} \sum_{u \in N(v)} x(u, v) & = & 1 & \forall v \in V \\ \sum_{v \in N(u)} x(u, v) & \leq & \Delta & \forall w \in W \\ x(u, v) & \in & \{0, 1\} & \forall (u, v) \in E\,. \end{cases}$$

Here $N(x)$ denotes the set of neighbors of vertex x in the graph. For each edge (u, v) the variable $x(u, v)$ determines whether the edge (u, v) is chosen. The variable Δ measures the maximum load.

[3] Typically, randomized rounding is applied to NP-hard problems, whereas the balanced matching problem here is actually solvable in polynomial time. We use it as an example for simplicity—the analysis captures the essential spirit of a similar analysis for the well-studied integer multicommodity flow problem. (A simple version of that problem is, "Given a network and a set of commodities (each a pair of vertices), choose a path for each commodity minimizing the maximum congestion on any edge.")

Relaxing the integrality constraints (i.e., replacing them as well as we can by linear inequalities) yields the linear program:

$$\text{minimize } \Delta$$
$$\text{subject to } \begin{cases} \sum_{u \in N(v)} x(u,v) & = & 1 & \forall v \in V \\ \sum_{v \in N(u)} x(u,v) & \leq & \Delta & \forall w \in W \\ x(u,v) & \geq & 0 & \forall (u,v) \in E\ . \end{cases}$$

Rounding a fractional solution to a true solution. This relaxed problem can be solved in polynomial time simply because it is a linear program. Suppose we have an optimal solution x^*, where each $x^*(e)$ is a fraction between 0 and 1. How can we convert such an optimal *fractional* solution into an *approximately optimal* integer solution? *Randomized rounding* is a *general* approach for doing just this [12, Ch. 5].

Consider the following polynomial-time randomized algorithm to find an integer solution $\hat{x}$ from the optimal solution x^* to the linear program:

1. Solve the linear program to obtain a **fractional solution** x^* of load Δ^*.
2. For each vertex $v \in V$:
   (a) Choose a single edge incident to v *at random,* so that the probability that a given edge (u, v) is chosen is $x^*(u, v)$. (Note that $\Sigma_{u \in N(v)} x^*(u, v) = 1$.)
   (b) Let $\hat{x}(u, v) \leftarrow 1$.
   (c) For all other edges (u', v) incident to v, let $\hat{x}(u', v) \leftarrow 0$.

The algorithm will always choose one edge adjacent to each vertex in V. Thus, $\hat{x}$ is a feasible solution to the original integer program. What can we say about the load? For any particular vertex $w \in W$, the load on w is $\Sigma_{u \in N(v)} \hat{x}(u, v)$. For any particular edge $(u, v) \in E$, the probability that $\hat{x}(u, v) = 1$ is $x^*(u, v)$. Thus the *expected* value of the load on a vertex $u \in U$ is $\Sigma_{v \in N(u)} x^*(u, v)$, which is at most Δ^*. This is a good start. Of course, the *maximum* load over all $u \in U$ is likely to be larger. How much larger?

To answer this, we need to know more about the distribution of the load on v than just the expected value. The key fact that we need to observe is that the load on any $v \in V$ is a sum of *independent* $\{0, 1\}$-*random variables.* This means it is not likely to deviate much from its expected value. Precise estimates come from standard bounds, called "Chernoff" or "Hoeffding" bounds, such as the following:

THEOREM 34.1 *Let X be the sum of independent $\{0, 1\}$ random variables. Let $\mu > 0$ be the expected value of X. Then for any $\epsilon > 0$,*

$$\Pr[X \geq (1 + \epsilon)\mu] < \exp\left(-\mu \min\left\{\epsilon, \epsilon^2\right\}/3\right)\ .$$

(See, e.g.,[12, Ch. 4.1].) This is enough to analyze the performance guarantee of the algorithm. It is slightly complicated, but not too bad:

Claim *With probability at least 1/2, the maximum load induced by $\hat{x}$ exceeds the optimal by at most an additive error of*

$$\max\left\{3\ln(2m), \sqrt{3\ln(2m)\Delta^*}\right\}\ ,$$

where $m = |W|$.

Proof sketch: As observed previously, for any particular v, the load on v is a sum (of independent random $\{0, 1\}$-variables) with expectation bounded by Δ^*. Let ϵ be just large enough so that $\exp(-\Delta^* \min\{\epsilon, \epsilon^2\}/3) = 1/(2m)$. By the Chernoff-type bound above, the probability that the load

exceeds $(1+\epsilon)\Delta^*$ is then less than $1/(2m)$. Thus, by the naive union bound,[4] the probability that the *maximum* load on any $v \in V$ is more than $\Delta^*(1+\epsilon) = \Delta^* + \epsilon\Delta^*$ is less then $1/2$. We leave it to the reader to verify that the choice of ϵ makes $\epsilon\Delta^*$ equal the expression in the statement of the claim.

Summary. This is the general randomized-rounding recipe:

1. Formulate the original NP-hard problem as an integer linear programming problem (IP).
2. Relax the program IP to obtain a linear program (LP).
3. Solve the linear program, obtaining a fractional solution.
4. Randomly round the fractional solution to obtain an approximately optimal integer solution.

34.5 Performance Ratios and ρ-Approximation

Relative (multiplicative) performance guarantees are more common than absolute (additive) performance guarantees. One reason is that many NP-hard optimization problems are **rescalable:** given an instance of the problem, one can construct a new, equivalent instance by scaling the objective function. For instance, the traveling salesman problem is rescalable—given an instance, multiplying the edge weights by any $\lambda > 0$ yields an equivalent problem with the objective function scaled by λ. For rescalable problems, the best one can hope for is a relative performance guarantee [15].

A ρ-**approximation algorithm** is an algorithm that returns a feasible solution whose objective function value is at most ρ times the minimum (or, in the case of a maximization problem, the objective function value is at least ρ times the maximum). We say that the **performance ratio** of the algorithm is ρ.[5]

34.6 Polynomial Approximation Schemes

The *knapsack problem* is an example of a rescalable NP-hard problem. An instance consists of a set of pairs of numbers $(\text{weight}_i, \text{profit}_i)$, and the goal is to select a subset of pairs for which the sum of weights is at most 1 so as to maximize the sum of profits. (Which items should one put in a knapsack of capacity 1 so as to maximize profit?)

Since the knapsack problem is rescalable and NP-hard, we assume that there is no approximation algorithm achieving, say, a fixed absolute error. One is therefore led to ask, what is the best performance ratio achievable by a polynomial-time approximation algorithm? In fact (assuming P $\neq$ NP), there is no such *best* performance ratio: for any given $\epsilon > 0$, there is a polynomial approximation algorithm whose performance ratio is $1+\epsilon$. The smaller the value of ϵ, however, the greater the running time of the corresponding approximation algorithm. Such a collection of approximation algorithms, one for each $\epsilon > 0$, is called a *(polynomial) approximation scheme.*

Think of an approximation scheme as an algorithm that takes an additional parameter, the value of ϵ, in addition to the input specifying the instance of some optimization problem. The running time of this algorithm is bounded in terms of the size of the input and in terms of ϵ. For example, there is an approximation scheme for the knapsack problem that requires time $O(n\log(1/\epsilon) + 1/\epsilon^4)$ for instances with n items. Below we sketch a much simplified version of this algorithm that requires time $O(n^3/\epsilon)$. The algorithm works by coarsening.

[4] The probability that any of several events happens is at most the sum of the probabilities of the individual events.

[5] This terminology is the most frequently used, but one also finds alternative terminology in the literature. Confusingly, some authors have used the term $1/\rho$-approximation algorithm or $(1-\rho)$-approximation algorithm to refer to what we call a ρ-approximation algorithm.

The algorithm is given the pairs $(\text{weight}_1, \text{profit}_1), \ldots, (\text{weight}_n, \text{profit}_n)$, and the parameter ϵ. We assume without loss of generality that each weight is less than or equal to 1. Let $\text{profit}_{\max} = \max_i \text{profit}_i$. Let OPT denote the (unknown) optimal value. Since the item of greatest profit itself constitutes a solution, albeit not usually a very good one, we have $\text{profit}_{\max} \leq \text{OPT}$. In order to achieve a relative error of at most ϵ, therefore, it suffices to achieve an absolute error of at most $\epsilon\ \text{profit}_{\max}$.

We transform the given instance into a coarsened instance by rounding each profit down to a multiple of $K = \epsilon\ \text{profit}_{\max}/n$. In so doing, we reduce each profit by less than $\epsilon\ \text{profit}_{\max}/n$. Consequently, since the optimal solution consists of no more than n items, the profit of this optimal solution is reduced by less than $\epsilon\ \text{profit}_{\max}$ in total. Thus, the optimal value for the coarsened instance is at least $\text{OPT} - \epsilon\ \text{profit}_{\max}$, which is in turn at least $(1-\epsilon)\text{OPT}$. The corresponding solution, when measured according to the original profits, has value at least this much. Thus we need only solve the coarsened instance optimally in order to get a performance guarantee of $1 - \epsilon$.

Before addressing the solution of the coarsened instance, note that the optimal value is the sum of at most n profits, each at most $\text{profit}_{\max}$. Thus $\text{OPT} \leq n^2 K/\epsilon$. The optimal value for the coarsened instance is therefore also at most $n^2 K/\epsilon$.

To solve the coarsened instance optimally, we use dynamic programming. Note that for the coarsened instance, each achievable total profit can be written as $i \cdot K$ for some integer $i \leq n^2/\epsilon$. The dynamic-programming algorithm constructs an $\lceil n^2/\epsilon \rceil \times (n+1)$ table $T[i, j]$ whose i, j entry is the minimum weight required to achieve profit $i \cdot K$ using a subset of the items 1 through j. The entry is infinity if there is no such way to achieve that profit.

To fill in the table, the algorithm initializes the entries $T[i, 0]$ to infinity, then executes the following step for $j = 1, 2, \ldots, n$:

$$\text{For each } i\text{, set } T[i, j] := \min\left\{T[i, j-1], \text{weight}_j + T\left[i - \left(\widehat{\text{profit}}_j/K\right), j-1\right]\right\}$$

where $\widehat{\text{profit}}_j$ is the profit of item j in the rounded-down instance. A simple induction on j shows that the calculated values are correct. The optimal value for the coarsened instance is

$$\widehat{\text{OPT}} = \max\{iK \mid T[i, n] \leq 1\}\ .$$

The above calculates the optimal *value* for the coarsened instance; as usual in dynamic programming, a corresponding feasible solution can easily be computed if desired.

Other Problems Having Polynomial Approximation Schemes

The running time of the knapsack approximation scheme depends polynomially on $1/\epsilon$. Such a scheme is called a *fully polynomial* approximation scheme. Most natural NP-complete optimization problems are **strongly NP-hard,** meaning essentially that the problems are NP-hard even when the numbers appearing in the input are restricted to be no larger in magnitude than the size of the input. For such a problem, we cannot expect a **fully polynomial approximation scheme** to exist [5, Section 4.2]. On the other hand, a variety of NP-hard problems in fixed-dimensional Euclidean space have approximation schemes. For instance, given a set of points in the plane:

Covering with Disks: Find a minimum set of area-1 disks (or squares, etc.) covering all the points [7, Section 9.3.3].

Euclidean Traveling Salesman: Find a closed loop passing through each of the points and having minimum total arc length [1].

Euclidean Steiner Tree: Find a minimum-length set of segments connecting up all the points [1].

Similarly, many problems in planar graphs or graphs of fixed genus can have **polynomial approximation schemes** [7, Section 9.3.3], For instance, **given a planar graph with weights assigned to its vertices:**

Maximum-Weight Independent Set: Find a maximum-weight set of vertices, no two of which are adjacent.

Minimum-Weight Vertex Cover: Find a minimum-weight set of vertices such that every edge is incident to at least one of the vertices in the set.

The above algorithms use relatively more sophisticated and varied coarsening techniques.

34.7 Constant-Factor Performance Guarantees

We have seen that, assuming P $\neq$ NP, rescalable NP-hard problems do not have polynomial-time approximation algorithms with small absolute errors but may have fully polynomial approximation schemes, while strongly NP-hard problems do not have fully polynomial approximation schemes but may have polynomial approximation schemes. Further, there is a class of problems that do not have approximation schemes: for each such problem there is a constant c such that any polynomial-time approximation algorithm for the problem has relative error at least c (assuming P $\neq$ NP). For such a problem, the best one can hope for is an approximation algorithm with constant performance ratio.

Our example of such a problem is the *vertex cover* problem: given a graph G, find a minimum-size set C (a *vertex cover*) of vertices such that every edge in the graph is incident to some vertex in C. Here the feasible region $\mathcal{P}$ consists of the vertex covers in G, while the objective function is the size of the cover. Here is a simple approximation algorithm [7]:

1. Find a maximal independent set S of edges in G.
2. Let C be the vertices incident to edges in S.

(A set S of edges is *independent* if no two edges in S share an endpoint. The set S is *maximal* if no larger independent set contains S.) The reader may wish to verify that the set S can be found in linear time, and that because S is maximal, C is necessarily a cover.

What performance guarantee can we show? Since the edges in S are independent, *any* cover must have at least one vertex for each edge in S. Thus S is a witness proving that any cover has at least $|S|$ vertices. On the other hand, the cover C has $2|S|$ vertices. Thus the cover returned by the algorithm is at most *twice* the size of the optimal vertex cover.

The Weighted Vertex Cover Problem. The *weighted* vertex cover problem is a generalization of the vertex cover problem. An instance is specified by giving a graph $G = (V, E)$ and, for each vertex v in the graph, a number $\mathrm{wt}(v)$ called its *weight.* The goal is to find a vertex cover minimizing the total weight of the vertices in the cover. Here is one way to represent the problem as an integer linear program:

$$\begin{aligned} \text{minimize} \quad & \sum_{v \in V} \mathrm{wt}(v) x(v) \\ \text{subject to} \quad & \begin{cases} x(u) + x(v) \geq 1 & \forall \{u, v\} \in E \\ x(v) \in \{0, 1\} & \forall v \in V\,. \end{cases} \end{aligned}$$

There is one $\{0, 1\}$-variable $x(v)$ for each vertex v representing whether v is in the cover or not, and there are constraints for the edges that model the covering requirement. The feasible region of this program corresponds to the set of vertex covers. The objective function corresponds to the total weight of the vertices in the cover. Relaxing the integrality constraints yields

$$\begin{aligned} \text{minimize} \quad & \sum_{v \in V} \mathrm{wt}(v) x(v) \\ \text{subject to} \quad & \begin{cases} x(u) + x(v) \geq 1 & \forall \{u, v\} \in E \\ x(v) \geq 0 & \forall v \in V\,. \end{cases} \end{aligned}$$

This relaxed problem is called the *fractional* weighted vertex cover problem; feasible solutions to it are called *fractional* vertex covers.[6]

Rounding a Fractional Solution to a True Solution. By solving this linear program, an optimal fractional cover can be found in polynomial time. For this problem, it is possible to convert a fractional cover into an approximately optimal true cover by rounding the fractional cover in a simple way:

1. Solve the linear program to obtain an optimal fractional cover x^*.
2. Let $C = \left\{v \in V : x^*(v) \geq \frac{1}{2}\right\}$.

The set C is a cover because for any edge, at least one of the endpoints must have fractional weight at least $1/2$. The reader can verify that the total weight of vertices in C is at most twice the total weight of the fractional cover x^*. Since the fractional solution was an optimal solution to a relaxation of the original problem, this is a 2-approximation algorithm [7].

For most problems, this simple kind of rounding is not sufficient. The previously discussed technique called *randomized rounding* is more generally useful.

Primal-Dual Algorithms—Witnesses Via Duality. For the purposes of approximation, solving a linear program *exactly* is often unnecessary. One can often design a faster algorithm based on the witness technique, using the fact that *every linear program has a well-defined notion of "witness."* The witnesses for a linear program P are the feasible solutions to another related linear program called the *dual* of P.

Suppose our original problem is a minimization problem. Then for each point y in the feasible region of the dual problem, the value of the objective function at y is a lower bound on the value of the optimal value of the original linear program. That is, any feasible solution to the dual problem is a possible witness—both for the original integer linear program and its relaxation. For the weighted vertex cover problem, the dual is the following:

$$\text{maximize} \sum_{e \in E} y(e)$$

$$\text{subject to} \begin{cases} \sum_{e \ni v} y(e) \leq \text{wt}(v) & \forall v \in V \\ y(e) \geq 0 & \forall e \in E\,. \end{cases}$$

A feasible solution to this linear program is called an *edge packing.* The constraints for the vertices are called *packing constraints.*

Recall the original approximation algorithm for the unweighted vertex cover problem: find a maximal independent set of edges S; let C be the vertices incident to edges in S. In the analysis, the set S was the witness.

Edge packings generalize independent sets of edges. This observation allows us to generalize the algorithm for the unweighted problem. Say an edge packing is *maximal* if, for every edge, one of the edge's vertices has its packing constraint met. Here is the algorithm:

1. Find a maximal edge packing y.
2. Let C be the vertices whose packing constraints are tight for y.

The reader may wish to verify that a maximal edge packing can easily be found in linear time and that the set C is a cover because y is maximal.

---

[6]The reader may wonder whether additional constraints of the form $x(v) \leq 1$ are necessary. In fact, assuming the vertex weights are nonnegative, there is no incentive to make any $x(v)$ larger than 1, so such constraints would be redundant.

What about the performance guarantee? Since only vertices whose packing constraints are tight are in C, and each edge has only two vertices, we have

$$\sum_{v \in C} \mathrm{wt}(v) = \sum_{v \in C} \sum_{e \ni v} y(e) \leq 2 \sum_{e \in E} y(e) .$$

Since y is a solution to the dual, $\Sigma_e y(e)$ is a lower bound on the weight of any vertex cover, fractional or otherwise. Thus, the algorithm is a 2-approximation algorithm.

Summary. This is the general primal-dual recipe:

1. Formulate the original NP-hard problem as an integer linear programming problem (IP).
2. Relax the program IP to obtain a linear program (LP).
3. Use the dual (DLP) of LP as a source of witnesses.

Beyond these general guidelines, the algorithm designer is still left with the task of figuring out *how* to find a good solution and witness. See [7, Ch. 4] for an approach that works for a wide class of problems.

Other Optimization Problems with Constant-Factor Approximations

Constant-factor approximation algorithms are known for problems from many areas. In this section, we describe a sampling of these problems. For each of the problems described here, there is no polynomial approximation scheme (unless P = NP); thus constant-factor approximation algorithms are the best we can hope for. For a typical problem, there will be a simple algorithm achieving a small constant factor while there may be more involved algorithms achieving better factors. The factors known to be achievable typically come close to, but do not meet, the best lower bounds known (assuming P $\neq$ NP).

For the problems below, we omit discussion of the techniques used; many of the problems are solved using a relaxation of some form, and (possibly implicitly) the primal-dual recipe. Many of these problems have polynomial approximation schemes if restricted to graphs induced by points in the plane or constant-dimensional Euclidean space (see "Other Problems Having Polynomial Approximation Schemes").

MAX-SAT: Given a propositional formula in conjunctive normal form (an "and" of "or"'s of possibly negated Boolean variables), find a truth assignment to the variables that maximizes the number of clauses (groups of "or"'ed variables in the formula) that are true under the assignment. A variant called MAX-3SAT restricts to the formula to have three variables per clause. MAX-3SAT is a canonical example of a problem in the complexity class **MAX-SNP** [7, Section 10.3].

MAX-CUT: Given a graph, partition the vertices of the input graph into two sets so as to maximize the number of edges with endpoints in distinct sets. For MAX-CUT and MAX-SAT problems, the best approximation algorithms currently known rely on randomized rounding and a generalization of linear programming called **semidefinite programming** [7, Section 11.3].

Shortest Superstring: Given a set of strings $\sigma_1, \ldots, \sigma_k$, find a minimum-length string containing all σ_i's. This problem has applications in computational biology [3, 10].

K-Cluster: Given a graph with weighted edges and given a parameter k, partition the vertices into k clusters so as to minimize the maximum distance between any two vertices in the same cluster. For this and related problems see [7, Section 9.4].

Traveling Salesman: Given a complete graph with edge weights satisfying the **triangle inequality,** find a minimum-length path that visits every vertex of the graph [7, Ch. 8].

Edge and Vertex Connectivity: Given a weighted graph $G = (V, E)$ and an integer k, find a minimum-weight edge set $E' \subseteq E$ such that between any pair of vertices, there are k edge-disjoint paths in the graph $G' = (V, E')$. Similar algorithms handle the goal of k *vertex-*

disjoint paths and the goal of *augmenting* a given graph to achieve a given connectivity [7, Ch. 6]

Steiner Tree: Given an undirected graph with positive edge-weights and a subset of the vertices called *terminals,* find a minimum-weight set of edges through which all the terminals (and possibly other vertices) are connected [7, Ch. 8]. The Euclidean version of the problem is "Given a set of points in $\mathbb{R}^n$, find a minimum-total-length union of line segments (with arbitrary endpoints) that is connected and contains all the given points."

Steiner Forest: Given a weighted graph and a collection of *groups* of terminals, find a minimum-weight set of edges through which every pair of terminals within each group are connected [7, Ch. 4]. The algorithm for this problem is based on a primal-dual framework that has been adapted to a wide variety of network design problems. See Section "Other Problems Having Poly-Logarithmic Performance Guarantees."

34.8 Logarithmic Performance Guarantees

When a constant-ratio performance guarantee is not possible, a slowly-growing ratio is the next best thing. The canonical example of this is the *set cover* problem: Given a family of sets $\mathcal{F}$ over a universe $\mathcal{U}$, find a minimum-cardinality *set cover* C—a collection of the sets that collectively contain all elements in $\mathcal{U}$. In the weighted version of the problem, each set also has a weight and the goal is to find a set cover of minimum total weight. This problem is important due to its generality. For instance, it generalizes the vertex cover problem.

Here is a simple greedy algorithm:

1. Let $C \leftarrow \emptyset$.
2. Repeat until all elements are covered: add a set S to C maximizing

$$\frac{\text{the number of elements in } S \text{ not in any set in } C}{\text{wt}(S)} .$$

3. Return C.

The algorithm has the following performance guarantee [7, Section 3.2]:

THEOREM 34.2 *The greedy algorithm for the weighted set cover problem is an H_s-approximation algorithm, where s is the maximum size of any set in $\mathcal{F}$.*

By definition $H_s = 1 + \frac{1}{2} + \frac{1}{3} + \cdot + \frac{1}{s}$; also, $H_s \leq 1 + \ln s$.

We will give a direct argument for the performance guarantee and then relate it to the general primal-dual recipe. Imagine that as the algorithm proceeds, it assigns *charges* to the elements as they are covered. Specifically, when a set S is added to the cover C, if there are k elements in S not previously covered, assign each such element a charge of $\text{wt}(S)/k$. Note that *the total charge assigned over the course of the algorithm equals the weight of the final cover C.*

Next we argue that *the total charge assigned over the course of the algorithm is a lower bound on H_s times the weight of the optimal vertex cover.* These two facts together prove the theorem.

Suppose we could prove that for any set T in the optimal cover C^*, the elements in T are assigned a total charge of at most $\text{wt}(T)H_s$. Then we would be done, because every element is in at least one set in the optimal cover:

$$\sum_{i \in U} charge(i) \leq \sum_{T \in C^*} \sum_{i \in T} charge(i) \leq \sum_{T \in C^*} \text{wt}(T) H_s .$$

So, consider, for example, a set $T = \{a, b, c, d, e, f\}$ with $\text{wt}(T) = 3$. For convenience, assume that the greedy algorithm covers elements in T in alphabetical order. What can we say about the charge assigned to a? Consider the iteration when a was first covered and assigned a charge. At the beginning of that iteration, T was not yet chosen and none of the 6 elements in T were yet covered. Since the greedy algorithm had the option of choosing T, whatever set it did choose resulted in a charge to a of at most $\text{wt}(T)/|T| = 3/6$.

What about the element b? When b was first covered, T was not yet chosen, and at least 5 elements in T remained uncovered. Consequently, the charge assigned to b was at most $3/5$. Reasoning similarly, the elements c, d, e, and f were assigned charges of at most $3/4$, $3/3$, $3/2$, and $3/1$, respectively. The total charge to elements in T is at most

$$3 \times (1/6 + 1/5 + 1/4 + 1/3 + 1/2 + 1/1) = \text{wt}(T)H_{|T|} \leq \text{wt}(T)H_s \ .$$

This line of reasoning easily generalizes to show that for any set T, the elements in T are assigned a total charge of at most $\text{wt}(T)H_s$.

Underlying Duality. What role does duality and the primal-dual recipe play in the above analysis? A natural integer linear program for the weighted set cover problem is

$$\begin{aligned} &\text{minimize} \sum_{S \in \mathcal{F}} \text{wt}(S)x(S) \\ &\text{subject to} \begin{cases} \sum_{S \ni i} x(S) & \geq & 1 & \forall i \in \mathcal{U} \\ x(S) & \in & \{0, 1\} & \forall S \in \mathcal{F} \ . \end{cases} \end{aligned}$$

Relaxing this integer linear program yields the linear program

$$\begin{aligned} &\text{minimize} \sum_{S \in \mathcal{F}} \text{wt}(S)x(S) \\ &\text{subject to} \begin{cases} \sum_{S \ni i} x(S) & \geq & 1 & \forall i \in \mathcal{U} \\ x(S) & \geq & 0 & \forall S \in \mathcal{F} \ . \end{cases} \end{aligned}$$

A solution to this linear program is called a *fractional* set cover. The dual is

$$\begin{aligned} &\text{minimize} \sum_{i \in \mathcal{U}} y(i) \\ &\text{subject to} \begin{cases} \sum_{i \in S} y(i) & \leq & \text{wt}(S) & \forall S \in \mathcal{F} \\ y(i) & \geq & 0 & \forall i \in \mathcal{U} \ . \end{cases} \end{aligned}$$

The inequalities for the sets are called *packing constraints.* A solution to this **dual linear program** is called an *element packing.* In fact, the "charging" scheme in the analysis is just an element packing y, where $y(i)$ is the charge assigned to i divided by H_s. In this light, the previous analysis is simply constructing a dual solution and using it as a witness to show the performance guarantee.

Other Problems Having Poly-Logarithmic Performance Guarantees

Minimizing a Linear Function Subject to a Submodular Constraint. This is a natural generalization of the weighted set cover problem. Rather than state the general problem, we give the following special case as an example: Given a family $\mathcal{F}$ of sets of n-vectors, with each set in $\mathcal{F}$ having a cost, find a subfamily of sets of minimum total cost whose union has rank n. A natural generalization of the greedy set cover algorithm gives a logarithmic performance guarantee [13].

Vertex-Weighted Network Steiner Tree. Like the network Steiner tree problem described in "Other Optimization Problems With Constant-Factor Approximations," an instance consists of a graph and a set of terminals; in this case, however, the graph can have vertex weights in addition to edge weights. An adaptation of the greedy algorithm achieves a logarithmic performance ratio.

Network Design Problems. This is a large class of problems generalizing the Steiner forest problem (see "Other Optimization Problems With Constant-Factor Approximations"). An example of a problem in this class is *survivable network design:* given a weighted graph $G = (V, E)$ and a nonnegative integer r_{uv} for each pair of vertices, find a minimum-cost set of edges $E' \subseteq E$ such that for every pair of vertices u and v, there are at least r_{uv} edge-disjoint paths connecting u and v in the graph $G = (V, E')$. A primal-dual approach, generalized from an algorithm for the Steiner forest problem, yields good performance guarantees for problems in this class. The performance guarantee depends on the particular problem; in some cases it is known to be bounded only logarithmically [7, Ch. 4]. For a commercial application of this work see [11].

Graph Bisection. Given a graph, partition the nodes into two sets of equal size so as to minimize the number of edges with endpoints in different sets. An algorithm to find an approximately minimum-weight bisector would be remarkably useful, since it would provide the basis for a divide-and-conquer approach to many other graph optimization problems. In fact, a solution to a related but easier problem suffices.

Define a $\frac{1}{3}$-*balanced cut* to be a partition of the vertices of a graph into two sets each containing at least one-third of the vertices; its weight is the total weight of edges connecting the two sets. There is an algorithm to find a $\frac{1}{3}$-balanced cut whose weight is $O(\log n)$ times the minimum weight of a bisector. Note that this algorithm is not, strictly speaking, an approximation algorithm for any one optimization problem: the output of the algorithm is a solution to one problem while the quality of the output is measured against the optimal value for another. (We call this kind of performance guarantee a "bait-and-switch" guarantee.) Nevertheless, the algorithm is nearly as useful as a true approximation algorithm would be because in many divide-and-conquer algorithms the precise balance is not critical. One can make use of the balanced-cut algorithm to obtain approximation algorithms for many problems, including the following.

Optimal Linear Arrangement. Assign vertices of a graph to distinct integral points on the real number line so as to minimize the total length of edges.

Minimizing Time and Space for Sparse Gaussian Elimination. Given a sparse, positive-semidefinite linear system, the order in which variables are eliminated affects the time and storage space required for solving the system; choose an ordering to simultaneously minimize both time and storage space required.

Crossing Number. Embed a graph in the plane so as to minimize the number of edge-crossings.

The approximation algorithms for the above three problems have performance guarantees that depend on the performance guarantee of the balanced-separator algorithm. It is not known whether the latter performance guarantee can be improved: there might be an algorithm for balanced separators that has a constant performance ratio.

There are several other graph-separation problems for which approximation algorithms are known, e.g., problems involving directed graphs. All these approximation algorithms for cut problems make use of linear-programming relaxation. See [7, Ch. 5].

34.9 Multi-Criteria Problems

In many applications, there are two or more objective functions to be considered. There have been some approximation algorithms developed for such *multi-criteria* optimization problems (though much work remains to be done). Several problems in previous sections, such as the k-cluster problem described in "Other Optimization Problems With Constant-Factor Approximations," can be viewed as a bi-criteria problem: there is a budget imposed on one resource (the number of clusters), and the algorithm is required to approximately optimize use of another resource (cluster diameter) subject to that budget constraint. Another example is scheduling unrelated parallel machines with costs: for a given budget on cost, jobs are assigned to machines in such a way that the cost of the assignment is under budget and the makespan of the schedule is nearly minimum.

Other approximation algorithms for bi-criteria problems use the bait-and-switch idea mentioned in "Other Problems Having Poly-Logarithmic Performance Guarantees." For example, there is a polynomial approximation scheme for variant of the minimum-spanning-tree problem in which there are two unrelated costs per edge, say weight and length: given a budget L on length, the algorithm finds a spanning tree whose length is at most $(1 + \epsilon)L$ and whose weight is no more than the minimum weight of a spanning tree having length at most L [14].

34.10 Hard-to-Approximate Problems

For some optimization problems, worst-case performance guarantees are unlikely to be possible: it is NP-hard to approximate these problems even if one is willing to accept very poor performance guarantees. Following are some examples [7, Sections 10.5, 10.6].

Maximum Clique. Given a graph, find a largest set of vertices that are pairwise adjacent (see also [6]).

Minimum Vertex Coloring. Given a graph, color the vertices with a minimum number of colors so that adjacent vertices receive distinct colors.

Longest Path. Given a graph, find a longest simple path.

Max Linear Satisfy. Given a set of linear equations, find a largest possible subset that are simultaneously satisfiable.

Nearest Codeword. Given a linear error-correcting code specified by a matrix, and given a vector, find the codeword closest in Hamming distance to the vector.

Nearest Lattice Vector. Given a set of vectors $v_1, \ldots, v_n$ and a vector v, find an integer linear combination of the v_i that is nearest in Euclidean distance to v.

34.11 Research Issues and Summary

We have given examples for the techniques most frequently used to obtain approximation algorithms with provable performance guarantees, the use of witnesses, relaxation, and coarsening. We have categorized NP-hard optimization problems according to the performance guarantees achievable in polynomial time:

1. A small additive error,
2. A relative error of ϵ for any fixed positive ϵ,
3. A constant-factor performance guarantee,
4. A logarithmic- or polylogarithmic-factor performance guarantee,
5. No significant performance guarantee.

The ability to categorize problems in this way has been greatly aided by recent research developments in complexity theory. Novel techniques have been developed for proving the hardness of approximation of optimization problems. For many fundamental problems, we can state with considerable precision how good a performance guarantee can be achieved in polynomial time: known lower and upper bounds match or nearly match. Research toward proving matching bounds continues. In particular, for several problems for which there are logarithmic-factor performance guarantees (e.g., balanced cuts in graphs), researchers have so far not ruled out the existence of constant-factor performance guarantees.

Another challenge in research is methodological in nature. This chapter has presented methods of *worst-case analysis:* ways of universally bounding the error (relative or absolute) of an approximation algorithm. This theory has led to the development of many interesting and useful algorithms, and has proved useful in making distinctions between algorithms and between optimization problems. However, worst-case bounds are clearly not the whole story. Another approach is to develop algorithms tuned for a particular probability distribution of inputs, e.g., the uniform distribution. This approach is of limited usefulness because the distribution of inputs arising in a particular application rarely matches that for which the algorithm was tuned. Perhaps the most promising approach would address a hybrid of the worst-case and probabilistic models. The performance of an approximation algorithm would be defined as the probabilistic performance on a probability distribution selected by an adversary from among a large class of distributions. Blum [2] has presented an analysis of this kind in the context of graph coloring, and others (see [7, Section 13.7]) have addressed similar issues in the context of on-line algorithms.

34.12 Defining Terms

ρ-Approximation algorithm: An approximation algorithm that is guaranteed to find a solution whose value is at most (or at least, as appropriate) ρ times the optimum. The ratio ρ is the *performance ratio* of the algorithm.

Absolute performance guarantee: An approximation algorithm with an **absolute performance guarantee** is guaranteed to return a feasible solution whose value differs additively from the optimal value by a bounded amount.

Approximation algorithm: For solving an optimization problem. An algorithm that runs in time polynomial in the length of the input and outputs a feasible solution that is guaranteed to be nearly optimal in some well-defined sense called the *performance guarantee.*

Coarsening: To *coarsen* a problem instance is to alter it, typically restricting to a less complex feasible region or objective function, so that the resulting problem can be efficiently solved, typically by dynamic programming. This is not standard terminology.

Dual linear program: Every linear program has a corresponding linear program called the dual. For the linear program under **linear program,** the dual is $\max_y \{b \cdot y : A^T y \leq c \text{ and } y \geq \overline{0}\}$. For any solution x to the original linear program and any solution y to the dual, we have $c \cdot x \geq (A^T y)^T x = y^T (Ax) \geq y \cdot b$. For optimal x and y, equality holds. For a problem formulated as an integer linear program, feasible solutions to the dual of a relaxation of the program can serve as witnesses.

Feasible region: See **optimization problem.**

Feasible solution: Any element of the feasible region of an optimization problem.

Fractional solution: Typically, a solution to a relaxation of a problem.

Fully polynomial approximation scheme: An approximation scheme in which the running time of A_ϵ is bounded by a polynomial in the length of the input and $1/\epsilon$.

Integer linear program: A linear program augmented with additional constraints specifying that the variables must take on integer values. Solving such problems is NP-hard.

Linear program: A problem expressible in the following form. Given an $n \times m$ real matrix A, m-vector b and n-vector c, determine $\min_x \left\{c \cdot x : Ax \geq b \text{ and } x \geq \overline{0}\right\}$ where x ranges over all n-vectors and the inequalities are interpreted component-wise (i.e., $x \geq \overline{0}$ means that the entries of x are nonnegative).

MAX-SNP: A complexity class consisting of problems that have constant-factor approximation algorithms, but no approximation schemes unless P = NP.

Mixed integer linear program: A linear program augmented with additional constraints specifying that some of the variables must take on integer values. Solving such problems is NP-hard.

Objective function: See **optimization problem.**

Optimal solution: To an optimization problem. A feasible solution minimizing (or possibly maximizing) the value of the objective function.

Optimal value: The minimum (or possibly maximum) value taken on by the objective function over the feasible region of an optimization problem.

Optimization problem: An optimization problem consists of a set $\mathcal{P}$, called the *feasible region* and usually specified implicitly, and a function $f : \mathcal{P} \to \mathbb{R}$, the *objective function.*

Performance guarantee: See **approximation algorithm.**

Performance ratio: See **ρ-approximation algorithm.**

Polynomial approximation scheme: A collection of algorithms $\{A_\epsilon : \epsilon > 0\}$, where each A_ϵ is a $(1 + \epsilon)$-approximation algorithm running in time polynomial in the length of the input. There is no restriction on the dependence of the running time on ϵ.

Randomized rounding: A technique that uses the probabilistic method to convert a solution to a relaxed problem into an approximate solution to the original problem.

Relative performance guarantee: An approximation algorithm with a **relative performance guarantee** is guaranteed to return a feasible solution whose value is bounded by a multiplicative factor times the optimal value.

Relaxation: A relaxation of an optimization problem with feasible region $\mathcal{P}$ is another optimization problem with feasible region $\mathcal{P}' \supset \mathcal{P}$ and whose objective function is an extension of the original problem's objective function. The relaxed problem is typically easier to solve. Its value provides a bound on the value of the original problem.

Rescalable: An optimization problem is rescalable if, given any instance of the problem and integer $\lambda > 0$, there is an easily computed second instance that is the same except that the objective function for the second instance is (element-wise) λ times the objective function of the first instance. For such problems, the best one can hope for is a multiplicative performance guarantee, not an absolute one.

Semidefinite programming: A generalization of linear programming in which any subset of the variables may be constrained to form a semidefinite matrix. Used in recent results obtaining better approximation algorithms for cut, satisfiability, and coloring problems.

Strongly NP-hard: A problem is strongly NP-hard if it is NP-hard even when any numbers appearing in the input are bounded by some polynomial in the length of the input.

Triangle inequality: A complete weighted graph satisfies the triangle inequality if $\text{wt}(u, v) \leq \text{wt}(u, w) + \text{wt}(w, v)$ for all vertices u, v, and w. This will hold for any graph representing points in a metric space. Many problems involving edge-weighted graphs have better approximation algorithms if the problem is restricted to weights satisfying the triangle inequality.

Witness: A structure providing an easily verified bound on the optimal value of an optimization problem. Typically used in the analysis of an approximation algorithm to prove the performance guarantee.

Scheduling Algorithms

David Karger
Massachusetts Institute of Technology

Cliff Stein
Dartmouth College

Joel Wein
Polytechnic University

35.1 Introduction

Scheduling theory is concerned with the *optimal allocation of scarce resources to activities over time.* The *practice* of this field dates to the first time two humans contended for a shared resource and developed a plan to share it without bloodshed. The *theory* of the design of algorithms for scheduling is younger, but still has a significant history—the earliest papers in the field were published more than forty years ago.

Scheduling problems arise in a variety of settings, as is illustrated by the following examples:

EXAMPLE 35.1:

Consider the central processing unit of a computer that must process a sequence of jobs that arrive over time. In what order should the jobs be processed in order to minimize, on average, the time that a job is in the system from arrival to completion?

EXAMPLE 35.2:

Consider a team of five astronauts preparing for the reentry of their space shuttle into the atmosphere. There is a set of tasks that must be accomplished by the team before reentry. Each task must be carried out by exactly one astronaut, and certain tasks can not be started until other tasks are completed. Which tasks should be performed by which astronaut, and in which order, to ensure that the entire set of tasks is accomplished as quickly as possible?

EXAMPLE 35.3:

Consider a factory that produces different sorts of widgets. Each widget must first be processed by machine 1, then machine 2, and then machine 3, but different widgets require different amounts of processing time on different machines. The factory has orders for batches of widgets; each order has a date by which it must be completed. In what order should the machines work on different widgets in order to insure that the factory completes as many orders as possible on time?

More generally, scheduling problems involve *jobs* that must scheduled on *machines* subject to certain *constraints* to optimize some *objective function.* The goal is to specify a *schedule* that specifies when and on which machine each job is to be executed.

Researchers have studied literally thousands of scheduling problems, and it would be impossible even to enumerate all known variants in the space of this chapter. Our goal is more modest. We wish to make the reader familiar with an assortment of algorithmic techniques that have proved useful for solving a large variety of scheduling problems. We will demonstrate these techniques by drawing from a collection of "basic problems" that model important issues arising in many scheduling problems, while at the same time remaining simple enough to permit elegant and useful analysis. These basic problems have received much attention, and their centrality was reinforced by two influential surveys [13, 29]. All three examples above fit into the basic problem framework.

In this survey we focus exclusively on algorithms that provably run, in the worst case, in time polynomial in the size of the input. If the algorithm always gives an optimum solution, we call it an *exact* algorithm. Many of the problems that we consider, however, are $\mathcal{NP}$-hard, and it thus seems unlikely that polynomial-time algorithms exist to solve them. In these cases we will be interested in *approximation algorithms;* we define a *ρ-approximation algorithm* to be an algorithm that runs in polynomial time and delivers a solution of value at most ρ times the optimum.

The rest of this chapter is organized as follows. We complete this introduction by laying out a standard framework covering the basic scheduling problems and a notation for describing them. We then explore various techniques that can be used to solve them. In Section 35.2 we present a collection of heuristics that use some simple rule to assign a priority to each job and then schedule the jobs in priority order. These heuristics are useful both for solving certain problems optimally in polynomial time, and for giving simple but high-quality approximations for certain $\mathcal{NP}$-hard scheduling problems. Many scheduling problems require a more complex approach than a simple priority rule; in Section 35.3 we study algorithms that are more sophisticated in their greedy choices. In Section 35.4 we discuss the application of some basic tools of combinatorial optimization, such as network optimization and linear programming, to the design of scheduling algorithms. We then turn exclusively to $\mathcal{NP}$-hard problems. In Section 35.5 we introduce the

notion of a *relaxation* of a problem, and show how to use relaxations to design approximation algorithms. Finally, in Section 35.6 we discuss enumeration and scaling techniques by which certain other $\mathcal{NP}$-hard scheduling problems can be approximated arbitrarily closely in polynomial time.

The Framework of Basic Problems

A scheduling problem is defined by three separate elements: the **machine environment,** the *optimality criterion,* and a set of *side constraints and characteristics.* We first discuss the simplest machine environment, and use that to introduce a variety of **optimality criteria** and side constraints. We then introduce and discuss more complex machine environments.

The One-Machine Environment

In all of our scheduling problems we begin with a set $\mathcal{J}$ of n jobs, numbered $1, \ldots, n$. In the *one-machine* environment we have one machine that can process at most one job at a time. Each job j has a processing requirement p_j; namely, it requires processing for a total of p_j units of time on the machine. If each job must be processed in an uninterrupted fashion, we have a *nonpreemptive* scheduling environment, whereas if a job may be processed for a period of time, interrupted and continued at a later point in time, we have a *preemptive* environment. A schedule S for the set $\mathcal{J}$ specifies, for each job j, which p_j units of time the machine uses to process job j. Given a schedule S, we denote the *completion time* of job j in schedule S by C_j^S.

The goal of a scheduling algorithm is to produce a "good" schedule, but the definition of "good" will vary depending on the application. In Example 35.2 above, the goal is to process the entire batch of jobs as quickly as possible, or, in other words, to minimize the completion time of the last job finished in the schedule. In Example 35.1 we care less about the completion time of the last job in the batch as long as, on average, the jobs receive good service. Therefore, given a set of jobs and a machine environment, we must specify an *optimality criterion;* the goal of a scheduling algorithm will be to construct a schedule that optimizes this criterion. The two optimality criteria discussed in our examples are among the most basic optimality criteria: the *average completion time* of a schedule and its *makespan.* We define the makespan $C_{\max}^S = \max_j C_j^S$ of a schedule S to be the maximum completion time of any job in S, and the average completion of schedule S to be $\frac{1}{n}\Sigma_{j=1}^n C_j^S$. Note that optimizing the average completion time is equivalent to optimizing the *sum* of completion times $\Sigma_{j=1}^n C_j^S$.

We next turn to *side constraints and characteristics* that modify the one-machine environment. A number of side constraints and characteristics are possible; for example, we must specify whether or not preemption is allowed. Two other possible constraints model the arrival of jobs over time or the possibility of logical dependence between jobs. In a scheduling environment with *release date* constraints, we associate with each job j a release date r_j; job j is only available for processing at time r_j or later. In a scheduling environment with *precedence constraints* we are given a partial order $\prec$ on the set $\mathcal{J}$ of jobs; if $j' \prec j$ then we may not begin processing job j until job j' is completed.

Although we are early in our discussion of scheduling models, we already have enough information to define a number of problems. We refer to various scheduling problems in the now-standard notation defined by [13]. A problem is denoted by $\alpha|\beta|\gamma$, where (i) α denotes the machine environment, (ii) β denotes various side constraints and characteristics, and (iii) γ denotes an optimality criterion.

For the one-machine environment α is 1. For the optimality criteria we have introduced so far, γ is either ΣC_j or $C_{\max}$. At this point in our discussion, β is a subset of r_j, *prec*, and *pmtn*, where these denote respectively the presence of (nontrivial) release date constraints, precedence constraints, and the ability to schedule preemptively. Any of the side constraints not explicitly listed are assumed *not* to be present—e.g., we default to a nonpreemptive model unless *pmtn* is given in the side constraints. As an illustration, $1||\Sigma C_j$ denotes the problem of nonpreemptively scheduling independent jobs on one machine so as to minimize their average completion time, while $1|r_j|\Sigma C_j$ denotes the variant of the problem in which jobs have release

dates. As another example, $1|r_j, pmtn, prec|C_{\max}$ denotes the problem of preemptively scheduling jobs with release dates and precedence constraints on one machine so as to minimize their makespan. Note that Example 35.1, given above, can be modeled by $1|r_j|\Sigma C_j$, or, if preemption is allowed, by $1|r_j, pmtn|\Sigma C_j$.

Two other possible elements of a scheduling application might lead to different objective functions in the one-machine environment. It is possible that not all jobs are of equal importance, and thus, when measuring average service provided to a job, one might wish to weight the average so as to give more importance to certain jobs. We model this by assigning a weight $w_j > 0$ to each job j, and generalize the ΣC_j criterion to the *average weighted completion time* of a schedule, $\frac{1}{n}\Sigma_{j=1}^{n} w_j C_j$. In the scheduling notation this optimality criterion is denoted by $\Sigma w_j C_j$.

It is also possible that each job j may have an associated *due date* d_j by which it should be completed. This gives rise to two different optimality criteria. Given a schedule S, we define $L_j = C_j^S - d_j$ to be the *lateness* of job j, and we will be interested in constructing a schedule that minimizes $L_{\max} = \max_{j=1}^{n} L_j$, the *maximum lateness* of any job in the schedule. Alternatively, we concern ourselves with constructing a schedule that maximizes the number of jobs that complete by their due dates. To capture this, given a schedule S we define $U_j = 0$ if $C_j^S \leq d_j$ and $U_j = 1$ otherwise; we can thus describe our optimality criterion as the minimization of ΣU_j, or more generally, $\Sigma w_j U_j$. As illustrations, $1|r_j|L_{\max}$ denotes the problem of nonpreemptively scheduling, on one machine, jobs with release dates and due dates so as to minimize the maximum lateness of any job, and $1|prec|\Sigma w_j U_j$ denotes the problem of nonpreemptively scheduling precedence-constrained jobs on one machine so as to minimize the total (summed) weight of the late jobs. Deadlines are not listed in the side constraints since they are implicit in the objective function.

Finally, we will consider one scheduling problem that deals with a more general optimality criterion. For each job j, we let $f_j(t)$ be any function that is nondecreasing with the completion time of the job, and, with respect to a schedule S, define $f_{\max} = \max_{j=1}^{n} f_j(C_j^S)$. The specific problem that we will consider (in Section 35.3) is $1|prec|f_{\max}$—the scheduling of precedence-constrained jobs on one machine so as to minimize the maximum value of $f_j(C_j)$ over all $j \in \mathcal{J}$.

More Complex Machine Environments: Parallel Machines and the Shop

Having introduced all of the optimality criteria, side characteristics and conditions that we will use in this survey, we now discuss more complex machine environments.

We first discuss *parallel machine* environments. In these environments we are given m machines. A job j with processing requirement p_j can be processed on any one of the machines, or, if preemption is allowed, started on one machine, and when preempted potentially continued on another machine. A machine can process at most one job at a time and a job can be processed by at most one machine at a time.

In the *identical parallel machine* environment the machines are identical, and job j requires p_j units of processing time when processed on any machine. In the *uniformly related machines* environment each machine i has a speed $s_i > 0$, and thus job j, if processed entirely on machine i, would take a total of p_j/s_i time to process. In the *unrelated parallel machines* environment we model machines that have different capabilities and thus their relative performance on a job is unrelated. In other words, the speed of machine i on job j, s_{ij}, depends on both the machine and the job; job j requires p_j/s_{ij} processing time on machine i. We define $p_{ij} = p_j/s_{ij}$.

In the *shop environment,* which primarily models various sorts of production environments, we again have m machines. In this setting a job j is made up of *operations,* with each operation requiring processing on a specific one of the m machines. Different operations may take different amounts of time (possibly 0). In the *open shop* environment, the operations of a job can be processed in any order, as long as no two operations are processed on different machines simultaneously. In the *job shop environment,* there is a total order on the operations of a job, and one operation can not be started until its predecessor in the total order is completed. A special case of the job shop is the *flow shop,* in which the order of the operations

is the same—each job requires processing on the same machines and in the same order, but different jobs may require different amounts of processing on the same machine. Typically in the flow shop and open shop environment, each job is processed exactly once on each machine.

In the scheduling notation, the identical, uniformly related and unrelated machine environments are denoted respectively by P, Q, and R. The open, flow and job shop environments are denoted by O, F, and J. When the environment has a fixed number of machines the number is included in the environment specification; so, for example, P2 denotes the environment with two identical parallel machines. Note that Example 35.2 can be modeled by P5$|prec|C_{\max}$, and Example 35.3 can be modeled by F3$|r_j|\Sigma U_j$.

35.2 Priority Rules

The most obvious approach to solving a scheduling problem is a greedy one: whenever a machine becomes available, assign some job to it. A more sophisticated variant of this approach is to give each job a *priority* derived from the particular optimality criterion, and then, whenever a machine becomes available, assign the available job of highest priority to it. In this section we discuss such scheduling strategies for one-machine, parallel-machine and shop problems. In all of our algorithms, the priority of a job can be determined without reference to other jobs. This typically gives a simple scheduling algorithm that runs in $O(n \log n)$ time—the bottleneck being the time needed to sort the jobs by priority. We also discuss the limitations of these approaches, giving examples where they do not perform well.

One Machine

We first focus on algorithms for single-machine problems in which we give each job a priority, sort by priorities, and schedule in this order. To establish the correctness of such algorithms, it is often possible to apply an *interchange argument.* Suppose that there is an optimal schedule with jobs processed in nonpriority order. It follows that some adjacent pair of jobs in the schedule has inverted priorities. We show that if we swap these two jobs, the scheduling objective function is improved, thus contradicting the claim that the original schedule was optimal.

Average Weighted Completion Time: $1||\Sigma w_j C_j$

In perhaps the simplest scheduling problem, our objective is to minimize the sum of completion times ΣC_j. Intuitively, it makes sense to schedule the largest job at the end of the schedule to ensure that it does not contribute to the delay on any other job. We formalize this by defining the *shortest processing time* (SPT) algorithm: order the jobs by nondecreasing processing time (breaking ties arbitrarily) and schedule in that order.

THEOREM 35.1 SPT *is an exact algorithm for* $1||\Sigma C_j$.

PROOF To establish the optimality of the schedule constructed by SPT we use an interchange argument. Suppose for the purpose of contradiction that the jobs in the optimal schedule are *not* scheduled in nondecreasing order of completion time. Then there is some pair of jobs j and k such that j immediately precedes k in the schedule but $p_j > p_k$.

Suppose we exchange jobs j and k. All jobs other than j and k still start, and thus complete, at the same time as they did before the swap. All that changes is the completion times of jobs j and k. Suppose that originally job j started at time t and ended at time $t + p_j$, so that job k started at time $t + p_j$ and finished at time $t + p_j + p_k$. It follows that the original contribution of these two jobs to the sum of completion times, namely $(t + p_j) + (t + p_j + p_k) = 2t + 2p_j + p_k$, is replaced by their new contribution

of $2t + 2p_k + p_j$. This gives a net decrease of $p_j - p_k$ in ΣC_j, which is positive if $p_j > p_k$, implying that our original ordering was not optimal—a contradiction.

This algorithm and its proof of optimality generalize to the optimization of average *weighted* completion time, $1||\Sigma w_j C_j$. Intuitively, we would like to schedule as much weight as possible with each unit of processing time. This suggests scheduling jobs in nonincreasing order of w_j/p_j; the optimality of this rule can be established by a simple generalization of the previous interchange argument.

THEOREM 35.2 **[39]** *Scheduling jobs in nonincreasing order of w_j/p_j gives an optimal schedule for $1||\Sigma w_j C_j$.*

Maximum Lateness: $1||L_{\max}$

Maximum Lateness: $1||\mathrm{L}_{\max}$

A simple greedy algorithm also solves $1||L_{\max}$, in which we seek to minimize the maximum job lateness. A natural strategy is to schedule the job that is closest to being late, which suggests the `EDD` algorithm: order the jobs by nondecreasing due dates (breaking ties arbitrarily) and schedule in that order.

THEOREM 35.3 **[23]** `EDD` *is an exact algorithm for* $1||L_{\max}$.

PROOF We again use an interchange argument to prove that the schedule constructed by `EDD` is optimal. Assume without loss of generality that all due dates are distinct, and number the jobs so that $d_1 < d_2 < \cdots < d_n$. Among all optimal schedules, we consider the one with the fewest *inversions,* where an inversion is a pair of jobs j, k such that $j < k$ but k is scheduled before j. Suppose the given optimal schedule S is not the `EDD` schedule. Then there is a pair of jobs j and k such that $d_j < d_k$ but k immediately precedes j in the schedule.

Suppose we exchange jobs j and k. This does not change the completion time or lateness of any job other than j and k. We claim that we can only decrease $\max(L_j, L_k)$, so we do not increase the maximum lateness. Furthermore, since $j < k$, swapping jobs j and k decreases the number of inversions in the schedule. It follows that the new schedule has the same or better lateness than the original one but fewer inversions, a contradiction.

To prove the claim, note that in schedule S $C_j^S > C_k^S$ but $d_j < d_k$. It follows that $\max(L_j^S, L_k^S) = C_j^S - d_j$. Under the exchange, job j's completion time, and thus lateness, decreases. Job k's completion time rises to C_j^S, but this gives it a lateness of $C_j^S - d_k < C_j^S - d_j$. Thus, the maximum of the two latenesses has decreased.

Preemption and Release Dates

We now consider the more complex one-machine environment in which jobs may arrive over time, as modeled by the introduction of release dates. The greedy heuristics of the previous sections are not immediately applicable, since jobs of high priority might be released relatively late and thus not be available for processing before jobs of lower priority. The most natural idea to cope with this complication is to always process the available (released) job of highest priority. In a preemptive setting, this would mean, upon the release of a job of higher priority, preempting the currently running job and switching to the "better" job. We will show that this idea in fact yields optimal scheduling algorithms.

We thus define the *Shortest Remaining Processing Time Algorithm* `SRPT` : at each point in time, schedule the job with shortest remaining processing time, preempting when jobs of shorter processing time are released. We also generalize `EDD` : upon the release of jobs with earlier dues dates than the job currently being processed, preempt the current job and process the job with the earliest due date.

THEOREM 35.4 **[2, 22]** SRPT *is an exact algorithm for* $1|r_j, pmtn|\Sigma C_j$, *and* EDD *is an exact algorithm for* $1|r_j, pmtn|L_{\max}$

PROOF As before, we argue by contradiction, using a similar greedy exchange argument. However, instead of exchanging entire jobs, we exchange pieces of jobs, which is now allowed in our preemptive environment.

We focus on $1|r_j, pmtn|\Sigma C_j$. Consider a schedule in which available job j with the shortest remaining processing time is not being processed at time t, and instead available job k is being processed. Let p'_j and p'_k denote the remaining processing times for jobs j and k after time t, so $p'_j < p'_k$. In total, $p'_j + p'_k$ time is spent on jobs j and k after time t. We now perform an exchange. Take the first p'_j units of time that were devoted to either of jobs j and k after time t, and use them instead to process job j to completion. Then, take the remaining p'_k units of time that were spent processing jobs j and k, and use them to schedule job j. This exchange preserves feasibility since both jobs were released by time t.

In the new schedule, all jobs other than j and k have the same completion times as before. Job k finishes when job j originally finished. But job j, which needed $p'_j < p'_k$ additional work, finishes *before* job k originally finished. Thus we have reduced $C_j + C_k$ without increasing any other completion time, meaning we have reduced ΣC_j, a contradiction.

The argument that EDD solved $1|r_j, pmtn|L_{\max}$ goes much the same way. If at time t, job j with the earliest remaining due date is not being processed and job k with a later due date is, we reallocate the time spent processing job k to job j. This makes job j finish earlier, and makes job k finish when job j did originally. This cannot increase objective function value.

By considering how SRPT and EDD function if all jobs are available at time 0, we conclude that on one machine, in the absence of release dates, the ability to preempt jobs does not yield schedules with improved ΣC_j or $L_{\max}$ optimality criteria. This is not the case when jobs have release dates; intuitively, a problem such as $1|r_j|\Sigma C_j$ seems more difficult, as one can not simply preempt the current job for a newly-arrived better one, but rather must decide whether to start a worse job or wait for the better one. This intuition about the additional difficulty of this setting is justified—$1|r_j|\Sigma C_j$ and $1|r_j|L_{\max}$ are in fact $\mathcal{NP}$-complete problems. We discuss approximation algorithms for these problems in later sections.

We also note that these ideas have their limitations, and do not generalize to the $\Sigma w_j C_j$ criterion – $1|r_j, pmtn|\Sigma w_j C_j$ is $\mathcal{NP}$-hard. Finally, we note that SRPT and EDD are *on-line* algorithms – their decisions about which job to schedule currently do not require any information about which jobs are to be released in the future. See [38] for a comprehensive survey of on-line scheduling.

The Two-Machine Flow Shop

We now consider a more complex machine environment in which we want to minimize the makespan in a flow shop. In general, this problem is $\mathcal{NP}$-hard, even in the case of three machines. However, in the special case of the two-machine flow shop $F2||C_{\max}$, a priority-based ordering approach due to Johnson [24] yields an exact algorithm. We denote the operations of job j on the first and second machines as a pair (a_j, b_j). Intuitively, we want to get jobs done on the first machine as quickly as possible so as to minimize idleness on the second machine due to waiting for jobs from the first machine. This suggests using an SPT rule on the first machine. On the other hand, it would be useful to process the jobs with large b_j as early as possible on the second machine, while machine 1 is still running, so they will not create a large tail of processing on machine 2 after machine 1 is finished. This suggests some kind of *longest processing time first* (LPT) rule for machine 2.

We now formalize this intuition. We partition our jobs into two sets. A is the set of jobs j for which $a_j \leq b_j$, while B is the set for which $a_j > b_j$. We construct a schedule by first ordering all the jobs in A

by nondecreasing a_j value, and then all the jobs in B by nonincreasing b_j values. We process jobs in this order on both machines. This is called *Johnson's rule.*

It may be surprising that we do not reorder jobs to process them on the second machine. It turns out that for two-machine flow shops, such reordering is not necessary. A schedule in which all jobs are processed in the same order is called a *permutation schedule.*

LEMMA 35.1 An instance of F2$||C_{\max}$ always has an optimal schedule that is a permutation schedule.

Note that for three or more machines there is not necessarily an optimal permutation schedule.

PROOF Consider any optimal schedule, and number the jobs according to the time at which they complete on machine 1. Suppose that job k immediately precedes job j in the order in which jobs are completed on machine 2, but $j < k$. Let t be the time at which job k is started on machine 2. It follows that job k has completed on machine 1 by time t. Numbering $j < k$ means that j is processed earlier than k on machine 1, so it follows that job j also has completed on machine 1 by time t. Therefore, we can swap the order of jobs j and k on machine 2, and still have a legal schedule (since no other job's start time changes) with the same makespan. We can continue performing such swaps until there are none left to be done, implying that jobs on machine 2 are processed in the same order as those on machine 1.

Having limited our search for optimal schedules to permutation schedules, we present a clever argument given by Lawler et al. [29] to establish the optimality of the permutation schedule specified by Johnson's rule.

Renumber the jobs according to the ordering given by Johnson's rule. Notice that in a permutation schedule for F2$||C_{\max}$, there must be a job k that is started on machine 2 immediately after its completion on machine 1; for example, the job that starts immediately after the last idle time on machine 2. The makespan of the schedule is thus determined by the processing times of k jobs on machine 1 and $n-k+1$ jobs on machine 2, which is just a sum of $n+1$ processing times. If we reduce *all* the a_i and b_i by the same value p, then *every* sum of $n+1$ processing times decreases by $(n+1)p$, so the makespan of every permutation schedule is reduced by $(n+1)p$.

Now note that if a job has $a_i = 0$ it is scheduled first in some optimal permutation schedule, since it delays no jobs on machine 1 and only "buys time" for jobs that are processed later than it on machine 2. Similarly, if a job has $b_i = 0$, it is scheduled last in some optimal schedule.

Therefore, we can construct an optimal permutation schedule by repeatedly finding the minimum operation size amongst all the a_j and b_j values of the unscheduled jobs, subtracting that value from all of the operation sizes, and then scheduling the job with the new zero processing time according to the above rules. Now observe that the schedule constructed is exactly the schedule that orders the jobs by Johnson's rule. We have therefore proved the following.

THEOREM 35.5 **[24]** *Johnson's rule yields an optimal schedule for* F2$||C_{\max}$.

Parallel Machines

We now turn to the case of parallel machines. In the move to parallel machines, many problems that are easily solvable on one machine become $\mathcal{NP}$-hard; the focus therefore tends to be on approximation algorithms. In some cases, the simple priority-based rules we used for one machine generalize well. That is, we assign a priority to every job, and, whenever a machine becomes available, it starts processing the job that has the highest remaining priority. The schedules created by such algorithms, which immediately give work to any machine that becomes idle, will be referred to as *busy schedules.*

In this section, we also introduce a new method of analysis. Instead of arguing correctness based on interchange arguments, we give lower bounds on the quality of the optimal schedule. We then show that our algorithm produces a schedule whose quality is within some factor of the lower bound, thus demonstrating *a fortiori* that it is within this factor of the optimal schedule. This is a general technique for approximation, and it has the pleasing feature that we are able to guarantee that we are within a certain factor of the optimal value, *without knowing what that optimal value is.* Sometimes we can show that our greedy algorithm *achieves* the lower bound, thus demonstrating that the algorithm is actually optimal.

In this section, we devote most of our attention to the problem of minimizing the makespan (schedule length) on m parallel machines, and study the behavior of the greedy algorithm for the problem. We remark that for the average-completion-time problem $P||\Sigma C_j$, the greedy SPT algorithm also turns out to yield an optimal schedule. We discuss this further in Section "Applications of Matching."

As was mentioned in Section "One Machine," $P||C_{\max}$ is trivial when $m = 1$, as any schedule with no idle time will be optimal. Once we have more than one machine, things become more complicated. With preemption, it is possible to greedily construct an optimal schedule in polynomial time. In the nonpreemptive setting, however, it is unlikely that there is a polynomial time exact algorithm, since the problem is $\mathcal{NP}$-complete via a simple reduction from the $\mathcal{NP}$-complete partition problem [7]. We will thus focus on finding an approximately optimal solution. First, we will show that any busy schedule gives a 2-approximation. We will then see how this can be improved with a slightly smarter algorithm, the *Longest Processing Time* (LPT) algorithm, which is a 4/3-approximation algorithm. In Section 35.6 we will show that a more complicated algorithm can guarantee an even better quality of approximation.

Our analyses of these algorithms are all based on comparing their performance to certain lower bounds on the quality of the optimal schedule; their performance compared to the optimum can only be better. Our algorithms will make use of two simple lower bounds on the makespan $C^*_{\max}$ of the optimal schedule:

$$C^*_{\max} \geq \sum_{j=1}^{n} p_j/m \tag{35.1}$$

$$C^*_{\max} \geq p_j \text{ for all jobs } j\ . \tag{35.2}$$

The first lower bound says that the schedule is at least as long as the average machine load, and the second says that the schedule is as least as long as the size of any job. To demonstrate the power of these lower bounds, we begin with the preemptive problem, $P|pmtn|C_{\max}$. In this case, we show how to find a schedule that matches the maximum of the two lower bounds given above. We then use the lower bounds to establish performance guarantees for approximation algorithms for the nonpreemptive case.

Minimizing $C_{\max}$ with Preemptions

We give a simple algorithm, called McNaughton's wrap-around rule [32], that creates an optimal schedule for $P|pmtn|C_{\max}$ with at most $m - 1$ preemptions. This algorithm is different from many scheduling algorithms in that it creates the schedule machine by machine, rather than over time.

Observing that the lower bounds (35.1) and (35.2) still apply to preemptive schedules, we will give a schedule of length $D = \max\{\Sigma_j p_j/m, \max_j p_j\}$. We order the jobs arbitrarily. Then we begin placing jobs on the machines, in order, filling machine i up until time D before starting machine $i + 1$. Thus, a job of length p_j may be split, assigned to the last t units of time of machine i and the first $p_j - t$ units of time on machine $i + 1$, for some t. It is now easy to verify that since there are no more than mD units to be processed, every job is scheduled, and because $D - t \geq p_j - t$ for any t, a job is scheduled on at most one machine at any time. Thus we have created an optimal preemptive schedule.

THEOREM 35.6 **[32]** *McNaughton's wrap-around rule gives an optimal schedule for* $P|pmtn|C_{\max}$.

List Scheduling for $P||C_{max}$

In contrast to $P|pmtn|C_{max}$, $P||C_{max}$ is $\mathcal{NP}$-hard. We consider the performance of the list scheduling (LS) algorithm, which is a generic greedy algorithm: whenever a machine becomes available, process any unprocessed job.

THEOREM 35.7 **[11]** LS *is a* 2*-approximation algorithm for* $P||C_{max}$.

PROOF Let j' be the last job to finish in the schedule constructed by LS and let $s_{j'}$ be the time that j' begins processing. C_{max} is therefore $s_{j'} + p_{j'}$. All machines must be busy up to time $s_{j'}$, since otherwise job j' could have been started earlier. The maximum amount of time that all machines can be busy is $\Sigma_{j=1}^{n} p_j/m$, and so we obtain that

$$\begin{aligned} C_{max} &\leq s_{j'} + p_{j'} \\ &\leq \sum_{j=1}^{n} p_j + p_{j'} \\ &\leq C^*_{max} + C^*_{max} = 2C^*_{max} . \end{aligned}$$

The last inequality comes from lower bounds (35.1) and (35.2) above.

This algorithm can easily be implemented in $O(n + m)$ time. By a similar analysis, the algorithm guarantees an approximation of the same quality even if the jobs have release dates [14].

Longest Processing Time First for $P||C_{max}$

It is useful to think of the analysis of LS in the following manner. Every job starts being processed before time $\Sigma_{j=1}^{n} p_j$, and hence the schedule length is no more than $\Sigma_{j=1}^{n} p_j$ plus the length of the longest job that is running at time $\Sigma_{j=1}^{n} p_j$.

This motivates the natural idea that it is good to run the longer jobs early in the schedule and the shorter jobs later. This is formalized in the *Longest Processing Time* (LPT) rule: sort jobs in nonincreasing order of processing time and list schedule in that order.

THEOREM 35.8 **[12]** LPT *is a* 4/3*-approximation algorithm for* $P||C_{max}$.

PROOF We start by simplifying the problem. Suppose that j', the last job to finish in our schedule, is not the last job to start. Remove all jobs that start after time $s_{j'}$. This does not affect the makespan of our schedule, since these jobs must have run on other machines. Furthermore, it can only decrease the optimal makespan for the modified instance. Thus, if we prove an approximation bound for this new instance, it applies *a fortiori* to our original instance.

We can therefore assume that the last job to finish is the last to start, namely the smallest job. In this case, by the analysis of Theorem 35.7 above, LPT returns a schedule of length no more than $C^*_{max} + p_{min}$. We now consider two cases:

Case 1: $p_{min} \leq C^*_{max}/3$. In this case $C^*_{max} + p_{min} \leq C^*_{max} + (1/3)C^*_{max} \leq (4/3)C^*_{max}$.

Case 2: $p_{min} > C^*_{max}/3$. In this case, all jobs have $p_j > C^*_{max}/3$, and hence in the optimal schedule there are at most 2 jobs per machine. Number the jobs in order of nonincreasing p_j. If $n \leq m$, then the optimal schedule trivially puts one job on each machine. We thus consider the remaining case with $m < n \leq 2m$. In this case, we claim that, for each $j = 1, \ldots, m$ the optimal schedule pairs job j with job $2m + 1 - j$ if $2m + 1 - j \leq n$ and places job j by itself otherwise. This can be shown to be optimal via a simple

interchange argument. We finish the proof by observing that this is exactly the schedule that LPT would construct.

This algorithm needs to sort the jobs, and can be implemented in $O(m + n \log n)$ time. If we are willing to spend substantially more time, we can obtain a $(1+\epsilon)$-approximation algorithm for any fixed $\epsilon > 0$; see Section 35.6.

List Scheduling for $P|prec|C_{max}$

Even when our input contains precedence constraints, list scheduling is still a 2-approximation algorithm. Given a precedence relation *prec*, we say that a job is *available* at time t if all its predecessors have completed processing by time t. Recall that in list scheduling, whenever a machine becomes idle, any available job is scheduled. Before giving the algorithm, we give one additional lower bound that is relevant to scheduling with precedence constraints. Let $j_{i_1}, j_{i_2}, \ldots, j_{i_k}$ be any set of jobs such that $j_{i_1} \prec j_{i_2} \prec \cdots \prec j_{i_k}$, then

$$C^*_{max} \geq \sum_{\ell=1}^{k} p_{i_\ell} \ . \tag{35.3}$$

In other words, the total processing time of any chain of jobs is a lower bound on the makespan.

THEOREM 35.9 **[11]** LS *is a* 2*-approximation algorithm for* $P|prec|C_{max}$.

PROOF Let j_1 be the last job to finish. Define j_2 to be the latest-finishing predecessor of j_1, and inductively define $j_{\ell+1}$ to be the latest-finishing predecessor of j_ℓ, continuing until reaching j_k, a job with no predecessors. Let $\mathcal{C} = \{j_1, \ldots, j_k\}$. We partition time into two sets, A, the points in time when a job in $\mathcal{C}$ is running, and B, the remaining time. Observe that during all times in B, all machines must be busy, for if they were not, there would be a job from $\mathcal{C}$ that had all its predecessors completed and would be ready to run. Hence, $C_{max} \leq |A| + |B| \leq \Sigma_{j \in \mathcal{C}} p_j + \Sigma_{j=1}^{n} p_j \leq 2C^*_{max}$, where the last inequality follows by applying lower bounds (35.3) and (35.1). Note that $|A|$ is the total length of intervals in A.

For the case when all processing times are exactly one, $P|prec|C_{max}$ is solvable in polynomial time if there are only two machines [27], and is $\mathcal{NP}$-complete if there are an arbitrary number of machines [40]. The complexity of the problem in the case when there are a fixed constant number of machines is one of the more famous open problems in scheduling.

List Scheduling for $O||C_{max}$

List scheduling can also be applied to $O||C_{max}$. Recall that in this problem, each job must be processed for disjoint intervals of time on several different machines. By an analysis similar to that used for $P||C_{max}$, we will show that any algorithm that constructs a busy schedule for $O||C_{max}$ is a 2-approximation algorithm. Let P_{max} be the maximum total processing time, summed over all machines, for any one job, and let Π_{max} be the maximum total processing time, summed over all jobs, of any one machine. Clearly, both P_{max} and Π_{max} are lower bounds on the makespan of the optimal schedule. We show that any busy schedule has makespan at most $P_{max} + \Pi_{max}$.

To see this, consider the machine M' that finishes processing last, and consider the last job j' to finish on machine M'. At any time during the schedule, either M' is processing a job or job j' is being processed (if neither of these is true, then list scheduling would require that j' be running on M', a contradiction). However, the total length of time during which j' undergoes processing is at most P_{max}. During all the remaining time in the schedule, machine M' must be busy. But machine M' is busy for at most

$\Pi_{\max}$ time units. Thus the total length of the schedule is at most $P_{\max} + \Pi_{\max}$, as claimed. Since $P_{\max} + \Pi_{\max} \leq C^*_{\max} + C^*_{\max} = 2C^*_{\max}$, we obtain

THEOREM 35.10 **(Racsmány, see [3])** *List scheduling is a 2-approximation algorithm for* $O||C_{\max}$.

Limitations of Priority Rules

For many problems, simple scheduling rules do not yield good schedules, and thus given a scheduling problem, the algorithm designer should be careful about applying one of these rules without justification. In particular, for many problems, particularly those with precedence constraints and release dates, the optimal schedule has *unforced idle time.* That is, if one is constructing the schedule over time, there may be a time t when there is an idle machine m and an available job j, but scheduling job j on machine m at time t will yield a suboptimal schedule.

Consider the problem $Q||C_{\max}$ and recall that for $P||C_{\max}$, list scheduling is a 2-approximation algorithm. Consider a two-job two-machine instance in which $s_1 = 1$, $s_2 = x$, $p_1 = 1$, $p_2 = 1$, and $x > 2$. Then `LS` , `SPT`, and `LPT` all schedule one job on machine 1 and one on machine 2, and the makespan is thus 1. However, the schedule that places both jobs on machine 2 has makespan $2/x < 1$. By making x arbitrarily large, we see that none of these simple algorithms, which all have approximation ratio at least $x/2$, have bounded approximation ratios.

For this problem there is actually a simple heuristic that comes within a factor of 2 of optimal, but for some problems, such as $Q|prec|C_{\max}$ and $R||C_{\max}$, there is no simple algorithm known that comes anywhere close to optimal. We also note that even though list scheduling is a 2-approximation for $O||C_{\max}$, for $F||C_{\max}$ busy schedules can be of makespan $\Omega(m)$ times optimal [10].

35.3 Sophisticated Greedy Approaches

As we have just argued, for many problems, the priority algorithms that consider jobs in isolation, as in Section 35.2, are not sufficient. In this section, we consider algorithms that do more than sort jobs by some priority measure — they take other jobs into account when making a decision about where to schedule a job. The algorithms we study here are "incremental" in nature: they start with an empty solution and grow it, one job at a time, until the optimal solution is revealed. At each step the decision about which job to add to the growing solution is made greedily, but is based on the current context of jobs which have already been scheduled. We present two examples which are classic examples of the *dynamic programming* paradigm, and several others that are more specialized.

All the algorithms share an analysis based on the idea of *optimal substructure.* Namely, if we consider the optimal solution to a problem, we can often argue that its "subparts" (e.g., prefixes of the optimal schedule) are optimal solutions to "subproblems" (e.g., the problem of scheduling the set of jobs in that prefix). This lets us argue that as our algorithms build their solution incrementally, they are building optimal solutions to bigger and bigger subproblems of the original problem, until they reach an optimal solution to the entire problem.

An Incremental Greedy Algorithm for $1||f_{\max}$

The first problem we consider is $1||f_{\max}$, which was defined in Section 35.1. In this problem, each job has some nondecreasing *penalty function* on its completion time C_j, and the goal is to find a schedule minimizing the maximum $f_j(C_j)$. As one example, $1||L_{\max}$ is captured by setting $f_j(t) = t - d_j$.

A greedy strategy still applies, when suitably modified. It is convenient, instead of talking about scheduling the "most penalizing" (e.g., earliest due date) job first, to talk about scheduling the "least penalizing" (e.g., latest due date) job last. Let $p(\mathcal{J}) = \Sigma_{j \in \mathcal{J}} p_j$ be the total processing time of the entire set of

jobs. Note that some job must complete at time $p(\mathcal{J})$. We find the job j that minimizes $f_j(p(\mathcal{J}))$, and schedule this job last. We then (recursively) schedule all the remaining jobs before j so as to minimize their maximum penalty. We call this algorithm `Least-Cost-Last`.

Observe the difference between this and our previous scheduling rules. In this new scheme, we cannot determine the best job to schedule second-to-last until we know which job is scheduled last (we need to know the processing time of the last job in order to know the processing time of the recursive subproblem). Thus, instead of a simple $O(n \log n)$-time sorting algorithm based on absolute priorities, we are faced with an algorithm that inspects k jobs in order to identify the job to be scheduled kth, giving a total running time of $O(n + (n-1) + \cdots + 1) = O(n^2)$.

This change in algorithm is matched by a change in analysis. Since the notion of which job is worst can change as the schedule is constructed, there is no obvious fixed priority to which we can apply a local exchange argument. Instead, as with $P|pmtn|C_{\max}$ in Section "Minimizing $C_{\max}$ with Preemptions," we show that our algorithm's greedy decisions are in agreement with a provable lower bound on the quality of the optimal schedule. Our algorithm produces a schedule that matches the lower bound and must therefore be optimal.

Let $f^*_{\max}(S)$ denote the optimal value of the objective function if we are only scheduling the jobs in S. Consider the following two facts about $f^*_{\max}$:

$$\begin{aligned} f^*_{\max}(\mathcal{J}) &\geq \min_{j \in N} f_j(p(\mathcal{J})) \\ f^*_{\max}(\mathcal{J}) &\geq f^*_{\max}(\mathcal{J} - \{j\}) \end{aligned}$$

The first of these statements follows from the fact that some job must be scheduled last. The second follows from the fact that if we have an optimal schedule for $\mathcal{J}$ and remove a job from the schedule, then we do not increase the completion time of any job. Therefore, since the f_j are increasing functions, we do not increase any penalty.

We use these inequalities to prove by induction that our schedule is optimal. According to our scheduling rule, we schedule last the job j minimizing $f_j(p(\mathcal{J}))$. By induction, this gives us a schedule with objective $\max\{f_j(p(\mathcal{J})), f^*_{\max}(\mathcal{J} - \{j\})\}$. But since each of these quantities is (by the equations above) a lower bound on the optimal $f^*_{\max}(\mathcal{J})$, we see that in fact we obtain a schedule whose value is a lower bound on $f^*_{\max}(\mathcal{J})$, and thus must in fact equal $f^*_{\max}(\mathcal{J})$.

Extension to $1|prec|f_{\max}$

Our argument from the previous section continues to apply even if we introduce *precedence constraints*. In the $1|prec|f_{\max}$ problem, a partial order on jobs is given, and we must build a schedule that does not start a job until all jobs preceding it in the partial order have completed. Our above algorithm applies essentially unchanged to this case. Note that the last job in the schedule must be a job with no successors. We therefore build an optimal schedule by scheduling last the job j that, among jobs with no successors, minimizes $f_j(P(\mathcal{J}))$. We then recursively schedule all other jobs before it. The proof of optimality goes exactly as before, using the fact that if L is the set of all jobs without successors, then

$$f^*_{\max}(\mathcal{J}) \geq \min_{j \in L} f_j(P(\mathcal{J}))$$

This is the same as the first equation above, except that the minimum is taken only over jobs without successors. The remainder of the proof proceeds unchanged.

THEOREM 35.11 **[26]** `Least-Cost-Last` *is an exact algorithm for* $1|prec|f_{\max}$.

It should also be noted that, once again, the fact that our algorithm is greedy makes preemption a moot point. One job needs to finish last, and it immediately follows that we can do no better than executing all of that job last. Thus, our greedy algorithm continues to be optimal.

An Alternative Approach

Moore [33] gave a different approach to $1||f_{\max}$ that may be faster in some cases. His scheme is based on a reduction to the maximum lateness problem and its solution by the EDD rule. To see how an algorithm for $L_{\max}$ can be applied to $1||f_{\max}$, suppose we want to know whether there is a schedule with $f_{\max} \leq B$. We can decide this as follows. Give each job j a deadline d_j equal to the maximum t for which $f_j(t) \leq B$. It is easy to see that a schedule has $f_{\max} \leq B$ precisely when every job finishes by its specified deadline, i.e., $L_{\max} \leq 0$. Thus, we have converted the feasibility problem for $f_{\max}$ into an instance of the lateness problem. The optimization problem may therefore be solved by a binary search for the correct value of B.

Dynamic Programming for $1||\Sigma w_j U_j$

We now consider $1||\Sigma w_j U_j$ problem, in which the goal is to minimize the total weight of late jobs. This problem is *weakly $\mathcal{NP}$-complete.* That is, although it is $\mathcal{NP}$-complete, for integral weights it is possible to solve the problem exactly in $O(n\Sigma w_j)$ time, which is polynomial if the w_j are bounded by a polynomial. The necessary algorithm is a classical dynamic program that builds the solution out of solutions to smaller problems (a detailed introduction to dynamic programming can be found in many algorithms textbooks, see, for example [6]). This $O(n\Sigma w_j)$ dynamic programming algorithm has several consequences. First, it immediately yields an $O(n^2)$-time algorithm for $1||\Sigma U_j$ problem–just take all weights to be 1. Furthermore, we will show in Section 35.6 that this algorithm can be used to derive a *fully polynomial approximation scheme* for the general problem that finds a schedule with $\Sigma w_j U_j$ within $(1+\epsilon)$ of the optimum in time polynomial in $1/\epsilon$ and n.

The first observation to make is that under this objective, a schedule partitions the jobs into two types: those completed by their due dates, and those not completed. Clearly, we might as well process all the jobs that meet their due date before processing any that do not. Furthermore, the processing order of these jobs might as well be determined using the Earliest Due Date (EDD) rule from Section "Maximum Lateness:$1||L_{\max}$:" when all jobs can be completed by their due date (implying nonpositive maximum lateness), EDD, which minimizes maximum lateness, will clearly find a schedule that does so.

It is therefore convenient to discuss *feasible subsets* of jobs that can all be scheduled together to complete by their due dates. The question of finding a minimum weight set of late jobs can then be equivalently restated as finding a maximum weight feasible subset of the jobs.

To solve this problem, we aim to solve a harder one: namely, to identify the fastest-completing maximum weight feasible subset. We do so via dynamic programming. Order the jobs according to increasing due date. Let T_{wj} denote the minimum completion time of a weight w-or-greater feasible subset of $1, \ldots, j$, or ∞ if there is no such subset. Note that $T_{0j} = 0$, while $T_{w0} = \infty$ for all $w > 0$. We now give a dynamic program to compute the other values T_{wj}. Consider the fastest completing weight w-or-greater feasible subset S of $\{1, \ldots, j+1\}$. Either $j+1 \in S$ or it is not. If $j+1 \notin S$, then $S \subseteq \{1, \ldots, j\}$ and is then clearly the fastest completing weight w-or-greater subset of $\{1, \ldots, j\}$, so S completes in time T_{wj}. If $j+1 \in S$, then since we can schedule feasible subsets using EDD , $j+1$ can be scheduled last. The jobs preceding it have weight at least $w - w_{j+1}$, and clearly form the minimum-completion-time subset of $1, \ldots, j$ with this weight. Thus, the completion time of this feasible set is $T_{w-w_{j+1},j} + p_{j+1}$. It follows that

$$T_{w,j+1} = \begin{cases} \min\left(T_{w,j}, T_{w-w_{j+1}} + p_{j+1}\right) & \text{if } T_{w-w_{j+1},j} + p_j \leq d_{j+1} \\ T_{wj} & \text{otherwise} \end{cases}$$

Now observe that there is clearly no feasible subset of weight exceeding Σw_j, so we can stop our dynamic program once we reach this value of w. This takes $O(n\Sigma w_j)$ time. Once we have all the values T_{wj}, we can find the maximum weight feasible subset by identifying the largest value of w for which some T_{wj} (and thus T_{wn}) is finite.

This gives a standard $O(n\Sigma_j w_j)$ time dynamic program for computing T_{wn} for every relevant value w; the maximum w for which T_{wn} is finite is the maximum total weight of jobs that can be completed by their due date.

THEOREM 35.12 **[30]** *Dynamic programming yields an $O(n\Sigma w_j)$-time algorithm for exactly solving $1||\Sigma w_j U_j$.*

We remark that a similar dynamic program can be used to solve the problem in time $O(n\Sigma p_j)$, which is effective when the processing times are polynomially bounded integers. We also note that a quite simple greedy algorithm due to Moore [33] can solve the unweighted $1||\Sigma U_j$ problem in $O(n \log n)$ time.

Dynamic Programming for $P||C_{max}$

For a second example of the applicability of dynamic programming, we return to the $\mathcal{NP}$-hard problem $P||C_{max}$, and focus on a special case that is solvable in polynomial time—the case in which the number of different job processing times is bounded by a constant. While this special case might appear to be somewhat contrived, in Section 35.6 we will show that it can form the core of a polynomial approximation scheme for $P||C_{max}$.

LEMMA 35.2 [18] Given an instance of $P||C_{max}$ in which the p_j take on at most s distinct values, there exists an algorithm which finds an optimal solution in time $n^{O(s)}$.

PROOF Assume for now that we are given a target schedule length T. We again use dynamic programming. Let the different processing times be $z_1, \ldots, z_s$. The key observation is that the set of jobs on a machine can be described by an s-dimensional vector $V = (v_1, \ldots, v_s)$, where v_k is the number of jobs of length z_k. There are at most n^s such vectors since each entry has value at most n. Let $\mathcal{V}$ be the set of all such vectors whose total processing time (that is, $\Sigma v_i z_i$) is less than T. In the optimal schedule, every machine is assigned a set of jobs corresponding to a vector from this set. We now define $M(x_1, \ldots, x_s)$ to be the minimum number of machines needed to schedule a job set consisting of x_i jobs of size z_i, for $i = 1, \ldots, s$. We observe that

$$M(x_1, \ldots, x_s) = 1 + \min_{V \in \mathcal{V}} M(x_1 - v_1, \ldots, x_s - v_s) \ .$$

The minimization is over all possible vectors that could be processed by the "first" machine counted by the quantity 1, and the recursive expression denotes the best way to process the remaining work. Thus we need to compute a table with n^s entries, where each entry depends on $O(n^s)$ other entries, and therefore the computation takes time $O(n^{2s})$.

It remains to handle the assumption that we know T. The easiest way to do this is to perform a binary search on all possible values of T. A slightly more sophisticated approach is to search only over the $O(n^s)$ makespans of vectors describing sets of jobs, as one of these clearly determines the makespan of the solution.

35.4 Matching and Linear Programming

Networks and linear programs are central themes in combinatorial optimization, and are useful tools in the solution of many problems. Therefore, it is not surprising that these techniques can be applied profitably to scheduling problems as well. In this section, we discuss applications of *bipartite matching* and *linear*

programming to the exact solution of certain scheduling problems; in Section 35.5 we will revisit both techniques in the design of approximation algorithms for $\mathcal{NP}$-hard problems.

Applications of Matching

Given a bipartite graph on two sets of vertices A and B and an edge set $E \subseteq A \times B$, a *matching* M is a subset of the edges, such that each vertex A and B is an endpoint of at most one edge of M. A natural matching that is useful in scheduling problems is one that matches jobs to machines; the matching constraints force each job to be scheduled on at most one machine, and each machine to be processing at most one job. If A has no more vertices than B, we call a matching *perfect* if every vertex of A is in some matching edge. It is also possible to assign weights to the edges, and define the weight of a matching to be the sum of the weights of the matching edges. The key fact that we use in this section is that minimum weight perfect matchings can be computed in polynomial time (see, e.g.,[1]).

Matching to Schedule Positions for $R||\Sigma C_j$

In this section we give a polynomial-time algorithm for $R||\Sigma C_j$ that matches jobs to *positions* in the schedule on each machine. For any schedule, let κ_{ik} be the kth-from-last job to run on machine i, and let ℓ_i be the number of jobs that run on machine i. By observing that the completion time of a job is equal to the sum of the processing times of the jobs that run before it, we have that

$$\sum_j C_j = \sum_{i=1}^{m} \sum_{k=1}^{\ell_i} C_{\kappa_{ik}} = \sum_{i=1}^{m} \sum_{k=1}^{\ell_i} \sum_{x=k}^{\ell_i} p_{i,\kappa_{xi}} = \sum_{i=1}^{m} \sum_{k=1}^{\ell_i} k p_{i,\kappa_{ki}} \ . \tag{35.4}$$

From this, we see that the kth from last job to run on a machine contributes exactly k times its processing time to the sum of completion times. Based on this observation, Horn [21] and Bruno, Coffman and Sethi [4] proposed formulating $R||\Sigma C_j$ problem as a minimum-weight bipartite matching problem. We define a bipartite graph $G = (V, E)$ with $V = A \cup B$ as follows. A will contain n vertices v_j, one for each of the n jobs $j = 1, \ldots, n$. B will contain nm nodes w_{ik}, where vertex w_{ik} represents the kth-from-last position on machine i, for $i = 1, \ldots, m$ and $k = 1, \ldots, n$. We include in E an edge (v_j, w_{ik}) between every node in A and every node in B. Using (35.4) we define the weights on the edges from A to B as follows: edge (v_j, w_{ik}) is assigned weight kp_{ij}.

We now argue that a minimum-weight perfect matching in this graph corresponds to an optimal schedule. First, note that for each valid schedule there is a perfect matching in G. Not every perfect matching in G corresponds to a schedule, since a job might be assigned to the kth from last position while less than k jobs are assigned to that machine; however, such a perfect matching is clearly not of minimal weight—a better matching can be obtained by pushing the $k' < k$ jobs assigned to that machine into the k' from last slots. Therefore, a schedule of minimum total completion time corresponds to a minimum-weight perfect matching in the bipartite graph.

THEOREM 35.13 **[4, 21]** *There is a polynomial-time algorithm for* $R||\Sigma C_j$.

In the special case of parallel identical machines, it remains true that the kth-from-last job to run on a machine contributes exactly k times its processing time to the sum of completion times. Since in this case the processing time of each job is the same on any machine, the algorithm is clear: schedule the m largest jobs last on each machine, schedule the next m largest jobs next to last, etc. The schedule constructed is exactly that constructed by the `SPT` algorithm.

COROLLARY 35.1 **[5]** `SPT` is an exact algorithm for $P||\Sigma C_j$.

Matching Jobs to Machines: $O|pmtn|C_{max}$

For our second example of the utility of matching, we give an algorithm for $O|pmtn|C_{max}$ due to Gonzales and Sahni [9]. This algorithm will not find just one matching, but rather a sequence of matchings, each of which will correspond to a partial schedule, and then concatenate all of these partial schedules together. Recall from our discussion of $O||C_{max}$ in Section 35.2 that two lower bounds on the makespan of a nonpreemptive schedule are the *maximum machine load* Π_{max} and the *maximum job size* P_{max}. Both of these remain lower bounds when preemption is allowed. In the nonpreemptive setting, a simple greedy algorithm gives a schedule with makespan bounded by $P_{max} + \Pi_{max}$. We now show that when preemption is allowed, matching can be used to achieve a makespan equal to $\max(P_{max}, \Pi_{max})$.

The intuition behind the algorithm is the following. Consider the schedule at any point in time. At this time, each machine is processing at most one job. In other words, the schedule at each point in time defines a matching between jobs and machines. We aim to find a matching that forms a part of the optimal schedule, and process jobs according to it for some time. Our goal is that processing the matched jobs on their matched machines for some amount of time t, and adjusting P_{max} and Π_{max} to reflect the decreased remaining processing requirements, should reduce $\max(P_{max}, \Pi_{max})$ by t. It follows that if we repeat this process for a total amount of time equal to $\max(P_{max}, \Pi_{max})$, we will reduce $\max(P_{max}, \Pi_{max})$ to 0, implying that there is no work remaining in the system.

What properties should our matching of jobs to machines have? Recall that our goal is to reduce our lower bound. Call a job *tight* if its total processing cost is P_{max}. Call a machine *tight* if its total load is Π_{max}. Clearly, it is necessary that every tight job undergo processing in our matching, since otherwise we will fail to subtract t from P_{max}. Similarly, it is necessary that every tight machine be in the matching in order to ensure that we reduce Π_{max} by t. Lastly, we can only execute the matching for t time if every job–machine pair in the matching actually requires t units of processing. In other words, we are seeking a matching in which every tight machine and job is matched, and each matching edge requires positive processing time. Such a matching is referred to as a *decrementing set.* That it always exists is a nontrivial fact (about stochastic matrices) whose proof is beyond the scope of this survey; we refer the reader to Lawler and Labetoulle's presentation of this algorithm [28].

To find a decrementing set, we construct a (bipartite) graph with a node representing each job and machine, and include an edge between machine node i and job node j if job j requires a nonzero amount of processing on machine i. In this graph we require a matching that matches each tight machine or job node; this can easily be found with a variant of traditional matching algorithms. Note that we must include the nontight nodes in the matching problem, since tight nodes can be matched to them.

Once we have found our decrementing set via matching, we have machines execute the jobs matched to them until one of the matched jobs completes its work on its machine, or until a new job or machine becomes tight (this can happen because some jobs and machines are not being processed in the matching). Whenever this happens, we find a new decrementing set. For simplicity, we assume that $P_{max} = \Pi_{max}$; this can easily be arranged by adding dummy operations, which can only make our task harder. Since our decrementing set includes every tight job and machine, it follows that executing for time t will reduce both P_{max} and Π_{max} by t. It follows that after $P_{max} = \Pi_{max}$ time, both quantities will be reduced to 0. Clearly this means that we are done in time equal to the lower bound.

One might worry that the number of decrementing set calculations we must perform could be non-polynomially bounded, making our approximation algorithm too slow. But this turns out not to happen. We only compute a new decrementing set when a job or machine finishes or when a new job or machine becomes tight. Each job–processor pair can finish only once, meaning that this occurs only nm times during our schedule. Also, each job or machine stays tight forever after it becomes tight; thus, new tight jobs and machines only occur $n + m$ times. Thus, constructing our schedule of optimal length requires only $mn + m + n$ matching computations.

THEOREM 35.14 **[9]** *There is a polynomial time algorithm for* $O|pmtn|C_{\max}$*, that finds an (optimal) schedule of makespan* $\max(P_{\max}, \Pi_{\max})$.

Linear Programming

We now discuss the application of *linear programming* to the design of scheduling algorithms. A *linear program* is given by a vector of variables $x = (x_1, \cdots, x_n)$, a set of m linear constraints of the form $a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n \leq b_i, 1 \leq i \leq m$, and a *cost vector* $c = (c_1, \ldots, c_n)$; the goal is to find an x that satisfies these constraints and that minimizes $cx = c_1x_1 + c_2x_2 + \cdots + c_nx_n$. Alternatively but equivalently, some of the inequality constraints might be given as equalities, and/or we may have no objective function and desire simply to find a feasible solution to the set of constraints. Many optimization problems can be formulated as linear programs, and thus solved efficiently, since a linear program can be solved in polynomial time [25].

In this section we consider $R|pmtn|C_{\max}$. To model this problem as a linear program, we use nm variables $x_{ij}, 1 \leq i \leq m, 1 \leq j \leq n$. Variable x_{ij} denotes the fraction of job j that is processed on machine i; for example, we would interpret a linear-programming solution with $x_{1j} = x_{2j} = x_{3j} = \frac{1}{3}$ as assigning $\frac{1}{3}$ of job j to machine 1, $\frac{1}{3}$ to machine 2 and $\frac{1}{3}$ to machine 3.

We now consider what sorts of linear constraints on the x_{ij} are necessary to ensure that they describe a valid solution to an instance of $R|pmtn|C_{\max}$. Clearly the fraction of a job assigned to any machine must be nonnegative, so we will create nm constraints

$$x_{ij} \geq 0 .$$

In any schedule, we must fully process each job. We capture this requirement with the n constraints:

$$\sum_{i=1}^{m} x_{ij} = 1, \quad 1 \leq j \leq n .$$

Note that, along with the previous constraints, these constraints imply that $x_{ij} \leq 1 \; \forall \, i, j$.

Our objective, of course, is to minimize the makespan D of the schedule. Recall that the amount of processing that job j would require, if run entirely on machine i, is p_{ij}. Therefore, for a set of fractional assignments x_{ij}, we can determine the amount of time machine i will work: it is just $\Sigma x_{ij} p_{ij}$, which must be at most D. We model this with the m constraints

$$\sum_{j=1}^{n} p_{ij}x_{ij} \leq D \text{ for } i = 1, \ldots, m .$$

Finally, we must ensure that no job is processed for more than D time; we model this with the n constraints

$$\sum_{i=1}^{m} x_{ij}\, p_{ij} \leq D, 1 \leq j \leq n .$$

To summarize, we formulate the problem as the following linear program:

$$\min \quad D \tag{35.5}$$

$$\sum_{i=1}^{m} x_{ij} \quad = \quad 1, \qquad \text{for } j = 1, \ldots, n , \tag{35.6}$$

$$\sum_{j=1}^{n} p_{ij}x_{ij} \quad \leq \quad D, \qquad \text{for } i = 1, \ldots, m , \tag{35.7}$$

$$\sum_{i=1}^{n} p_{ij} x_{ij} \leq D, \quad \text{for } j = 1, \ldots, n, \tag{35.8}$$

$$x_{ij} \geq 0 \quad \text{for } i = 1, \ldots, m, \ j = 1, \ldots, n. \tag{35.9}$$

It is clear that any feasible schedule for our problem yields an assignment of values to the x_{ij} that satisfies the constraints of our above linear program. However, it is not completely clear that solving the linear program yields a solution to the scheduling problem; this linear program does not specify the ordering of the jobs on a specific machine, but simply assigns the jobs to machines while constraining the maximum load on any machine. It thus fails to explicitly require that a job not be processed simultaneously on more than one machine.

Interestingly enough, we can resolve this difficulty with an application of open-shop scheduling. We define an open shop problem by creating an operation o_{ij} for each positive variable x_{ij}, and define the size of o_{ij} to be $x_{ij} p_{ij}$. We then find an optimal preemptive schedule for this instance, using the matching-based algorithm discussed in Section 35.4 We know that both the maximum machine load and maximum job size of this open shop instance are bounded above by D, and therefore the makespan of the resulting open shop schedule is at most D. If we now reinterpret the operations of each job in the open-shop schedule as fragments of the original job in the unrelated machines instance, we see that we have given a preemptive schedule of length D in which no two fragments of a job are scheduled simultaneously.

We thus have established the following.

THEOREM 35.15 [**28**] *There is an exact algorithm for* $\mathrm{R}|pmtn|C_{\max}$.

We will see further applications of linear programming to the development of approximation algorithms for $\mathcal{NP}$-hard scheduling problems in the next section.

35.5 Using Relaxations to Design Approximation Algorithms

We now turn exclusively to the design of approximation algorithms for $\mathcal{NP}$-hard scheduling problems. Recall that a *ρ-approximation algorithm* is one that is guaranteed to find a solution with value within a multiplicative factor of ρ of the optimum. Many of the approximation algorithms in this area are based on a *relaxation* of the $\mathcal{NP}$-hard problem. A relaxation of a problem is a version of the problem with some of the requirements or constraints removed ("relaxed"). For example, we might consider $1|r_j, pmtn|\Sigma C_j$ to be a relaxation of $1|r_j|\Sigma C_j$ in which the "no preemption" constraint has been relaxed. A second example of a relaxation might be a version of the problem in which we relax the constraint that a machine processes at most one job at a time; a solution to this relaxation may have several jobs scheduled at one time on the same machine.

A solution to the original problem is a solution to the relaxation, but a solution to the relaxation is not necessarily a solution to the original problem. This is clearly illustrated by our nonpreemptive/preemptive example—a nonpreemptive schedule is a legal solution to a preemptive problem, although perhaps not an optimal one, but the converse is not true. It follows that in the case of a minimization problem, the value of the optimal solution to the relaxation is a not-necessarily-tight lower bound on the optimal solution to the original problem.

An idea that has proven quite useful is to define first a relaxation of the problem which can be solved in polynomial time, and then to give an algorithm to convert the relaxation's solution into a valid solution to the original problem, with some degradation in the quality of solution. The key to making this work well

is to find a relaxation that preserves enough of the structure of the original problem to make the optimal relaxed solution "similar" to the original optimum, so that the relaxed solution does not degrade too much when converted to a valid solution.

In this section we discuss two sorts of relaxations of scheduling problems and their use in the design of approximation algorithms, namely the preemptive version of a nonpreemptive problem and a linear-programming relaxation of a problem.

There are generally two different ways to infer a valid schedule from the relaxed solution: one is to infer an *assignment* of jobs to machines while the other is to infer a *job ordering.* We give examples of both methods.

Before going any further, we introduce the notion of a relaxed decision procedure, which we will use both in Section "Rounding a Fractional Assignment to Machines:R$||C_{\max}$" and later in Section 35.6. A *ρ-relaxed decision procedure* (RDP) for a minimization problem accepts as input a target value T, and returns either **no,** asserting that no solution of value $\leq T$ exists, or returns a solution of value at most ρT. A polynomial-time ρ-relaxed decision procedure can easily be converted into a ρ-approximation algorithm for the problem via binary search for the optimum T; see [18, 19] for more details. This simple idea is quite useful, as it essentially lets us assume that we know the value T of an optimal solution to a problem. (Note that this is a different use of the word relax than the term "relaxation.")

Rounding a Fractional Assignment to Machines: R$||C_{\max}$

In this section we give a 2-relaxed decision procedure for R$||C_{\max}$. Recall the linear program that we used in giving an algorithm for R$|pmtn|C_{\max}$. If, instead of the constraints $x_{ij} \geq 0$, we could constrain the x_{ij} to be 0 or 1, the solution would constitute a valid nonpreemptive schedule. Furthermore, note that these integer constraints combined with the constraints (35.7) make the constraints (35.8) unnecessary (if a job is assigned integrally to a machine, constraint (35.7) ensures that is a fast enough machine, thus satisfying constraint (35.8) for that job). In other words, the following formulation has a feasible solution if and only if there is a nonpreemptive schedule of makespan D.

$$\sum_{i=1}^{m} x_{ij} = 1, \qquad \text{for } j = 1, \ldots, n\,, \tag{35.10}$$

$$\sum_{j=1}^{n} p_{ij} x_{ij} \leq D, \qquad \text{for } i = 1, \ldots, m\,, \tag{35.11}$$

$$x_{ij} \in \{0, 1\}, \quad \text{for } i = 1, \ldots, m,\ j = 1, \ldots, n\,. \tag{35.12}$$

This is an example of an *integer linear program,* in which the variables are constrained to be integers. Unfortunately, in contrast to linear programming, finding a solution to an integer linear program is $\mathcal{NP}$-complete. However, this integer programming formulation will still be useful. A very common method for obtaining a relaxation of an optimization problem is to formulate it as an integer linear program, and then to relax the integrality constraints. One obtains a fractional solution and then *rounds* the fractions to integers in a fashion that (hopefully) does not degrade the solution too dramatically.

In our setting, we relax the constraints (35.12) to $x_{ij} \geq 0$. We will also add an additional set of constraints that will ensure that the fractional solutions to this linear program have enough structure to be useful for approximation. Specifically, we disallow any part of a job j being processed on a machine i on which it could not complete in D time in a nonpreemptive schedule. Specifically, we include the following constraints:

$$x_{ij} = 0, \qquad \text{if } p_{ij} \geq D\,. \tag{35.13}$$

(In fact, instead of adding constraints, we can simply remove such variables from the linear program.) As argued above, this constraint is actually implicit in the integer program given by the constraints (35.10)

through (35.12), but was no longer guaranteed when we relaxed the integer constraints. Our new constraints can be seen as a replacement for the constraints (35.8) that we did not need in the integer formulation. Note also that these new constraints are only linear constraints when D is *fixed.* This is why we use an RDP instead of taking the more obvious approach of writing a linear program to minimize D.

To recap, constraints (35.10), (35.11), and (35.13) along with $x_{ij} \geq 0$ constitute a *linear-programming relaxation* of $R||C_{\max}$. Our relaxed decision procedure attempts solve this relaxation, obtaining a solution $\bar{x}_{ij}, 1 \leq i \leq m, 1 \leq j \leq n$. If there is no feasible solution, our RDP can output **no**—nonpreemptive schedule has makespan D or less. If the linear program is feasible, we will give a way to derive an integral assignment of jobs to machines from the fractional solution. Our job is made much easier by the fact, which we cite from the theory of linear programming, that we can find a so-called *basic* solution of this linear program that has at most $n + m$ positive variables. Since these $n + m$ positive variables must be distributed amongst n jobs, there are at most m jobs that are assigned in a fractional fashion to more than one machine.

We may now state our rounding procedure. For each (machine, job) pair (i, j) such that $\bar{x}_{ij} = 1$, we assign job j to machine i. We call the schedule of these jobs S_1. For the remaining at most m jobs, we simply construct a matching of the jobs to machines such that each job is matched to a machine it is already partially assigned to. We schedule each job on the machine to which it is matched, and call the schedule of these jobs S_2.

We defer momentarily the question of whether such a matching exists, and analyze the makespan of the resulting schedule, which is at most the sum of the makespans of S_1 and S_2. Since the x_{ij} form a feasible solution to the relaxed linear program, the makespan of S_1 is at most D. Since S_2 schedules at most one job per machine, and assigns j to i only if $x_{ij} > 0$, meaning $p_{ij} < D$, the makespan of S_2 is at most D (this argument is the reason we had to add constraint (35.13) to our linear program). Thus the overall schedule has length at most $2D$.

The argument that a matching always exists is somewhat complex and can only be sketched here. We create a graph G in which there is one node for each machine and one for each job, and an edge between each machine node i and job node j if $x_{ij} > 0$. We are again helped by the theory of linear programming, as the linear program we solved is a *generalized assignment problem.* As a result, for any basic solution, the structure of G is a forest of trees and 1-*trees*, which are trees with one edge added; for further details see [1]. We need not consider jobs that are already integrally assigned, so for every pair (i, j) such that $x_{ij} = 1$, we remove from G the nodes representing machine i, job j and their mutual edge (note that the constraints imply that this machine and job is not connected to any other machine or job). In the forest that remains, the only leaves are machine nodes, since every remaining job node represents a job that is fractionally assigned by the linear program and thus has an edge to at least two machines.

It is now straightforward to find a matching in G. We first consider the 1-trees, and in particular consider the unique cycle in each 1-tree. The nodes in these cycles alternate between machine nodes and job nodes, with an equal number of each. We arbitrarily choose an orientation of the cycle and assign each job to the machine that follows it in the oriented cycle. We then remove all of the matched nodes from G. What remains is a forest of trees; furthermore, it is possible that for each of these trees we have created at most one new leaf that is a job node. We then root each of the trees in the forest, either at its leaf job node, or, if it does not have one, at an arbitrary vertex. Finally, we assign each job node to one of its children machine nodes in the rooted tree. Each machine node has at most one parent, and thus is assigned at most one job. We have thus successfully matched all job nodes to machine nodes, as we required.

Thus, there exists a 2-relaxed decision procedure for $R||C_{\max}$, and we have the following theorem.

THEOREM 35.16 **[31]** *There is a* 2*-approximation algorithm for* $R||C_{\max}$.

Inferring an Ordering from a Preemptive Schedule for $1|r_j|\Sigma C_j$

In this section and the next we discuss techniques for inferring an ordering of jobs from a relaxation. In this section we consider the problem $1|r_j|\Sigma C_j$. Recall, as mentioned in Section "One Machine," that this problem is $\mathcal{NP}$-hard. However, we can find a good relaxation by the simple expedient of allowing preemption. Specifically, we use $1|r_j, pmtn|\Sigma C_j$ as a relaxation of $1|r_j|\Sigma C_j$. We have seen that $1|r_j, pmtn|\Sigma C_j$ can be solved without linear programming, simply by using the `SRPT` rule. We will make use of this relaxation by extracting from it the order of completion of the jobs in the optimal preemptive schedule, and create a nonpreemptive schedule with the same order of completion.

Our algorithm, which we call `Convert-Preempt-Schedule`, is as follows. We first obtain an optimal preemptive schedule P for the instance in question. We then order the jobs in their order of completion in P; assume by renumbering that $C_1^P \leq \cdots \leq C_n^P$. We schedule the jobs nonpreemptively in the same order. If at some point the next job in the order has not been released, we wait idly until its release date and then schedule it.

THEOREM 35.17 [35] `Convert-Preempt-Schedule` *is a* 2*-approximation algorithm for* $1|r_j|\Sigma C_j$.

PROOF The nonpreemptive schedule N constructed by `Convert-Preempt-Schedule` can be understood as follows. For each job j, consider the point of completion of the last piece of j scheduled in P, insert p_j extra units of time into the schedule at the completion point of j in P (delaying by an additional p_j time the part of the schedule after C_j^P) and then schedule j nonpreemptively in the newly inserted block of length p_j. Then, remove from the schedule all of the time originally allocated to processing job j. Finally, cut out any idle time in the resulting schedule that can be removed without changing the scheduled order of the jobs or violating a release date constraint. The result is exactly the schedule computed by `Convert-Preempt-Schedule`.

Note that the completion of job j is only delayed by insertion of blocks for jobs that finish earlier in P and hence

$$C_j^N \leq C_j^P + \sum_{k \leq j} p_k \, .$$

However, $\Sigma_{k \leq j} p_k \leq C_j^P$, since all of these jobs completed before j in P, and therefore

$$\sum_{j=1}^{n} C_j^N \leq 2 \sum_{j=1}^{n} C_j^P \, .$$

The theorem now follows from the fact that the total completion time of the optimal preemptive schedule is a lower bound on the total completion time of the optimal nonpreemptive schedule.

An Ordering from a Linear Programming Relaxation for $1|r_j, prec|\Sigma w_j C_j$

In this section we generalize the techniques of the previous section, applying them not to a preemptive schedule but instead to a linear programming relaxation of $1|r_j, prec|\Sigma w_j C_j$.

The Relaxation

We begin by describing the linear programming relaxation of our problem. Unlike our previous relaxation, this one does not arise from relaxing the integrality constraints of an integer linear program. Rather, we give several classes of inequalities that would be satisfied by feasible solutions to $1|r_j, prec|\Sigma w_j C_j$. These constraints are necessary but not sufficient to describe a valid solution to the problem.

The linear-programming formulation that we considered for $R||C_{\max}$ assigned jobs to machines but captured no information about the ordering of jobs on a machine. For $1|r_j, prec|\Sigma w_j C_j$ the ordering of jobs on a machine is a critical element of a high-quality solution, so we seek a formulation that can model this. We do this by making time explicit in the formulation: we will have n variables C_j, one for each of the n jobs; C_j will represent the completion time of job j in a schedule.

Consider the following formulation in these C_j variables, solutions to which correspond to optimal solutions of $1|r_j, prec|\Sigma w_j C_j$.

$$\text{minimize} \sum_{j=1}^{n} w_j C_j \tag{35.14}$$

subject to

$$C_j \geq r_j + p_j, \qquad j = 1, \ldots, n\,, \tag{35.15}$$

$$C_k \geq C_j + p_k, \qquad \text{for each pair } j, k \text{ such that } j \prec k\,, \tag{35.16}$$

$$C_k \geq C_j + p_k \quad \text{or} \quad C_j \geq C_k + p_j, \quad \text{for each pair } j, k\,. \tag{35.17}$$

Unfortunately, the last set of constraints are not linear constraints. Instead, we use a class of valid inequalities, introduced by Wolsey [41] and Queyranne [37]. Recall that we denote the entire set of jobs $\{1, \ldots, n\}$ as $\mathcal{J}$, and, for any subset $S \subseteq \mathcal{J}$, we define $p(S) = \Sigma_{j \in S} p_j$ and $p^2(S) = \Sigma_{j \in S} p_j^2$. We claim that for any feasible one-machine schedule (independent of constraints and objective)

$$\sum_{j \in S} p_j C_j \geq \frac{1}{2}\left(p^2(S) + p(S)^2\right), \quad \text{for each } S \subseteq \mathcal{J}\,. \tag{35.18}$$

We show that these inequalities are satisfied by the completion times of any valid schedule for one machine and thus in particular by the completion times of a valid schedule for $1|r_j, prec|\Sigma w_j C_j$.

LEMMA 35.3 [37, 41] Let $C_1, \ldots, C_n$ be the completion times of jobs in any feasible schedule on one machine. Then the C_j must satisfy the inequalities

$$\sum_{j \in S} p_j C_j \geq \frac{1}{2}\left(p(S)^2 + p^2(S)\right) \quad \text{for each } S \subseteq \mathcal{J}\,. \tag{35.19}$$

PROOF We assume that the jobs are indexed so that $C_1 \leq \cdots \leq C_n$. Consider first the case $S = \{1, \ldots, n\}$. Clearly for any job j, $C_j \geq \Sigma_{k=1}^{j} p_k$. Multiplying by p_j and summing over all j, we obtain

$$\sum_{j=1}^{n} p_j C_j \geq \sum_{j=1}^{n} p_j \sum_{k=1}^{j} p_k = \frac{1}{2}\left(p^2(S) + p(S)^2\right)\,.$$

Thus (35.19) holds for $S = \{1, \ldots, n\}$. The general case follows from the fact that for any other set of jobs S, the jobs in S are feasibly scheduled by the schedule of $\{1, \ldots, n\}$—just ignore the other jobs. So we may view S as our entire set of jobs and apply the previous argument.

In the special case of $1||\Sigma w_j C_j$ the constraints (35.19) give an exact characterization of the problem [37, 41]; specifically, any set of C_j that satisfy these constraints must describe the completion times of a feasible schedule, and thus these linear constraints effectively replace the disjunctive constraints (35.17). When we extend the formulation to include constraints (35.15) and (35.16), we no longer have an exact formulation, but rather a linear-programming relaxation of $1|r_j, prec|\Sigma w_j C_j$.

We note that this formulation has an exponential number of constraints; however, it can be solved in polynomial time by the use of the ellipsoid algorithm for linear programming [37, 41]. We also note that in the special case in which we just have release dates, a slightly strengthened version can (remarkably) be solved optimally in $O(n \log n)$ time [8].

Constructing a Schedule from a Solution to the Relaxation

We now show that a solution to this relaxation can be converted efficiently to an approximately optimal schedule. For simplicity, we ignore release dates and consider only $1|prec|\Sigma w_j C_j$. Our approximation algorithm, which we call `Schedule-by-`$\bar{C}_j$, is simple to state. We first solve the linear programming relaxation given by (35.14), (35.16), and (35.18) and call the solution $\bar{C}_1, \ldots, \bar{C}_n$; we renumber the jobs so that $\bar{C}_1 \leq \bar{C}_2 \leq \cdots \leq \bar{C}_n$. We then schedule the jobs in the order $1, \ldots, n$. Since there are no release dates there is no idle time. Note that this ordering of the jobs respects the precedence constraints, because if the $\bar{C}_j$ satisfy (35.14) then $j \prec k$ implies that $\bar{C}_j < \bar{C}_k$.

To analyze `Schedule-by-`$\bar{C}_j$, we begin by understanding why it is not an optimal algorithm. Unfortunately, $\bar{C}_1 \leq \cdots \leq \bar{C}_n$ being a feasible solution to (35.18) does not guarantee that, in the schedule in which job j is designated to complete at time $\bar{C}_j$ (thus defining its start time), at most one job is scheduled at any point in time. More formally, the intervals $(\bar{C}_j - p_j, \bar{C}_j]$, $j = 1, \ldots, n$, are not constrained to be disjoint. If $\bar{C}_1 \leq \cdots \leq \bar{C}_n$ actually corresponded to a valid schedule, then $\bar{C}_j$ would be no less than $\Sigma_{k=1}^{j} p_k$ for all j. We will see that, although the formulation does not guarantee this property, it does yield a relaxation of it, which is sufficient for the purposes of approximation.

THEOREM 35.18 **[17]** `Schedule-by-`$\bar{C}_j$ *is a 2-approximation algorithm for* $1|prec|\Sigma w_j C_j$.

PROOF Since $\bar{C}_j$ optimized a relaxation, we know that $\Sigma w_j \bar{C}_j$ is a lower bound on the true optimum. It therefore suffices to show that our algorithm gets within a factor of 2 of this lower bound. So we let $\tilde{C}_1, \ldots, \tilde{C}_n$ denote the completion times in the schedule found by `Schedule-by-`$\bar{C}_j$, and show that $\Sigma w_j \tilde{C}_j \leq 2\Sigma w_j \bar{C}_j$.

Since the jobs have been renumbered so that $\bar{C}_1 \leq \cdots \leq \bar{C}_n$, taking $S = \{1, \ldots, j\}$ gives

$$\tilde{C}_j = p(S) .$$

We now show that $\bar{C}_j \geq \frac{1}{2} p(S)$. (Again, if the $\bar{C}_j$ were feasible completion times in an actual schedule, we would have $\bar{C}_j \geq p(S)$. This relaxed version of the property is the key to the approximation.)

We use inequality (35.18) for $S = \{1, 2, \ldots, j\}$.

$$\sum_{k=1}^{j} p_k \bar{C}_k \geq \frac{1}{2} \left(p^2(S) + p(S)^2 \right) \geq \frac{1}{2} p(S)^2 . \tag{35.20}$$

Since $\bar{C}_k \leq \bar{C}_j$, for each $k = 1, \ldots, j$, we have

$$\bar{C}_j p(S) = \bar{C}_j \sum_{k=1}^{j} p_k \geq \sum_{k=1}^{j} \bar{C}_k p_k \geq \frac{1}{2} p(S)^2 .$$

Dividing by $p(S)$, we obtain that $\bar{C}_j$ is at least $\frac{1}{2} p(S)$. We therefore see that $\tilde{C}_j \leq 2\bar{C}_j$ and the result follows.

35.6 Polynomial Approximation Schemes Using Enumeration and Rounding

For certain $\mathcal{NP}$-hard scheduling problems there is a limit to our ability to approximate them in polynomial time; for example, Lenstra, Shmoys and Tardos proved that there is no ρ-approximation algorithm, with $\rho < 3/2$, for $R||C_{\max}$ unless $\mathcal{P} = \mathcal{NP}$ [31]. For certain problems, however, we can approximate their optimal solutions arbitrarily closely in polynomial time. In this section we present three *polynomial time approximation schemes (PTAS);* that is, polynomial time algorithms that, for any constant $\rho > 1$, deliver a solution whose objective value is at most ρ times optimal. The running time will depend on ρ—the smaller ρ is, the slower the algorithm will be.

We will present two approaches to the design of such algorithms. The first approach is based on rounding processing times or weights to small integers so that we can apply pseudopolynomial-time algorithms such as that for $1||\Sigma w_j U_j$. A second approach is based on identifying the "important" jobs—those that have the greatest impact on the solution—and processing them separately. In one version, illustrated for $P||C_{\max}$, we round the large jobs so that there are only a constant number of large job sizes, schedule them using dynamic programming, and then schedule the small jobs arbitrarily. In a second version, illustrated for $1|r_j|L_{\max}$, we enumerate all possible schedules for the large jobs, and then fill in the small jobs around them.

From Pseudopolynomial to PTAS: $1||\Sigma w_j U_j$

In Section 35.3, we gave an $O(n\Sigma w_j)$ time algorithm for $1||\Sigma w_j U_j$. Since this gives an algorithm that runs in polynomial time when the weights are polynomial in n, a natural idea is to try to reduce any instance to such a special case. We will scale the weights so that the optimal solution is bounded by a polynomial in n; this will allow us to apply our dynamic programming algorithm to weights of polynomial size.

Assume for now that we know W^*, the value of $\Sigma w_j U_j$ in the optimal schedule. Multiply every weight by $n/(\epsilon W^*)$; now the optimal $\Sigma w_j U_j$ becomes n/ϵ. Clearly, a schedule with $\Sigma w_j U_j$ within a multiplicative $(1+\epsilon)$-factor of optimum under these weights is also within a multiplicative $(1+\epsilon)$-factor of optimum under the original weights. Thus, it suffices to find a schedule with $\Sigma w_j U_j$ at most $(1+\epsilon)n/\epsilon = n/\epsilon + n$ under the new weights.

To do so, increase the weight of every job to the next larger integer. This increases the weight of each job by at most 1 and thus, for any schedule, increases $\Sigma w_j U_j$ by at most n. Under these new weights, $\Sigma w_j U_j$ for the original optimal schedule is now at most $n/\epsilon + n$, so the optimal schedule under these integral weights has $\Sigma w_j U_j \leq n/\epsilon + n$. Since all weights are integers, we can apply the dynamic programming algorithm of Section 35.3 to find an optimal schedule for the rounded instance. Since we only rounded up, the same schedule under the original weights can only have a smaller $\Sigma w_j U_j$. Thus, we find a schedule with weight at most $n/\epsilon + n$ in the (scaled) original weights, i.e., a $(1+\epsilon)$ times optimum schedule.

The running time of our dynamic program is proportional to n times the sum of the (new) weights. This might be a problem, since the weights can be arbitrarily large. However, any job with new weight exceeding $n/\epsilon + n$ *must* be scheduled before its deadline. We therefore identify all such jobs, and modify our dynamic program: T_{wj} becomes the minimum time needed to complete all these jobs that must complete by their deadlines plus other jobs from $1, \ldots, j$ of total weight w. The dynamic programming argument goes through unchanged, but now we consider only jobs of weight $O(n/\epsilon)$. It follows that the largest value of w that we consider is $O(n^2/\epsilon)$, which means that the total running time is $O(n^3/\epsilon)$.

It remains to deal with our assumption that we know W^*. One approach is to use the RDP scheme that performs a binary search on W^*. Of course, we do not expect to arrive at W^* exactly, but note that an estimate will suffice. If we test a value W' with $W^*/\alpha \leq W' \leq W^*$, the analysis above will go through with the running time increased by a factor of α. So we can wait for the RDP binary search to bring us within (say) a constant factor of W^* and then solve the problem.

Of course, if the weights w are extremely large, our binary search could go through many iterations before finding a good value of W'. An elegant trick lets us avoid this problem. We will solve the following problem: find a schedule that minimizes the weight of the maximum-weight late job. The value of this schedule, W', is clearly a lower bound on W^*, as all schedules that minimize $\Sigma w_j U_j$ must have a late job of weight at least W'. Further, W^* is at most nW', since the schedule returned must have at most n late jobs each of which has weight at most W'. Hence our value W' is within a factor of n of optimal. Thus $O(\log n)$ binary search steps suffice to bring us within a constant factor of W^*.

To compute W', we formulate a $1||f_{\max}$ problem. For each job j,

$$f_j(C_j) = \begin{cases} w_j & \text{if } C_j > d_j \\ 0 & \text{if } C_j \leq d_j \end{cases}.$$

This will compute the schedule that minimizes the weight of the maximum weight late job. By the results in the section on "One Machine," we know we can compute this exactly in polynomial time.

THEOREM 35.19 *There exists a $O(n^3(\log n)/\epsilon)$-time $(1+\epsilon)$-approximation algorithm for $1||\Sigma w_j U_j$*

Rounding and Dynamic Programming for $P||C_{\max}$

We now return to the problem of $P||C_{\max}$. Recall that in Lemma 35.2 we gave a polynomial-time algorithm for a special case in which there are a constant number of different job sizes. For the general case, we will focus mainly on the big jobs. We will round and scale these jobs so that there is at most a constant number of sizes of big jobs, and apply the dynamic programming algorithm of Section 35.3 to these rounded jobs. We then finish up by scheduling the small jobs greedily. By the definition of big and small, the overall contribution of the small jobs to the makespan will be negligible.

We will give a $(1+\epsilon)$-RDP for this problem that can be transformed as before into a $(1+\epsilon)$-approximation algorithm. We therefore assume that we have a target optimum schedule length T, We also assume for the rest of this section that ϵT, $\epsilon^2 T$, ϵ^{-1} and ϵ^{-2} are integers. The proofs can easily be modified to handle the case of arbitrary rational numbers.

We first show how to handle the large jobs.

LEMMA 35.4 [18] Let I be an instance of $P||C_{\max}$, let T be a target schedule length, and $\epsilon > 0$. Assume that all $p_j \geq \epsilon T$. Then, for this case, there is a $(1+\epsilon)$-RDP for $P||C_{\max}$.

PROOF We assume $T \geq \max_j p_j$, since otherwise we immediately know that the problem is infeasible. Form instance I' from I with processing times p'_j by rounding each p_j down to an integer multiple of $\epsilon^2 T$. This creates an instance in which

1. $0 \leq p_j - p'_j \leq \epsilon^2 T$
2. There are at most $\frac{T}{\epsilon^2 T} = \frac{1}{\epsilon^2}$ different job sizes,
3. In any feasible schedule, each machine has at most $\frac{T}{\epsilon T} = \frac{1}{\epsilon}$ jobs.

Thus, we can apply Lemma 35.2 to instance I' and obtain an optimal solution to this scheduling problem; let its makespan be D. If $D > T$, then we know that there is no schedule of length $\leq T$ for I, since job sizes in I' are no greater than those in I. In this case we can answer "no schedule of length $\leq T$ exists." If $D \leq T$, then we will answer "there exists a schedule of length $\leq (1+\epsilon)T$." We now show that this answer will be correct. We simply take our schedule for I' and replace the rounded jobs with the original jobs from I. By 1 and 3 in the above list, we add at most $\epsilon^2 T$ to the processing time of each job, and since

there are at most $\frac{1}{\epsilon}$ jobs per machine, we add at most ϵT to the processing time per machine. Thus we can create a schedule with makespan at most $T + \epsilon T = (1 + \epsilon)T$.

We now give the complete algorithm. The idea will be to remove the "small" jobs, use Lemma 35.4 to schedule the remaining jobs, and then add the small jobs back greedily. Given input I_0, target schedule length T, and $\rho = 1 + \epsilon > 1$, we execute the following algorithm.

```
Let R be the set of jobs with p_j ≤ εT. Let I = I_0 − R
Apply Lemma 35.4 to I, T, and ρ.
If this algorithm returns no,
(†)   then output "no schedule of length ≤ T exists."
      else
          for each job j in R
                if there is a machine i with load ≤ T,
                      then add job j to machine i
(*)                   else return "no schedule of length ≤ T exists"
          return "yes, a schedule of length ≤ ρT exists"
```

THEOREM 35.20 *[18] The algorithm above is a ρ-relaxed decision procedure for* $P||C_{\max}$.

PROOF If the algorithm outputs "yes, a schedule of length $\leq \rho T$ exists," then it has constructed such a schedule, and is clearly correct. If the algorithm outputs "no schedule of length $\leq T$ exists" on line (†), then it is because no schedule of length T exists for instance I. But instance I is a subset of the original jobs and so if no schedule exists for I, then no schedule exists for I_0, and the output is correct. If the algorithm outputs "no schedule of length $\leq T$ exists" on line (*), then at this point in the algorithm, every machine must have more than T units of processing on it. Thus, we have that $\Sigma_j p_j > mT$, which means that no schedule of length $\leq T$ exists.

The running time is dominated by the dynamic programming in Lemma 35.2. It is polynomial in n, but the exponent is a polynomial in $1/\epsilon$. While for ρ very close to 1, the running time is prohibitively large, for larger, fixed values of ρ, a modified algorithm yields good schedules with near-linear running times; see [18] for details.

Exhaustive Enumeration for $1|r_j|L_{\max}$

We now turn to the problem of minimizing the maximum lateness in the presence of release dates. Recall from Section 35.2 that without release dates `EDD` is an exact algorithm for this problem. Once we add release dates the problem becomes $\mathcal{NP}$-hard. As we think about approximation algorithms, we come upon an immediate obstacle, namely that the objective function can be 0 or even negative, and hence a solution of value at most $\rho C^*_{\max}$ is clearly impossible. In order to get around this, we must guarantee that the value of the objective function is positive. One simple way to do so is to decrease all the d_j's uniformly by some value δ. This decreases the objective value by exactly δ and does not change the structure of the optimal solution. In particular, if we pick δ large enough so that all the d_j's are negative, we are guaranteed that $L_{\max}$ is positive.

Forcing d_j to be negative is somewhat artificial and so we do not concentrate on this interpretation (note that by taking δ arbitrarily large, we can make any algorithm into an arbitrarily good approximation algorithm). We instead use an equivalent but natural *delivery time* formulation which, in addition to

modeling a number of applications, is a key subroutine in computational approaches to shop scheduling problems [29]. In this formulation, each job, in addition to having a release date r_j and a processing time p_j, has a *delivery time* q_j. A delivery time is an amount of time that must elapse between the completion time of a job on a machine and when it is truly considered finished. Our objective is now to minimize $\max_j\{C_j + q_j\}$. To see the connection to our original problem, note that by setting $q_j = -d_j$ (recall that we made all d_j negative, so all q_j are positive), the delivery-time problem is equivalent to minimizing maximum lateness, and in fact we will overload L_j and define it as $C_j + q_j$.

Jackson's Rule is a 2-Approximation Algorithm

In the delivery-time model, `EDD` translates to Longest Delivery Time First. This is often referred to as *Jackson's rule.* [23]. Let $L^*_{\max}$ be the optimum maximum lateness. The following two lower bounds for this problem are the easily derived analogs of (35.1) and (35.2):

$$L^*_{\max} \geq \sum_j p_j \ , \tag{35.21}$$

$$L^*_{\max} \geq r_j + p_j + q_j \text{ for all } j \ . \tag{35.22}$$

LEMMA 35.5 Jackson's Rule is a 2-approximation algorithm for the delivery time version of $1|r_j|L_{\max}$.

PROOF Let j' be a job for which $L_{j'} = L_{\max}$. Since Jackson's rule creates a schedule with no unforced idle time, we know that there is no idle time between time $r_{j'}$ and $C_{j'}$. Let J' be the set of jobs that run between $r_{j'}$ and $C_{j'}$. Then

$$\begin{aligned} L_{j'} &= C_{j'} + q_{j'} && (35.23)\\ &= r_{j'} + \sum_{j\in J'} p_j + q_{j'} && (35.24)\\ &\leq \left(r_{j'} + q_{j'}\right) + \sum_j p_j && (35.25)\\ &= 2L^*_{\max} \ , && (35.26) \end{aligned}$$

where the last line follows by applying the two lower bounds (35.21) and (35.22).

A PTAS Using Enumeration

The presentation of this section follows that of Hall [16]. The original approximation scheme for this problem is due to Hall and Shmoys [15].

To obtain an algorithm with an improved performance guarantee, we need to look more carefully at when Jackson's rule can go wrong. Let s_j be the starting time of job j, let $r_{\min}(S) = \min_{j\in S} r_j$, let $q_{\min}(S) = \min_{j\in S} q_j$, and recall that $p(S) = \Sigma_{j\in S} p_j$. Then clearly, for any $S \subseteq J$

$$L^*_{\max} \geq r_{\min}(S) + p(S) + q_{\min}(S) \ . \tag{35.27}$$

Now consider a job j' for which $L_{j'} = L_{\max}$. Let t_i be the latest time before $s_{j'}$ at which the machine is idle, and let a be the job that runs immediately after this idle time. Let S be the set of jobs that run between s_a and $C_{j'}$. We call S a *critical section.* Because of the idle time immediately before s_a, we know that for all $j \in S$, $r_j \geq r_a$. In other words we have a set of jobs, all of which were released after time r_a, and which end with the job that achieves $L_{\max}$. Now if for all $j \in S$ $q_j \geq q_{j'}$, then we claim that $Ł_{j'} = L^*_{\max}$. This follows from the fact that

$$L_{\max} = L_{j'} = r_a + p(S) + q_{j'} = r_{\min}(S) + p(S) + q_{\min}(S) \ ,$$

and that the right-hand side, by (35.27), is also a lower bound on $L^*_{\max}$. So, as long as, in a critical section, the job with the shortest delivery time is last, we have an optimal schedule. Thus, if Jackson's rule is not optimal, there must be a job b in the critical section which has $q_b < q_{j'}$. We call the latest-scheduled job in the critical section with $q_b < q_{j'}$ an *interference job.* The following lemma shows the relationship between the interference job and its effect on $L_{\max}$.

LEMMA 35.6 Let b be an interference job in a schedule created by Jackson's rule. Then $L_{\max} < L^*_{\max} + p_b$.

Thus, if interference jobs have small processing times, Jackson's rule does very well. To make sure that this is the case, we will handle the large jobs separately, to ensure that they are not interference jobs, and then use Jackson's rule on the remaining jobs.

Let us assume for now that we know the optimal schedule for instance I. Let s^*_j be the starting time of job j in the optimal schedule, and let $\delta > 0$ be a parameter to be chosen later. Partition the jobs into small jobs $S = \{j : p_j < \delta\}$ and big jobs $B = \{j : p_j \geq \delta\}$. We create instance $\tilde{I}$ as follows: if $j \in S$, then $\tilde{r}_j = r_j$, $\tilde{p}_j = p_j$, and $\tilde{q}_j = q_j$, otherwise, $\tilde{r}_j = s^*_j$, $\tilde{p}_j = p_j$, and $\tilde{q}_j = L^*_{\max}(I) - p_j - s^*_j$. Instance $\tilde{I}$ is no easier than instance I, since we have not decreased any release dates or delivery times. Yet, the optimal schedule for I remains an optimal schedule for $\tilde{I}$, by construction. In $\tilde{I}$ we have given the large jobs a release date equal to their optimal starting time, and a delivery time that is equal to the schedule length minus their completion time, and hence have constrained the large jobs to run exactly when they would run in the optimal schedule for instance I. Thus, in an optimal schedule for $\tilde{I}$, the big jobs run at exactly time $\tilde{r}_j$ and have $L_j = \tilde{r}_j + \tilde{p}_j + \tilde{q}_j = L^*_{\max}$.

Now we claim that if we run Jackson's rule on $\tilde{I}$, the big jobs will not be interference jobs.

LEMMA 35.7 If we run Jackson's rule on $\tilde{I}$, no job $b \in B$ will be an interference job.

PROOF Assume that some job $b \in B$ is an interference job. As above, define the critical section, and jobs a and j'. Since b is an interference job, we know that $\tilde{q}_{j'} > \tilde{q}_b$ and $\tilde{r}_{j'} > \tilde{r}_b$. We also know that $\tilde{r}_b = s^*_b$, and so j' must run after b in the optimal schedule for I. Applying (35.27) to the set consisting of jobs b and j', we get that

$$L^*_{\max} \geq \tilde{r}_b + \tilde{p}_b + \tilde{p}_{j'} + \tilde{q}_{j'} \geq r_b + p_b + p_{j'} + \tilde{q}_b = L^*_{\max} + p_{j'} ,$$

which is a contradiction.

So if we run Jackson's rule on $\tilde{I}$, we get a schedule whose length is at most $L^*_{\max}(I) + \delta$. Choosing $\delta = \epsilon \Sigma_j p_j$, and recalling that $L^*_{\max} \geq \Sigma p_j$, we get a schedule of length at most $(1+\epsilon)L^*_{\max}$. Further, there can be at most $\Sigma_j p_j / (\epsilon \Sigma_j p_j) = 1/\epsilon$ big jobs. The only problem is that we don't know $\tilde{I}$.

We now argue that it is not necessary to know $\tilde{I}$. First, observe that the set of big jobs is purely a function of the input, and ϵ. Now, if we knew the starting times of the big jobs in the optimal schedule for I, we would know $\tilde{I}$, and could run Jackson's rule on the job in S, inserting the big jobs at the appropriate time. This implies a numbering of the big jobs, i.e., each big job j_i is, for some k, the kth job in the schedule for $\tilde{I}$. Thus, we really only need to know k, and not the starting time for job j_i. Thus we just enumerate all possible numberings for the big jobs. There are $n^{1/\epsilon}$ such numberings. Given a numbering, we can run Jackson's rule on the small jobs, and insert the big jobs at the appropriate places in $O(n \log n)$ time, and thus we get an algorithm that in $O(n^{1+1/\epsilon} \log n)$ time finds a schedule with $L_{\max} \leq (1+\epsilon)L^*_{\max}$.

35.7 Research Issues and Summary

In this chapter we have surveyed some of the basic techniques for deterministic scheduling. Scheduling is an old and therefore mature field, but important opportunities for research contributions remain. In addition to some of the outstanding open questions (see the survey by Lawler et al. [29]) it is our feeling that the most meaningful research contributions will be either new and innovative techniques for attacking old problems or new problem definitions that model more realistic applications.

There are other schools of approach to the design of algorithms for scheduling, such as those relying on techniques from artificial intelligence or from computational optimization. It will be quite valuable to forge stronger connections between these different approaches to solving scheduling problems.

35.8 Defining Terms

n**:** Number of jobs.

m**:** Number of machines.

p_j**:** Processing time of job j.

C_j^S**:** Completion time of job j in schedule S.

w_j**:** Weight of job j.

r_j**:** Release date of job j; job j is unavailable for processing before time r_j.

d_j**:** Due date of job j.

$L_j := C_j - d_j$ the lateness of job j.

U_j**:** 1 is job j is scheduled by d_j and 0 otherwise.

$\alpha|\beta|\gamma$**:** Denotes scheduling problem with machine environment α, optimality criterion γ, and side characteristics and constraints denoted by β.

Machine environments:

- 1: One machine.
- P: Parallel identical machines.
- Q: Parallel machines of different speeds.
- R: Parallel unrelated machines.
- O: Open shop.
- F: Flow shop.
- J: Job shop.

Possible characteristics and constraints:

- $pmtn$: Job preemption allowed.
- r_j: Jobs have nontrivial release dates.
- $prec$: Jobs are precedence-constrained.

Optimality criteria:

- ΣC_j: Average (sum) of completion times.
- $\Sigma w_j C_j$: Weighted average (sum) of completion times.
- $C_{\max}$: Makespan (schedule length).
- $L_{\max}$: Maximum lateness over all jobs.
- ΣU_j: Number of on-time jobs.
- $\Sigma w_j U_j$: Weighted number of on-time jobs.

Further Information

We conclude by reminding the reader what this chapter is not. In no way is this chapter a comprehensive survey of even the most basic and classical results in scheduling theory, and it is certainly not an up-to-date survey on the field. It also essentially entirely ignores "nontraditional" models, and does not touch on

stochastic scheduling or on any of the other approaches to scheduling and resource allocation. The reader interested in a comprehensive survey of the field should consult the textbook by Pinedo [34] and the survey by Lawler et al. [29]. These sources provide pointers to a number of other references. In addition, we also recommend an annotated bibliography by Hoogeveen et al. that contains information on recent results in scheduling theory [20], the surveys by Queyranne and Schulz on polyhedral formulations [36], by Hall on approximation algorithms [16], and by Sgall on online scheduling [38]. Research on deterministic scheduling theory is published in many journals; for example see *Mathematics of Operations Research, Operations Research, SIAM Journal on Computing,* and *Journal of the ACM.*

Artificial Intelligence Search Algorithms[1]

Richard E. Korf
University of California, Los Angeles

36.1 Introduction

Search is a universal problem-solving mechanism in artificial intelligence (AI). In AI problems, the sequence of steps required for solution of a problem are not known *a priori,* but often must be determined by a systematic trial-and-error exploration of alternatives. The problems that have been addressed by AI

[1]This work was supported in part by NSF Grant IRI-9619447, and a grant from Rockwell International.

search algorithms fall into three general classes: **single-agent pathfinding problems, two-player games,** and **constraint-satisfaction problems.**

Classic examples in the AI literature of pathfinding problems are the sliding-tile puzzles, including the 3×3 Eight Puzzle (see Fig. 36.1) and its larger relatives the 4×4 Fifteen Puzzle, and 5×5 Twenty-Four Puzzle. The Eight Puzzle consists of a 3×3 square frame containing eight numbered square tiles, and an empty position called the blank. The legal operators are to slide any tile that is horizontally or vertically adjacent to the blank into the blank position. The problem is to rearrange the tiles from some random initial configuration into a particular desired goal configuration. The sliding-tile puzzles are common testbeds for research in AI search algorithms because they are very simple to represent and manipulate, yet finding optimal solutions to the $N \times N$ generalization of the sliding-tile puzzles is NP-complete [43]. Other well-known examples of single-agent pathfinding problems include Rubik's Cube and theorem proving. Real-world examples include the Travelling Salesman Problem, vehicle navigation, and the wiring of VLSI circuits. In each case, the task is to find a sequence of operations that map an initial state to a goal state.

A second class of search problems include two-player perfect-information games, such as chess, checkers, and Othello. The third category is constraint-satisfaction problems, such as the Eight Queens Problem. The task is to place eight queens on an 8×8 chessboard, such that no two queens are on the same row, column or diagonal. Real-world examples of constraint-satisfaction problems are ubiquitous, including planning and scheduling applications.

We begin by describing the problem-space model on which search algorithms are based. Brute-force searches are then considered including breadth-first, uniform-cost, depth-first, depth-first iterative-deepening, and bidirectional search. Next, various heuristic searches are examined including pure heuristic search, the A* algorithm, iterative-deepening-A*, depth-first branch-and-bound, the heuristic path algorithm, and recursive best-first search. We then consider single-agent algorithms that interleave search and execution, including minimin lookahead search, real-time-A*, and learning-real-time-A*. Next, we consider two-player game searches, including minimax and alpha-beta pruning. Finally, we examine constraint-satisfaction algorithms, such as backtracking, constraint recording, and heuristic repair. The efficiency of these algorithms, in terms of the costs of the solutions they generate, the amount of time the algorithms take to execute, and the amount of computer memory they require are of central concern throughout. Since search is a universal problem-solving method, what limits its applicability is the efficiency with which it can be performed.

36.2 Problem Space Model

A *problem space* is the environment in which a search takes place [34]. A problem space consists of a set of *states* of the problem, and a set of *operators* that change the state. For example, in the Eight Puzzle, the states are the different possible permutations of the tiles, and the operators slide a tile into the blank position. A *problem instance* is a problem space together with an initial state and a goal state. In the case of the Eight Puzzle, the initial state would be whatever initial permutation the puzzle starts out in, and the goal state is a particular desired permutation. The problem-solving task is to find a sequence of operators that map the initial state to a goal state. In the Eight Puzzle the goal state is given explicitly. In other problems, such as the Eight Queens Problem, the goal state is not given explicitly, but rather implicitly specified by certain properties that must be satisfied by a goal state.

A **problem-space graph** is often used to represent a problem space. The states of the space are represented by **nodes** of the graph, and the operators by **edges** between nodes. Edges may be undirected or directed, depending on whether their corresponding operators are reversible or not. The task in a single-agent path-finding problem is to find a path in the graph from the initial node to a goal node. Figure 36.1 shows a small part of the Eight Puzzle problem-space graph.

Although most problem spaces correspond to graphs with more than one path between a pair of nodes, for simplicity they are often represented as trees, where the initial state is the root of the tree. The cost

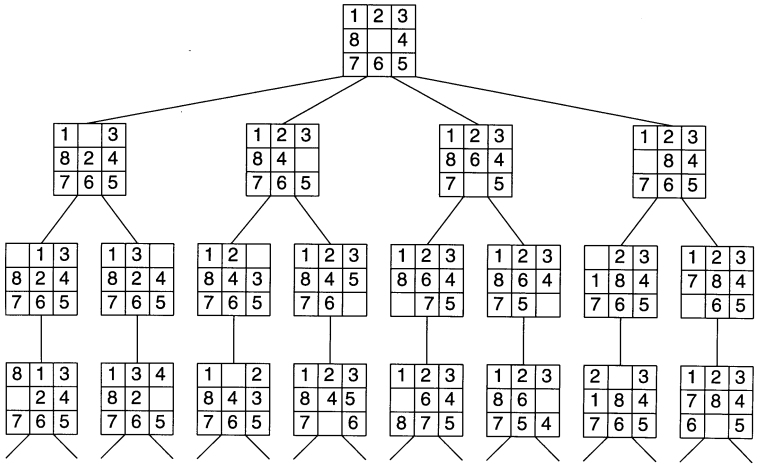

FIGURE 36.1 Eight puzzle search tree fragment.

of this simplification is that any state that can be reached by two different paths will be represented by duplicate nodes, increasing the size of the tree. The benefit of a tree is that the absence of cycles greatly simplifies many search algorithms. In this survey, we will restrict our attention to trees, but there exist graph versions of most of the algorithms we describe as well.

One feature that distinguishes AI search algorithms from other graph-searching algorithms is the size of the graphs involved. For example, the entire chess graph is estimated to contain over 10^{40} nodes. Even a simple problem like the Twenty-Four Puzzle contains almost 10^{25} nodes. As a result, the problem-space graphs of AI problems are never represented explicitly by listing each state, but rather are implicitly represented by specifying an initial state and a set of operators to generate new states from existing states. Furthermore, the size of an AI problem is rarely expressed as the number of nodes in its problem-space graph. Rather, the two parameters of a search tree that determine the efficiency of various search algorithms are its *branching factor* and its *solution depth.* The branching factor is the average number of children of a given node. For example, in the Eight Puzzle the average branching factor is $\sqrt{3}$, or about 1.732. The solution depth of a problem instance is the length of a shortest path from the initial state to a goal state, or the length of a shortest sequence of operators that solves the problem. If the goal were in the bottom row of Fig. 36.1, the depth of the problem instance represented by the initial state at the root would be three moves.

36.3 Brute-Force Search

The most general search algorithms are *brute-force* searches, since they do not require any domain-specific knowledge. All that is required for a brute-force search is a state description, a set of legal operators, an initial state, and a description of the goal state. The most important brute-force techniques are breadth-first, uniform-cost, depth-first, depth-first iterative-deepening, and bidirectional search. In the descriptions of the algorithms below, to *generate* a node means to create the data structure corresponding to that node, whereas to *expand* a node means to generate all the children of that node.

Breadth-First Search

Breadth-first search expands nodes in order of their distance from the root, generating one level of the tree at a time until a solution is found (see Fig. 36.2). It is most easily implemented by maintaining a queue of nodes, initially containing just the root, and always removing the node at the head of the queue, expanding it, and adding its children to the tail of the queue.

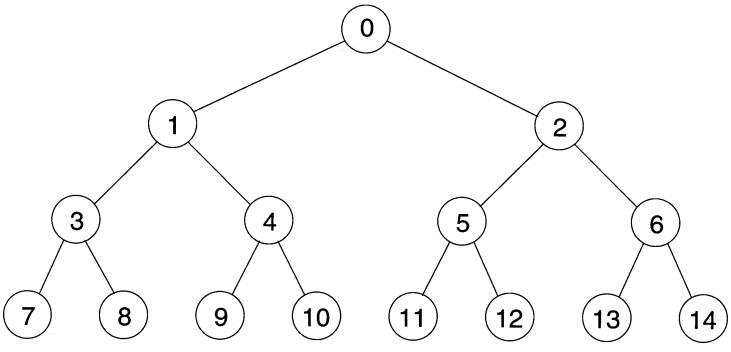

FIGURE 36.2 Order of node generation for breadth-first search.

Since it never generates a node in the tree until all the nodes at shallower levels have been generated, breadth-first search always finds a shortest path to a goal. Since each node can be generated in constant time, the amount of time used by breadth-first search is proportional to the number of nodes generated, which is a function of the branching factor b and the solution depth d. Since the number of nodes at level d is b^d, the total number of nodes generated in the worst case is $b + b^2 + b^3 + \cdots + b^d$, which is $O(b^d)$, the asymptotic time complexity of breadth-first search.

The main drawback of breadth-first search is its memory requirement. Since each level of the tree must be saved in order to generate the next level, and the amount of memory is proportional to the number of nodes stored, the space complexity of breadth-first search is also $O(b^d)$. As a result, breadth-first search is severely space-bound in practice, and will exhaust the memory available on typical computers in a matter of minutes.

Uniform-Cost Search

If all edges do not have the same cost, then breadth-first search generalizes to *uniform-cost search.* Instead of expanding nodes in order of their depth from the root, uniform-cost search expands nodes in order of their cost from the root. At each step, the next node n to be expanded is one whose cost $g(n)$ is lowest, where $g(n)$ is the sum of the edge costs from the root to node n. The nodes are stored in a priority queue. This algorithm is also known as Dijkstra's single-source shortest-path algorithm [6].

Whenever a node is chosen for expansion by uniform-cost search, a lowest-cost path to that node has been found. The worst-case time complexity of uniform-cost search is $O(b^{c/m})$, where c is the cost of an optimal solution, and m is the minimum edge cost. Unfortunately, it also suffers the same memory limitation as breadth-first search.

Depth-First Search

Depth-first search remedies the space limitation of breadth-first search by always generating next a child of the deepest unexpanded node (see Fig. 36.3). Both algorithms can be implemented using a list of unexpanded nodes, with the difference that breadth-first search manages the list as a first-in first-out queue, whereas depth-first search treats the list as a last-in first-out stack. More commonly, depth-first search is implemented recursively, with the recursion stack taking the place of an explicit node stack.

The advantage of depth-first search is that its space requirement is only linear with respect to the search depth, as opposed to exponential for breadth-first search. The reason is that the algorithm only needs to store a stack of nodes on the path from the root to the current node. The time complexity of a depth-first search to depth d is $O(b^d)$, since it generates the same set of nodes as breadth-first search, but simply in a different order. Thus, as a practical matter, depth-first search is time-limited rather than space-limited.

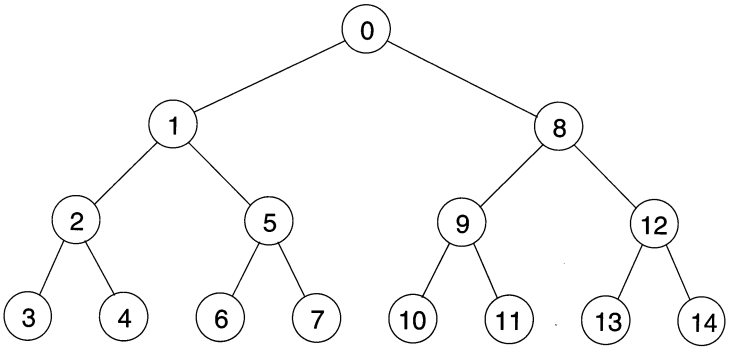

FIGURE 36.3 Order of node generation for depth-first search.

The disadvantage of depth-first search is that it may not terminate on an infinite tree, but simply go down the left-most path forever. Even a finite graph can generate an infinite tree. The usual solution to this problem is to impose a cutoff depth on the search. Although the ideal cutoff is the solution depth d, this value is rarely known in advance of actually solving the problem. If the chosen cutoff depth is less than d, the algorithm will fail to find a solution, whereas if the cutoff depth is greater than d, a large price is paid in execution time, and the first solution found may not be an optimal one.

Depth-First Iterative-Deepening

Depth-first iterative-deepening (DFID) combines the best features of breadth-first and depth-first search [17, 48]. DFID first performs a depth-first search to depth one, then starts over, executing a complete depth-first search to depth two, and continues to run depth-first searches to successively greater depths, until a solution is found (see Fig. 36.4).

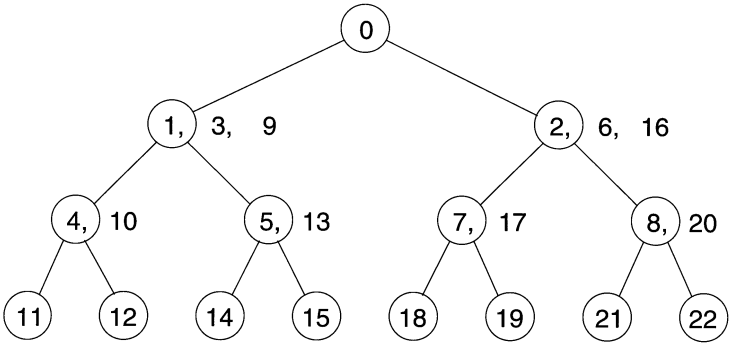

FIGURE 36.4 Order of node generation for depth-first iterative-deepening search.

Since it never generates a node until all shallower nodes have been generated, the first solution found by DFID is guaranteed to be along a shortest path. Furthermore, since at any given point it is executing a depth-first search, saving only a stack of nodes, and the algorithm terminates when it finds a solution at depth d, the space complexity of DFID is only $O(d)$.

Although it appears that DFID wastes a great deal of time in the iterations prior to the one that finds a solution, this extra work is usually insignificant. To see this, note that the number of nodes at depth d is b^d, and each of these nodes are generated once, during the final iteration. The number of nodes at depth $d-1$ is b^{d-1}, and each of these are generated twice, once during the final iteration, and once during the

penultimate iteration. In general, the number of nodes generated by DFID is $b^d + 2b^{d-1} + 3b^{d-2} + \cdots + db$. This is asymptotically $O(b^d)$ if b is greater than one, since for large values of d the lower order terms become insignificant. In other words, most of the work goes into the final iteration, and the cost of the previous iterations is relatively small. The ratio of the number of nodes generated by DFID to those generated by breadth-first search on a tree is approximately $b/(b-1)$. In fact, DFID is asymptotically optimal in terms of time and space among all brute-force shortest-path algorithms on a tree [17].

If the edge costs differ from one another, then one can run an iterative deepening version of uniform-cost search, where the depth cutoff is replaced by a cutoff on the $g(n)$ cost of a node. At the end of each iteration, the threshold for the next iteration is set to the minimum cost of all nodes generated on the previous iteration whose cost exceeded the previous threshold.

On a graph with cycles, however, breadth-first search may be much more efficient than any depth-first search. The reason is that a breadth-first search can check for duplicate nodes whereas a depth-first search cannot. Thus, the complexity of breadth-first search grows only as the number of nodes at a given depth, while the complexity of depth-first search depends on the number of paths of a given length. For example, in a square grid, the number of nodes within a radius r of the origin is $O(r^2)$, whereas the number of paths of length r is $O(3^r)$, since there are three children of every node, not counting its parent. Thus, in a graph with a large number of very short cycles, breadth-first search is preferable to depth-first search, if sufficient memory is available. For two approaches to the problem of pruning duplicate nodes in depth-first search, see [49] and [7].

Bidirectional Search

Bidirectional search is a brute-force algorithm that requires an explicit goal state instead of simply a test for a goal condition [40]. The main idea is to simultaneously search forward from the initial state, and backward from the goal state, until the two search frontiers meet. The path from the initial state is then concatenated with the inverse of the path from the goal state to form the complete solution path.

Bidirectional search still guarantees optimal solutions. Assuming that the comparisons for identifying a common state between the two frontiers can be done in constant time per node, by hashing for example, the time complexity of bidirectional search is $O(b^{d/2})$ since each search need only proceed to half the solution depth. Since at least one of the searches must be breadth-first in order to find a common state, the space complexity of bidirectional search is also $O(b^{d/2})$. As a result, bidirectional search is space bound in practice.

Combinatorial Explosion

The problem with all brute-force search algorithms is that their time complexities grow exponentially with problem size. This is called *combinatorial explosion,* and as a result, the size of problems that can be solved with these techniques is quite limited. For example, while the Eight Puzzle, with about 10^5 states, is easily solved by brute-force search, the Fifteen Puzzle contains over 10^{13} states, and hence cannot be solved with brute-force techniques on current machines. Faster machines will not have a significant impact on this problem, since the 5×5 Twenty-Four Puzzle contains almost 10^{25} states, for example.

36.4 Heuristic Search

In order to solve larger problems, domain-specific knowledge must be added to improve search efficiency. In AI, *heuristic search* has a general meaning, and a more specialized technical meaning. In a general sense, the term *heuristic* is used for any advice that is often effective, but is not guaranteed to work in every case. Within the heuristic search literature, however, the term heuristic usually refers to the special case of a *heuristic evaluation function.*

Heuristic Evaluation Functions

In a single-agent path-finding problem, a heuristic evaluation function estimates the cost of an optimal path between a pair of states. For example, Euclidean or airline distance is an estimate of the highway distance between a pair of locations. A common heuristic function for the sliding-tile puzzles is called Manhattan distance. It is computed by counting the number of moves along the grid that each tile is displaced from its goal position, and summing these values over all tiles. For a fixed goal state, a heuristic evaluation is a function of a node, $h(n)$, that estimates the distance from node n to the given goal state.

The key properties of a heuristic evaluation function are that it estimate actual cost, and that it be inexpensive to compute. For example, the Euclidean distance between a pair of points can be computed in constant time. The Manhattan distance between a pair of states can be computed in time proportional to the number of tiles. In addition, most heuristic functions are derived from relaxations of the original problem, and hence are lower bounds on actual cost, a property referred to as *admissibility.* For example, airline distance is a lower bound on road distance between two points, since the shortest path between a pair of points is a straight line. Similarly, Manhattan distance is a lower bound on the actual number of moves necessary to solve an instance of a sliding-tile puzzle, since every tile must move at least as many times as its distance in grid units from its goal position.

A number of algorithms make use of heuristic functions, including pure heuristic search, the A* algorithm, iterative-deepening-A*, depth-first branch-and-bound, and the heuristic path algorithm. In addition, heuristic information can be employed in bidirectional search as well.

Pure Heuristic Search

The simplest of these algorithms, pure heuristic search, expands nodes in order of their heuristic values $h(n)$ [9]. It maintains a *Closed list* of those nodes that have already been expanded, and an *Open list* of those nodes that have been generated but not yet expanded. The algorithm begins with just the initial state on the Open list. At each cycle, a node on the Open list with the minimum $h(n)$ value is expanded, generating all of its children, and is placed on the Closed list. The heuristic function is applied to the children, and they are placed on the Open list in order of their heuristic values. The algorithm continues until a goal state is chosen for expansion.

In a graph with cycles, multiple paths will be found to the same node, and the first path found may not be the shortest. When a shorter path is found to an Open node, the shorter path is saved and the longer one discarded. When a shorter path to a Closed node is found, the node is moved to Open, and the shorter path is associated with it. The main drawback of pure heuristic search is that since it ignores the cost of the path so far to node n, it does not find optimal solutions.

Breadth-first search, uniform-cost search, and pure heuristic search are all special cases of a more general algorithm called *best-first search.* In each cycle of a best-first search, the node that is best according to some cost function is chosen for expansion. These best-first algorithms differ only in their cost functions: the depth of node n for breadth-first search, $g(n)$ for uniform-cost search, and $h(n)$ for pure heuristic search.

A* Algorithm

The *A* algorithm* [13] combines features of uniform-cost search and pure heuristic search to efficiently compute optimal solutions. A* is a best-first search in which the cost associated with a node is $f(n) = g(n) + h(n)$, where $g(n)$ is the cost of the path from the initial state to node n, and $h(n)$ is the heuristic estimate of the cost of a path from node n to a goal. Thus, $f(n)$ estimates the lowest total cost of any solution path going through node n. At each point a node with lowest f value is chosen for expansion. Ties among nodes of equal f value should be broken in favor of nodes with lower h values. The algorithm terminates when a goal node is chosen for expansion.

A* finds an optimal path to a goal if the heuristic function $h(n)$ is admissible, meaning it never overestimates actual cost [13]. For example, since airline distance never overestimates actual highway distance, and Manhattan distance never overestimates actual moves in the sliding-tile puzzles, A* using these evaluation functions will find optimal solutions to these problems. In addition, A* makes the most efficient use of a given heuristic function in the following sense: among all shortest-path algorithms using a given heuristic function $h(n)$, A* expands the fewest number of nodes [4].

The main drawback of A*, and indeed of any best-first search, is its memory requirement. Since at least the entire Open list must be saved, A* is severely space-limited in practice, and is no more practical than breadth-first search on current machines. For example, while it can be run successfully on the Eight Puzzle, it exhausts available memory in a matter of minutes on the Fifteen Puzzle.

Iterative-Deepening-A*

Just as depth-first iterative-deepening solved the space problem of breadth-first search, *iterative-deepening-A** (IDA*) eliminates the memory constraint of A*, without sacrificing solution optimality [17]. Each iteration of the algorithm is a depth-first search that keeps track of the cost, $f(n) = g(n) + h(n)$, of each node generated. As soon as a node is generated whose cost exceeds a threshold for that iteration, its path is cut off, and the search backtracks before continuing. The cost threshold is initialized to the heuristic estimate of the initial state, and in each successive iteration is increased to the total cost of the lowest-cost node that was pruned during the previous iteration. The algorithm terminates when a goal state is reached whose total cost does not exceed the current threshold.

Since IDA* performs a series of depth-first searches, its memory requirement is linear with respect to the maximum search depth. In addition, if the heuristic function is admissible, IDA* finds an optimal solution. Finally, by an argument similar to that presented for DFID, IDA* expands the same number of nodes, asymptotically, as A* on a tree, provided that the number of nodes grows exponentially with solution cost. These facts, together with the optimality of A*, imply that IDA* is asymptotically optimal in time and space over all heuristic search algorithms that find optimal solutions on a tree. Additional benefits of IDA* are that it is much easier to implement, and often runs faster than A*, since it does not incur the overhead of managing the Open and Closed lists.

Depth-First Branch-and-Bound

For many problems, the maximum search depth is known in advance, or the search tree is finite. For example, consider the Traveling Salesman Problem (TSP) of visiting each of a given set of cities and returning to the starting city in a tour of shortest total distance. The most natural problem space for this problem consists of a tree where the root node represents the starting city, the nodes at level one represent all the cities that could be visited first, the nodes at level two represent all the cites that could be visited second, etc. In this tree, the maximum depth is the number of cities, and all candidate solutions occur at this depth. In such a space, a simple depth-first search guarantees finding an optimal solution using space that is only linear with respect to the number of cities.

The idea of depth-first branch-and-bound (DFBnB) is to make this search more efficient by keeping track of the lowest-cost solution found so far. Since the cost of a partial tour is the sum of the costs of the edges traveled so far, whenever a partial tour is found whose cost equals or exceeds the cost of the best complete tour found so far, the branch representing the partial tour can be pruned, since all its descendents must have equal or greater cost. Whenever a lower-cost complete tour is found, the cost of the best tour is updated to this lower cost. In addition, an admissible heuristic function, such as the cost of the minimum spanning tree of the remaining unvisited cities, can be added to the cost so far of a partial tour to increase the amount of pruning. Finally, by carefully ordering the children of a given node from smallest to largest estimated total cost, a lower-cost solution can be found more quickly, further improving the pruning efficiency.

Interestingly, IDA* and DFBnB exhibit complementary behavior. Both are guaranteed to return an optimal solution using only linear space, assuming that their cost functions are admissible. In IDA*, the cost threshold is always a lower bound on the optimal solution cost, and increases in each iteration until it reaches the optimal cost. In DFBnB, the cost of the best solution found so far is always an upper bound on the optimal solution cost, and decreases until it reaches the optimal cost. While IDA* never expands any nodes whose cost exceeds the optimal cost, its overhead consists of expanding some nodes more than once. While DFBnB never expands any node more than once, its overhead consists of expanding some nodes whose cost exceeds the optimal cost. For problems whose search trees are of bounded depth, or for which it is easy to construct a good solution, such as the TSP, DFBnB is usually the algorithm of choice for finding an optimal solution. For problems with infinite search trees or for which it is difficult to construct a low-cost solution, such as the sliding-tile puzzles or Rubik's Cube, IDA* is usually the best choice.

Complexity of Finding Optimal Solutions

The time complexity of a heuristic search algorithm depends on the accuracy of the heuristic function. For example, if the heuristic evaluation function is an exact estimator, then A* runs in linear time, expanding only those nodes on an optimal solution path. Conversely, with a heuristic that returns zero everywhere, A* becomes uniform-cost search, which has exponential complexity.

In general, the time complexity of A* and IDA* is an exponential function of the error in the heuristic function [36]. For example, if the heuristic has constant absolute error, meaning that it never underestimates by more than a constant amount regardless of the magnitude of the estimate, then the running time of A* is linear with respect to the solution cost [11]. A more realistic assumption is constant relative error, which means that the error is a fixed percentage of the quantity being estimated. In that case, the running times of A* and IDA* are exponential [38]. The base of the exponent, however, is smaller than the brute-force branching factor, reducing the asymptotic complexity and allowing larger problems to be solved. For example, using appropriate admissible heuristic functions, IDA* can optimally solve random instances of the Twenty-Four Puzzle [26] and Rubik's Cube [27].

Heuristic Path Algorithm

Since the complexity of finding optimal solutions to these problems is generally exponential in practice, in order to solve significantly larger problems, the optimality requirement must be relaxed. An early approach to this problem was the *heuristic path algorithm (HPA)* [39]. HPA is a best-first search algorithm, where the figure of merit of a node n is $f(n) = (1 - w) * g(n) + w * h(n)$. Varying w produces a range of algorithms from uniform-cost search ($w = 0$), through A* ($w = 1/2$), to pure heuristic search ($w = 1$). Increasing w beyond $1/2$ generally decreases the amount of computation, while increasing the cost of the solution generated. This tradeoff is often quite favorable, with small increases in solution cost yielding huge savings in computation [22]. Furthermore, it can be shown that the solutions found by this algorithm are guaranteed to be no more than a factor of $w/(1-w)$ greater than optimal [3], but often are significantly better.

Recursive Best-First Search

The memory limitation of the heuristic path algorithm can be overcome simply by replacing the best-first search with IDA* using the same weighted evaluation function. However, with $w \geq 1/2$, IDA* is no longer a best-first search, since the total cost of a child can be less than that of its parent, and thus nodes are not necessarily expanded in best-first order. An alternative algorithm is recursive best-first search (RBFS) [22]. RBFS is a best-first search that runs in space that is linear with respect to the maximum search depth, regardless of the cost function used. Even with an admissible cost function, RBFS generates fewer nodes than IDA*, and is generally superior to IDA*, except for a small increase in the cost per node generation.

It works by maintaining on the recursion stack the complete path to the current node being expanded, as well as all immediate siblings of nodes on that path, along with the cost of the best node in the subtree explored below each sibling. Whenever the cost of the current node exceeds that of some other node in the previously expanded portion of the tree, the algorithm backs up to their deepest common ancestor, and continues the search down the new path. In effect, the algorithm maintains a separate threshold for each subtree diverging from the current search path. See [22] for full details on RBFS.

36.5 Interleaving Search and Execution

In the discussion above, it is assumed that a complete solution can be computed, before even the first step of the solution need be executed. This is in contrast to the situation in two-player games, discussed below, where because of computational limits and uncertainty due to the opponent's moves, search and execution are interleaved, with each search determining only the next move to be made. This paradigm is also applicable to single-agent problems. In the case of autonomous vehicle navigation, for example, information is limited by the horizon of the vehicle's sensors, and it must physically move to acquire more information. Thus, one move must be computed at a time, and that move executed before computing the next. Below we consider algorithms designed for this scenario.

Minimin Search

Minimin search determines individual single-agent moves in constant time per move [19]. The algorithm searches forward from the current state to a fixed depth determined by the informational or computational resources available. At the search horizon, the A* evaluation function $f(n) = g(n) + h(n)$ is applied to the frontier nodes. Since all decisions are made by a single agent, the value of an interior node is the minimum of the frontier values in the subtree below the node. A single move is then made to the neighbor of the current state with the minimum value.

Most heuristic functions obey the triangle inequality characteristic of distance measures. As a result, $f(n) = g(n) + h(n)$ is guaranteed to be monotonically nondecreasing along a path. Furthermore, since minimin search has a fixed depth limit, we can apply depth-first branch-and-bound to prune the search tree. The performance improvement due to branch-and-bound is quite dramatic, in some cases extending the achievable search horizon by a factor of five relative to brute-force minimin search on sliding-tile puzzles [19].

Minimin search with branch-and-bound is an algorithm for evaluating the immediate neighbors of the current node. As such, it is run until the best child is identified, at which point the chosen move is executed in the real world. We can view the static evaluation function combined with lookahead search as simply a more accurate, but computationally more expensive, heuristic function. In fact, it provides an entire spectrum of heuristic functions trading off accuracy for cost, depending on the search horizon.

Real-Time-A*

Simply repeating minimin search for each move ignores information from previous searches and results in infinite loops. In addition, since actions are committed based on limited information, often the best move may be to undo the previous move. The principle of rationality is that backtracking should occur when the estimated cost of continuing the current path exceeds the cost of going back to a previous state, plus the estimated cost of reaching the goal from that state. *Real-time-A** (RTA*) implements this policy in constant time per move on a tree [19].

For each move, the $f(n) = g(n) + h(n)$ value of each neighbor of the current state is computed, where $g(n)$ is now the cost of the edge from the current state to the neighbor, instead of from the initial state. The problem solver moves to the neighbor with the minimum $f(n)$ value, and stores with the previous state the

best $f(n)$ value among the remaining neighbors. This represents the $h(n)$ value of the previous state from the perspective of the new current state. This is repeated until a goal is reached. To determine the $h(n)$ value of a previously visited state, the stored value is used, while for a new state the heuristic evaluator is called. Note that the heuristic evaluator may employ minimin lookahead search with branch-and-bound as well.

In a finite problem space in which there exists a path to a goal from every state, RTA* is guaranteed to find a solution, regardless of the heuristic evaluation function [19]. Furthermore, on a tree, RTA* makes locally optimal decisions given the information it has seen so far.

Learning-Real-Time-A*

If a problem is to be solved repeatedly with the same goal state but different initial states, one would like an algorithm that improves its performance over time. Learning-real-time-A* (LRTA*) is such an algorithm. It behaves almost identically to RTA*, except that instead of storing the second-best f value of a node as its new heuristic value, it stores the best value instead. Once one problem instance is solved, the stored heuristic values are saved and become the initial values for the next problem instance. While LRTA* is less efficient than RTA* for solving a single problem instance, if it starts with admissible initial heuristic values, over repeated trials its heuristic values eventually converge to their exact values, at which point the algorithm returns optimal solutions.

36.6 Two-Player Games

The second major application of heuristic search algorithms in AI is two-player games. One of the original challenges of AI, which in fact predates the term "artificial intelligence," was to build a program that could play chess at the level of the best human players [50], a goal recently achieved.

Minimax Search

The standard algorithm for two-player perfect-information games, such as chess, checkers, or Othello, is minimax search with heuristic static evaluation [46]. The algorithm searches forward to a fixed depth in the game tree, limited by the amount of time available per move. At this *search horizon,* a heuristic function is applied to the frontier nodes. In this case, a heuristic evaluation is a function that takes a board position and returns a number that indicates how favorable that position is for one player relative to the other. For example, a very simple heuristic evaluator for chess would count the total number of pieces on the board for one player, appropriately weighted by their relative strength, and subtract the weighted sum of the opponent's pieces. Thus, large positive values would correspond to strong positions for one player, called MAX, whereas large negative values would represent advantageous situations for the opponent, called MIN.

Given the heuristic evaluations of the frontier nodes, values for the interior nodes in the tree are recursively computed according to the minimax rule. The value of a node where it is MAX's turn to move is the maximum of the values of its children, while the value of a node where MIN is to move is the minimum of the values of its children. Thus, at alternate levels of the tree, the minimum or the maximum values of the children are backed up. This continues until the values of the immediate children of the current position are computed, at which point one move to the child with the maximum or minimum value is made, depending on whose turn it is to move.

Alpha-Beta Pruning

One of the most elegant of all AI search algorithms is alpha-beta pruning. While it was in use in the late 1950s, a thorough treatment of the algorithm can be found in [28]. The idea, similar to branch-and-bound, is that the minimax value of the root of a game tree can be determined without examining all the nodes at the search frontier.

Figure 36.5 shows an example of alpha-beta pruning. Only the labeled nodes are generated by the algorithm, with the heavy black lines indicating pruning. At the square nodes MAX is to move, while at the circular nodes it is MIN's turn. The search proceeds depth-first to minimize the memory required, and only evaluates a node when necessary. First, nodes e and f are statically evaluated at 4 and 5, respectively, and their minimum value, 4, is backed up to their parent node d. Node h is then evaluated at 3, and hence the value of its parent node g must be less than or equal to 3, since it is the minimum of 3 and the unknown value of its right child. Thus, we label node g as $<= 3$. The value of node c must be 4 then, because it is the maximum of 4 and a value that is less than or equal to 3. Since we have determined the minimax value of node c, we do not need to evaluate or even generate the brother of node h.

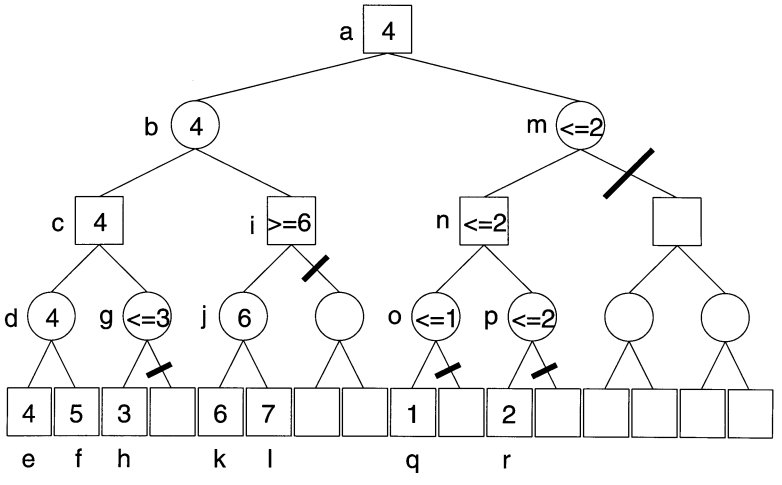

FIGURE 36.5 Alpha-beta pruning example.

Similarly, after statically evaluating nodes k and l at 6 and 7, respectively, the backed up value of their parent node j is 6, the minimum of these values. This tells us that the minimax value of node i must be greater than or equal to 6, since it is the maximum of 6 and the unknown value of its right child. Since the value of node b is the minimum of 4 and a value that is greater than or equal to 6, it must be 4, and hence we achieve another cutoff.

The right half of the tree shows an example of *deep pruning*. After evaluating the left half of the tree, we know that the value of the root node a is greater than or equal to 4, the minimax value of node b. Once node q is evaluated at 1, the value of its parent node o must be less than or equal to 1. Since the value of the root is greater than or equal to 4, the value of node o cannot propagate to the root, and hence we need not generate the brother of node q. A similar situation exists after the evaluation of node r at 2. At that point, the value of node o is less than or equal to 1, and the value of node p is less than or equal to 2, hence the value of node n, which is the maximum of the values of nodes o and p, must be less than or equal to 2. Furthermore, since the value of node m is the minimum of the value of node n and its brother, and node n has a value less than or equal to 2, the value of node m must also be less than or equal to 2. This causes

the brother of node n to be pruned, since the value of the root node a is greater than or equal to 4. Thus, we computed the minimax value of the root of the tree to be 4, by generating only seven of sixteen leaf nodes in this case.

Since alpha-beta pruning performs a minimax search while pruning much of the tree, its effect is to allow a deeper search with the same amount of computation. This raises the question of how much alpha-beta improves performance. The best way to characterize the efficiency of a pruning algorithm is in terms of its *effective branching factor.* The effective branching factor is the d^{th} root of the number of frontier nodes that must be evaluated in a search to depth d, in the limit of large d.

The efficiency of alpha-beta pruning depends upon the order in which nodes are encountered at the search frontier. For any set of frontier node values, there exists some ordering of the values such that alpha-beta will not perform any cutoffs at all. In that case, all frontier nodes must be evaluated and the effective branching factor is b, the brute-force branching factor.

On the other hand, there is an optimal or perfect ordering in which every possible cutoff is realized. In that case, the effective branching factor is reduced from b to $b^{1/2}$, the square root of the brute-force branching factor. Another way of viewing the perfect ordering case is that for the same amount of computation, one can search twice as deep with alpha-beta pruning as without. Since the search tree grows exponentially with depth, doubling the search horizon is a dramatic improvement.

In between worst-possible ordering and perfect ordering is random ordering, which is the average case. Under random ordering of the frontier nodes, alpha-beta pruning reduces the effective branching factor to approximately $b^{3/4}$ [35]. This means that one can search 4/3 as deep with alpha-beta, yielding a 33% improvement in search depth.

In practice, however, the effective branching factor of alpha-beta is closer to the best case of $b^{1/2}$ due to *node ordering.* The idea of node ordering is that instead of generating the tree left to right, we can reorder the tree based on static evaluations of the interior nodes. In other words, the children of MAX nodes are expanded in decreasing order of their static values, while the children of MIN nodes are expanded in increasing order of their static values.

Quiescence, Iterative-Deepening, and Transposition Tables

Two other important ideas are quiescence and iterative-deepening. The idea of quiescence is that the static evaluator should not be applied to positions whose values are unstable, such as those occurring in the middle of a piece trade. In those positions, a small secondary search is conducted until the static evaluation becomes more stable. In games such as chess or checkers, this can be achieved by always exploring any capture moves one level deeper.

Iterative-deepening is used to solve the problem of where to set the search horizon [47], and in fact predated its use as a memory-saving device in single-agent search. In a tournament game, there is a limited amount of time allowed for moves. Unfortunately, it is very difficult to accurately predict how long it will take to perform an alpha-beta search to a given depth. The solution is to perform a series of searches to successively greater depths. When time runs out, the move recommended by the last completed search is made.

The search graphs of most games, such as chess, contain multiple paths to the same node, often reached by making the same moves in a different order, referred to as a transposition of the moves. Since alpha-beta is a depth-first search, it is important to detect when a node has already been searched, in order to avoid researching it. A *transposition table* is a table of previously encountered game states, together with their backed-up minimax values. Whenever a new state is generated, if it is stored in the transposition table, its stored value is used instead of searching the tree below the node.

Almost all two-player game programs use full-width, fixed-depth, alpha-beta minimax search with node ordering, quiescence, iterative-deepening, and transposition tables, among other techniques.

Special-Purpose Hardware

While the basic algorithms are described above, much of the performance advances in computer chess have come from faster hardware. The faster the machine, the deeper it can search in the time available, and the better it plays. Despite the rapidly advancing speed of general-purpose computers, the best machines today are based on special-purpose hardware designed and built only to play chess. For example, DeepBlue is a chess machine that can evaluate about 200 million chess positions per second [33]. In May 1997, it defeated Gary Kasparov, the world champion, in a six-game tournament.

Multiplayer Games, Imperfect and Hidden Information

Minimax search with static evaluation and alpha-beta pruning is most appropriate for two-player games with perfect information, and alternating moves among the players. This paradigm extends in a straightforward way to more than two players, but alpha-beta becomes less effective [20]. Games with chance elements, such as the roll of the dice in backgammon for example, tend to foil search algorithms because of the need to search over all possible chance outcomes. In addition to chance, card games have information that is available to some players but hidden from others, such as the cards in the different hands in bridge. Perhaps poker is one of the ultimate challenges in this area, combining all of the above complexities as well as active deception and the need to model the opponents.

36.7 Constraint-Satisfaction Problems

In addition to single-agent path-finding problems and two-player games, the third major application of heuristic search is constraint-satisfaction problems. The Eight Queens Problem mentioned previously is a classic example. Other examples include graph coloring, Boolean satisfiability, and scheduling problems.

Constraint-satisfaction problems are modeled as follows: There is a set of variables, a set of values for each variable, and a set of constraints on the values that the variables can be assigned. A unary constraint on a variable specifies a subset of all possible values that can be assigned to that variable. A binary constraint between two variables specifies which possible combinations of assignments to the pair of variables satisfy the constraint. For example, in a map or graph coloring problem, the variables would represent regions or nodes, and the values would represent colors. The constraints are binary constraints on each pair of adjacent regions or nodes that prohibit them from being assigned the same color.

Chronological Backtracking

The brute-force approach to constraint satisfaction is called *chronological backtracking*. One selects an order for the variables, and an order for the values, and starts assigning values to the variables one at a time. Each assignment is made so that all constraints involving any of the variables that have already been assigned are satisfied. The reason for this is that once a constraint is violated, no assignment to the remaining variables can possibly resatisfy that constraint. Once a variable is reached which has no remaining legal assignments, then the last variable that was assigned is reassigned to its next legal value. The algorithm continues until either a complete, consistent assignment is found, resulting in success, or all possible assignments are shown to violate some constraint, resulting in failure. Figure 36.6 shows the tree generated by brute-force backtracking to find all solutions to the Four Queens problem. The tree is searched depth-first to minimize memory requirements.

Limited Discrepancy Search

Limited discrepancy search (LDS) [14, 25] is a completely general tree-search algorithm, but is most useful in the context of constraint-satisfaction problems in which the entire tree is too large to search exhaustively.

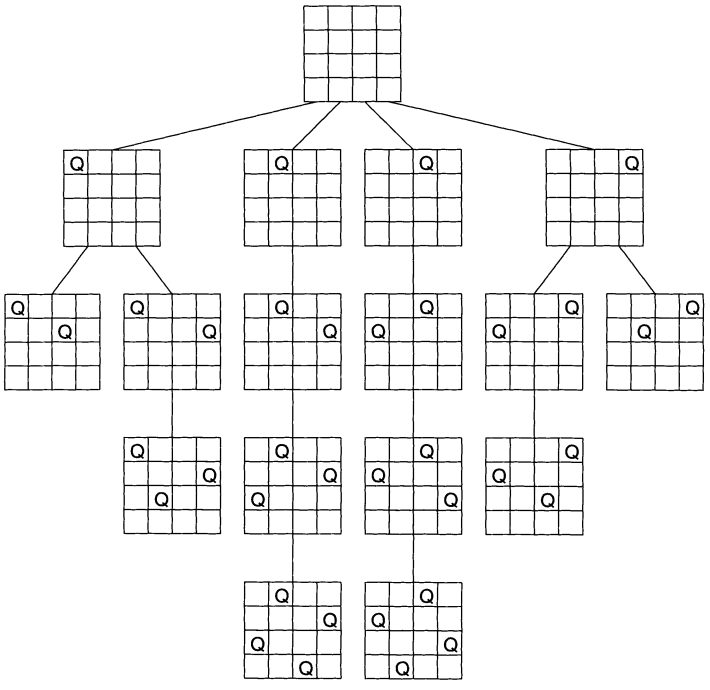

FIGURE 36.6 Tree generated to solve Four Queens Problem.

In that case, we would like to search that subset of the tree that is most likely to yield a solution in the time available. Assume that we can heuristically order a binary tree so that at any node, the left branch is more likely to lead to a solution than the right branch. LDS then proceeds in a series of depth-first iterations. The first iteration explores just the left-most path in the tree. The second iteration explores those root-to-leaf paths with exactly one right branch, or discrepancy, in them. In general, each iteration explores those paths with exactly k discrepancies, with k ranging from zero to the depth of the tree. The last iteration explores just the rightmost branch. Under certain assumptions, one can show that LDS is likely to find a solution sooner than a strict left-to-right depth-first search.

Intelligent Backtracking

One can improve the performance of brute-force backtracking using a number of techniques, such as variable ordering, value ordering, backjumping, and forward checking.

The order in which variables are instantiated can have a large effect on the size of the search tree. The idea of variable ordering is to order the variables from most constrained to least constrained [10, 42]. For example, if a variable has only a single value remaining that is consistent with the previously instantiated variables, it should be assigned that value immediately. In general, the variables should be instantiated in increasing order of the size of their remaining domains. This can either be done statically at the beginning of the search, or dynamically, reordering the remaining variables each time a variable is assigned a new value.

The order in which the values of a given variable are chosen determines the order in which the tree is searched. Since it doesn't effect the size of the tree, it makes no difference if all solutions are to be found. If only a single solution is required, however, value ordering can decrease the time required to find a solution. In general, one should order the values from least constraining to most constraining, in order to minimize the time required to find a first solution [5, 12].

An important idea, originally called backjumping, is that when an impasse is reached, instead of simply

undoing the last decision made, the decision that actually caused the failure should be modified [11]. For example, consider a three-variable problem where the variables are instantiated in the order x, y, z. Assume that values have been chosen for both x and y, but that all possible values for z conflict with the value chosen for x. In chronological backtracking, the value chosen for y would be changed, and then all the possible values for z would be tested again, to no avail. A better strategy in this case is to go back to the source of the failure, and change the value of x, before trying different values for y.

When a variable is assigned a value, the idea of forward checking is to check each remaining uninstantiated variable to make sure that there is at least one assignment for each of them that is consistent with the previous assignments. If not, the original variable is assigned its next value.

Constraint Recording

In a constraint-satisfaction problem, some constraints are explicitly specified, and others are implied by the explicit constraints. Implicit constraints may be discovered either during a backtracking search, or in advance in a preprocessing phase. The idea of constraint recording is that once these implicit constraints are discovered, they should be saved explicitly so that they don't have to be rediscovered.

A simple example of constraint recording in a preprocessing phase is called arc consistency [10, 29, 32]. For each pair of variables x and y that are related by a binary constraint, we remove from the domain of x any values that do not have at least one corresponding consistent assignment to y, and vice versa. In general, several iterations may be required to achieve complete arc consistency. Path consistency is a generalization of arc consistency where instead of considering pairs of variables, we examine triples of constrained variables. The effect of performing arc or path consistency before backtracking is that the resulting search space can be dramatically reduced. In some cases, this preprocessing of the constraints can eliminate the need for search entirely.

Heuristic Repair

Backtracking searches a space of consistent partial assignments to variables, in the sense that all constraints among instantiated variables are satisfied, looking for a complete consistent assignment to the variables, or in other words a solution. An alternative approach is to search a space of inconsistent but complete assignments to the variables, until a consistent complete assignment is found. This approach is known as heuristic repair [31]. For example, in the Eight Queens problem, this amounts to placing all eight queens on the board at the same time, and moving the queens one at a time until a solution is found. The natural heuristic, called min-conflicts, is to move a queen that is in conflict with the most other queens, and move it to a position where it conflicts with the fewest other queens.

What is surprising about this simple strategy is how well it performs, relative to backtracking. While backtracking techniques can solve on the order of hundred-queen problems, heuristic repair can solve million-queen problems, often with only about 50 individual queen moves! This strategy has been extensively explored in the context of Boolean satisfiability, where it is referred to as GSAT [45]. GSAT can satisfy difficult formulas with several thousand variables, whereas the best backtracking-based approach, the Davis–Putnam algorithm [2] with unit propagation, can only satisfy difficult formulas with several hundred variables.

The main drawback of this approach is that it is not complete, in that it is not guaranteed to find a solution in a finite amount of time, even if one exists. If there is no solution, these algorithms will run forever, whereas backtracking will eventually discover that a problem is not solvable.

While constraint-satisfaction problems appear somewhat different from single-agent path-finding problems and two-player games, the is a strong similarity among the algorithms employed. For example, backtracking can be viewed as a form of branch-and-bound, where a node is pruned when a constraint is violated. Similarly, heuristic repair can be viewed as a heuristic search where the evaluation function is the total number of constraints that are violated, and the goal is to find a state with zero constraint violations.

36.8 Research Issues and Summary

Research Issues

The primary research problem in this area is the development of faster algorithms. All the above algorithms are limited by efficiency either in the size of problems that they can solve optimally, or in the quality of the decisions they can make or solutions they can find within practical computational limits. Thus, there is a continual demand for faster algorithms.

A related research area is the development of space-efficient algorithms [23]. While the exponential-space algorithms are clearly impractical, the linear-space algorithms use very little of the memory available on current machines. The primary issue here is given a fixed amount of memory, how to make the best use of it to speed up a search as much as possible. In a two-player game search, the extra memory is used primarily in the transposition table. In single-agent path-finding problems, one of the most effective uses of additional memory is a form of bidirectional search known as perimeter search [8, 15, 30]. The idea is to search breadth-first backward from the goal state until memory is nearly exhausted. Then, the forward search proceeds until it encounters a state on the perimeter of the backward search. The main advantage to this approach is that the nodes on the perimeter can be used to refine the heuristic estimates in the forward search.

Another research area is the development of parallel search algorithms. Most search algorithms have a tremendous amount of potential parallelism, since the basic step of node generation and evaluation is often performed billions of times. As a result, many such algorithms are readily parallelized with nearly linear speedups. The algorithms that are difficult to parallelize are branch-and-bound algorithms, such as alpha-beta pruning, because the results of searching one part of the tree determine whether another part of the tree needs to be examined at all.

Since the performance of a search algorithm depends critically on the quality of the heuristic evaluation function, another important research area is the automatic generation of such functions. This was pioneered in the area of two-player games by Arthur Samuel's landmark checkers program that learned to improve its evaluation function through repeated play [44]. In the area of single-agent problems, a dominant theory is that the exact cost of a solution to a simplified version of a problem can be used as an admissible heuristic evaluation function for the original problem [36]. For example, in the sliding-tile puzzles, if we remove the constraint that a tile can only be slid into the blank position, then any tile can be moved to any adjacent position at any time. The optimal number of moves required to solve this simplified version of the problem is the Manhattan distance, which is an admissible heuristic for the original problem. Automating this approach, however, is still a research problem [41].

Another important research area is the development of selective search algorithms for two-player games. While Deep Blue defeated Gary Kasparov, it did it by evaluating 200 million chess positions per second. Obviously, humans are much more selective in their choices of what positions to examine. The development of alternatives to full-width, fixed-depth minimax search is an active area of research. See [24] for one example of a selective search algorithm, along with pointers to other work in this area.

Summary

We have described search algorithms for three different classes of problems. In the first, single-agent path-finding problems, the task is to find a sequence of operators that map an initial state to a desired goal state. Much of the work in this area has focused on finding optimal solutions to such problems, often making use of admissible heuristic functions to speed up the search without sacrificing optimality. In the second area, two-player games, finding optimal solutions is infeasible, and research has focused on algorithms for making the best move decisions possible given a limited amount of computing time. This approach has also been applied to single-agent problems as well. In the third class of problems, constraint-satisfaction problems, the task is to find a state that satisfies a set of constraints. While all three

of these types of problems are different, the same set of ideas, such as brute-force searches and heuristic evaluation functions, can be applied to all three.

36.9 Defining Terms

Admissible: A heuristic is said to be admissible if it never overestimates actual distance from a given state to a goal. An algorithm is said to be admissible if it always finds an optimal solution to a problem if one exists.

Branching factor: The average number of children of a node in a problem-space graph.

Constraint-satisfaction problem: A problem where the task is to identify a state that satisfies a set of constraints.

Depth: The length of a shortest path from the initial state to a goal state.

Heuristic evaluation function: A function from a state to a number. In a single-agent problem, it estimates the distance from the state to a goal. In a two-player game, it estimates the merit of the position with respect to one player.

Node expansion: Generating all the children of a given state.

Node generation: Creating the data structure that corresponds to a problem state.

Operator: An action that maps one state into another state, such as a twist of Rubik's Cube.

Problem instance: A problem space together with an initial state of the problem and a desired set of goal states.

Problem space: A theoretical construct in which a search takes place, consisting of a set of states and a set of operators.

Problem-space graph: A graphical representation of a problem space, where states are represented by nodes, and operators are represented by edges.

Search: A trial-and-error exploration of alternative solutions to a problem, often systematic.

Search tree: A problem-space graph with no cycles.

Single-agent path-finding problem: A problem where the task is to find a sequence of operators that map an initial state to a goal state.

State: A configuration of a problem, such as the arrangement of the parts of a Rubik's Cube at a given point in time.

37.1 Introduction

This chapter will present the essential components of the *simulated annealing (SA)* algorithm and review its origins and potential for solving a wide range of optimization problems, in a manner that is accessible to the widest possible audience. Some historical perspective and description of recent research results will also be provided. During the course of this review bibliographical references will be provided to guide the interested reader to sources that contain additional theoretical results and complete details of individual applications.

Many problems in a variety of disciplines can be formulated as optimization problems; and most of these can be solved by adopting one of two "popular" approaches: *divide-and-conquer* or *hill-climbing* techniques (other approaches can be adopted, see for example, [31], and see also Chapters 31–33 in this volume). In the first approach, the solution is problem-dependent, and typically detailed information about the problem is required in order to develop a solution strategy. Also, not many problems can be subdivided into smaller parts that can be solved separately and then recombined. In the second approach, most hill-climbing algorithms are based on gradient descent methods. These methods suffer from a major

drawback of getting trapped in a local minimum. That is, the algorithm may get "tarpped" in a valley, from which all paths lead to locally worse solutions, and will never get to an optimal solution that lies outside the valley. The SA algorithm avoids local minima by introducing an element of randomness into the search process [36].

Over the last few years the SA algorithm and its many extensions and refinements have been extensively employed to solve a wide range of application domains, especially in combinatorial optimization problems [2, 5, 8, 13, 15, 47, 54, 57, 58]. An important characteristic of the SA algorithm is that it does not require specialist knowledge about how to solve a particular problem. This makes the algorithm generic in the sense that it can be used in a variety of optimization problems without the need to change the basic structure of the computations.

The versatility of SA has attracted many researchers over a number years, and has recently spawned a number of variations to the original algorithm, including parallel versions to speed up the rate of computations [18, 19, 25, 42, 51, 62].

37.2 The Basic Idea

The SA is a stochastic optimization method modelled on the behavior of condensed matter at low temperatures. It borrows techniques from *statistical mechanics* to find global optima of systems with large numbers of degrees of freedom. The method is analogous to the way that liquids freeze and crystallize or metals cool and anneal. The core of the process is slow cooling, allowing enough time for the redistribution of atoms as they lose mobility until a minimum energy state is reached [57].

During the physical annealing process a solid is placed in a heat bath and the temperature is continually raised until the solid has melted and the particles of the solid are physically disarranged or positioned in random order. The orientation of the particles are referred to as the *spins.* From such a high energy level, the heat bath is cooled slowly by lowering the temperature to allow the particles to align themselves in a regular crystalline lattice structure. This final structure corresponds to a stable low energy state.

The temperature must be lowered slowly to allow the solid to reach equilibrium after each temperature drop. Otherwise, irregular alignments may occur, resulting in defects that get frozen into the solid. Of course, this can result in a metastable (highly unstable) structure rather than the required stable low energy structure.

The idea of annealing was combined with the well-known *Monte Carlo* algorithm [40], which was originally used to perform numerical averaging over large systems in statistical mechanics. The SA algorithm maintains the speed and reliability of gradient descent algorithms while at the same time avoiding local minima [36].

37.3 Global Optimization Problems

There are two classes of algorithms that can be used to solve *global optimization* problems [48]. The first are random or Monte Carlo type of algorithms that make use of pseudo random variables. The second are deterministic algorithms that do not take advantage of randomization; the earliest global optimization methods belong to this class. Global optimization techniques aim at solving the following general class of problems [31]:

$$\begin{aligned} &\text{maximize} && f(x) \\ &\text{subject to:} && h_i(x) \leq 0 \quad i = 1, 2, ..., n \\ & && x \in X \end{aligned} \tag{37.1}$$

where f and h_i (for $i = 1, 2, \ldots, n$) are real-valued functions defined on a domain containing $X \subseteq \Re^m$, where m is the number of variables. If $n = 0$ and $X = [a_1, b_1] \times [a_2, b_2] \times \ldots \times [a_m, b_m]$ defines a hyperrectangle of $\Re^m$, the problem is called *unconstrained,* and if $m = 1$, the problem is *univariate.*

An assumption that is usually made to enable the solution of (37.1) is that the functions f and $h_i (i = 1, 2, ..., n)$ can be evaluated at all points of X. This means that there are methods by which given the values of variables, the corresponding evaluations of functions can be provided. This is true in a number of practical situations in which measurements of functions can be made through empirical means, but no analytical (or closed-form) expressions are available [41, 43, 46].

If no other assumptions are made on f and $h_i (i = 1, 2, ..., n)$, the problem is intractable. It is important to note that no matter how many function evaluations are performed, there is no guarantee that the minimum can be obtained [29]. To help in finding a solution, another simple assumption that is usually made is that the slopes of the functions f and $h_i (i = 1, 2, \ldots, n)$ are bounded. In such case, these function are said to be *Lipschitz.* A real-valued function defined on a compact set $X \subseteq \mathcal{R}^m$ said to be Lipschitz if it satisfies the condition

$$\forall x \in X \quad \forall y \in X \quad | \alpha(x) - \alpha(y) | \leq L \parallel x - y \parallel \tag{37.2}$$

where L is a constant (Lipschitz constant) and $\parallel \bullet \parallel$ is the Euclidean norm (other norms can also be used). In general, deterministic algorithms evaluate a given cost function at points on a grid. A major problem with such deterministic algorithms is that they require knowledge about the problem, or in other words, the cost function (such as the Lipchitz constant L) that needs to be evaluated.

Most global optimization algorithms are of the random type and are related to the so-called *multistart* algorithm [7]. In this case, a local optimization algorithm is executed from different initial or starting points that are chosen at random, usually from a uniform distribution on the domain of the cost function. However, a multistart algorithm is still inefficient because it will inevitably find each local extremum (maximum or minimum) several times. In addition, local search are the most time consuming part of any procedure (the multistart algorithm in this case). A typical multistart algorithm that can take advantage of a local search procedure Ω is shown below.

PROCEDURE MULTISTART
1 k $\leftarrow$ 1
2 $\prod(0) = -\infty$
3 **Generate** a point x from the uniform
distribution over X
4 **Apply** Ω to x to get $\tilde{x}$
5 **If** $f(\tilde{x}) > \prod(k-1)$ **then**
6 $\prod(k) \leftarrow f(\tilde{x})$
7 $x_k = \tilde{x}$
8 **Else**
9 $\prod(k) \leftarrow \prod(k-1)$
10 $x_k = x_{k-1}$
11 **Increment** k; **Return** to 3

From a computational point of view, a local search procedure should not be called more than once in every region of attraction. In this case, the region of attraction of the local maximum $\bar{x}_k$ is defined as the set of points in X from which the local search procedure (Ω) will converge to $\bar{x}_k$.

The SA algorithm can also be classified as a random search technique, but the algorithm avoids getting trapped in local minima by accepting, in addition to movements corresponding to improvement in cost function value, also movements corresponding to a deterioration in cost function value. However, the deterioration movements are accepted with a finite probability. These two different types of movements allow the algorithm to move away from local minima and traverse more states in the region X (Fig. 37.1).

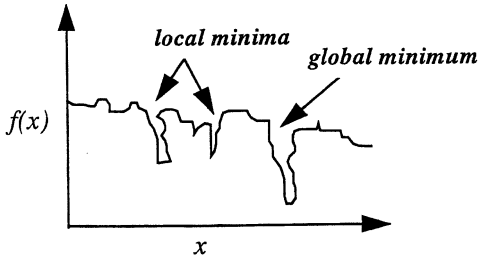

FIGURE 37.1 Local and global minima.

The Metropolis Algorithm

The SA algorithm is based on a procedure introduced by [40] to simulate the equilibrium states of a multibody system at a given finite temperature. The Metropolis procedure consisted of a number of simple principles. At each step, a small perturbation of the configuration (of the given system) is chosen at random and the resulting change in the energy of the system, Δ, is calculated. The new configuration is accepted with probability 1 if $\Delta \leq 0$, and with probability $e^{-\Delta/k_BT}$ if $\Delta > 0$. To temperature (T) can be viewed as a control parameter. The procedure is given below.

PROCEDURE METROPOLIS
1 **Generate** some random initial configuration s
2 **Repeat**
3 $s' \leftarrow$ Some random neighboring configuration of s
4 $\Delta \leftarrow E(s') - E(s)$
5 $\rho_T(\Delta) \leftarrow \min(1, e^{-\Delta/k_BT})$
6 **If** $random(0.1) \leq \rho_T(\Delta)$ **then** $s \leftarrow s'$
7 **Until false**
8 **End**

In the above algorithm, $E(s)$ stands for the energy associated with state s and k_B is the Boltzmann constant ($k_B = 1.38 \times 10^{-16} ergs/K(Kelvin)$). The energy function $E(\bullet)$ is usually replaced by a cost function; then the above procedure can be used to simulate the behavior of the optimization problem with the given cost function.

The essence of the Metropolis procedure can be summarized as follows. If Φ_s is the set of states $\varphi \in S$ reachable in exactly one move (perturbation) from s. Each move must be *reversible* ($\varphi \in \Phi_s \Rightarrow s \in \Phi_\varphi$). The number of possible moves (i.e., $\omega = |\Phi_s|$) must be the same from any state s. It also must be possible to reach any state in Φ from any other in a finite number of moves.

The function $\rho_T(\Delta) = \min(1, e^{-\Delta/k_BT})$ is used to choose a random move, and each move has a probability of $1/\omega$ of being accepted. Following the sequence of accept and reject moves given in the above algorithm, leads to a Markov process with transition function [7, 12]:

$$\Phi_T(s'|s) = \begin{cases} \dfrac{1}{\omega}\rho_T(E(s') - E(s)) & s' \in \Phi_s \\ 1 - \displaystyle\sum_{\varphi \in \Phi_s} \frac{1}{\omega}\rho_T(E(\varphi) - E(s)) & s' = s \\ 0 & \text{otherwise} \end{cases}$$

If T is positive, the above process is *irreducible,* which means that for any two states $s, \varphi \in \Phi$, there is a nonzero probability that state φ will be reached from s. Defining π_T as the stationary (equilibrium)

distribution of this process, it can be found that

$$\pi_T(s) = \frac{e^{(-E(s)/T)}}{\sum_{\varphi \in \Phi} e^{(-E(\varphi)/T)}} \quad \forall s \in \Phi$$

The above follows from the principle of detailed reversibility [7, 12],

$$\pi_T(s)\Omega_T(s'|s) = \pi_T(s')\Omega_T(s|s') \quad \forall s, s' \in \Phi$$

where π_T is the Boltzman distribution. Simply stated, detailed reversibility means that the likelihood of any transition equals that of the opposite transition (i.e., in the opposite direction).

37.4 Simulated Annealing

As mentioned earlier, the SA algorithm is an optimization technique based on the behavior of condensed matter at low temperatures. The procedure employs methods that originated from statistical mechanics to find global minima of systems with very large degrees of freedom. The correspondence between combinatorial optimization problems and the way natural systems search for the ground state (lowest energy state) was first realized by [10, 36]. Based on the analogy given in Fig. 37.2, Kirkpatrick et al. [36] applied Monte Carlo methods, which are usually found in statistical mechanics, to the solution of global optimization problems, and it was shown that better solutions can be obtained by simulating the annealing process that takes place in natural systems.

Further, Kirkpatrick et al. [36] generalized the basic concept that was introduced in [40] by using a *multi-temperature* approach in which the temperature is lowered slowly in stages. At each stage the system is simulated by the Metropolis procedure until the system reaches equilibrium.

At the outset, the system starts with a high T, then a cooling (or annealing) scheme is applied by slowly decreasing T according to some given procedure. At each T a series of random new states are generated. States that improve the cost function are accepted. Now, rather than always rejecting states that do not improve the cost function, these states can be accepted with some finite probability depending on the amount of increase and T. This process randomizes the iterative improvement phase and also allows occasional uphill moves (i.e., moves that do not improve the solution) in an attempt to reduce the probability of falling into a local minimum.

As T decreases, configurations that increase the cost function are more likely to be rejected and the process eventually terminates with a *configuration* (solution) that has the lowest cost. This whole procedure has been proved to lead to a solution that is arbitrary close to the global minimum [1, 38, 57].

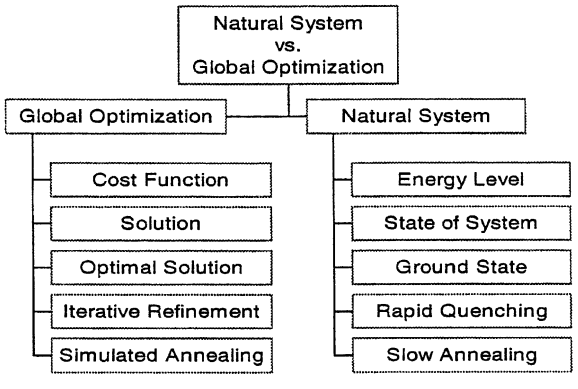

FIGURE 37.2 A one-to-one analogy between a natural process and global optimization.

In addition to having a well-formulated cost function, the design of an efficient annealing algorithm requires three other ingredients [1, 43]:

- The problem to be optimized must be represented by a set of data structures that provide a concise description of the nature of that problem. These data structures must allow for the fast generation and assessment of the different iterations as well as the efficient computation of the overall cost function.
- A large number of random rearrangements (i.e., perturbations, moves, or iterations) must be generated to adequately explore the search space.
- An annealing schedule should be devised to control the temperature during the annealing process. This procedure should specify the initial and final temperatures and the rate at which the temperature is lowered.

A general description of the SA algorithm is given below. After the cost function E is selected the algorithm can be described as follows:

PROCEDURE SIMULATED ANNEALING
Set $S \leftarrow S_0$ (random initial state)
Set $T \leftarrow T_0$ (initial temperature)
While (stopping criterion is not satisfied) **do**
  While (required number of states is not generated) **do**
    Generate a new state (S') by perturbing S.
    Evaluate E
    Compute $\Delta E = E(S') - E(S)$
    If ($\Delta E \leq 0$) **then**
      $S \leftarrow S'$
      Else
        Generate a random variable α, $0 \leq \alpha \leq 1$
        If $\alpha \leq e^{(-\Delta E)/T}$ **then** $S \leftarrow S'$
    End
  End
  Update T (decrement)
End

In the above procedure the Boltzmann constant (k_B) that appears in the Metropolis procedure is combined with the T, and the whole term is called temperature.

From a theoretical standpoint, the SA algorithm works in the following way. Assume a *random walk* on S that converges to a uniform distribution on S. Also denote the transition probability distribution by $\Lambda(s, \bullet)$ (the Markov chain is in state $s \in S$). In every iteration, given state s_i , a new state s' is generated from $\Lambda(s_i, \bullet)$. Then this new generated state is accepted with probability

$$\min\left\{1, e^{(f(s_{i+1})-f(s_i))/T}\right\}$$

which is the Metropolis criterion. In other words, with this probability we can set $s_{i+1} = s'$, otherwise, $s_{i+1} = s_i$. Now, if the Markov chain given by Λ is filtered using the procedure, the sequence of states generated will converge to the Boltzman distribution π_T (where T is the temperature). Therefore, a sequence of states can be generated $\{S_i(T)\}_{i=0}^{\infty}$ with the property that for every $\varepsilon > 0$,

$$\lim_{i\to\infty} \Pr\left(S_i(T) \in S_\varepsilon\right) = \pi_T\left(S_\varepsilon\right) \tag{37.3}$$

where S_ε is any level set ($S_\varepsilon \in S$). It is agreed upon that any *adaptive search* algorithm (e.g., SA) is based on the same property of the family of Boltzman distributions, which can be stated as [20, 27]:

$$\lim_{T \to 0} \pi_T (S_\varepsilon) = 1 \quad \forall \varepsilon > 0 \tag{37.4}$$

By using Eqs. (37.3) and (37.4), it can be concluded that

$$\lim_{T \to 0} \lim_{i \to \infty} \Pr (S_i(T) \in S_\varepsilon) = 1 \quad \forall \varepsilon > 0 \tag{37.5}$$

Basically, Eq. (37.5) governs the behavior of the SA algorithm. A number of states are generated $S_0, S_1, \ldots$ using the filtered random walk described above, except that now the temperature (T) will be decreased to zero as we iterate, according to some annealing schedule.

It can be noticed that the SA algorithm is characterized by its simple and elegant structure. However, a number of factors need to be considered to have an efficient implementation of the algorithm. These factors are, for example, the choice of cost function, the annealing schedule, and the algorithm termination condition.

Cost Function

The cost function is an application-dependent factor that measures the value of one solution relative to another [1, 57]. In some applications the cost function can be of an analytical nature, which means that the structure of the function can be determined *a priori* [46]. In other cases, the cost function is nonanalytical and need to be determined in some indirect manner from observing the process that is being optimized [43].

Nevertheless, the value of the difference in the cost function (i.e., ΔE) is crucial for the success of the iterative process. The value of $e^{-\Delta E/T}$ suggests that for a state to be accepted with, say, probability of 0.85 at the initial T, the T must be at least six times higher than ΔE (i.e., $e^{-1/6} = 0.846$). As the ratio of T and ΔE decreases, so does the probability of accepting that state, which means that when we get to ratios of 1:7, 1:8 or greater, there is extremely low probability of accepting poor solutions [47].

Annealing Schedule

The annealing schedule determines the process by which T should be decreased, which influences the performance of the overall algorithm to a great extent. In this case, two issues need to be considered: the first is how T should be decremented over time, and the second is how many iterations should be computed at any given T.

In some complex problems, the annealing schedule needs to be designed specifically to suit the application [21, 32, 59]. A worst-case scheduling scheme that is quite slow was developed to guarantee the convergence of the SA algorithm [21]. Other research showed that the SA algorithm can converge faster than the worst-case situation [30]. Also, an adaptive cooling schedule was developed that is based on the characteristics of the cost distribution and the annealing curve [32].

Staying at the same T for a long period of time will guarantee finding the best solution since the SA algorithm is *asymptotically* optimal. This means that the longer the algorithm runs the better is the quality of the solution obtained [49]. However, this is not acceptable from a practical point of view.

The number of iterations that need to be computed at any given T can be determined in two different ways [47, 55]. The number of iterations for any T can be given by

$$Y(T) = e^{(E_{\max} - E_{\min})/T} \tag{37.6}$$

where $E_{\max}$ and $E_{\min}$ are the highest and lowest values of the cost function obtained so far for the current T [32]. However, $Y(T)$ gets too large when T decreases, thus, requiring the introduction of an

arbitrary upper bound. Another method, which is based on experimental data, allows a certain number of acceptances or rejections at any given T before allowing T to decrease. A ratio of 1:10 of accepts and rejects, respectively, was proposed in [17].

The next step is to decrease T. It is recommended that T is decreased by a factor which is less than one. In this case, the rate of decrease of T becomes exponential. The advantage of this kind of rate is that it becomes slow when the search process is near completion, which gives the system a chance to find the global minimum. Also, if one uses the formula $T_i = a^i T_{i-1}$, where $a < 1$ (ideally set between 0.5–0.99) this will have the same effect. The a in this case will control the rate of annealing.

Another important factor in designing the annealing schedule is the choice of the initial value of T. A high initial T is usually selected to ensure that most of the moves attempted are accepted because they lead to a lower cost. This allows a wider search of the solution space at the beginning. A method suggested in [36] to find the initial T can be outlined as follows:

I. Begin with a random T.

II. Try a number of iterations at T, while keeping track of the percentage of the accepted moves (A) and rejected (R) ones.

III. If $A/(A + R) < 0.8$, then update T to $2T$ and then goto (II) and repeat the process until the system is "warm" enough.

However, one problem with this method is that the T might become too warm, which will consume much more time than what might be necessary.

Algorithm Termination

A number of schemes were proposed for estimating the termination (or freezing) temperature [47]. It was found that the value of T at which no further improvements can be made is [60]:

$$T_f = \frac{E_{m'} - E_m}{\ln \nu} \tag{37.7}$$

where E_m is the absolute minimum value of the cost function, which could be set to some predetermined value that depends on the application. $E_{m'}$ is the next largest value of the cost function (i.e., compared to E_m), and ν is the number of moves that takes to get from $E_{m'}$ to E_m. The freezing temperature determined by using Eq. (37.7) represents the worst-case scenario, because by using T_f the annealing process will not stop too soon, that is it will not stop before the minimum has been found.

Another approach which is employed by a commercial SA package named TimberWolf^R [53] stops the annealing process when no new solution have been accepted after four consecutive decreases in T. However, it has been shown that this approach might stop the annealing process prematurely [47, 55].

37.5 Convergence Conditions

The SA algorithm has a formal proof of convergence which depends on the annealing schedule. As seen from previous discussion, by manipulating the annealing schedule one can control the behavior of the algorithm. For any given T, a sufficient number of iterations always leads to equilibrium, at which point the temporal distribution of accepted states is stationary (the stationary distribution is Boltzmann). We also need to note, that at high T, almost any change is accepted. This means that the algorithm tries to span a very large neighborhood of the current state. At lower T, transitions to higher energy states becomes less frequent and the solution stabilizes.

The convergence of the SA algorithm to a global optimum can be proven by using Markov chain theory [12, 33, 38]. The sequence of perturbations (or moves) which are accepted by the algorithm form a Markov chain because the next state depends only on the current state and it is not influenced by past

states—no record is kept for the past states. So, given that the current state is j, the probability that the next state is k is the product of two probabilities: the probability that state k is generated by one move from state j and the probability of accepting state k.

A Markov chain is irreducible if for every pair of states (j, k), there is a sequence of moves which allows k to be reached from j. If the Markov chain ensures irreducibility, then the sequence of states accepted at a given T forms a Markov chain with stationary distribution [1, 49, 57]. If T takes on a sequence of values approaching zero, where there are a sufficient number of iterations at each value, then the probability of being at a global optimum at the termination of the execution of the algorithm is one.

Over the last few years a number of studies dealt with the convergence problem since it a major issue in optimization problem [1, 20, 21, 27, 28, 38, 57]. Actually, if one is to compare the SA algorithm with other stochastic methods such as *genetic algorithms* and *neural networks* one finds in the SA literature more solid studies as far as issues of convergence are concerned [39, 41, 45]. Also, it has been shown that even if several iterations of the SA algorithm result in deteriorations of the cost function, that the algorithm will eventually recover and move towards the global maximum (or its neighborhoods) [6].

However, there are a number of underlying principles that govern the convergence of the SA algorithm [23, 24, 38]:

- The existence of a unique asymptotic probability distribution (stationary distribution) for the stationary Markov chain corresponding to each strictly positive value of an algorithm control parameter (i.e., T).
- The existence of stationary distribution limits as $T \to 0$.
- The desired behavior of the stationary distribution limit (probability distribution with probability one) [see Eq. (37.5)].
- Sufficient conditions on the annealing schedule to ensure that the nonstationary algorithm asymptotically achieves the limiting distribution.

The work in [21] proposes a version of the SA algorithm which is called the *Gibbs sampler.* It is shown that for temperature schedules of the form

$$T_n = \frac{c}{\log n} \quad (n\text{:large})$$

that if c is sufficiently large, then convergence will be guaranteed. Along the same lines, Gidas [23] considers the convergence of the SA algorithm and similar algorithms that are based on Markov chain sampling methods that are related to the Metropolis algorithm.

For more theoretical details on convergence of the SA algorithm, the reader is referred to [1, 20, 21, 23, 27, 28, 38, 57] to name a few.

Before we conclude this section, it is important to note that the SA algorithm is closely related to another algorithm that has been used for global optimization and generated a lot of interest, which is called the *Langevin algorithm* [22]. This algorithm is based on the Langevin stochastic differential equation (proposed by Langevin in 1908 to describe the motion of a particle in a viscous fluid) given by

$$dx(t) = -\nabla g(x(t))dt + \gamma(t)dw(t) \tag{37.8}$$

where ∇g is the gradient of g and $w(t)$ is a standard r-dimensional *Wiener process* [44]. When $\gamma(t) \equiv \gamma_0(\gamma(t)$ is constant), then the probability density function of the solution process $x^{\gamma_0}(t)$ of Eq. (37.8) approaches

$$e^{(2g(x)/\gamma_0^2)} \tag{37.9}$$

as $t \to \infty$. Equation (37.8) could also have a normalization constant. This distribution is exactly the Boltzmann distribution at temperature $\gamma_0^2/2$. This observation has generated many interesting studies [11, 22].

However, only a few practical problems have been proposed along with some promising results. In [3], the authors use a modified Langevin algorithm which employs an interactive temperature schedule. They ran their tests on $g(\cdot)$ defined on $\Re^b$ where $b = 1, 2, \ldots, 14$. Other numerical results were reported by [23] that used a $g(\cdot)$ defined on $\Re$ with 400 local minima. Further, it was suggested that the Langevin algorithm be used with other multistart methods [31].

The comparison of different optimization algorithms is a very difficult task [20]. Some analytical results have been proposed to assist in such comparisons [52]. Also, a standard set of test functions have been developed in [16] to compare different optimization techniques. However, the applicability of these tests to the Langevin algorithm is rather questionable. This is due to the fact that such tests are more suited to compare algorithms in low dimensional spaces, but not the case of the Langevin algorithm which supposed to be used for functions in large dimensions. The structure and characteristics of such functions cannot be determined *a priori.*

37.6 Parallel Simulated Annealing Algorithms

One of the main drawbacks of the SA algorithm is the amount of time it takes to converge to a solution. As seen earlier, a number of approaches have been introduced to improve the computational efficiency of the SA algorithm [8, 21, 25, 32, 35, 53]. However, most of these techniques used heuristics to simplify the search process by either limiting the cost function or educe the chances of generating future moves that are going to be rejected.

A more effective way to improve the speed of computations is to run SA algorithms by using parallel processor platforms. For a parallel SA algorithm to have the same desirable convergence properties as the sequential algorithm, one must either maintain the serial decision sequence, or employ a different decision sequence such that the generated Markov chains have the same probability distribution as the sequential algorithm [42, 43].

Since, during the annealing process, a new state is generated by perturbing the previous state, it is natural to think that the SA algorithm is inherently sequential and cannot be parallelized. However, a number of ways have been used to remove this dependence between subsequent moves [4, 5, 37, 39, 42, 51, 62]. A number of other issues need to be considered when parallelizing the SA algorithm, such as the division of the search space among processors, and most importantly the amount of speedup obtained with the parallel algorithm.

With the large multitude of parallel SA algorithms proposed in the literature over the last few years, one could observe that most of these algorithms don't have the same convergence characteristics as the sequential algorithm, which to some extent compromises the range of their applicability. Successful parallel algorithms tend to be application-dependent [9, 14, 63].

Two problem-independent algorithms were proposed in [37]. These two algorithms were called move-decomposition and parallel-moves. The former divides the move-evaluate-decide task into several subtasks, and maps these subtasks onto several processors, while the latter generates many moves in parallel but only chooses a serializable subset of these moves to be performed. This subset consists of a number of moves which, when applied to the current state in any order, always produces the same final state. In addition, both methods were used in a hybrid scheme that consists of applying move-decompose at higher temperatures and parallel-moves at lower temperatures. The hybrid algorithm was mapped onto parallel processor system. Overall, limited levels of parallelism were achieved by this work: the speedup approached saturation with four processors.

Another method was developed in [51]. In this work, the authors developed a parallel scheme in which the states have the same probability distribution as the sequential algorithm. The algorithm applies two modes of operations depending on the value of the moves' acceptance rate $\lambda(T)$ which is more formally defined as the ratios of accepted moves to the number of attempted moves for a given T. For m processors, the algorithm has the following two modes:

- High temperature mode: if $\lambda(T) \geq \frac{1}{m}$ each processor evaluates only one move and one of the accepted moves is chosen randomly. The processors' memories are updated with the new solution and the next step takes place. For the Markov chain to have the same acceptance rate as its sequential counterpart, the number of moves attempted is computed as follows: when m evaluations are performed in parallel and at least one move has been accepted, the algorithm assumes that $\frac{m+1}{m-l+1}$ moves have been attempted (l: number of rejected moves). On the other hand, if no moves have been accepted, the algorithm assumes that m moves have been attempted.
- Low temperature mode: in case of $\lambda(T) < \frac{1}{m}$, the different processors perform moves, in parallel, until a move is accepted. Then, the processors are synchronized and their memories updated with the new solution. Now, the next evaluation step takes place.

The high temperature mode is inefficient since many moves are not counted. In addition, since few moves are rejected at high temperatures, the value $\frac{m+1}{m-l+1}$, which represents speedup of the algorithm, approaches one. The results produced by the work showed that the computing time in this mode is higher than the sequential mode. It is important to note, that the time spent in this mode (i.e., high temperature) increases as the number of processor grows. In the low temperature mode, the algorithm is biased towards moves that can be generated rapidly.

The above problem was also encountered in the work by [37]. In their work, the authors evaluate the cost function for VLSI circuit placement in parallel, while simultaneously an additional processor is selecting the next state. However, the maximum speedup that was reported is bounded by $1 + 2\alpha + \eta$, where α is the average number of cells affected per move, and η is the average number of wires affected per move. Most cost function based computations exploit fine-grain parallelism, which lead to communication and synchronization dominating this type of algorithms [26], and so speedups due to parallelism are minimal.

Another approach to developing parallel SA is based on exploiting parallelism in making accept-reject decisions [62]. If a processor is assigned to each node in the tree shown below (Fig. 37.3), then cost function evaluation for each suggested move can proceed in parallel.

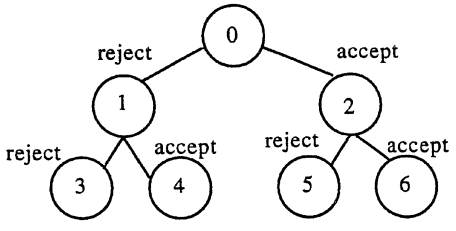

FIGURE 37.3 Decision tree.

The above algorithm maintains the serial decision sequence. The algorithm is based on the concurrency technique of *speculative computation* in which work is performed before it is known whether or not it is needed. As noted earlier, each move in the SA algorithm results in either an accept or a reject decision. Therefore, while one processor evaluates the current move, two other moves can be speculatively computed.

For each temperature, the algorithm forms an unbalanced binary tree of processors which identifies the future work which is likely to be needed. Computation in the tree begins at the root and continues until a processor makes a decision but does not have a corresponding slave processor. The current solution is communicated to the root.

The main problem with the work proposed by [62] is the accompanied heavy communication cost. The root sends the solution to the reject node, generates a move, and then sends a new solution to the accept processor. Then, each node transfers the solutions to its slaves. After making a decision, the node at the end of the correct path sends its solution to the root processor. In the case of large networks of processors,

the solution has to travel through several nodes to reach the root processor. In at least one experiment, the reported computation time of the sequential algorithm was lower than that of the parallel algorithm [61].

A more efficient variation of the above algorithm was developed in [42, 43], which attempts to minimize the communication overhead. It is based on the observation that the difference between the solution at a node and any of its slaves and master is a maximum of one move. The gist of the work is to communicate only the new moves.

Initially, the root processor broadcasts a solution to all the processors in the network. Moreover, the algorithm ensures that all the nodes have the current solution at the beginning of each computation phase. The root generates the first move and then each other processor receives only the number of moves required for its operation.

Figure 37.4 shows an unbalanced tree which consists of ten processors. Each node has a maximum of two slaves: the one on the left is the reject processor, while the one on the right is the accept processor. Node (0) is the root processor and the dotted arrows show the communication direction (i.e., they point to the destination processor). Note that the number attached to the arrow is the number of moves required to be transferred.

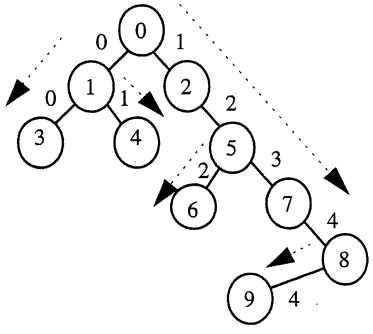

FIGURE 37.4 Moves transfer in a 10-processor unbalanced tree.

In Fig. 37.4, node (1) is the root's reject processor—it does not require any moves. The same applies to node (3). The move generated by node (1) is sent to node (4). Node (2) requires the move generated by the root processor. It receives the move, generate its new move, and then sends both moves to node (5). The technique is applied to all the nodes in the network. A node evaluates its solution immediately after communicating with its slaves.

Once the correct path is identified, the node at the end of this path transfers the number of moves required to update its neighbors which, in turn, send the number of moves to update their neighbors. The maneuver is repeated until all the nodes are updated. The new iteration begins when the root processor completes communicating with its slaves.

Figure 37.5 illustrates the updating process in the 10-processor network described above. It is assumed that the correct path ends at node (8), hence the move generated by node (8) is accepted. Nodes (7) and (9) need to know only this move to update their solution. Node (5) requires the two moves generated by nodes (7) and (8). Simultaneously, node (5) updates the solution of its master and its reject processor. The same procedure is applied to all other nodes in the network.

The algorithm exhibits several salient advantages over the work of [61, 62], for example,

- For problems of large size, the communication overhead is significantly reduced.
- The communication time depends only on the shape of the tree and the number of its nodes. Thus, in comparison to [61, 62], as the size of the problem increases, the performance of the method improves as compared with a sequential solution.

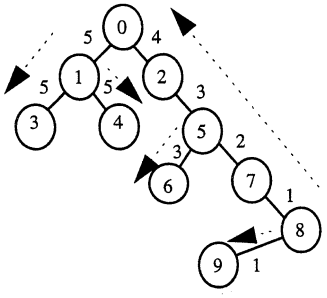

FIGURE 37.5 Updating the nodes of the 10-processor unbalanced tree.

- At low temperatures, less moves are required to be transferred because there are more rejects and, accordingly, the efficiency of the algorithm increases.

The two methods (i.e., [62] and [42]) were compared using the Traveling Salesman Problem as a benchmark [46]. Figures 37.6, 37.7, and 37.8 below show the results of both algorithms in the case of 20, 50, and 100 cities. The results show that the performance of the [42] algorithm improves as the number of cities increases.

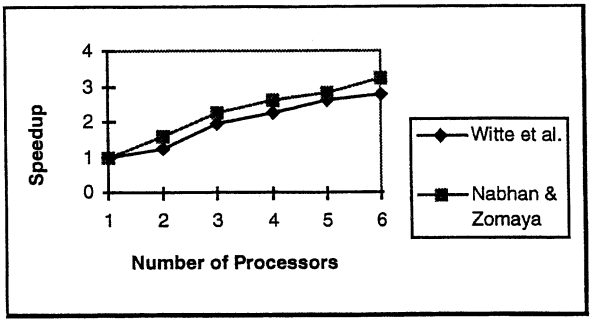

FIGURE 37.6 Speedup comparisons for 20 cities.

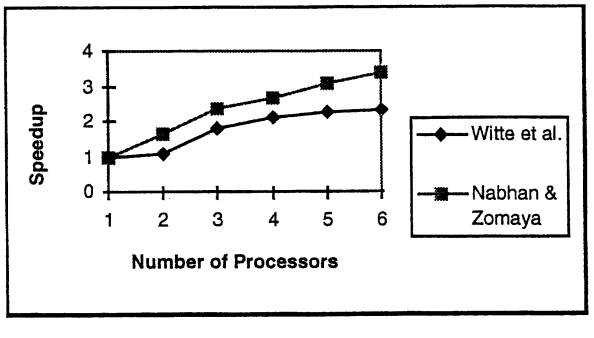

FIGURE 37.7 Speedup comparisons for 50 cities.

The annealing schedule for the above experiments was $T_k = \eta^k T_{k-1}$, where $\eta = 0.99$ (to ensure a slow cooling rate). Normally, an initial high T is chosen to allow a good search of the solution space

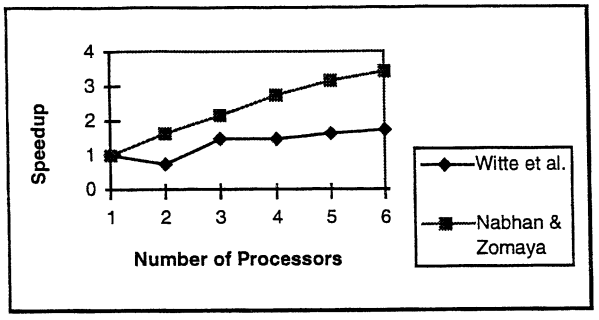

FIGURE 37.8 Speedup comparisons for 100 cities.

at the outset. The maximum number of moves (μ) attempted at each T was set equal to 100 times the number of cities. At each T a series of moves are generated until μ moves are computed, or the number of accepted moves equals to 0.1μ. The initial T (i.e., T_0) was set to 50, and the final (freezing) T set to 0.2. It is important to note, that in all the experiments, the solutions in the case of the parallel algorithm were identical to that of the sequential algorithm. For more details the reader is referred to [42].

The parallel SA algorithm developed in [43] was applied with success to wider range of problems such as solving the scheduling problem in parallel processor systems. In general, SA implementations based on speculative computation seem to produce high quality solutions in reasonable amounts of time [56].

Other parallel implementations of the SA algorithm have been proposed in the literature. These are based on the idea that the SA algorithm can tolerate, to some extent, increases or errors in the cost function without jeopardizing convergence to the correct global minimum. This type of parallel algorithms is known as *asynchronous* [26], since different processors can operate on old data, under certain conditions, and still converge to a reasonable solution [5, 14, 34, 50]. In this case, the processors do not need to update their states in a synchronous fashion and can minimize the amount of information that they need to transmit. This helps in reducing the synchronization barrier quite considerably.

However, Greening [26] argues that one could construct a problem that can converge to a good solution in the sequential SA algorithm, but which converges to a local minimum in an asynchronous case. A number of other approaches can be found in the literature that employ both synchronous and asynchronous techniques [26]. Overall, synchronous methods seem to provide higher quality solutions.

In general, an efficient parallel SA algorithm should be *scalable*. Scalability is a general requirement for any well-designed parallel algorithm [64]. Scalability requires that a given algorithm be reasonably efficient when the size of the problem grows and the number of processors increases.

37.7 Research Issues and Summary

This chapter reviewed the SA algorithm and provided an insight into its origins and its more recent developments. The algorithm is a very powerful optimization technique that was motivated by the behavior of condensed matter at low temperatures. The analogy arises from the way that liquids freeze or metals cool and anneal.

The basic idea is to allow enough time for the states (atoms) of the system to rearrange themselves so that they achieve the lowest energy state (cost function value). Of course, in the case of an optimization problem, the sequence of states is generated through some Monte Carlo probability selection method.

The main strength of the SA algorithm is that of accepting states that may not improve immediately the value of the cost function. Accepting such states is limited by some probabilistic acceptance criterion. This enables the algorithm to escape from local minima and to find an optimal (globally minimal) solution. An important factor discussed in this chapter that contributes to the success of the algorithm in finding a good solution is the annealing schedule.

Parallel versions of the SA algorithm were also discussed in this chapter. These algorithms aim to speedup the rate of convergence of the sequential algorithm. One important issue that a parallel algorithm needs to maintain is the continuity of the Markov chain. If the Markov chain is broken, then there is no guarantee that the parallel algorithm will eventually converge, and most probably it will get trapped into local minima.

The SA algorithm (sequential or parallel) has been applied to a wide range of problems as can be seen from the list of references at the end of this chapter. However, there is still great potential in using the SA algorithm to solve more formidable problems that can be formulated as optimization problems. There is however, an even greater opportunity: using the SA algorithm in combination with other stochastic techniques such as neural networks and genetic algorithms to produce more powerful problem solving tools.

Another aspect that needs more research is the production of more efficient parallel SA algorithms. At this stage, the algorithms that provide high quality solutions within reasonable amounts of time are of the synchronous type. This means that their speedup is hindered by the need to synchronize and also to communicate massive amounts of data. These performance limitations don't occur in the case of asynchronous SA algorithms, however, asynchronous algorithms don't produce high quality solutions and might fail to converge. Therefore, there is a need to develop more efficient parallel SA algorithms that provide high quality solutions along with large speedup ratios.

37.8 Defining Terms

Asymptotic optimality: A given algorithm is called asymptotically optimal when the quality of the solution that can be obtained improves the more the algorithm is executed.

Detailed reversibility: The probability of a transition from state i to state j is equal to the probability in the reverse direction, from state j to state i.

Global optimization: Finding the lowest minimum of a nonlinear function $f(x)$ in some closed subregion U of $\Re^n$, in cases, where $f(x)$ may have multiple local minima in this subregion.

Irreducible Markov chain: A Markov chain is irreducible if for every two states i and j, there is a sequence of iterations or moves which enables j to be reached from i.

Local minimum: This is any point that has the lowest cost function value among all points in some open n-dimensional region around itself.

Markov chain: A sequence of trials where the outcome of any trial corresponds to the state of the system. A main characteristic of the Markov chain is that the new state depends only on the previous state and not on any earlier state.

Scalability: A parallel algorithm is scalable if it is capable of delivering an increase in performance proportional to the increase in the number of processors utilized.

Further Information

The list of references given in this chapter is quite extensive, and it shows that the use of the SA algorithm is quite ubiquitous. Actually, at the time of the writing of this chapter, one HotBot search on the Web returned 14,797 hits. This gives the reader some indication of the popularity of the SA algorithm.

There are no specific journals or conference proceedings that exclusively publish material related to the SA algorithm. However, it could be noticed from the list of references that the *IEEE Transactions on Computer-Aided Design* and the *IEEE Transactions on Parallel and Distributed Systems* often publish material related to the SA algorithm. Also, proceedings of the IEEE/ACM Conference on Computer-Aided Design and the International Conference on Computer Design are good sources of material. The range of applications is quite diverse: parallel processing, graph drawing (Chapter 9 in this volume), VLSI design (Chapter 23 in this volume), scheduling (Chapter 35 in this volume), to name a few.

A good starting point is the paper by Kirkpatrick et al. [36] and the books given in references [1, 57], after which one could proceed to more advanced topics, such as convergence issues and other theoretical themes [3, 6, 11, 20, 21, 23, 30, 38] and parallelizing techniques [4, 26]. One could also try to learn

more bout the type of applications that the SA algorithm can be applied to solve by reading some of the references cited in this chapter. Furthermore, the reader might want to download some of the readily available software packages from Web. These could provide a valuable starting point to experiment with SA code.

Cryptographic Foundations

Yvo Desmedt
University of Wisconsin – Milwaukee

38.1 Introduction

Cryptography studies methods to protect several aspects of data, in particular *privacy* and *authenticity*, against a malicious adversary who tries to break the security. In contrast with steganography, where the data and its existence is physically hidden, cryptography transforms the data mathematically, usually using a key. **Cryptanalysis** is the study of methods to break cryptosystems.

Cryptography has been studied for centuries, although initially it focused only on protecting privacy. Originally it was used in the context of military and diplomatic communication. Most of these historical cryptoschemes have no practical value nowadays since they have been cryptanalyzed, i.e., broken. However, it should be noted that it has taken **cryptanalysts** (those researchers or technicians trying to break cryptosystems) more than 300 years to find a general method to solve polyalphabetic ciphers with repeating keywords (see "Other Historical Ciphers"). This contrasts with popular modern cryptosystems, such as DES and RSA (see Sections 38.5 and "RSA" of Chapter 39), that have only been around for a few decades, which brings us now to modern cryptography.

Modern cryptography differs from historical cryptography in many respects. First of all, mathematics plays a more important role than ever before. By means of probability theory, Shannon was able to prove that Vernam's one-time pad (see Section 38.4) is secure. Second, the rather new area of computational complexity has been used as a foundation for cryptography. Indeed, the concept of **public key**, which facilitates the use of cryptography (see "Conventional Cryptography Versus Public Key") finds its origin there. Third, the widespread use of communication implies that cryptography is no longer a uniquely

military topic. High-speed networks and computers are responsible for a world in which postal mail is being replaced by electronic communication in such applications as bank transactions, access to worldwide databases as in the World Wide Web, e-mail, etc. This also implies a whole new range of security needs that need to be addressed, for example, anonymity (see Chapter 44), authenticity (see Chapter 40), commitment and identification, law enforcement, nonrepudiation (see Chapter 40), revocation, secure distributed computation, timestamping, traceability, witnessing, etc.

To illustrate the concept, we will first describe some historical cryptosystems in Section 38.2, explain how these can be broken and, in Section 38.3, define cryptosystems.

38.2 Historical Cryptosystems

We will now discuss some historical cryptosystems to lay the foundation for describing how they are broken. For a more complete survey of historical cryptosystems, the reader may refer to the literature.

The Caesar Cipher and Exhaustive Key Search

One of the oldest cryptosystems is the *Caesar cipher*, often incorrectly cited as the first cryptosystem. Caesar replaced each symbol in the original text, now called **plaintext** or **cleartext**, by one that was three positions further in the alphabet, counted cyclically. The word "plaintext," for example, would become "sodlqwhaw" in this system. The result is called **ciphertext**. The problem with this scheme is that anyone who knows how the text is encoded can break it. To prevent this, a *key* is used.

To describe a more modern variant of the Caesar cipher, let n be the cardinality of the alphabet being used, which is 26 for the English alphabet, or 27 when the space symbol is included in the alphabet. (In many old cryptoschemes, the space symbol was dropped since it would facilitate breaking the code.) The first symbol of the plaintext is mapped into the number 0, the second into 1, etc. To **encrypt** with the Caesar cipher, one adds modulo n the key k to the symbol m, represented as an integer between 0 and $n-1$. (Two integers a and b are equivalent modulo n, denoted as $a \equiv b \bmod n$, when a and b have the same nonnegative remainder when divided by n). The corresponding symbol, then, in the ciphertext is $c = m + k \bmod n$, where the equality indicates that $0 \leq c < n$. If a long enough message contains redundancy, as plain English does, then an **exhaustive search** of all possible keys will reveal the correct plaintext. **Decryptions** (the process that permits the person who knows the secret key to compute the plaintext from the ciphertext) with the wrong key will (likely) not produce an understandable text; therefore, the keyspace in the Caesar cipher is too small.

Substitution Cipher and Ciphertext-Only Attack

We will now consider the substitution cipher. In plaintext, each symbol m is replaced by the symbol $E_k(m)$, specified by the key k. To allow unique decryption the function E_k must be one-to-one. Moreover, if the same symbols are used in the ciphertext as in the plaintext, it must be a bijection. If the key can specify any such bijection, the cipher is called a *simple substitution cipher*. Obviously, for the English alphabet there are $26! = 403291461126605635584000000$, roughly $4 * 10^{26}$, different keys. We will now discuss the security of the scheme, assuming that the cryptanalyst only knows the ciphertext and the fact that a substitution cipher was used. Such an attack is called a *ciphertext-only attack*. Note that an exhaustive key search would take too long on a modern computer. Indeed, a modern parallel computer can perform 10^9 operations per second. For simplicity, assume that such a computer could perform 10^9 symbol decryptions per second. One wonders then how long the ciphertext needs to be before one can be certain that the cryptanalyst has found a sufficiently correct key. This measure is called the *unicity distance.* Shannon's theory of secrecy [25] tells us that this is 28 symbols for an English text. An exhaustive key search would roughly take $3.6 * 10^{11}$ years before finding a sufficiently correct key. However, a much faster method for breaking a substitution cipher exists, which we will now describe.

In English the letter "e" is the most frequently used. Furthermore, no other letter has a frequency of occurrence that comes close to that of "e." A cryptanalyst starts the procedure by counting how many times each letter appears in the ciphertext. When the ciphertext is long enough, the most frequent letter in the ciphertext corresponds to the letter "e" in the plaintext. The frequencies of the letters "T,O,A,N,I,R,S,H" are too similar to decide by which letter they have been substituted. Therefore the cryptanalyst will use the frequency distribution of two or three consecutive letters, called a *digram* and a *trigram*. When the space symbols have been discounted, the most frequent digrams are: "th;" "e" as the first letter, decreasing in order as follows: "er,ed,es,en,ea;" and "e" as the second letter: "he,re." The digram "he" is also quite common. This permits the identification of the letter "h," and then the letter "t." The next step is to distinguish the vowels from the consonants. With the exception of the digrams "ea,io" two vowels rarely follow one another. This allows one to identify the letter "n," since 4 out of 5 letters following "n" are vowels. Using similar properties of other digrams and trigrams, the full key is found. If mistakes are made, they are easily spotted and one can recover using backtracking.

Ideal Ciphers and Known-Plaintext Attack

Redundancy in a language permits breaking a substitution cipher; however, one may question the security of a text if it is compressed first. Shannon proved that if *all* redundancy is removed by the source coder, a cryptanalyst using a ciphertext-only attack cannot find a unique plaintext solution. In fact there are 26! meaningful plaintexts! Shannon [25] called such systems *ideal*. However, one cannot conclude that such a system is secure. Indeed, if a cryptanalyst knows just one (not too short) plaintext and its corresponding ciphertext, finding the key and breaking all future ciphertexts encrypted with the same key is a straightforward procedure. Such an attack is known as a *known-plaintext attack*.

Other types of attacks are the *chosen text attacks,* which comprise *chosen-plaintext* and *chosen-ciphertext attacks*. In a chosen-plaintext attack, the cryptanalyst succeeds in having a plaintext of his choice being encrypted. In a chosen-ciphertext attack, it is a ciphertext of his choice that is decrypted. The cryptanalyst can, in this context, break the simple substitution cipher having the string of all the different symbols in the alphabet encrypted or decrypted. Chosen-plaintext attacks in which the text is not excessively long are quite realistic in a commercial environment. Indeed, company A could send an (encrypted) message about a potential collaboration to a local branch of company B. This company, after having decrypted the message, will most likely forward it to its headquarters, encrypting it with a key that the cryptanalyst in company A wants to break. In order to break it, it is sufficient to eavesdrop on the corresponding ciphertext. Note that a chosen-ciphertext attack is a little harder. It requires access to the output of the decryption device, for example, when the corresponding, and likely unreadable, text is discarded.

Although ideal ciphers are a nice information theoretical concept, their applicability is limited in an industrial context where standard letters, facilitating a known-plaintext attack, are often sent. Information theory is unable to deal with known-plaintext attack. Indeed, finding out whether a known-plaintext is difficult or not is a computational complexity issue. A similar note applies to the unicity distance. Many modern ciphers, such as DES (see Section 38.5), have unicity distances shorter than that of the substitution cipher, but no method is known to break them in a very efficient way. Therefore, we will not discuss in further detail the results of ideal ciphers and unicity distance.

Other Historical Ciphers

Before finishing the discussion on historic cryptosystems, we will briefly mention the transposition cipher and the polyalphabetic ciphers with repeating keywords. In a transposition cipher, also known as a permutation cipher, the text is split into blocks of equal length and the order of the letters in each block is mixed according to the key. Note that in a transposition cipher the frequency of individual letters is not affected by encrypting the data, but the frequency of digrams is. It can be cryptanalyzed by trying to restore the distribution of digrams and trigrams. In most polyalphabetic ciphers, known as periodic

substitution ciphers, the plaintext is also split into blocks of equal length, called the period d. One uses d substitution ciphers by encrypting the i^{th} symbol ($1 \leq i \leq d$) in a block using the i^{th} substitution cipher. The cryptanalysis is similar to the simple substitution cipher once the period d has been found. The Kasiski method [14] analyzes repetition in the ciphertext to find the exact period. Friedman [10] index of coincidence to find the period is beyond the scope of this introduction. Other types of polyalphabetic ciphers are running key ciphers, the Vernam's one-time pad (see Section 38.4), and rotor machines, such as Enigma.

Many modern cryptosystems are **polygram substitution ciphers,** which are a substitution of many symbols at once. To make them practical, only a subset of keys is used. For example DES (see Section 38.5) used in Electronic Code Book mode substitutes 64 bits at a time using a 56 bit key instead of a $\log_2(2^{64}!)$ bit key (which is longer than 2^{64} bits) if any polygram substitution were allowed. Substitution and transposition ciphers are examples of **block ciphers,** in which the plaintext and ciphertext are divided into strings of equal length, called blocks, and each block is encrypted one at a time.

38.3 Definitions

As mentioned in Section 38.1, modern cryptography covers more than simply the protection of privacy, but to give all these definitions is beyond the scope of this chapter. We will focus on privacy and authenticity.

Privacy

DEFINITION 38.1 A cryptosystem used to protect privacy, also called an *encryption scheme* or system, consists of an *encryption* algorithm E and a *decryption* algorithm D. The input to E is a plaintext message $m \in M$ and a key k in the key space K. The algorithm might use randomness $r \in R$ as an extra input. The output of the encryption is called the ciphertext $c \in C$ and $c = E_k(m) = f_E(k, m, r)$.

The decryption algorithm (which may use randomness) has input a key $k' \in K'$ and a ciphertext $c \in C$ and outputs the plaintext m, so, $m = D_{k'}(E_k(m))$. To guarantee unique decryption, the following must be satisfied:

$$\text{for all } k \in K, \text{ for all } m, \text{ for all } m' \neq m, \text{ for all } r \text{ and } r' : f_E(k, m, r) \neq f_E(k, m', r') \ .$$

Security

Clearly, in order to prevent any unauthorized person from decrypting the ciphertext, the decryption key k' must be secret. Indeed, revealing parts of it may help the cryptanalyst.

The types of attacks that a cryptanalyst can use have been informally described in Section 38.2. The most powerful attack is the adaptive chosen text attack, in which the cryptanalyst employs several chosen texts. In each run, the cryptanalyst observes the output and adapts the next chosen text based on the previous ones and the output of previous attacks.

An encryption scheme is *secure* if, given public parameters and old plaintext-ciphertext pairs obtained using known-plaintexts and/or chosen text attacks, the new ciphertext is indistinguishable from a random string of the same length uniformly chosen. We will discuss this further in Sections "Levels of Security" and "Security."

Authenticity

While the terminology is rather standard for cryptosystem's protecting privacy, that for authenticity is not. Research and a better understanding of the topic have made it clear that using concepts as encryption and decryption makes no sense. This was done in the early stages when the concept was introduced.

DEFINITION 38.2 A cryptosystem used to protect authenticity, also called an *authentication scheme* or system, consists of an *authenticator generation* algorithm G and a *verification* algorithm V. The input to G is a message $m \in M$ and a key k' in the key space K'. The algorithm might use randomness $r \in R$ as an extra input. The output of the generation algorithm is the authenticated message (m, a) where m is the message m and a is the authenticator. In other words $(m, a) = G_{k'}(m) = (m, f_G(k', m, r))$.

The inputs of the verification algorithm V (which may use randomness) are a key $k \in K$ and a string (m', a'). The message is accepted as authentic if $V(m', a', k)$ returns a one (if the Turing machine accepts), else it is rejected. To guarantee that authentic messages are accepted one needs that $V_k(G_{k'}(m))$ is (almost always) one.

Security

It is clear that to prevent any unauthorized person from authenticating fraudulent messages the key k' must be secret. Indeed, revealing parts of it may help the cryptanalyst.

The types of attacks that a cryptanalyst can use are similar to those that have been informally described in Section 38.2. The goal of the cryptanalyst has changed. It is to construct a new, not yet authenticated message. The most powerful attack is the adaptive chosen text attack, in which the cryptanalyst employs several chosen messages which are given as input to G. The cryptanalyst observes the output of G in order to adapt the next chosen message based on previous ones and the output of previous attacks.

An authentication scheme is *secure* if, given public parameters and old message-authenticator pairs obtained using known message and/or chosen message attacks, the probability that any cryptanalyst can construct a *new* pair (m', a') which the verification algorithm V will accept as authentic, is negligible. Chapter 40 discusses this in more detail.

Levels of Security

Modern cryptography uses different models to define security. One distinguishes between: heuristic security, as secure as, proven secure, and unconditionally secure.

A cryptographic system or protocol is *heuristically secure* as long as no attack has been found. Many practical cryptosystems fall within this category.

One says that a cryptosystem or protocol is *as secure as* another if it can be proven that a new attack against one implies a new attack against the other and vice versa. A much stronger statement is that a system is proven secure.

To speak about proven security, one must first formally model what security is, which is not always obvious. A system or protocol is said *proven secure relative to an assumption* if one can prove that if the assumption is true, this implies that the formal security definition is satisfied for that system or protocol.

In all aforementioned cryptosystems one usually assumes that the opponent, e.g., the eavesdropper, has a bounded computer power. In the modern theoretical computer science model, this is usually expressed as having the running time of the opponent be bounded above by a polynomial in function of the security parameter, which often is the length of the secret key. Infeasible corresponds with a minimum running time bounded below by a superpolynomial in the length of the security parameter. Note that there is no need to use a polynomial versus superpolynomial model. Indeed, having a huge constant as a lower bound for a cryptanalytic effort would be perfectly satisfactory. For example, according to quantum physics, time is discrete. A huge constant could be the estimated number of time units that have elapsed since the (alleged) big bang.

A cryptosystem is unconditionally secure when the computer power of the opponent is unbounded and it satisfies a formal definition of security. Although these systems are not based on mathematical or computational assumptions, usually these systems can only exist in the real world when true randomness can be extracted from the universe. In Section 38.4 we will discuss an unconditionally secure encryption scheme.

A special class of cryptosystems assumes the correctness of the laws of quantum physics. These cryptosystems are known as quantum cryptography.

Conventional Cryptography Versus Public Key

We will now discuss whether k must remain secret and the relationship between k' and k. If it is easy to compute k' from k, it is obvious that k must also remain secret. The key is unique to a sender–receiver pair. In this case, the cryptosystem is called a **conventional** or **symmetric cryptosystem**.

If, on the other hand, given k it is hard to compute k' and hard to compute a k'', which allows partial cryptanalysis, then the key k can be made public. The system, the concept of which was invented by Diffie and Hellman [7] and independently by Merkle [19], is called a public key or **asymmetric cryptosystem**. This means that for privacy protection each receiver R will publish a personal k_R, and for authentication, the sender S makes k_S public. In the latter case the obtained authenticator is called a **digital signature**, since anyone who knows the correct public key k_S can verify the correctness. The scheme is then called a signature scheme.

The public key k is considered a given input in the discussion on the security of encryption and authentication schemes (see "Privacy – Security" and "Authenticity – Security").

Security

It was stated in the literature that digital signature schemes have the property that the sender cannot deny having sent the message. However, the sender can claim that the secret key was physically stolen. That would allow him to deny ever having sent a message. Such situations must be dealt with by an authority. Protocols have been presented in which the message is being deposited to a notary public or arbiter. Schemes have been developed in which the arbiter does not need to know the message that was authenticated. Another solution is digital timestamping based on cryptography (the signer needs to alert an authority that his public key must have been stolen).

The original description of public key systems did not explain the importance of the authenticity of the public key. Indeed, if it is not authentic, the one who created the fake public key can decrypt messages intended for the legitimate receiver, or can sign claiming to be the sender. So the security is then lost. In practice, this problem is solved by using a *certificate* that is itself a digital signature(s) of a message. It is provided by a known trusted entity(ies) who guarantee(s) that the public key of S is k_S.

We will now explain the need to use randomness in public key encryption systems. If no random input is used, the public key system is vulnerable to a partially known-plaintext attack. In particular, if the sender S, e.g., a supervisor, uses a standard letter to send almost the same message to different receivers, e.g., to inform them about their salary increase, the system does not guarantee privacy. Indeed, any of the receivers of these letters can exhaustively fill in the nonstandard part and encrypt the resulting letter using the public key of the receiver until the obtained ciphertext corresponds with the eavesdropped one! So, if no redundancy is used the eavesdropper can always verify whether a particular message has been encrypted. It is easy to see that if no randomness is used the resulting ciphertext will have a probability distribution which is 0 for all values, except for the deterministic encryption of the plaintext. Although these attacks are well known, very few practical public key systems take precautions against it. Goldwasser and Micali [11] called schemes avoiding this weakness **probabilistic encryption schemes** and presented a first solution (see Section 39.7). It is secure against known-plaintext attack under a computational number theoretic assumption.

Practical Concerns

To be practical the encryption, decryption, authentication and verification algorithms must be efficient. In the modern theoretical computer science model, this is usually expressed as having a running time

bounded by a polynomial in function of the length of the key and by stating that the length of the message is bounded by a polynomial in function of the length of the key.

It is clear that to be useful $M = \{0, 1\}^*$ (or have a polynomial length). However, this is often not the case. A mode or protocol is then needed to specify how the encryption and decryption algorithms (or the authentication and verification algorithms) are used on a longer text. For an example, see Section "The Modes".

38.4 The One-Time Pad

The *one-time pad* (a conventional cryptosystem) and Shannon's [25] analysis of its security is one of the most important discoveries in modern cryptography. We will first discuss the scheme, then give a formal definition of the security, prove it to be secure, and briefly discuss some of the applications of the one-time pad.

The Scheme

In Vernam's one-time pad the key is (at least) as long as the message. Let the message be a string of symbols belonging to the alphabet (a finite set) S, for example $\{0, 1\}$, on which a binary operation "$*$" is defined, for example the exor (exclusive or). We assume that $S(*)$ forms a group.

Before encrypting the message the sender and receiver have obtained a secret key, a string, of which the symbols have been chosen uniformly random in the set S and independent. Let m_i, k_i, and c_i be the i^{th} symbols of, respectively, the message, the key, and the ciphertext, each belonging to S. The encryption algorithm produces $c_i = m_i * k_i$ in S. To decrypt, the receiver computes $m_i = c_i * k_i^{-1}$. *The key is used only once.* This implies that if a new message needs to be encrypted a new key is chosen, which explains the terminology: one-time pad.

It is trivial to verify that this is an encryption scheme. In the case $S(*) = Z_2(+) = \{0, 1\}(+)$, the integers modulo 2, the encryption algorithm and the decryption algorithm are identical and the operation corresponds with an exor (exclusive or). We will now define what privacy means.

Security

DEFINITION 38.3 Shannon defined an encryption system to be perfect when, for a cryptanalyst not knowing the secret key, the message m is independent of the ciphertext c, formally:

$$\text{prob}\,(\mathbf{m} = m \mid \mathbf{c} = E_k(m)) = \text{prob}(\mathbf{m} = m)\ . \tag{38.1}$$

THEOREM 38.1 *The one-time pad is perfect.*

PROOF Let the length of the message be l (expressed as the number of symbols). Then the message, key, and ciphertext belong to $S^l = S \times S \cdots \times S$. Since S^l is a group it is sufficient to discuss the proof for the case $l = 1$. Let $c = E_k(m) = m * k$ in S. Now, if $k' = m^{-1} * c = k$, then $\text{prob}(\mathbf{c} = c \mid \mathbf{m} = m, \mathbf{k} = k') = 1$, else it is zero. Using this fact, we obtain

$$\begin{aligned}
\text{prob}(\mathbf{m} = m, \mathbf{c} = c) &= \sum_{k' \in S} \text{prob}\left(\mathbf{c} = c \mid \mathbf{m} = m, \mathbf{k} = k'\right) \cdot \text{prob}\left(\mathbf{m} = m, \mathbf{k} = k'\right) \\
&= \text{prob}(\mathbf{m} = m, \mathbf{k} = k) \\
&= \text{prob}(\mathbf{m} = m) \cdot \text{prob}(\mathbf{k} = k) \qquad (\mathbf{k} \text{ is independent of } \mathbf{m})
\end{aligned}$$

$$= \quad \text{prob}(\mathbf{m} = m) \cdot \frac{1}{|S|} \qquad (\mathbf{k} \text{ is uniform.})$$

Also, if $c = m' * k'$ then $\text{prob}(\mathbf{c} = E_k(m) \mid \mathbf{m} = m', \mathbf{k} = k') = 1$, else it is 0. This gives

$$\begin{aligned}
\text{prob}(\mathbf{c} = c) &= \sum_{k',m'} \text{prob}\left(\mathbf{c} = c \mid \mathbf{m} = m', \mathbf{k} = k'\right) \cdot \text{prob}\left(\mathbf{m} = m', \mathbf{k} = k'\right) \\
&= \sum_{\substack{k',m' \\ c=m'*k'}} \text{prob}\left(\mathbf{m} = m', \mathbf{k} = k'\right) \\
&= \sum_{m'} \text{prob}\left(\mathbf{m} = m'\right) \cdot \text{prob}\left(\mathbf{k} = \left(m'\right)^{-1} * c\right) \qquad (\mathbf{k} \text{ is independent of } \mathbf{m}) \\
&= \frac{1}{|S|} \cdot \sum_{m' \in S} \text{prob}\left(\mathbf{m} = m'\right) \qquad (\mathbf{k} \text{ is uniform}) \\
&= \frac{1}{|S|},
\end{aligned}$$

implying that $\text{prob}(\mathbf{m} = m, \mathbf{c} = c) = \text{prob}(\mathbf{m} = m) \cdot \text{prob}(\mathbf{c} = c)$.

COROLLARY 38.1 In the one-time pad, the ciphertext has a uniform distribution.

This corollary corresponds with the more modern view on the definition of privacy. Note that it is easy to make variants of the one-time pad that are also perfect.

Shannon proved that the length of the key must be at least, what he called, the entropy (see Chapter 40) of the message. Recent work has demonstrated that the length of the key must be at least the length of the message.

Its Use

The use of the one-time pad to protect private communication is rather limited, since a new secret key is needed for each message. However, many zero-knowledge interactive proofs use the principle that the product in a group of a uniformly chosen element with any element of the group, whatever distribution, gives a uniform element.

Also, the idea of *stream cipher,* in which the truly random tape is replaced by a pseudo-random tape, finds its origin in the one-time pad.

38.5 DES and Block Ciphers

As already observed in "Other Historical Ciphers," many modern encryption schemes, in particular conventional encryption schemes, are (based on) polygram substitution ciphers. To obtain a practical scheme, the number of possible keys needs to be reduced from the maximal possible ones. To solve this problem Shannon [25] proposed the use of *mixing transformation,* in which the plaintext is iteratively transformed using substitution and transposition ciphers. Feistel adapted this idea. The data encryption standard (DES) is a typical example of such an encryption scheme, which we will now describe. The messages belong to $\{0, 1\}^{64}$ and the key has 56 bits. To encrypt a message longer than 64 bits, a *mode* is used. The official modes used for DES are discussed in "The Modes." We will now describe the actual algorithm.

The Algorithm

First note that the detailed design criteria of the DES algorithm are classified, while the algorithm itself is public. The DES algorithm, as described by NBS (now called NIST), consists of three fundamental parts:

- The enciphering computation which follows a typical Feistel approach,
- The calculation of $f(R, K)$, and
- The key schedule calculation.

They are represented, respectively, in Figs. 38.1, 38.2, and 38.4 are briefly described below.

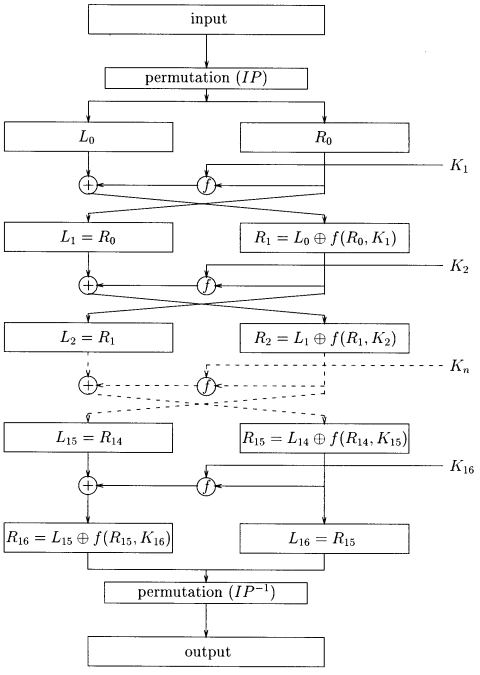

FIGURE 38.1 DES block diagram of the enciphering computation.

First observe that several boxes are used in the DES algorithm. It would be too long an explanation to give the details of all these boxes; this can be found in the literature. The kind of boxes (e.g., permutation) will be mentioned. Remark that the input numbering starts from 0 for some boxes and from 1 for some other ones.

In the *enciphering computation,* the input is first permuted by a fixed permutation IP from 64 bits into 64 bits. The result is split up into the 32 left bits and the 32 right bits, respectively. In Fig. 38.1 this corresponds to L and R. Then a bitwise modulo 2 sum of the left part L_i and of $f(R_i, K_i)$ is carried out. The function f is described in Fig. 38.2. After this transformation, the left and right 32 bit blocks are interchanged. From Fig. 38.1, one can observe that the encryption operation continues iteratively for 16 steps or rounds. In the last round, no interchange of the final obtained left and right parts is performed. The output is obtained by applying the inverse of the initial permutation IP to the result of the 16^{th} round.

In the *calculation of* $f(R_i, K_i)$ the 32 right bits are first expanded to 48 bits in the box E, (see Figs. 38.2 and 38.3) by taking some input bits twice, others only once. Then a bitwise modulo 2 sum of the expanded right bits and of 48 bits of the key, called the *subkey* is performed. This subkey is obtained from the *key schedule calculation,* which will be explained later on. The results of the modulo 2 sum go to eight S-boxes.

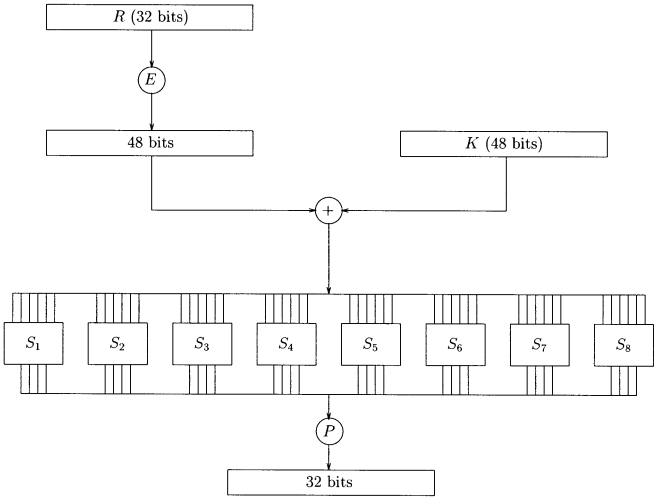

FIGURE 38.2 DES block diagram of $f(R, K)$.

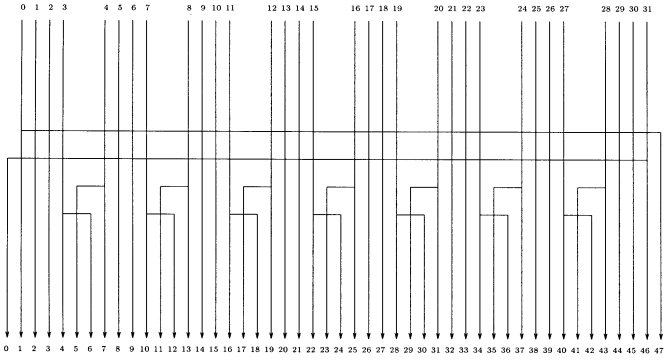

FIGURE 38.3 The box E.

Each S-box has six inputs and four outputs. The S-boxes are nonlinear functions. The 32 output bits of the S-boxes are permuted in the box P.

Let us finally describe the *key schedule calculation* (see Fig. 38.4). The key consists of 64 bits, of which only 56 bits are used. The other 8 bits are not used in the algorithm. The selection of the 56 bits is performed in box PC_1, together with a permutation. The result is split into two 28 bit words C and D. To obtain the 48 bit subkey, the words C and D are first rotated to the left once or twice (as indicated in a table). PC_2, which consists of a selection and a permutation, is then applied to the result. The output of PC_2 is the 48 bit subkey K_i which is used in $f(R_i, K_i)$.

Due to the symmetry, the decryption algorithm is identical to the encryption operation, except that one uses K_{16} as first subkey, K_{15} as second, etc. Since the total number of rotations in the key scheduling is 28, in a 28 bit register, $C_{16} = C_0$ and $D_{16} = D_0$. So the subkeys in the decryption operation can be obtained by rotating the registers C and D to the right instead of to the left and reading the table, specifying the number of rotations from the bottom up.

The Modes

The data encryption standard can be used in four standard modes: the ECB mode (electronic code book), sometimes called the block mode, the CBC mode (cipher block chaining), the CFB mode (cipher feedBack)

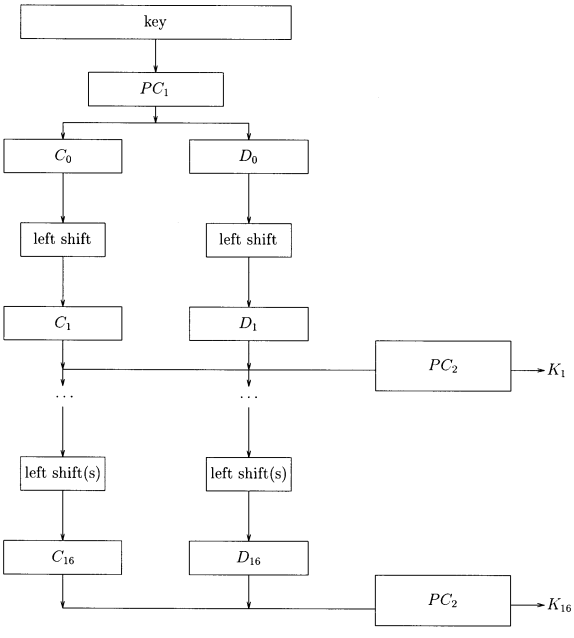

FIGURE 38.4 DES block diagram of key scheduling.

and the OFB mode (output feedBack). Nonstandard modes have been developed and are, for example, used in Kerberos. It is beyond the scope of this chapter to give all the details and properties for these modes; the reader can find them in several publications. Let us quickly survey these modes when used to encrypt data. How these work for decryption is left as an exercise. When we refer to the DES encryption algorithm, we silently assume that each time a 56 bit key is given as input.

The *ECB mode,* in encryption, works similarly to a substitution cipher. The plaintext is divided into blocks, m_i of 64 bits. The i^{th} input to DES is the plaintext block m_i. The output corresponds to the ciphertext block c_i. This mode is not recommended. As we discussed in Section 38.2, most texts contain redundancy. If the same key is used for too long a time, most parts of the plaintext can be recovered.

In the *CBC mode* in encryption, the ciphertext block c_i is the 64 bit output of the DES encryption algorithm. The input to the DES is the bitwise modulo 2 sum (Exor) of the 64 bit plaintext m_i and of the previous 64 bit ciphertext c_{i-1}.

In the *CFB and OFB mode* the ciphertext block c_i and the plaintext block m_i are n bits, where $1 \leq n \leq 64$. In both modes, the ciphertext block $c_i = m_i \oplus \text{Select}_n(\text{DES}_k(d_i))$, where d_i is the input to DES, $\oplus$ is the bitwise modulo 2 sum, and Select_n selects the n most significant bits.

The input d_i to the DES in the CFB encryption mode is constructed from the $(64 - n)$ least significant bits of d_{i-1} (the previous input), shifted to the left by n positions, and concatenated with c_{i-1}, the n bits of the ciphertext.

In the *OFB mode* in encryption, DES is used as a stream cipher (see "Its Use"). The output of DES is used as a pseudo-random generator. The input d_i is the concatenation of the $(64 - n)$ least significant bits of d_{i-1} (the previous input), shifted to the left by n positions, and the n most significant bits of $\text{DES}_k(d_{i-1})$.

Authentication

The CBC and CFB modes of DES can also be used to achieve authentication. The main difference with previous modes is that there is no ciphertext output. When the CBC mode is used, the final output of the DES encryption algorithm is used as authenticator, called the message authentication code (MAC). When the CFB mode is used, the DES encryption algorithm is used one more time.

The maximum length of an authenticator that can be obtained this way is 64 bits. Although this is definitely too short, no standard has fixed this problem yet.

Variants

Since the introduction of the data encryption standard, several variants were proposed. The popularity of these variants is different from country to country. Some examples are FEAL, IDEA, and GOST. The security of these schemes varies. Note that the security of DES is coming near its end. Therefore, the U.S. Federal Government is considering the development of a new, fast alternative to DES. To avoid this weakness, double and triple encryption is used. Both use a 112 bit key. Double encryption DES is obtained by running $\mathrm{DES}_{k_1} \circ \mathrm{DES}_{k_2}$. The triple encryption uses DES as encryption and as decryption, denoted as DES^{-1} giving: $\mathrm{DES}_{k_1} \circ \mathrm{DES}_{k_2}^{-1} \circ \mathrm{DES}_{k_1}$.

38.6 Research Issues and Summary

It is important to remark that cryptography does not solve all modern security problems. Cryptography, although rarely stated explicitly, assumes the existence of secure and reliable hard or software. Some research on secure distributed computation has allowed this assumption to be relaxed slightly. Also in the communication context, modern cryptography only addresses part of a bigger problem. Spread spectrum techniques prevent jamming attacks, and reliable fault tolerant networks reduce the impact of the destruction of communication equipment.

Finally it should be pointed out that cryptography is not sufficient to protect data. For example, it only eliminates the threat of eavesdropping while transmitted remotely. However, data can often be gathered at the source or at the destination using, for example, physical methods. These include theft (physical or virtual), the caption of electromagnetic radiation when data is displayed on a normal screen, etc.

This chapter introduced elementary principles of modern cryptography, including the concepts of conventional cryptosystems and public key systems, several different types of attacks, the different levels of security schemes can have, the one-time pad, and DES as an example of a block cipher.

38.7 Defining Terms

Asymmetric cryptosystem: A cryptosystem in which given the key of one party (sender or receiver, depending from context), it is computationally difficult or, when using information theory, impossible to obtain the other party's secret key.

Block cipher: A family of cryptosystems in which the plaintext and ciphertext are divided into strings of equal length, called blocks, and each block is encrypted one at a time.

Ciphertext: The result of an encryption operation.

Cleartext: The unencrypted, usually readable text.

Conventional cryptosystem: A cryptosystem in which the keys of all parties must remain secret.

Cryptanalysis: The study of methods to break cryptosystems.

Cryptanalyst: A person who (wants to) breaks cryptosystems.

Decryption: The operation that transforms ciphertext into plaintext using a key.

Digital signature: The digital equivalent of a handwritten signature. A digital signature of a message is strongly message-dependent and is generated by the sender using his/her secret key and a suitable public key cryptosystem.

Encrypt: The operation that transforms plaintext into ciphertext.

Exhaustive search: A method to break a cryptosystem by trying all possible inputs, in particular all possible keys.

Plaintext: A synonym for cleartext, i.e., the unencrypted text.

Polygram substitution cipher: A substitution cipher of many symbols at once.

Probabilistic encryption schemes: A public key system in which randomness is used, such that two encryptions of the same ciphertext give, very likely, different ciphertexts.

Public key: A key that is public, or a family of cryptosystems in which a key of one of the parties can be made public.

Symmetric cryptosystem: A system in which it is easy to find one party's key from the other party's key.

Further Information

Since the introduction of public key, the research on cryptography has boomed. Readers interested in applied oriented cryptography should consult [18]. This book discusses block ciphers in great length. Those who prefer a textbook can consult [27].

The most known annual conferences on the topic of cryptography are Eurocrypt and Crypto, running since the early 1980s, of which the proceedings are published in *Springer's Lecture Notes in Computer Science.* More recent conferences include Asiacrypt (which absorbed Auscrypt) and the Workshop on Fast Software Encryption. Some conferences focus on computer security issues as well as cryptography, as for example the Workshop on Cryptographic Protocols and the ACM Conference on Computer and Communications Security. Several local and regional conferences are also organized, many with proceedings published in *Springer's Lecture Notes in Computer Science,* for example the IMA Conference on Cryptography and Coding in Britain. Some results on the topic have appeared in less specialized conferences such as FOCS, STOC, etc.

Articles on the topic appear in a wide variety of journals, but unfortunately several years after the results have been presented at conferences. The *Journal of Cryptology* is dedicated to research on cryptography. Some other specialized journals have a different focus, e.g., *Cryptologia* is primarily on historic aspects of cryptography.

39

Encryption Schemes

Yvo Desmedt
University of Wisconsin–Milwaukee

39.1 Introduction

Several conventional encryption schemes were discussed in Chapter 38. The concept of public key was introduced in the section on "Conventional Cryptography Versus Public Key" of Chapter 38. In this chapter we will discuss some public key encryption systems based on number theory. We first give the minimal number theory and algebraic background needed to understand these schemes from a mathematical viewpoint (see Section 39.2). Then, we present in Section 39.3 the most popular schemes based on number theory. We explain in Section 39.4 the computational number theory required to understand why these schemes run in (expected) polynomial time. To avoid overburdening the reader with number theory, we will postpone the number theory needed to understand the computational aspect until Section 39.4.

39.2 Minimal Background

Algebra

For the reader not familiar with elementary algebra, we review the definition of a semigroup, monoid, group, etc.

DEFINITION 39.1 A set M with an operator "$*$", denoted as $M(*)$, is a *semigroup* if the following conditions are satisfied:

1. The operation is *closed* in M, *i.e.,* $\forall a, b \in M : (a * b) \in M$,
2. The operation is *associative* in M, *i.e.,* $\forall a, b, c \in M : (a * b) * c = a * (b * c)$,

When additionally

3. The operation has an *identity element* in M, i.e., $\exists e : \forall a \in M : a * e = e * a = a$,

we call $M(*)$ a *monoid.* When $M(*)$ is a monoid, we call the cardinality of M the *order* of M.

When using multiplicative notation $(*)$ we will usually denote the identity element as 1 and when using additive notation $(+)$ as 0.

DEFINITION 39.2 In a monoid $M(*)$ the element $a \in M$ has an *inverse* if an element denoted as a^{-1} exists such that

$$a * a^{-1} = a^{-1} * a = e \ ,$$

where e is the identity element in $M(*)$. Two elements $a, b \in M$ *commute* if $a * b = b * a$.

An element having an inverse is often called a *unit.* When working in a monoid, we define $a^{-n} = (a^{-1})^n$ and $a^0 = 1$.

DEFINITION 39.3 A monoid $G(*)$ is a *group* if each element in G has an inverse. It is an *Abelian group* if, additionally, any two elements of G commute.

If H is a monoid (group) and $H \subseteq G$, where G is a monoid (group), then H is called a submonoid (subgroup).

DEFINITION 39.4 Let $M(*)$ be a monoid and $a \in M$. One defines

$$\langle a \rangle = \left\{ a^k \mid k \in N \right\}$$

where N are the natural numbers, i.e., $\{0, 1, \ldots\}$. If $\langle a \rangle$ is a group, we call it a **cyclic group** and call the order of $\langle a \rangle$ the **order** of a, or $\mathrm{ord}(a)$.

Note that in modern cryptography, finite sets are more important than infinite sets. In this respect the following result is interesting.

THEOREM 39.1 *Let $M(*)$ be finite monoid. If $a \in M$ has an inverse in $M(*)$, then $\langle a \rangle$ is an Abelian group. Also,* $\mathrm{ord}(a)$ *is the smallest positive integer m for which $a^m = 1$.*

PROOF Since the set M is finite, positive integers k_1 and k_2 must exist, where $k_1 < k_2$, such that $a^{k_1} = a^{k_2}$. Now, since a is invertible, this means $a^{k_1 - k_2} = 1$. This implies that $\langle a \rangle$ is an Abelian group. So, then $\langle a \rangle = \{a^k \mid 0 \leq k < \mathrm{ord}(a)\}$.

We will now define what a ring is. Unfortunately, there are two different definitions for it in the literature, but we will use the one that is most relevant to modern cryptography.

DEFINITION 39.5 A set R with two operations $+$ and $*$ and two distinct elements 0 and 1 is a ring if

1. $R(+)$ is an Abelian group with identity element 0.
2. $R(*)$ is a monoid with identity element 1.
3. R is distributive, *i.e.,* $\forall a, b, c \in R$:

$$\begin{aligned} a * (b + c) &= (a * b) + (a * c) \\ (a + b) * c &= (a * c) + (b * c) \, . \end{aligned}$$

A ring R is commutative if it is commutative for the multiplication. A ring R in which $R^0 = R \setminus \{0\}$ is an Abelian group for the multiplication is called a field.

A subring is defined similarly as a subgroup.

Number Theory

Integers

We denote the set of integers as Z, and the positive integers as Z^+, i.e., $\{1, 2, \ldots\}$.

DEFINITION 39.6 If α is a real number we call $\lfloor \alpha \rfloor$ the integer such that

$$\lfloor \alpha \rfloor \leq \alpha < \lfloor \alpha \rfloor + 1 \, . \tag{39.1}$$

THEOREM 39.2 $\forall a \in Z \; \forall b \in Z^+ \; \exists q, r \in Z : a = q \cdot b + r$ *where* $0 \leq r < b$.

PROOF From (39.1) it follows that

$$0 \leq \frac{a}{b} - \left\lfloor \frac{a}{b} \right\rfloor < 1 \, .$$

Since $b > 0$ this gives

$$0 \leq a - b \cdot \left\lfloor \frac{a}{b} \right\rfloor < b \, .$$

By taking $q = \lfloor a/b \rfloor$ and $r = a - b \cdot \lfloor a/b \rfloor$ we obtain the result.

The reader has probably recognized q and r as the quotient and nonnegative remainder of the division of a by b. If the remainder is zero then a is a *multiple* of b, or b *divides* a, written as $b \mid a$. We also say that b is a factor of a. If b is different from 1 and a, then b is a nontrivial factor, or a proper divisor of a.

One can categorize the positive integers based on the number of distinct positive divisors. The element 1 has one positive divisor. **Primes** have exactly two, and the other elements, called **composites**, have more than two. In cryptography, a prime number is usually denoted as p or q. Theorem 39.3 is easy to prove using induction and the following lemma.

LEMMA 39.1 When n is composite, the least positive nontrivial factor of n is a prime.

PROOF Let $a, b, c \in Z^+$. It is easy to prove that if $b \mid a$ and $c \mid b$, then $c \mid a$. Also, if b is a nontrivial factor of a, then $1 < b < a$. Using contradiction, this implies the lemma.

THEOREM 39.3 *If $n \geq 2$, then n is the product of primes.*

Greatest Common Divisor

Using a definition other than the standard one and proving these to be equivalent will allow us to introduce several important results. First we will define what an integral modulus is.

DEFINITION 39.7 A modulus is a subset of the integers which is closed under addition and subtraction. A modulus that contains only 0 is called the zero modulus.

THEOREM 39.4 *For each nonzero modulus a positive integer d exists such that all the elements of the modulus are multiplies of d.*

PROOF If such an element exists, it must clearly be the least positive integer. We will now prove its existence by contradiction. Suppose that a is not a multiple of d. Then, using Theorem 39.2, we have $a = qd + r$, where q and r are integers such that $1 \leq r < d$. Clearly, r is then an element of the modulus and is smaller than d. We obtain a contradiction.

It is obvious that if a and b are integers, then $am + bn$, where m and n are any integers, form a modulus. (For those familiar with ring theory, this implies that this modulus is an ideal.) We are now ready to define the greatest common divisor.

DEFINITION 39.8 When a and b are integers, not both zero, then the least positive integer d in the modulus $am + bn$ is the greatest common divisor of a and b, denoted as $\gcd(a, b)$ or (a, b). If $(a, b) = 1$, a and b are called co-prime.

COROLLARY 39.1 Theorem 39.4 implies

$$\exists x, y \in Z : ax + by = \gcd(a, b) \tag{39.2}$$

$$\forall x, y \in Z : \gcd(a, b) \mid ax + by \tag{39.3}$$

$$\text{If } c \mid a \text{ and } c \mid b, \text{ then } c \mid \gcd(a, b)\,. \tag{39.4}$$

PROOF (39.2) and (39.3) follow from Theorem 39.4 and (39.2) implies (39.4).

Due to (39.4), the definition of the greatest common divisor is equivalent to the traditional one.

Congruences

In the section on "The Caesar Cipher and Exhaustive Key Search" of Chapter 38 we defined what it means for two numbers to be equivalent modulo n. It is easy to see that this satisfies the definition of equivalence relation. The corresponding equivalence classes are called *residue classes.* When a is an integer, we let $\widehat{a} = \{b \mid b \equiv a \bmod n\}$. When we work modulo n, we call $Z_n = \{\widehat{0}, \widehat{1}, \ldots, \widehat{n-1}\}$ the set of all residue classes. Other notations for Z_n, which we do not explain, are $Z/(n)$ and Z/nZ. The following theorem is trivial to prove.

THEOREM 39.5 *If $a \equiv b \pmod n$ and $c \equiv d \pmod n$, then $a + c \equiv b + d \pmod n$ and $a * c \equiv b * d \pmod n$.*

Due to this theorem we can say that if $a \equiv b \bmod n$, that a and b are **congruent** modulo n. Now let A and B be two residue classes and we define $A + B = \{a + b \mid a \in A \text{ and } b \in B\}$ and similarly $A * B$. Theorem 39.5 tells us that $A + B$ and $A * B$ are residue classes. This implies the following:

COROLLARY 39.2 Z_m is a commutative ring.

PROOF Given that Z is a commutative ring, this follows easily from Theorem 39.5.

If one selects one representative out of each residue class, we call the resulting set of integers a *complete residue system.* It is easy to see that $\{0, 1, \ldots, m-1\}$ is a complete residue system. Adding (multiplying) two integers a and b in this complete residue system is easy by adding (multiplying) them as integers and taking the non-negative remainder after division by m. If c is the result we write $c = a + b \bmod n$ ($c = a * b \bmod n$), as was done in Chapter 38 in the section on "The Caesar Cipher and Exhaustive Key Search". Using this addition (multiplication) one can view the ring Z_n as corresponding to the set $\{0, 1, \ldots, n-1\}$. We do not discuss this formally.

THEOREM 39.6 *Let $n \geq 2$. The element $a \in Z_n$ has an inverse modulo n if and only if $gcd(a, n) = 1$.*

PROOF If $\gcd(a, n) = 1$ then (39.2) implies that integers x and y exist such that $xa + yn = 1$, or $xa = 1 \bmod n$. So $x \equiv a^{-1}$.

Now if an inverse $a^{-1} \in Z_n$ exists, then $a \cdot a^{-1} \equiv 1 \bmod n$. Using the definition of congruence this means that $n \mid (a \cdot a^{-1} - 1)$, or that $a \cdot a^{-1} - 1 = yn$, where y is an integer. From (39.3) this implies that $\gcd(a, n) \mid 1$.

COROLLARY 39.3 Z_n^*, the set of elements in Z_n relatively prime to n is an Abelian group for the multiplication.

COROLLARY 39.4 When p is a prime, Z_p is a finite field.

COROLLARY 39.5 If $\gcd(a, n) = 1$ then the equation $ax \equiv b \bmod n$ has exactly one solution modulo n.

PROOF Assume that we had different solutions modulo n. Let us say x_1 and x_2. Then $ax_1 \equiv ax_2 \bmod n$, and since a has an inverse, we obtain that $x_1 \equiv x_2 \bmod n$. This is a contradiction.

Euler–Fermat Theorem

The Euler–Fermat theorem is probably the most important theorem for understanding the RSA cryptosystem (see "RSA"). We first give the following definition.

DEFINITION 39.9 The order of Z_n^* is denoted as $\phi(n)$. The function ϕ is called the Euler-totient function, or Euler function. If one selects one representative out of each residue class co-prime to n, we call the resulting set of integers a *reduced residue system.*

LEMMA 39.2 If $\{a_1, a_2, \ldots, a_{\phi(n)}\}$ is a reduced residue system, and $\gcd(k, n) = 1$, then $\{ka_1, ka_2, \ldots, ka_{\phi(n)}\}$ is a reduced residue system.

PROOF First $\gcd(ka_i, n) = 1$. Secondly, if $i \neq j$, then $ka_i \not\equiv ka_j \mod n$, by contradiction.

This lemma implies the Euler–Fermat Theorem.

THEOREM 39.7 $\forall b \in Z_n^* : b^{\phi(n)} \equiv 1 \mod n$.

PROOF Let $\{a_1, a_2, \ldots, a_{\phi(n)}\}$ be a reduced residue system. Lemma 39.2 implies that

$$\prod_{h=1}^{\phi(n)} (ba_h) \equiv \prod_{h=1}^{\phi(n)} a_h \mod n . \tag{39.5}$$

Since $\gcd(a_h, n) = 1$, a_h^{-1} exists, so

$$\begin{aligned} \prod_{h=1}^{\phi(n)} \left(a_h^{-1} a_h b\right) &\equiv \prod_{h=1}^{\phi(n)} a_h^{-1} a_h \mod n, \qquad \text{implying} \\ b^{\phi(n)} &\equiv 1 \mod n . \end{aligned}$$

COROLLARY 39.6 If $m \in Z_n^*$, then $m^{\phi(n)+a} \equiv m^a \mod n$.

It is easy to see that when p is a prime, $\phi(p) = p - 1$. The next corollary is known as Fermat's little theorem.

COROLLARY 39.7 Let p be a prime. $\forall b \in Z_p : b^p \equiv b \mod p$.

39.3 Encryption Schemes

We will explain some encryption schemes from a mathematical viewpoint without addressing the algorithms needed. These are explained in Section 39.4.

Discrete Log

Given an element $b \in \langle a \rangle$, a cyclic group, we know that a k exists such that $b = a^k$ in this cyclic group. This k is called the **discrete logarithm** of b in the base a and often denoted as $k = \log_a(b)$. To have any value to cryptography it must be hard to find this k. So a proper group needs to be chosen, which we discuss later.

One of the first schemes that was based on discrete logarithm is a key distribution scheme (see Chapter 40). Here we discuss the El Gamal encryption scheme [12].

Generating a Public Key

We assume that a finite group $\langle g \rangle(\cdot)$ has been chosen of a large enough order, and that q, a multiple of the order of the $\text{ord}(g)$, is given (it is sufficient that not too large an upperbound on q is known). Note

that q is not necessarily a prime. For simplicity we assume that q is public. This information could be part of a person's public key. We also assume that the group operation $(\cdot)$ and the inverse of an element can be computed in (expected) polynomial time.

When Alice wants to generate her public key, she chooses a uniform random $a \in Z_q$ and computes $y_A = g^a$ in this group and makes y_A public.

El Gamal Encryption

To encrypt a message $m \in \langle g \rangle$ (otherwise a mode[1] is used), the sender finds the public key y_A of the receiver. The sender chooses[2] a uniformly random $k \in Z_q$ and sends as ciphertext $c = (c_1, c_2) = (g^k, m \cdot y_A^k)$ computed in $\langle g \rangle$.

El Gamal Decryption

To decrypt the ciphertext, the legitimate receiver knowing the secret key a computes $m' = c_2 \cdot (c_1^a)^{-1}$. It is easy to verify that $m' = m \cdot (g^a)^k \cdot (g^k)^{-a} = m$.

Suitable Group

As we already mentioned, to have any cryptographic value the discrete logarithm must be hard. Unfortunately, there is no proof that the discrete logarithm is a hard problem. One can only state that so far no one has found an algorithm running in polynomial time for the general problem. For some groups the problem is a little easier than in the general case. For some the discrete logarithm is even easy. Indeed, for example, for the cyclic group $Z_n(+)$ the discrete logarithm corresponds with finding x such that $ax = b \bmod n$, which is easy as we will discuss in "Gcd and Modulo Inverses" and "Linear Equations."

Groups that are used in practice are the multiplicative group of a finite field (see also "Primitive Elements"), or a subgroup of it and elliptic curve groups.

RSA

RSA, which is a heuristic cryptosystem, is an acronym for the inventors of the scheme, Rivest, Shamir, and Adleman [25]. It is basically an application of the Euler–Fermat Theorem.

Generating a Public Key

To select her public key, Alice chooses two random primes p and q, large enough, and multiplies these to obtain $n = p \cdot q$. She chooses a random element $e \in Z_{\phi(n)}^*$ uniformly and computes $d = e^{-1} \bmod \phi(n)$. She publishes (n, e) as public key and keeps d as a secret key. Note that p, q, and $\phi(n)$ need to remain secret.

Encryption

To encrypt a message the sender finds the public key of the receiver, which we call (n, e). When $m \in Z_n$ (otherwise a mode[1] is used) the resulting ciphertext $c = m^e \bmod n$.

---

[1] If one uses modes discussed for DES, the CFB and OFB modes cannot be used, since the encryption mode as well as the decryption mode use the encryption algorithm.

[2] It is possible that q is secret. For example, when the group $\langle g \rangle$ was selected by the one who constructed the public key. We then assume that a not too large upperbound on q is public and is used instead of q.

Decryption

To decrypt a ciphertext $c \in Z_n$, the legitimate receiver, let us say Alice, knowing her secret key d computes $m' = c^d \bmod n$.

We will now explain why the decryption works for the case $m \in Z_n^*$. This can easily be generalized for all $m \in Z_n$, using the Chinese Remainder Theorem (see "Chinese Remainder Theorem"). Since $e \cdot d = 1 \bmod \phi(n)$ we have $e \cdot d = 1 + k\phi(n)$ for some integer k. So, due to Euler–Fermat Theorem (see Corollary 39.6), when $m \in Z_n^*$ we have that $c^d = m^{ed} = m^{k \cdot \phi(n)+1} = m \bmod n$. So $m' = m$.

Notes

Since RSA is rather slow compared to DES, RSA is often used to send a uniformly random key to the receiver. The message itself is then encrypted using a conventional cryptosystem. RSA is also very popular as a signature scheme (see Chapter 40).

To speed up encryption, it has been suggested to choose $e = 3$, or a small e, or an e such that $w(e)$, the Hamming[3] weight of e, is small. Numerative attacks have been presented against such solutions. To avoid these it seems best to choose e as described.

When m is chosen as a uniformly random element in Z_n, and p and q are large enough, no attack is known for finding m. It has been argued, without proof (see "Euler-Totient Function" for more details), that this is as hard as **factoring** n.

39.4 Computational Number Theory: Part 1

When describing the RSA and the ElGamal public key systems, we silently assumed many efficient algorithms. Indeed for the ElGamal system we need efficient algorithms to

- Select an element of large enough order (when choosing the public key).
- Select a uniformly random element in Z_q (when generating a public key and when encrypting).
- Raise an element in a group to a power (when constructing the public key, when encrypting and decrypting).
- Multiply two elements in the group (when encrypting and decrypting).
- Compute an inverse, for example in Z_p^* (when decrypting).
- Guarantee that $m \in \langle g \rangle$ (when encrypting).

For RSA we need algorithms to

- Select a random prime (when generating a public key).
- Multiply two large integers (when constructing a public key).
- Compute $\phi(n)$, or a multiple of it (when constructing a public key).
- Randomly select an element in $Z_{\phi(n)}^*$ (when constructing a public key).
- Compute an inverse (when constructing a public key).
- Raise an element in a group to a power (when encrypting and decrypting).

We now discuss the necessary algorithms. To avoid repetition we will proceed in a different order than listed above. If necessary we will discuss more number theory before giving the algorithm.

[3] The Hamming weight of a binary string is the number of ones in the string.

Multiplication and Modulo Multiplication

Discussing fast integer multiplication and modulo multiplication is a chapter in itself, and therefore beyond the scope of this chapter. Although algorithms based on FFT (see Chapter 17) are order-wise very fast, the numbers used in modern cryptography are too small to compensate for the rather large constants in FFT based algorithms.

The algorithms used are the trivial ones learned in elementary school. However, usually the base is a power of 2, instead of 10.

Fast Exponentiation

Assume that we have a semigroup $M(*)$ in which an efficient algorithm exists for multiplying two elements. Since squaring an element might be faster [17] than multiplying, we allow for a separate algorithm **square** to square an element.

Input declaration: an element $a \in M$ and b a positive integer.
Output declaration: a^b in $M(*)$

function fastexpo(a, b)
begin
case
$b = 1$ then fastexpo:= a
$b > 1$ and odd then fastexpo:= $a*$**fastexpo**$(a, b-1)$
b is even then fastexpo:=**square**(**fastexpo**$(a,b/2)$)
end

The above function uses, at maximum, $2|b|$ multiplications, where $|b|$ is the binary length of b.

Gcd and Modulo Inverses

Let $a \geq b \geq 0$. The algorithm to compute the greatest common divisor goes back to Euclid, and is therefore called the Euclidean algorithm. It is based on the observation that $\gcd(a, b) = \gcd(a - b, b)$. This trick can be repeated until $0 \leq r = a - mb < b$, which exists (see Theorem 39.2). This gives the modern version of the Euclidean algorithm:

Input declaration: non-negative integers a, b where $a \geq b$
Output declaration: $\gcd(a, b)$

function gcd(a, b)
begin
if $b = 0$ then gcd := a
else gcd :=**gcd**$(b, a \bmod b)$
end

Note: We assume that $a \bmod b$ returns the least nonnegative remainder of a when divided by b. When $a = b = 0$ the function returns 0.

THEOREM 39.8 *The number of divisions required to compute the* $\gcd(a, b)$ *when* $0 < b < a$*, is, at maximum,* $1 + \lfloor \log_R a \rfloor$*, where* $R = (1 + \sqrt{5})/2$.

PROOF We denote $r_{-1} = a, r_0 = b$ and r_i the remainder obtained in the i^{th} division. Note that the $\gcd(a, b)$ will be such a remainder. We define n such that $r_{n-1} = \gcd(a, b)$, implying that $r_n = 0$. We call the i^{th} quotient d_i. So, we have

$$\begin{aligned} d_i &= \left\lfloor \frac{r_{i-2}}{r_{i-1}} \right\rfloor \qquad (1 \leq i \leq n) && (39.6) \\ r_{i-2} &= d_i \cdot r_{i-1} + r_i \qquad (1 \leq i \leq n) && (39.7) \\ r_{n-2} &= d_n \cdot r_{n-1} \, . \end{aligned}$$

Note that $r_i < r_{i-1}$ $(0 \leq i \leq n)$, $r_{n-1} \geq 1 = f_2$ and $r_{n-2} \geq 2 = f_3$, where f_n is the n^{th} Fibonacci number. Using this and the fact that $f_{n+1-i} = f_{n-i} + f_{n-i-1}$ and (39.7), it is easy to prove with inverse induction, starting from $i = n - 1$, that $r_i \geq f_{n+1-i}$. So, $a \geq f_{n+2}$ and $b \geq f_{n+1}$. Since $r_{n-2} \geq 2$, this implies the following. When the Euclidean algorithm takes exactly n divisions to compute $\gcd(a, b)$ we have $a \geq f_{n+2}$ and $b \geq f_{n+1}$. So, if $b' < a' < f_{n+2}$ then there are, at maximum, $n - 1$ divisions when computing the greatest common divisor of a' and b' using the Euclidean algorithm.

Now since $R^2 = R + 1$ we have $R^{n-1} = R^{n-2} + R^{n-3}$. This implies, using induction, that $\forall n \geq 1 : R^{n-2} \leq f_n \leq R^{n-1}$. So, if $0 < b' < a'$ and $R^{n-2} < a' < R^n$ there are, at maximum, $n - 1$ divisions. This corresponds to saying that if $n - 2 < \log_R(a') < n$, or $n - 2 \leq \lfloor \log_R(a') \rfloor < n$ there are, at maximum, $n - 1$ divisions.

An extended version of the Euclidean algorithm allows computing the inverse of b modulo a, where $0 < b < a$.

Algorithm 1

Input: *positive integers* a, b *where* $a > b > 0$

Output: $g = \gcd(a, b)$, x *and* y, *integers such that* $ax + by = \gcd(a, b)$ *and* $c = b^{-1}$ mod$a$ *if it exists (otherwise* $c = 0$*)*

begin
$r_{-1} = a; r_0 = b; x_{-1} := 1; y_{-1} := 0; x_0 := 0; y_0 := 1; i := 0;$
while $r_i \neq 0$ do
    begin
        $i := i + 1;$
        $d := \left\lfloor \frac{r_{i-2}}{r_{i-1}} \right\rfloor;$
        $r_i := r_{i-2} - d * r_{i-1};$
        $x_i := x_{i-2} - d * x_{i-1};$
        $y_i := y_{i-2} - d * y_{i-1};$
    end
$g := r_{i-1}; x := x_{i-1}; y := y_{i-1};$
if $g = 1$ then
        if $i \bmod 2 = 1$ then $c := y$
                else $c := y + a$
    else $c := 0;$
end

Observe that only $d, r_i, r_{i-1}, x_i, x_{i-1}, y_i$, and y_{i-1} are needed. So, a more careful implementation allows saving memory.

LEMMA 39.3 For $i \geq -1$ we have in Algorithm 1 that

$$ax_i + by_i = r_i \ . \tag{39.8}$$

PROOF We use the definition of d_i in (39.6). It is easy to verify that (39.8) holds for $i = -1$ and $i = 0$. For larger values, we use induction and assume that (39.8) has been proven for $i - 1$ and $i - 2$. Observe that $x_i = x_{i-2} - d_i x_{i-1}$ and $y_i = y_{i-2} - d_i y_{i-1}$. So

$$\begin{aligned} ax_i + by_i &= a\left(x_{i-2} - d_i x_{i-1}\right) + b\left(y_{i-2} - d_i y_{i-1}\right) \\ &= \left(ax_{i-2} + by_{i-2}\right) - d_i\left(ax_{i-1} + by_{i-1}\right) \\ &= r_{i-2} - d_i r_{i-1} \end{aligned}$$

using the induction hypothesis. Since $r_i = r_{i-2} - d_i * r_{i-1}$ we have proven the claim.

THEOREM 39.9 *In Algorithm 1* $c = b^{-1} \bmod a$ *if* $b^{-1} \bmod a$ *exists and* $0 \leq c < a$.

PROOF We assume that $\gcd(a, b) = 1$. From the proof of Theorem 39.8 and Lemma 39.3 we have for the x and y returned by Algorithm 1 that $ax + by = \gcd(a, b)$. This implies that $c \equiv b^{-1} \bmod a$. So, we only need to prove that $0 \leq c < a$.

We let n be as in the proof of Theorem 39.8 and d_i be as in (39.6). We first claim that

$$(-1)^i y_i \geq 0 \tag{39.9}$$

when $-1 \leq i \leq n$. This is easy to verify for $i = -1$ and $i = 0$. We now assume that (39.9) is true for $i = k - 1$ and $i = k - 2$. Since $d_i > 0$ when $0 < b < a$ and using the recursive definition of y_i we have $(-1)^k y_k = (-1)^k (y_{k-2} - d_k y_{k-1}) = (-1)^{k-2} y_{k-2} + (-1)^{k-1} d_k y_{k-1} \geq 0$ by the induction hypothesis.

Due to (39.9) we have $|y_i| = |y_{i-2}| + d_i * |y_{i-1}|$. Since $y_0 = 1$ and $d_i \geq 1$, we have

$$|y_1| \geq |y_0| \qquad \text{and} \qquad |y_i| > \left|y_{i-1}\right| \quad \text{for} \quad 2 \leq i \leq n \ , \tag{39.10}$$

as is easy to verify using induction.

Finally we claim that for all i $(0 \leq i \leq n)$:

$$y_{i-1} r_i - y_i r_{i-1} = (-1)^{i+1} a \tag{39.11}$$

$$x_{i-1} r_i - x_i r_{i-1} = (-1)^i b \tag{39.12}$$

For $i = 0$, (39.11) is trivially satisfied. Assume that the equations are satisfied for $i = k - 1$. Noticing that $r_k = r_{k-2} - d_k r_{k-1}$ and $y_k = y_{k-2} - d_k y_{k-1}$, we obtain for $i = k$ that

$$\begin{aligned} y_{k-1} r_k - y_k r_{k-1} &= y_{k-1}\left(r_{k-2} - d_k r_{k-1}\right) - \left(y_{k-2} - d_k y_{k-1}\right) r_{k-1} \\ &= y_{k-1} r_{k-2} - y_{k-2} r_{k-1} \\ &= -\left(y_{k-2} r_{k-1} - y_{k-1} r_{k-2}\right) \ , \end{aligned}$$

which, using the induction hypothesis, proves (39.11). Similarly one can prove (39.12).

Since $r_n = 0$ and $r_{n-1} = \gcd(a, b) = 1$, (39.11) and (39.12) imply that $y_n = (-1)^n a$ and, respectively, $x_n = (-1)^{n+1} b$. So if $n \geq 2$ then, using (39.10), $|y_{n-1}| < a$ and $|y_{n-1}| \neq 0$. If $n = 1$, then by the definition $x_1 = x_{-1} - d_1 * x_0 = 1$ and by (39.12) $x_1 = b$, so $b = 1$ and $y_{n-1} = y_0 = 1 < a$. Thus, $0 < |y_{n-1}| < a$. Using this and (39.9), we obtain that if n is odd $c = y_{n-1} < a$ and $c > 0$, else $-a < y_{n-1} < 0$, so $0 < c = a + y_{n-1} < a$.

Random Selection

We assume that the user has a binary random generator that outputs a string of independent bits with uniform distribution. Using this generator to output one bit is called a coin flip.

We will now describe how to select a natural number a with uniform distribution such that $0 \leq a \leq b$, where $2^{k-1} \leq b < 2^k$. One lets the generator output k bits. We view these bits as a binary representation of an integer x. If $x \leq b$, one outputs $a = x$, else one flips k new bits until $x \leq b$. The expected number of coin flips is bounded above by $2k$.

The case one requires that $b_1 \leq a \leq b_2$ is easy to reduce to the previous one. Indeed, choose a' uniformly such that $0 \leq a' \leq (b_2 - b_1)$ and add b_1 to the result.

Selecting an element in Z_n^* can be done by selecting an integer a such that $0 \leq a \leq n-1$ and by repeating the procedure until $\gcd(a, n) = 1$. The expected number of coin flips is $O(\log\log(n) \cdot \log(n))$, which we do not prove.

Before we discuss how to select a prime we will discuss more number theory. This number theory will also be useful to explain the first probabilistic encryption scheme (see Section 39.7).

39.5 More Algebra and Number Theory

Primes and Factorization

LEMMA 39.4 If p is a prime and $p \mid a \cdot b$, then p divides a or b.

PROOF If $p \not\mid a$, then $\gcd(a, p) = 1$. So, due to Corollary 39.1, integers x, y exists such that $xa + yp = 1$, or $xab + ybp = b$. Since $p \mid ab$, this implies that $p \mid b$.

THEOREM 39.10 *Prime factorization of any integer n is unique, i.e., the primes $p_1, \ldots, p_k$ and the integers $a_i \geq 1$ such that*

$$n = \prod_{i=1}^{k} p_i^{a_i}$$

are unique.

PROOF From Theorem 39.3 we know that n is a product of primes. Assume that

$$\prod_{i=1}^{k} p_i^{a_i} = \prod_{j=1}^{m} q_j^{b_j}\ , \tag{39.13}$$

where q_j are primes and $b_j \geq 1$. First, due to Lemma 39.4 and the fact that p_i and q_j are primes, a p_i is equal to some q_j and vice versa (by induction). So, $k = m$ and when renaming $p_i = q_i$. If $a_i > b_i$ then dividing both sides of (39.13) by $p_i^{b_i}$ we obtain a contradiction due to Lemma 39.4.

COROLLARY 39.8 The least common multiple of a and b, denoted as $\text{lcm}(a, b) = a \cdot b / \gcd(a, b)$.

PROOF The proof is left as an exercise.

Euler-Totient Function

The algorithm used to compute $\phi(n)$ when constructing an RSA public key is trivially based on the following theorem. First, we define what, in number theory, is called a multiplicative function and we also introduce the Möbius function.

DEFINITION 39.10 A real or a complex valued function defined on the positive integers is called an *arithmetical* or a *number-theoretic function.* An arithmetical function f is *multiplicative* if it is not the zero function and if for all positive integers m and n where $\gcd(m, n) = 1$ we have $f(m \cdot n) = f(m) \cdot f(n)$. If the gcd restriction is removed, it is *completely multiplicative*.

DEFINITION 39.11 A square is an integer to the power 2. The *Möbius function* is defined as being

$$\mu(n) \quad = \quad \begin{cases} 0 & \text{if } n \text{ is divisible by a square different from 1,} \\ (-1)^k & \text{if } n = p_1 \cdot p_2 \cdots p_k, \text{ where } p_i \text{ are distinct primes.} \end{cases}$$

A number is squarefree if $\mu(n) \neq 0$.

LEMMA 39.5 If $n \geq 1$ we have

$$\sum_{d|n} \mu(d) = \left\lfloor \frac{1}{n} \right\rfloor \quad = \quad \begin{cases} 1 & \text{if } n = 1, \\ 0 & \text{if } n > 1. \end{cases} \tag{39.14}$$

PROOF When $n = 1$, $\mu(1) = 1$ since it is the product of 0 different primes. We now discuss the case that $n > 1$. Then accordingly to Theorem 39.10 $n = \prod_{i=1}^{k} p_i^{a_i}$, where p_i are distinct primes. In (39.14) only when d is squarefree is $\mu(d) \neq 0$, so

$$\begin{aligned} \sum_{d|n} \mu(d) \quad &= \quad \mu(1) + \mu(p_1) + \cdots + \mu(p_k) + \mu(p_1 \cdot p_2) + \cdots + \mu(p_{k-1} \cdot p_k) \\ &\quad + \cdots + \mu(p_1 \cdot p_2 \cdots p_k) \\ &= \quad 1 + \binom{k}{1} \cdot (-1) + \binom{k}{2} \cdot (-1)^2 + \cdots + \binom{k}{k} (-1)^k = (1-1)^k = 0 \end{aligned}$$

LEMMA 39.6 If $n \geq 1$ then

$$\phi(n) = n \cdot \sum_{d|n} \frac{\mu(d)}{d} .$$

PROOF From the definition of the Euler-totient function, we immediately have

$$\phi(n) = \sum_{k=1}^{n} \left\lfloor \frac{1}{\gcd(k, n)} \right\rfloor .$$

This can be rewritten, using Lemma 39.5, as

$$\phi(n) = \sum_{k=1}^{n} \sum_{d|\gcd(k,n)} \mu(d) = \sum_{k=1}^{n} \sum_{\substack{d|k \\ d|n}} \mu(d) .$$

In the second sum, all d divide n. For such a fixed d, k must be a multiple of d, i.e., $k = md$. Now, $1 \le k \le n$, which is equivalent to the requirement that $1 \le m \le n/d$. Thus,

$$\phi(n) = \sum_{d|n} \sum_{m=1}^{\frac{n}{d}} \mu(d) = \sum_{d|n} \mu(d) \sum_{m=1}^{\frac{n}{d}} 1 = \sum_{d|n} \mu(d) \cdot \frac{n}{d} .$$

THEOREM 39.11 $\phi(n) = n \cdot \prod_{p|n} \left(1 - \frac{1}{p}\right)$, *where p are distinct primes.*

PROOF When $n = 1$, no primes divide n, so the product is equal to 1. We will now consider the case where $n > 1$, so $n = \prod_{i=1}^{m} p_i^{a_i}$, where p_i are distinct primes and $a_i \ge 1$. Obviously

$$\prod_{i=1}^{m} \left(1 - \frac{1}{p_i}\right) = 1 - \sum_{i=1}^{m} \frac{1}{p_i} + \sum_{\substack{i,j \\ i \neq j}} \frac{1}{p_i p_j} - \sum_{\substack{i,j,k \\ i \neq j \\ i \neq k \\ j \neq k}} \frac{1}{p_i p_j p_k} + \cdots + \frac{(-1)^m}{p_1 p_2 \cdots p_m} . \tag{39.15}$$

Each term on the right-hand side corresponds to a $\pm 1/d$, where d is a squarefree divisor of n. For those, the numerator is $\mu(d)$. For the other divisors of n, $\mu(d) = 0$, so the sum in (39.15) is $\sum_{d|n}(\mu(d)/d)$. Using Lemma 39.6, we have proven the theorem.

COROLLARY 39.9 $\phi(n)$ is multiplicative.

This corollary implies that, given the factorization of n, it is easy to compute $\phi(n)$. Assuming the correctness of the Extended Riemann Hypothesis and given $\phi(n)$, one can factor n in polynomial time, which we will not prove.

Linear Equations

THEOREM 39.12 *The equation*

$$ax = b \bmod n \tag{39.16}$$

has no solution if $\gcd(a, n) \not| b$, *else it has* $\gcd(a, n)$ *solutions.*

PROOF If $ax = b \bmod n$, an integer y exists such that $ax + ny = b$. Statement (39.3) in Corollary 39.1 tells us that $\gcd(a, n)$ must divide b. From now on, we assume it does. We will prove that there are then $\gcd(a, n)$ solutions.

Corollary 39.5 tells us that if $\gcd(a, n) = 1$, the solution is unique. Suppose now that $d = \gcd(a, n)$. If $ax = b \bmod n$, then $d \mid n \mid (ax - b)$, which implies that

$$\frac{a}{d}x = \frac{b}{d} \bmod \frac{n}{d} .$$

This has a unique solution x_0 modulo n/d, since $\gcd(a/d, n/d) = 1$. Using the definition of congruence, this implies that x_0 is a solution of (39.16). Another implication is that all other solutions modulo n must have the form

$$x = x_0 + m \cdot \frac{n}{d} \qquad \text{where } 0 \le m \le d - 1 .$$

Polynomials

The following theorem plays an important role in secret sharing (see Chapter 41).

THEOREM 39.13 *Let p be a prime and f a polynomial. The number of solutions (including repeating ones) of $f(x) = 0 \bmod p$ is, at maximum, the degree of f.*

PROOF The theorem is trivially satisfied when the number of solutions is zero. If a_1 is a solution then $f(x) = (x - a_1)q_1(x) + r_1(x)$, where $r_1(x)$ is the remainder, i.e., has degree zero. Since $p \mid f(a_1)$ and $p \mid (a_1 - a_1)q_1(a_1), r_1(x) = 0 \bmod p$. If a_1 is a solution of $q_1(x)$ obtain, $f(x) = (x - a_1)^2 q_1'(x) \bmod p$. In general, an $f_1(x)$ exists such that $f(x) = (x - a_1)^{h_1} f_1(x) \bmod p$ and $f_1(a_1) \not\equiv 0 \bmod p$. Clearly the degree of $f_1(x)$ is $m - h_1$. Suppose that a_2 is another solution modulo p. Then, $f(a_2) = (a_2 - a_1)^{h_1} f_1(a_2) = 0 \bmod p$. Since $a_2 \not\equiv a_1 \bmod p$, Lemma 39.4 implies $p \mid f_1(a_2)$, or, in other words, that $f_1(a_2) \bmod p$. So, using a similar argument as previously, we obtain that $f(x) = (x - a_1)^{h_1}(x - a_2)^{h_2} f_2(x)$ where a_1 nor a_2 are solutions of $f_2(x) = 0$. This gives (using induction) the following:

$$f(x) = \left(\prod_{i=1}^{l} (x - a_i)^{h_i} \right) f_l(x) \,,$$

where $f_l(x) = 0 \bmod p$ has no solutions. This immediately implies the theorem.

When p is composite, the theorem does not extend, as we will briefly discuss in Section "Chinese Remainder Theorem."

Quadratic Residues

DEFINITION 39.12 The set of **quadratic residue modulo** n, denoted as $\mathrm{QR}_n = \{x \mid \exists y \in Z_n^* : x \equiv y^2 \bmod n\}$. The set of **quadratic nonresidues modulo** n is $\mathrm{QNR}_n = Z_n^* \setminus \mathrm{QR}_n$.

THEOREM 39.14 *If p is an odd prime, then $|\mathrm{QR}_p| = |\mathrm{QNR}_p| = (p - 1)/2$.*

PROOF First $x^2 = a \bmod p$ has, at maximum, 2 solutions due to Theorem 39.13. Now, squaring all elements of Z_p^* and noticing that $x^2 \equiv (-x)^2 \bmod p$, we obtain the result.

DEFINITION 39.13 Let p be an odd prime. The *Legendre symbol*

$$\left(\frac{a}{p}\right) = (a \mid p) \quad = \quad \begin{cases} 1 & \text{if } a \in \mathrm{QR}_p, \\ -1 & \text{if } a \in \mathrm{QNR}_p, \\ 0 & \text{if } a \equiv 0 \bmod p \,. \end{cases}$$

We will now discuss Euler's criterion.

THEOREM 39.15 *Let p be an odd prime. $(a \mid p) = a^{(p-1)/2} \bmod p$.*

PROOF The case $a \equiv 0 \bmod p$ is trivial, which we will now exclude. If $(a \mid p) = 1$ then an integer x exists such that $x^2 = a \bmod p$, so $a^{(p-1)/2} = x^{p-1} = 1 \bmod p$ due to Fermat's little theorem

(Corollary 39.7). Since $|\mathrm{QR}_p| = (p-1)/2$ the polynomial equation

$$a^{\frac{p-1}{2}} = 1 \bmod p \tag{39.17}$$

in a has at least $(p-1)/2$ solutions (see Theorem 39.14), and using Theorem 39.13, this implies exactly $(p-1)/2$ solutions. So, if $a^{(p-1)/2} = 1 \bmod p$, then $(a \mid p) = 1$.

Similarly, using Fermat's little theorem, the equation

$$a^{p-1} - 1 = 0 \bmod p \tag{39.18}$$

in a has exactly $p-1$ solutions. Now $a^{p-1} - 1 = (a^{(p-1)/2} - 1)(a^{(p-1)/2} + 1)$. So, the $(p-1)/2$ solutions of (39.18) that are not solutions of (39.17) must be the solutions of the equation $(a^{(p-1)/2} + 1) = 0 \bmod p$. Since $|\mathrm{QNR}_p| = (p-1)/2$, and all solutions of (39.17) are quadratic residues, we have for all $a \in \mathrm{QNR}_p$ that $(a^{(p-1)/2} + 1) = 0 \bmod p$.

COROLLARY 39.10 If p is an odd prime, then $(a \mid p) \cdot (b \mid p) = (a \cdot b \mid p)$.

COROLLARY 39.11 If p is an odd prime, then $(-1 \mid p) = (-1)^{\frac{p-1}{2}}$.

We now discuss Gauss' lemma.

THEOREM 39.16 *Let p be an odd prime, n an integer such that $p \nmid n$, and m the cardinality of the set*

$$A = \left\{ a_i \mid a_i = k \cdot n \bmod p \text{ for } 1 \le k \le (p-1)/2 \text{ and } p/2 < a_i < p \right\} .$$

Then $(n \mid p) = (-1)^m$.

PROOF Let $B = \{b_k \mid b_k = k \cdot n \bmod p \text{ for } 1 \le k \le (p-1)/2\}$. We define $C = \{c_j\} = B \setminus A$, and let $|C| = l$. Observe that for all c_j and a_i we have that $p \neq a_i + c_j$, by contradiction. Indeed, otherwise $p \mid (a_i + c_j) = (k_i + k_j)n$, which is not possible. Therefore,

$$\left(\prod_{j=1}^{l} c_j \right) \cdot \left(\prod_{i=1}^{m} (p - a_i) \right) = \left(\frac{p-1}{2} \right)! \tag{39.19}$$

Now, trivially,

$$\left(\prod_{j=1}^{l} c_j \right) \cdot \left(\prod_{i=1}^{m} a_i \right) \equiv \prod_{k=1}^{\frac{p-1}{2}} (k \cdot n) = \left(\frac{p-1}{2} \right)! \cdot \left(n^{\frac{p-1}{2}} \right) \pmod p . \tag{39.20}$$

$$\equiv (-1)^m \cdot \left(\frac{p-1}{2} \right)! \pmod p \tag{39.21}$$

using (39.19) to obtain the last congruence. So, combining (39.20) and (39.21), we have $n^{(p-1)/2} \equiv (-1)^m \bmod p$, which gives the result using Euler's criterion.

COROLLARY 39.12 If p is an odd prime, then

$$\left(\frac{2}{p} \right) = \begin{cases} 1 & \text{if } p \equiv 1 \bmod 8 \text{ or } p \equiv 7 \bmod 8, \\ -1 & \text{if } p \equiv 3 \bmod 8 \text{ or } p \equiv 5 \bmod 8 . \end{cases}$$

PROOF It is easy to verify that when $n = 2$, the set $A = \{\lfloor (p+3)/4 \rfloor \cdot 2, \ldots, ((p-1)/2) \cdot 2\}$. So, $m = (p-1)/2 - \lfloor p/4 \rfloor$. Let $p = 8a + r$, where $r = 1, 3, 5$, or 7. Then m modulo 2 is, respectively, 0, 1, 1, and 0.

Using Gauss' lemma one can prove the law of quadratic reciprocity. Since the proof is rather long (but not complicated) we refer the reader to the literature.

THEOREM 39.17 *If p and q are odd distinct primes, we have*

$$\left(\frac{p}{q}\right) \cdot \left(\frac{q}{p}\right) = (-1)^{\frac{(p-1)(q-1)}{4}} .$$

Jacobi Symbol

DEFINITION 39.14 Let $n = \prod_{i=1}^{h} p_i$ where p_i are (not necessarily distinct) primes and a an integer. The Jacobi symbol $(a \mid n) = \prod_{i=1}^{h} (a \mid p_i)$. The set $Z_n^{+1} = \{a \in Z_n \mid (a \mid n) = 1\}$.

Since $1 = p^0$, we have that $(a \mid 1) = 1$. Also, if n is a prime, it is obvious that the Jacobi symbol is the same as the Legendre symbol. We will discuss why there is no need to factor n to compute the Jacobi symbol. The following theorems are useful in this respect.

THEOREM 39.18 *The Jacobi symbol has the following properties:*

1. *If $a \equiv b \bmod n$, then $(a \mid n) = (b \mid n)$.*
2. $(a \mid n) \cdot (a \mid m) = (a \mid n \cdot m)$.
3. $(a \mid n) \cdot (b \mid n) = (a \cdot b \mid n)$.

PROOF These follow immediately from the definition and Corollary 39.10.

THEOREM 39.19 *When n is an odd positive integer we have $(-1 \mid n) = (-1)^{(n-1)/2}$.*

PROOF When a and b are odd, then trivially

$$(a-1)/2 + (b-1)/2 \equiv (ab-1)/2 \bmod 2 . \tag{39.22}$$

This allows one to prove by induction that

$$\sum_{i=1}^{h} \frac{p_i - 1}{2} \equiv \frac{\left(\prod_{i=1}^{h} p_i\right) - 1}{2} \bmod 2 . \tag{39.23}$$

The rest follows from Corollary 39.11.

THEOREM 39.20 *If n is an odd positive integer, then*

$$\left(\frac{2}{n}\right) = \begin{cases} 1 & \text{if } n \equiv 1 \bmod 8 \text{ or } n \equiv 7 \bmod 8, \\ -1 & \text{if } n \equiv 3 \bmod 8 \text{ or } n \equiv 5 \bmod 8 . \end{cases}$$

PROOF It is easy to verify that Corollary 39.12 can be rewritten as $(2 \mid p) = (-1)^{(p^2-1)/8}$. The rest of the proof is similar to that of the preceding theorem replacing (39.22) by

$$\left(a^2-1\right)/8 + \left(b^2-1\right)/8 \equiv \left(a^2b^2-1\right)/8 \bmod 2\,,$$

where a and b are odd integers. Note that $k(k+1)$ is always even.

THEOREM 39.21 *If m and n are odd positive integers and* $\gcd(m,n) = 1$, *then*

$$\left(\frac{m}{n}\right)\cdot\left(\frac{n}{m}\right) = (-1)^{\frac{(m-1)(n-1)}{4}}\,.$$

PROOF Let $m = \prod_{i=1}^{k} p_i$ and $n = \prod_{j=1}^{l} q_j$, where p_i and q_j are primes. From Theorem 39.18, we have

$$\begin{aligned}\left(\frac{m}{n}\right)\cdot\left(\frac{n}{m}\right) &= \left(\prod_{i=1}^{k}\prod_{j=1}^{l}\left(\frac{p_i}{q_j}\right)\right)\cdot\left(\prod_{i=1}^{k}\prod_{j=1}^{l}\left(\frac{q_j}{p_i}\right)\right) = \left(\prod_{i=1}^{k}\prod_{j=1}^{l}\left(\frac{p_i}{q_j}\right)\cdot\left(\frac{q_j}{p_i}\right)\right)\\ &= \prod_{i=1}^{k}\prod_{j=1}^{l}(-1)^{\frac{(p_i-1)(q_j-1)}{4}} = (-1)^{\frac{(m-1)(n-1)}{4}}\end{aligned}$$

using Theorem 39.17 to obtain the second to last equation and (39.23) to obtain the last.

One could wonder whether $(a \mid n) = 1$ implies that $a \in \mathrm{QR}_n$. Before disproving this, we discuss the Chinese Remainder Theorem.

Chinese Remainder Theorem

THEOREM 39.22 *If* $\gcd(n_1, n_2) = 1$, *then the system of equations*

$$x \equiv a_1 \bmod n_1 \tag{39.24}$$

$$x \equiv a_2 \bmod n_2 \tag{39.25}$$

has exactly one solution modulo $n_1 \cdot n_2$.

PROOF Due to (39.24) and the definition of modulo computation, x must have the form $x = a_1 + n_1 \cdot y$ for some y. Using (39.25) $a_1 + n_1 \cdot y \equiv a_2 \bmod n_2$, which has exactly one solution in y modulo n_2. This follows from Corollary 39.5 since $\gcd(n_1, n_2) = 1$. So, $n_1 y$ has only one solution modulo $n_1 \cdot n_2$, or $x = a_1 + n_1 \cdot y$ is unique modulo $n_1 \cdot n_2$.

As an application we consider the equation $x^2 = a \bmod n$, where n is the product of two different primes, p and q. Since $p \mid n \mid (x^2 - a)$, a solution modulo n is also a solution modulo p (and q respectively). The Chinese Remainder Theorem tells us that it is sufficient to consider the solutions of $x^2 = a \bmod p$ and $x^2 = a \bmod q$, which we now discuss. If $(a \mid p) = 1$ then there are two solutions modulo p, when $(a \mid p) = -1$ there are no solutions modulo p, and finally when $(a \mid p) = 0$, there is one solution modulo p. So $a \in \mathrm{QR}_n$ only if $(a \mid p) = 1$ and $(a \mid q) = 1$, implying that $(a \mid n) = 1$. However, the converse is obviously not true, so $(a \mid n) = 1$ does not necessarily imply that $a \in QR_n$.

Order of an Element

We describe some general properties of an order of an element.

LEMMA 39.7 Let $\langle\alpha\rangle(\cdot)$ be a cyclic group of order l, an integer. If $\alpha^m = 1$, then $l \mid m$.

PROOF From Theorem 39.1 we have that l is the smallest positive integer for which $\alpha^l = 1$. Assume that $l \nmid m$. Then $m = ql + r$, where $0 < r < l$. So, $1 = \alpha^m = (\alpha^l)^q \cdot \alpha^r = 1 \cdot \alpha^r$. So, r is a smaller positive integer for which $\alpha^r = 1$. So, we have a contradiction.

LEMMA 39.8 Let $K(\cdot)$ be an Abelian group and $\alpha, \beta \in K$ with $k = \text{ord}(\alpha)$ and $l = \text{ord}(\beta)$. If $\gcd(k, l) = 1$, then $\text{ord}(\alpha \cdot \beta) = \text{ord}(\alpha) \cdot \text{ord}(\beta)$.

PROOF Let us call m the order of $\alpha \cdot \beta$. Since $(\alpha\beta)^m = 1$, we have $\alpha^m = \beta^{-m}$. This implies that $\alpha^{lm} = \beta^{-lm} = (\beta^l)^{-m} = 1$ and $\beta^{-km} = (\alpha^k)^m = 1$. Using Lemma 39.7, we obtain that $k \mid lm$ and respectively $l \mid km$. Since $\gcd(k, l) = 1$, this implies that $k \mid m$ and $l \mid m$. So, $kl \mid m$. Now, trivially, $(\alpha\beta)^{kl} = 1$. Using Lemma 39.7, this implies that kl must be the order of $\alpha\beta$.

THEOREM 39.23 *Let $K(\cdot)$ be an Abelian group and let*

$$m = \max_{\alpha \in K}(\text{ord}(\alpha)) .$$

We have that $\forall \beta \in K : \text{ord}(\beta) \mid m$.

PROOF We prove this by contradiction. When $\beta = 1$, the identity, the result is trivial. We now assume that $\beta \neq 1$. Let $d = \text{ord}(\beta)$ and suppose that $d \nmid m$. Then, a prime p and an integer $e \geq 1$ exit such that $p^e \mid d$, $p^e \nmid m$, but $p^{e-1} \mid m$. It is easy to verify that when $\text{ord}(\alpha) = m$ we have that $\text{ord}(\alpha^{p^{e-1}}) = m/(p^{e-1})$ and that $\text{ord}(\beta^{d/p^e}) = p^e$. Since, $\gcd(m/(p^{e-1}), p^e) = 1$, Lemma 39.8 implies that $\text{ord}(\alpha^{p^{e-1}} \cdot \beta^{d/p^e}) = m \cdot p$, which is larger than m. So, we obtain a contradiction.

DEFINITION 39.15 The *exponent,* $\exp(K)$, of a finite group K is the smallest positive integer such that $\forall \beta \in K : \beta^{\exp(K)} = 1$.

COROLLARY 39.13 When K is a finite Abelian group then $\exp(K) = \max_{\alpha \in K}(\text{ord}(\alpha))$.

The following theorem is used to prove that Z_p^*, where p is prime, is a cyclic group.

THEOREM 39.24 *Let K be a finite Abelian group. K is cyclic if and only if* $\exp(K) = |K|$.

PROOF First, if $K = \langle\alpha\rangle$, then $|K| = \text{ord}(\alpha)$, so $\exp(K) = |K|$. Secondly, let K be a finite Abelian group such that $\exp(K) = |K|$. By Corollary 39.13 an element α exists such that $\exp(K) = \text{ord}(\alpha)$. Since $\exp(K) = |K|$, we have that $|K| = \text{ord}(\alpha) = |\langle\alpha\rangle|$, implying that K is cyclic.

Primitive Elements

Before proving that Z_p^* (p is prime) is a cyclic group, we will define a **primitive element.**

DEFINITION 39.16 If the order of α in the group Z_n^* is $\phi(n)$, then we say that α is a primitive element of Z_n^*, or a primitive root mod$n$, or a generator of Z_n^*.

So, when Z_n^* has a primitive element, the group is cyclic.

THEOREM 39.25 *If p is prime, Z_p^* is cyclic.*

PROOF Due to Fermat's little theorem (Corollary 39.7) we have that $\forall a \in Z_p^* : a^{|Z_p^*|} = 1$. So $\exp(Z_p^*) \leq |Z_p^*|$. By the definition of the exponent of a group, all elements of Z_p^* satisfy the equation $x^{\exp(Z_p^*)} - 1 = 0$. Now by Theorem 39.13, this equation has at most $\exp(Z_p^*)$ solutions in Z_p, therefore at most $\exp(Z_p^*)$ solutions in Z_p^*. So, $|Z_p^*| \leq \exp(Z_p^*)$. Since these results imply $|Z_p^*| = \exp(Z_p^*)$ and using Theorem 39.24 the theorem is proven.

To prove that Z_{p^e} is cyclic when p is an odd prime, we use the following lemma.

LEMMA 39.9 When p is an odd prime, a primitive root $g \mod p$ exists such that for all integers $e > 1$:

$$g^{\phi\left(p^{e-1}\right)} \not\equiv 1 \mod p^e \,. \tag{39.26}$$

PROOF We will start with the case where $e = 2$. If g is a primitive root mod p which satisfies (39.26), then there is nothing to prove. Else, when $g^{\phi(p^{e-1})} = 1 \mod p^2$, we choose $g_0 = g + p$ (modulo p) as a primitive element. Now, using Theorem 39.11,

$$(g_0)^{\phi\left(p^{e-1}\right)} \equiv (g+p)^{p-1} \equiv \sum_{i=0}^{p-1} \binom{p-1}{i} p^i g^{p-1-i} \equiv 1 + (p-1)pg^{p-2} + 0 \not\equiv 1 \pmod{p^2} \,,$$

satisfying (39.26). So we assume from now on that g satisfies (39.26) when $e = 2$.

The case $e > 2$ is proven by induction. We will assume that (39.26), up to $e \geq 2$, has been proven. Due to the Euler–Fermat Theorem $g^{\phi(p^{e-1})} \equiv 1 \mod p^{e-1}$, or

$$g^{\phi\left(p^{e-1}\right)} = 1 + lp^{e-1} \,,$$

for an integer l. Due to our assumption, $p \not| \, l$. Since $e \geq 2$, $\phi(p^e) = p\phi(p^{e-1})$. So,

$$\begin{aligned} g^{\phi\left(p^{(e-1)+1}\right)} &= (1 + lp^{e-1})^p = \sum_{i=0}^{p} \binom{p}{i} l^i p^{i(e-1)} \\ &= 1 + plp^{e-1} + \frac{p(p-1)}{2} l^2 p^{2(e-1)} + rp^{3(e-1)} \,, \end{aligned} \tag{39.27}$$

for some integer r. Since p is odd, we have that $2 \mid (p-1)$. This implies $p^{e+1} \mid p(p-1)p^{2(e-1)}/2$, since $e + 1 \leq 2e - 1$ when $e \geq 2$. Also, $e + 1 \leq 3e - 3$ when $e \geq 2$. So, modulo p^{e+1} the equation (39.27) becomes

$$g^{\phi(p^e)} \equiv 1 + lp^e \not\equiv 1 \mod p^{e+1} \,.$$

THEOREM 39.26 *When p is an odd prime and $e \geq 1$ is an integer, Z_{p^e} is cyclic.*

PROOF The case $e = 1$ was proven in Theorem 39.25. When $e \geq 2$, we consider a g satisfying the conditions in Lemma 39.9 and call k the order of g modulo p^e. Since g is a primitive root modulo p, $p - 1 \mid k$, so $k = m(p-1)$. From Euler–Fermat Theorem $k \mid \phi(p^e)$, implying that $m \mid p^{e-1}$, or $m = p^s$. So, $k = (p-1)p^s$. Now, $s = e - 1$, otherwise we have a contradiction with Lemma 39.9.

DEFINITION 39.17 The Carmichael function $\lambda(n) = \exp(Z_n^*)$.

THEOREM 39.27 *We have that*

$$\lambda(2^k) \quad = \quad \begin{cases} 2^{k-1} & \text{if } k < 3 \\ 2^{k-2} & \text{if } k \geq 3\,. \end{cases}$$

PROOF It is easy to verify that 1 and 3 are primitive roots modulo 2 and 4, respectively. When $k \geq 3$, we prove by induction that

$$\forall a \in Z_{2^k}^* : \quad a^{2^{k-2}} = 1 \bmod 2^k\,. \tag{39.28}$$

First, if $k = 3$, then $2^{k-2} = 2$. Now all a are odd, and $a^2 = (2l+1)^2 = 4l(l+1) + 1$, for some l. Since $l(l+1)$ is even, $a^2 = 1 \bmod 8$. We will now assume that (39.28) is valid for k. This implies that for all odd integers $a^{2^{k-2}} = 1 + q2^k$ and squaring both sides gives $a^{2^{k-1}} = 1 + q2^{k+1} + q^2 2^{2k} \equiv 1 \bmod 2^{k+1}$. So when $k \geq 3$ and $a \in Z_{2^k}$ then $\text{ord}(a) \mid 2^{k-2}$. We now need to prove that an $a \in Z_{2^k}^*$ exists for which $\text{ord}(a) = 2^{k-2}$. We take $a = 3$ and need to prove that $3^{2^{k-3}} \not\equiv 1 \bmod 2^k$. Using (39.28) instead of the Euler–Fermat Theorem, the last part of the proof of Lemma 39.9 can easily be adapted to prove the claim, and this is left as an exercise.

The Chinese Remainder Theorem implies the following corollary.

COROLLARY 39.14 If $n = 2^{a_0} p_1^{a_1} \cdots p_k^{a_k}$, where p_i are different odd primes, then

$$\lambda(n) = \text{lcm}\left(\lambda\left(2^{a_0}\right), \phi\left(p_1^{a_1}\right), \ldots, \phi\left(p_k^{a_k}\right)\right)\,.$$

COROLLARY 39.15 When n is the product of two different odd primes, as in RSA, Z_n^* is *not* cyclic.

Lagrange Theorem

The following theorem is well known in elementary algebra.

THEOREM 39.28 *The order of a subgroup H of a finite group G is a factor of the order of G.*

PROOF Define the left coset of $x \in G$ relative to the subgroup H as $Hx = \{hx \mid h \in H\}$. First, any two cosets, let us say Hx and Hy, have the same cardinality. Indeed, the map mapping $a \in Hx$ to $ax^{-1}y$ is a bijection. Secondly, these cosets partition G. Obviously, a coset is not empty and any element $a \in G$ belongs to the coset Ha. Suppose now that b belongs to two different cosets Hx and Hy. Then, $b = h_1 x$, $h_1 \in H$ and $b = h_2 y$, where $h_2 \in H$. But then $y = h_2^{-1} h_1 x$, so $y \in Hx$. Then any element $z \in Hy$ will also belong to Hx, since $z = hy$ for some $h \in H$. So, we have a contradiction. Since each coset has the same cardinality and they form a partition, the result follows immediately.

39.6 Computational Number Theory: Part 2

Computing the Jacobi Symbol

Theorems 39.18 through 39.21 can easily be used to adapt the Euclidean algorithm to compute the Jacobi symbol.

Input declaration: integers a, n, where $0 \leq a < n$
Output declaration: $(a \mid n)$

function Jacobi(a, n)
begin

if $n = 1$
  then Jacobi
  else if $a = 0$
    then Jacobi:= 0
    else if $a = 1$
      then Jacobi:= 1
      else if a is even
        then if ($n \equiv 3 \bmod 8$) or ($n \equiv 5 \bmod 8$)
          then Jacobi:= $-$**Jacobi**$(a/2 \bmod n, n)$
          else Jacobi:= **Jacobi**$(a/2 \bmod n, n)$
        else if n is even
          then Jacobi:=**Jacobi**$(a \bmod 2, 2)\cdot$ **Jacobi**$(a \bmod n/2, n/2)$
          else if ($a \equiv 3 \bmod 4$) and ($n \equiv 3 \bmod 4$)
            then Jacobi:= $-$**Jacobi**$(n \bmod a, a)$
            else Jacobi:=**Jacobi**$(n \bmod a, a)$
end

Note that if $a \geq n$ that $(a \mid n) = (a \bmod n \mid n)$. The proof of correctness, the analysis of the algorithm, and a nonrecursive version are left as exercises.

Selecting a Prime

The methods used to select a (uniform random) prime of a certain length consist in choosing a (uniformly random) positive integer of a certain length and then testing whether the number is a prime. There are several methods to test whether a number is a prime. Since the research on the topic is so extensive, it is worth a book in itself. We will therefore limit our discussion.

Primality testing belongs to $\mathbf{NP} \cap \mathbf{co} - \mathbf{NP}$ as proven by Pratt [23]. It is not known whether the problem is in **P**. A random (Las Vegas) polynomial time algorithm has been presented [1], which is unfortunately not very practical. In most applications in cryptography, it is sufficient to know that a number is "likely" a prime. We distinguish two types of primality tests, depending on who chooses the prime. We will first discuss the case where the user of the prime chooses it.

Fermat Pseudoprimes

We will start by discussing primality tests where the user chooses a uniformly random number of a certain length and tests for primality. In this case a Fermat **pseudoprime** test is sufficient. The contrapositive of Fermat's little theorem (see Corollary 39.7) tells us that if a number is composite a

witness $a \not\equiv 0 \bmod n$ exists such that $a^{n-1} \not\equiv 1 \bmod n$, then n is composite. A number, n is called a Fermat pseudoprime to the base a if $a^{n-1} \not\equiv 1 \bmod n$. Although all primes are Fermat pseudoprimes, unfortunately not all pseudoprimes are necessarily primes. The Carmichael numbers are composite numbers but have the property that for $\underline{\text{all}}\ a \in Z_n^* : a^{n-1} = 1 \bmod n$. In other words, that $\lambda(n) \mid n-1$. It is easy to verify that $n = 3 * 11 * 17$ satisfies this. Alford, Granville and Pomerance [3] recently showed that there are infinitely many Carmichael numbers. We will use the following result.

THEOREM 39.29 *If n is a Carmichael number, then n is odd and squarefree.*

PROOF 2 is not a Carmichael number and if $n > 2$, then $2 \mid \lambda(n)$. Since n is a Carmichael number, $\lambda(n) \mid n-1$, so n is odd. Suppose now that $p^2 \mid n$, where p is a prime. Since $p \neq 2$, using Corollary 39.14, we have that $p \mid \lambda(n)$. This implies that $p \mid n-1$, since $\lambda(n) \mid n-1$. Now, $p \mid n$ and $p \mid n-1$, implying that $p \mid 1$, which is a contradiction.

In the case where an odd number n is chosen uniformly random among those of a given length and one uses Fermat's primality test with $a = 2$, the probability that the obtained number is not a prime is sufficiently small for cryptographic applications. However, if the number n is not chosen by the user and is given by an outsider, Fermat's test makes no sense due to the existence of Carmichael numbers, which the outsider could choose. We will now discuss how to check whether a number given by an outsider is "likely" to be a prime.

Probabilistic Primality Tests

We will now describe the Solovay–Strassen algorithm [26] in which the probability of receiving an incorrect statement that a composite n is prime can be made sufficiently small for each number n. The algorithm was also independently discovered by D. H. Lehmer.

We will assume that using a function call to **Random**, with input n, outputs a natural number a with a uniform distribution such that $1 \leq a < n$.

Input declaration: an odd integer $n > 2$.
Output declaration: element of {likely-prime, composite}

function Solovay-Strassen(n)
begin
a :=**Random**(n); (so, $1 \leq a \leq n-1$)
if gcd$(a, n) \neq 1$ then Solovay-Strassen:=composite
else if $(a \mid n) \not\equiv a^{\frac{n-1}{2}} \bmod n$ then Solovay-Strassen:=composite
else Solovay-Strassen:=likely-prime
end

To discuss how good this algorithm is, we first introduce the set

$$E(n) = \{a \in Z_n^* \mid (a \mid n) \equiv a^{\frac{n-1}{2}} \bmod n\}\ .$$

LEMMA 39.10 Let $n \geq 3$ be an odd integer. We have that n is prime if and only if $E(n) = Z_n^*$.

PROOF If n is an odd prime, the claim follows directly from Euler's criterion (Theorem 39.15).

We prove the converse using a contradiction. So, we assume that n is composite and $E(n) = Z_n^*$, which implies (by squaring) that $\forall a \in Z_n^* : a^{n-1} \equiv 1 \bmod n$. Thus n is a Carmichael number, implying that n is squarefree (see Theorem 39.29). So, $n = pr$, where p is a prime and $\gcd(p, r) = 1$. Let b be a quadratic nonresidue modulo p and $a \equiv b \bmod p$ and $a \equiv 1 \bmod r$. Now, from Theorem 39.18 $(a \mid n) = (a \mid p)(a \mid r) = (b \mid p) = -1$. Thus, due to our assumption $a^{(n-1)/2} = -1 \bmod n$, implying that $a^{(n-1)/2} = -1 \bmod r$, since $r \mid n \mid (a^{(n-1)/2} + 1)$. This contradicts with the choice of $a \equiv 1 \bmod r$.

THEOREM 39.30 *If n is an odd prime, then Solovay–Strassen(n) returns likely-prime. If n is an odd composite, then Solovay–Strassen(n) returns likely-prime with a probability less or equal to* $1/2$.

PROOF The first part follows from Corollary 39.4 and Theorem 39.15. To prove the second part, we use Lemma 39.10. It implies that $E(n) \neq Z_n^*$. So, since $E(n)$ is a subgroup of Z_n^*, as is easy to verify, $E(n)$ it is a proper subgroup. Applying Lagrange's theorem (see Theorem 39.28) implies that $|E(n)| \leq |Z_n^*|/2 = \phi(n)/2 \leq (n-1)/2$, which implies the theorem.

It is easy to verify that the protocol runs in expected polynomial time. If, when running the Solovay–Strassen algorithm k times for a given integer n, it returns each time likely-prime, then the probability that n is composite is, at maximum, 2^{-k}.

It should be observed that the Miller–Rabin primality test algorithm has an even smaller probability of making a mistake. Recent research has produced algorithms that are better in this respect.

Selecting an Element with a Larger Order

We will discuss how to select an element of large order in Z_p^*, p a prime. Based on the Chinese Remainder Theorem, Pohlig and Hellman [21] proved that if $p-1$ has only small prime factors, it is easy to compute the discrete logarithm in Z_p^*. Even if $p-1$ has one large prime factor, uniformly picking a random element will not necessarily imply that it has (with high probability) a high order. Therefore, we will discuss how one can generate a primitive element when the prime factorization of $p-1$ is given. The algorithm follows immediately from the following theorem.

THEOREM 39.31 *If p is a prime then an integer a exists such that*

$$\text{for all primes } q \mid p-1 \text{ we have } a^{\frac{p-1}{q}} \not\equiv 1 \bmod p\,. \tag{39.29}$$

Such an element a is a primitive root modulo p.

PROOF A primitive element must satisfy (39.29) and exists due to Theorem 39.25. We now prove, using a contradiction, that an element satisfying (39.29) must be a primitive element. Let $l = \text{ord}(a)$ modulo p. First Lemma 39.7 implies that $l \mid p-1$. So, when $p-1 = \prod_{i=1}^{m} q_i^{b_i}$, where q_i are different primes and $b_i \geq 1$, then $l = \prod_{i=1}^{m} q_i^{c_i}$, where $c_i \leq b_i$. Suppose $c_j < b_j$, then $a^{(p-1)/q_j} \equiv 1 \bmod p$, which is a contradiction.

As in the Solovay–Strassen algorithm, we will use a random generator.

Input declaration: a prime p and the prime factorization of $p-1 = \prod_{i=1}^{m} q_i^{b_i}$
Output declaration: a primitive root modulo p

function generator(p)
begin
repeat
    generator:=**Random**(p); (so, $1 \leq$ generator $\leq p-1$)
until for all q_i (generator)$^{(p-1)/q_i} \neq 1 \bmod p$
end

The expected running time follows from the following theorem.

THEOREM 39.32 *Z_p^*, p a prime has $\phi(p-1)$ different generators.*

PROOF Theorem 39.25 says that there is at least one primitive root. Assume that g is a primitive root modulo p and let $a \in Z_{p-1}^*$. Then an element $b = a^{-1} \bmod p-1$ exists, so $ab = k(p-1)+1$. We claim that $h = g^a \bmod p$ is a primitive root. Indeed, $h^b = g^{ab} = g^{k(p-1)+1} = g \bmod p$. Therefore any element $g^i = h^{bi} \bmod p$. So, we have proven that there are at least $\phi(p-1)$ primitive roots. Now if $d = \gcd(a, n) \neq 1$, then $h = g^a \bmod p$ cannot be a generator. Indeed, if h is generator, then $h^x = 1 \bmod p$ implies that $x \equiv 0 \bmod p-1$. Now, $h^x = g^{ax} = 1 \bmod p$, or $ax = 0 \bmod p-1$, which has only $\gcd(a, p-1)$ incongruent solutions modulo $p-1$ (see Theorem 39.12).

This algorithm can easily be adapted to construct an element of a given order. This is important in the DSS signature scheme. A variant of this algorithm allows one to prove that p is prime.

Other Algorithms

We have only discussed computational algorithms needed to explain the encryption schemes explained in this chapter. However, so much research has been done in the area of computational number theory, that a series of books are necessary to give a decent, up-to-date description of the area. For example, we did not discuss an algorithm to compute square roots, nor did we discuss algorithms used to cryptanalyze cryptosystems, such as algorithms to factor integers and to compute discrete logarithms. It is the progress on these algorithms and their implementations that dictates the size of the numbers one needs to choose to obtain a decent security.

39.7 Probabilistic Encryption

Although the Goldwasser–Micali probabilistic encryption is not very practical, its historical contribution is too significant to be ignored.

Generating a Public Key

When Alice wants to generate her public key, she first selects two primes p and q. She computes $n = p \cdot q$. Then she repeats choosing a random element y until $(y \mid n) = 1$ and $y \in \text{QNR}_n$. Knowing the prime factorization of n, the generation of such a y will take expected polynomial time. She then publishes (n, y) as her public key.

Note, that if $p \equiv q \equiv 3 \bmod 4$, $y = -1$ is such a number since $(-1 \mid p) = (-1 \mid q) = -1$, which is due to Corollary 39.11.

Encryption

To encrypt a bit b the sender uniformly chooses an $r \in Z_n^*$ and sends $c = y^b r^2 \bmod n$ as ciphertext.

Decryption

To decrypt, Alice sets $b = 0$ if $(c \mid p) = 1$. If, however, $(c \mid p) = -1$, then $b = 1$. Due to Corollary 39.10, the decryption is correct.

Let n be a composite, for example, the product of two primes of equal binary length. One can prove that the scheme is secure against a ciphertext-only and known-plaintext attack if it is hard to decide whether a number $a \in Z_n^{+1}$ is a quadratic residue or not.

39.8 Research Issues and Summary

This chapter surveyed some modern public key encryption schemes and the number theory and computational number theory required to understand these schemes. It has been argued, without a proof, that these encryption schemes are based on the discrete logarithm problem and the integer factorization problem. Worse, the computational difficulty of these problems is only assumed hard and it remains an open problem to prove or disprove this.

The problem of making new public key encryption schemes that are secure and significantly faster than these surveyed is an important issue. Many researchers have addressed this and have usually been unsuccessful.

39.9 Defining Terms

Composite: An integer with at least three different positive divisors.

Congruent: Two numbers a and b are congruent modulo c if they have the same nonnegative remainder after division by c.

Cyclic group: A group that can be generated by one element, i.e., all elements are powers of that one element.

Discrete logarithm problem: Given α and β in a group, the discrete logarithm decision problem is to decide whether β is a power of α in that group. The discrete logarithm search problem is to find what this power is (if it exists).

Integer factorization problem: To find a nontrivial divisor of a given integer.

Order of an element: The smallest positive integer such that the element raised to this integer is the identity element.

Prime: An integer with exactly two different positive divisors, namely 1 and itself.

Primitive element: An element that generates all the elements of the group, in particular of the group of integers modulo a given prime.

Pseudoprime: An integer, not necessarily prime, that passes some test.

Quadratic nonresidue modulo n: An integer relatively prime to n that is *not* congruent to a square modulo n.

Quadratic residue modulo n: An integer relatively prime to n that is congruent to a square modulo n.

Further Information

The *Further Information* section in the previous chapter discusses further information on public key encryption schemes.

The number theory required to understand modern public key systems can be found in many books on number theory such as [4, 13, 14]. These books discuss detailed proofs of the law of quadratic reciprocity (Theorem 39.17).

More information on computational number theory, also called algorithmic number theory, can be found in the recent book by Bach and Shallit [6]. In the first volume the authors have discussed number theoretical problems that can be solved in (expected) polynomial time. In the forthcoming second volume, they will discuss the number theoretical problems that are considered intractable today. Although Knuth's book on seminumerical algorithms [17] is rather old, it is still a worthy reference book. ANTS (Algorithmic Number Theory Symposium) is a rather new conference that takes place every two years. The proceedings of the conferences are published in the *Lecture Notes in Computer Science* (Springer-Verlag). The first two conferences (1994 and 1996) have volume numbers 877 and 1122. Results on the topic have appeared in a wide range of conferences and journals, such as FOCS and STOC.

Josef Pieprzyk, and
Rei Safavi-Naini
University of Wollongong

40.1 Introduction

In this chapter we discuss four related areas of cryptology, namely; authentication, hashing, message authentication codes (MACs), and digital signatures. These topics represent currently active and growing research topics in cryptology. Due to space limitations, we concentrate only on the essential aspects of each topic. The bibliography is intended to supplement our survey. We have included sufficiently many items to provide the interested reader with an overall view of the current state of knowledge in the above areas.

Authentication deals with the problem of providing assurance to a receiver that a communicated message originates from a particular transmitter, and that the received message has the same content as the transmitted message. A typical authentication scenario occurs in computer networks, where the identity of two communicating entities is established by means of authentication.

Hashing is concerned with the problem of providing a relatively short *fingerprint* of a much longer message or electronic document. A *hashing function* must satisfy (at least) the critical requirement that

the fingerprints of two distinct messages are distinct. Hashing functions have numerous applications in cryptology. They are often taken as primitives in constructing other cryptographic functions.

Message authentication codes (MACs) are symmetric key primitives that provide message integrity against active spoofing by appending a cryptographic checksum to a message that is verifiable only by the intended recipient of the message. Message authentication is one of the most important ways of ensuring the integrity of information that is transferred by electronic means.

Digital signatures provide electronic equivalents of handwritten signatures. They preserve the essential features of handwritten signatures, and can be used to sign electronic documents. Digital signatures can potentially be used in legal contexts.

40.2 Authentication

One of the main goals of a cryptographic system is to provide authentication, which simply means providing assurance about the content and origin of communicated messages.

Historically, cryptography began with secret writing, and this remained the main area of development until very recently. With the rapid progress in data communication, the need for providing message integrity and authenticity has escalated to the extent that currently authentication is seen as the more urgent goal of cryptographic systems.

Traditionally, it was assumed that a secrecy system provides authentication by the virtue of the secret key being only known by the intended communicants; this would prevent an enemy from constructing a fraudulent message. Simmons [66] argued that the two goals of cryptography are independent. He shows that a system that provides perfect secrecy might not provide any protection against authentication threats. Similarly, a system can provide perfect authentication without concealing messages.

In the rest of this chapter, we use the term *communication system* to encompass message transmission as well as storage. The system consists of a *transmitter* who wants to send a message, a *receiver* who is the intended recipient of the message, and an *enemy* who attempts to construct a fraudulent message with the aim of getting it accepted by the receiver unwittingly. In some cases, there is a fourth party, called the *arbiter,* whose basic role is to provide protection against cheating by the transmitter and/or the receiver. The communication is assumed to take place over a public channel, and hence the communicated messages can be seen by all the principals. An authentication threat is an attempt by an enemy in the system to modify a communicated message or inject a fraudulent message into the channel. In a secrecy system the attacker is passive, while in an authentication system the enemy is active and not only observes the communicated messages and gathers information such as plaintext and ciphertext, but also actively interacts with the system to achieve its goal. This view of the system clearly explains Simmons' motivation for basing authentication systems on game theory.

The most important criteria that can be used to classify authentication systems are

- The relation between authenticity and secrecy;
- The framework for the security analysis.

The first criterion divides authentication systems into those that provide *authentication with* and *without secrecy.* The second criterion divides systems into systems with *unconditional security,* systems with *computational security,* and systems with *provable security*. *Unconditional security* implies that the enemy has unlimited computational power, while in *computational security* the enemy's resources are limited and the security relies on the required computation exceeding the enemy's computational power. A system with *provable security* is in fact a subclass of computationally secure systems, and its compromise is equivalent to a solution of a known difficult problem.

These two classifications are orthogonal and produce four subclasses. Below we review the basic concepts of authentication theory, some known bounds and constructions in unconditional security, and then consider computational security.

Unconditional Security

A basic model introduced by Simmons [66] has remained the mainstay of most of the theoretical research on authentication systems. The model has the same structure as described in the previous section but excludes the arbiter. To provide protection against an enemy, the transmitter and receiver use an *authentication code (A-code)*. An A-code is a collection $\mathcal{E}$ of mappings called *encoding rules* (also called *keys*) from a set $\mathcal{S}$ of *source states* (also called *transmitter states*) into the set $\mathcal{M}$ of cryptogram (also called *codewords*). For A-codes without secrecy, also called *Cartesian A-codes*, a codeword uniquely determines a source state. That is, the set of codewords is partitioned into subsets each corresponding to a distinct source state. In a *systematic Cartesian A-code*, $\mathcal{M} = \mathcal{S} \times \mathcal{T}$ where $\mathcal{T}$ is a set of *authentication tags* and each codeword is of the form $s.t$, $s \in \mathcal{S}, t \in \mathcal{T}$ where '.' denotes concatenation. Let the cardinality of the set $\mathcal{S}$ of source states be denoted as k; that is, $|\mathcal{S}| = k$. Let $E = |\mathcal{E}|$ and $M = |\mathcal{M}|$. The encoding process adds key dependent redundancy to the message, so $k < M$. A key (or encoding rule) e determines a subset $\mathcal{M}_e \subset \mathcal{M}$ of codewords that are authentic under e.

The *incidence matrix* A of an A-code is a binary matrix of size $E \times M$ whose rows are labeled by encoding rules and columns by codewords, such that $A(e, m) = 1$ if m is a valid codeword under e, and $A(e, m) = 0$, otherwise.

An *authentication matrix* B of a Cartesian A-code is a matrix of size $E \times k$ whose rows are labeled by the encoding rules and columns by the source states, and $B(e, s) = t$ if t is the tag for the source state s under the encoding rule e.

To use the system, the transmitter and receiver must secretly share an encoding rule. The enemy does not know the encoding rule and uses an *impersonation* attack, in which it only uses its knowledge of the system, or a *substitution* attack in which it waits to see a transmitted codeword, and then constructs a fraudulent codeword. The security of the system is measured in terms of the enemy's chance of success with the chosen attack. The enemy's chance of success in an impersonation attack is denoted by P_0, and in a substitution attack by P_1. The best chance an enemy has in succeeding in either of the above attacks is called the *probability of deception*, P_d.

An attack is said to be *spoofing of order* ℓ if the enemy has seen ℓ communicated codewords under a single key. The enemy's chance of success in this case is denoted by P_ℓ.

The chance of success can be defined using two different approaches. The first approach corresponds to an average case analysis of the system and can be described as the enemy's payoff in the *game theory model*. It has been used by a number of authors, including MacWilliams, Gilbert and Sloane [32], Fak [28], and Simmons [66]. The second is to consider the worst-case scenario. This approach is based on the relation between A-codes and error correcting codes (also called E-codes).

Using the game theory model, P_j is the value of a zero-sum game between communicants and the enemy. For impersonation

$$P_0 = \max_{m \in \mathcal{M}} (\text{payoff}(m)) \ ,$$

and for substitution

$$P_1 = \sum_{j=1}^{E} \sum_{m \in \mathcal{M}} P(m) \max_{m'} \text{payoff}(m, m') \ ,$$

where $P(m)$ is the probability of a codeword m occurring in the channel, and payoff(m, m') is the enemy's payoff (best chance of success) when it substitutes an intercepted codeword m with a fraudulent one, m'.

Bounds on the Performance of the A-Code

The first types of bounds relate the main parameters of an A-code, that is, E, M, k, and hence are usually called *combinatorial bounds*. The most important combinatorial bound for A-codes with secrecy is

$$P_i \geq \frac{k - i}{M - i}, \ \ i = 1, 2, \ldots$$

and for A-codes without secrecy is

$$P_i \geq k/M, \ \ i = 1, 2, \ldots \ .$$

An A-code that satisfies these bounds with equality, that is, with $P_i = \dfrac{k-i}{M-i}$ for A-codes with secrecy and $P_i = k/M$ for Cartesian A-codes, is said to *provide perfect protection for spoofing of order* i. The enemy's best strategy in spoofing of order i for such an A-code is to randomly select one of the remaining codewords.

A-codes that provide perfect protection for all orders of spoofing up to r are said to be *r-fold secure*. These codes can be characterized using combinatorial structures such as orthogonal arrays and t-designs.

An orthogonal array $OA_\lambda(t, k, v)$ is an array with λv^t rows, each row of size k, from the elements of set X of v symbols, such that in any t columns of the array every t-tuple of elements of X occurs in exactly λ rows. Usually t is referred to as *the strength* of the OA.

EXAMPLE 40.1:

The following table gives a $OA_2(2, 5, 2)$ on the set {0, 1}:

0	0	0	0	0
1	1	0	0	0
0	0	0	1	1
1	1	0	1	1
1	0	1	0	1
0	1	1	0	1
1	0	1	1	0
0	1	1	1	0

A t-(v, k, λ) *design* is a collection of b subsets, each of size k, of a set, X, of size v where every distinct subset of size t occurs exactly λ times.

The *incidence matrix* of a t-(v, k, λ) is a binary matrix, $A = (a_{ij})$, of size $b \times v$ such that $a_{ij} = 1$ if element j is in block i and 0 otherwise.

EXAMPLE 40.2:

The following table gives a 3-(8, 4, 1) design on the set {0, 1, 2, 3, 4, 5, 6, 7}:

7	0	1	3
7	1	2	4
7	2	3	5
7	3	4	6
7	4	5	0
7	5	6	1
7	6	0	2
2	4	5	6
3	5	6	0
4	6	0	1
5	0	1	2
6	1	2	3
0	2	3	4
1	3	4	5

with incidence matrix:

$$\begin{array}{cccccccc}
1 & 1 & 0 & 1 & 0 & 0 & 0 & 1 \\
0 & 1 & 1 & 0 & 1 & 0 & 0 & 1 \\
0 & 0 & 1 & 1 & 0 & 1 & 0 & 1 \\
0 & 0 & 0 & 1 & 1 & 0 & 1 & 1 \\
1 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\
0 & 1 & 0 & 0 & 0 & 1 & 1 & 1 \\
1 & 0 & 1 & 0 & 0 & 0 & 1 & 1 \\
0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 \\
1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\
1 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\
1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 \\
0 & 1 & 1 & 1 & 0 & 0 & 1 & 0 \\
1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 1 & 1 & 1 & 0 & 0
\end{array}$$

The main theorems relating A-codes with r-fold security and combinatorial structures are due to a number of authors, including Stinson [69], and Tombak and Safavi-Naini [77]. The following are the most general forms of these theorems.

THEOREM 40.1 *[77] Let the source be r-fold uniform. Then an A-code provides r-fold security against spoofing if and only if the incidence matrix of the code is the incidence matrix of a $(r+1)$- (M, k, λ) design.*

In the above theorem, an r-fold uniform source is a source for which every string of r distinct outputs from the source has probability $\dfrac{1}{k(k-1)\cdots(k-r+1)}$.

THEOREM 40.2 *Let $P_0 = P_1 = P_2 = \cdots = P_r = k/M$. Then the authentication matrix is a $OA(r+1, k, \ell)$ where $\ell = M/k$.*

The so-called *information theoretic bounds* characterize the enemy's chance of success using uncertainty measures. The first such bound for Cartesian A-codes, derived by MacWilliams, Gilbert and Sloane [32], is

$$P_1 \geq 2^{-\frac{H(M)}{2}}$$

where $H(M)$ is the entropy of the codeword space. The first general bound on P_0, due to Simmons [66], is

$$P_0 \geq 2^{-(H(E)-H(E|M))}$$

where $H(E)$ is the entropy of the key space and $H(E|M)$ is the conditional entropy of the key when a codeword is intercepted. Write $I(E; M)$ for the mutual information of E and M. Then,

$$P_0 \geq 2^{-I(E;M)} .$$

The above bound relates the enemy's best chance of success to the mutual information between the cryptogram space and the key space. A general form of this bound, proved independently by Rosenbaum [63] and Pei [47], is

$$P_\ell \geq 2^{-I(E;M^\ell)} ,$$

where $I(E; M^\ell)$ is the mutual information between a string of ℓ codewords, and where m^ℓ is the key.

Similar bounds for A-codes without secrecy are proved by MacWilliams et al. [32] and by Walker [79]. A general bound on the probability of deception, P_{d_r}, derived by Rosenbaum [63], is

$$P_{d_r} \geq 2^{-\frac{H(E)}{r+1}} .$$

Other Types of Attack

Tombak and Safavi-Naini [76] consider other types of attacks, similar to those for secrecy systems. In a *plaintext attack* against A-codes with secrecy, the enemy not only knows the codeword but also knows the corresponding plaintext. In *chosen content attack* the enemy wants to succeed with a codeword that has a prescribed plaintext. It is shown that by applying some transformation on the A-code it is possible to provides immunity against the above attacks.

A-codes with secrecy are generally more difficult to analyze than Cartesian A-codes. Moreover, the verification process for the former is not as efficient. In the case of Cartesian A-codes, verification of a received codeword, $s.t$, amounts to recalculating the tag using the secret key and the source state s to obtain t' and comparing it with the received tag t. For an authentic codeword we have $t = t'$. In the case of A-codes with secrecy, when a codeword m is received, the receiver must try all authentic codewords using his secret key, otherwise there must be an inverse algorithm that allows the receiver to find and verify the source state. The former process is costly and the latter does not exist for a general A-code. For practical reasons, the majority of research has concentrated on Cartesian A-codes.

Efficiency

Authentication systems require secure transmission of key information prior to the communication and hence, similar to secrecy systems, it is desirable to have a small number of key bits.

Rees and Stinson [60] prove that for any (M, k, E) A-code that is onefold secure, $E \geq M$. For A-codes with secrecy that provide onefold security, Stinson [69] shows that

$$E \geq \frac{M^2 - M}{k^2 - k} .$$

Under similar conditions for Cartesian A-codes, Stinson [69] shows that

$$E \geq k(\ell - 1) + 1$$

where $\ell = k/M$.

For A-codes with r-fold security, Stinson [71] shows that

$$E \geq \frac{M(M-1)\cdots(M-r)}{k(k-1)\cdots(k-r)} .$$

An A-code *provides perfect authenticity of order r* if $P_{d_r} = k/M$. In such codes the probability of success of the spoofer does not improve with the interception of extra codewords.

The following bound is established by Tombak and Safavi-Naini [75] for codes of the above type:

$$E \geq \frac{M^{r+1}}{k^{r+1}} .$$

Their bound shows that the provision of perfect authenticity requires $\log M - \log k$ extra key bits on average for every added order of spoofing. Hence using the same key for authentication of more than one message is expensive.

A second measure of efficiency, often used for systematic Cartesian A-codes, is the size of the tag space for a fixed size of source space and probability of success in substitution. Stinson [72] shows that, for perfect

protection against substitution, the size of key space grows linearly with the size of the source. Johansson, Kabatianskii and Smeets [37] show that if $P_1 > P_0$, A-codes with an exponential (in E) number of source states can be obtained.

A-Codes and E-Codes

An error correcting code provides protection against random channel error. The study of error-correcting codes was motivated by Shannon's Channel Capacity Theorem and has been a very active research area since the early 1950s. Error-correcting codes add redundancy to a message in such a way that a codeword corrupted by the channel noise can be detected and/or corrected. The main difference between an A-code and an E-code is that in the former redundancy depends on a secret key while in the latter it only depends on the message being coded. There exists a duality between authentication codes and error correcting codes. In the words of Simmons [66], " ... one (coding theory) is concerned with clustering the most likely alterations as closely about the original code as possible and the other (authentication theory) with spreading the optimal (to the opponent) alterations as uniformly as possible over $\mathcal{M}$."

The relation between E-codes and A-codes is explored in the work of Johansson et al. [37], who show that it is possible to construct E-codes from A-codes and vice-versa. Their work uses a worst case analysis approach in analyzing the security of A-codes. That is, in the case of substitution attack, they consider the *best* chance of success an enemy has when it intercepts all possible codewords. This contrasts with the information theoretic (or game theory) approach in which the average success probability of the enemy over all possible intercepted codewords is calculated.

The work of Johansson et al. is especially useful as it allows the well-developed body of bounds and asymptotic results from the theory of error correcting codes to be employed in the context of authentication codes, to derive upper and lower bounds on the size of the source for A-codes with given E, T, and P_1.

Authentication with Arbiter

In the basic model of authentication discussed above, the enemy is an outsider and we assume that the transmitter and the receiver are trustworthy. Moreover, because the key is shared by the transmitter and the receiver, the two principals are cryptographically indistinguishable. In an attempt to model authentication systems in which the transmitter and the receiver are distinguished and to remove assumptions about the trustworthiness of the two, Simmons [66] introduced a fourth principal called the *arbiter*. The transmitter and receiver have different keys and the arbiter has access to all or part of the key information. The system has a *key distribution phase* during which keys satisfying certain conditions are chosen. After that there is a *transmission phase* during which the transmitter uses its key to produce a codeword and finally a *dispute phase* during which disputes are resolved with the aid of the arbiter. The arbiter in Simmons' model is active during the transmission phase and is assumed to be trustworthy. Yung and Desmedt [83] remove this assumption and consider a model in which the arbiter is only trusted to resolve disputes. Johansson [35] and Kurosawa [39] derive lower bounds on the probability of deception in such codes. Johansson [36] and Taylor [73] propose constructions.

Shared Generation of Authenticators

Many applications require the power to generate an authentic message and/or to verify the authenticity of a message to be distributed among a number of principals. An example of such a situation is multiple signatures in a bank account or court room. Desmedt and Frankel [25] introduced systems with *shared generation of authenticators (SGA-systems)*, which have been studied in recent papers by Safavi-Naini [64], Gehrmann, van Dijk and Smeets, [29], and Safavi-Naini and Martin [65]. In such systems there is a group P of transmitters created with an structure Γ that determines authorized subsets of P. Each principal has a secret key which is used to generate a partial tag. The system has two phases. In the key distribution

phase, a *trusted authority* generates keys for the transmitters and the receivers and securely delivers the keys to them. In the communication phase, the trusted authority is not active. When an authorized group of transmitters wants to construct an authentic codeword, using its key, each group member generates a partial tag for the source state s which needs to be authenticated, and sends it to a *combiner*. The combiner is a fixed algorithm with no secret input. It combines its inputs to produce a tag, t, to be appended to s. The receiver is able to authenticate this codeword using its secret key. Safavi-Naini and Martin [65] give a general construction for SGA-systems by combining A-codes and secret sharing schemes. Gehrmann et al. [29] propose an efficient construction for SGA-systems, based on maximum rank distance separable codes.

Multiple Authentication

As noted before, in the theory of A-codes the possible attacks by the enemy are limited to impersonation and substitution. This means that the security of the system is only for one message communication; after that the key must be changed. To extend protection over more than one message transmission, there exist a number of alternatives. The most obvious ones use A-codes that provide perfect protection against spoofing of order ℓ. However, little is known about the construction of such codes and it is preferable to use A-codes that provide protection against substitution for more that one message transmission. Vanroose, Smeets and Wan [82] suggest *key strategies* in which the communicants change their key after each transmitted codeword, using some prespecified strategy. In this case the key information shared by the communicants is the *sequence of keys* to be used for consecutive transmission slots. The resulting bounds on the probability of deception generalize the bounds given by the following authors: Pei [47], Rosenbaum [63], and Walker [79].

Another successful approach proposed by Wegman and Carter [80] uses a special class of hash functions together with a one time pad of random numbers. This construction is discussed in more detail in Section 40.5.

40.3 Computationally Secure Systems

The study of computationally secure A-systems is relatively informal, cf. Simmons [67]. The basic framework is similar to unconditionally secure systems. A simple computationally secure A-code can be obtained by considering $\mathcal{S} = GF(2^{40})$ and $\mathcal{M} = GF(2^{64})$. We use $\mathcal{E}$ to be the collection of DES [51] encryption functions and so $E = 2^{56}$. To construct the codeword corresponding to a source state s, using the key k, we append 24 zeros to s and then use DES with key k to encrypt $s.\mathbf{0}_{24}$, where $\mathbf{0}_{24}$ is the string of 24 zeros.

It is easy to see that the above scheme is an A-code with secrecy. It allows the receiver to easily verify the authenticity of a received codeword by decrypting a received codeword and checking the existence of the string of zeros. If an enemy wants to impersonate the transmitter its chance of success is 2^{-56}, which is the probability of guessing the correct key. For a substitution attack, the enemy waits to see a transmitted codeword. Then it uses all the keys to decrypt the codeword and once a decryption of the right form (ending in 24 zeros) is obtained, a possible key is found. In general there is more than one key with this property. On the average there are $2^{56} \times 2^{40}/2^{64} = 2^{32}$ pairs (s, k) that produce the same cryptogram and hence the chance of guessing correctly is 2^{-32}. A better strategy for the enemy is to randomly choose a cryptogram and send it to the receiver. In this case his chance of success is 2^{-24}, which is better than the previous case.

The security of computationally secure A-systems weakens very quickly as the enemy intercepts more cryptograms. Trying all possible keys on ℓ received cryptograms enables the enemy to uniquely identify the key, in which case the enemy's chance of success is one.

Computationally secure A-systems without secrecy are obtained by appending an *authenticator* to the message which is verifiable by the intended receiver. The authenticator can be produced by a *symmetric*

key algorithm or an *asymmetric key algorithm*. The former is the subject of the section on message authentication codes (MAC), while the latter is discussed in the section on digital signatures.

40.4 Hashing

In many cryptographic applications, it is necessary to produce a relatively short *fingerprint* of a much longer message or electronic document. The fingerprint is also called a digest of the message. Ideally, a hash function should produce a unique digest of a fixed length for a message of an arbitrary length. Obviously, this is impossible as any hash function is, in fact, a many-to-one mapping. The properties required for secure hashing can be summarized as follows:

- Hashing should be a many-to-one function producing a digest that is a complex function of all bits of the message;
- A hash function should behave as a random function that creates a digest for a given message by randomly choosing an element from the whole digest space;
- For any pair of messages, it should be computationally difficult to find a collision; i.e., distinct messages with the same digest; and
- A hash function should be one-way; i.e., it should be easy to compute the digest of a given message but difficult to determine the message corresponding to a given digest.

The main requirement of secure hashing is that it should be *collision-free* in the sense that finding two colliding messages is computationally intractable. This requirement must hold for long as well as short messages.

Strong and Weak Hash Functions

Hash functions can be broadly classified into two classes: *strong one-way hash functions* (also called *collision-free hash functions*) and *weak one-way hash functions* (also known as *universal one-way hash functions*). A strong one-way hash function is a function h satisfying the following conditions:

1. h can be applied to any message or document M of any size;
2. h produces a fixed size digest;
3. Given h and M, it is easy to compute the digest $h(M)$; and
4. Given h, it is computationally infeasible to find two distinct messages M_1, M_2 that collide, i.e., $h(M_1) = h(M_2)$.

On the other hand, a weak one-way hash function is a function that satisfies conditions 1, 2, 3 and the following:

4'. Given h and a randomly chosen message M, it is computationally intractable to find another message M' that collides with M, i.e., $h(M) = h(M')$.

Strong one-way hash functions are easier to use since there is no precondition on the selection of the messages. On the other hand, for weak one-way hash functions, there is no guarantee that a nonrandom selection of two messages is collision-free. This means that the space of easily found colliding messages must be small. Otherwise, a random selection of two messages would produce a collision with a nonnegligible probability.

Theoretic Constructions

Naor and Yung [44] introduced the concept of a universal one-way hash function (UOWHF) and suggested a construction based on a one-way permutation. In their construction, they employ the notion of a *universal family of functions with collision accessibility property* [80]. The above functions are defined as follows.

DEFINITION 40.1 Suppose $G = \{g \mid A \rightarrow B\}$ is a set of functions. G is strongly *universal*$_r$ if given any r distinct elements $a_1, \ldots, a_r \in A$, and any r elements $b_1, \ldots, b_r \in B$, there are $|G|/|B|^2$ functions which take a_1 to b_1, a_2 to b_2 etc. ($|G|$ and $|B|$ denote the cardinality of sets G and B, respectively.)

DEFINITION 40.2 A strongly *universal*$_r$ family of functions G has the collision accessibility property if it is possible to generate in polynomial time a function $g \in G$ that satisfies the equations

$$g(a_i) = b_i, \ 1 \leq i \leq r \ .$$

Naor and Yung construct a family of UOWHFs by concatenating any one-way permutation with a family of strongly universal$_2$ hash functions having the collision accessibility property. In this construction, the one-way permutation provides the one-wayness of the UOWHF, and the strongly universal$_2$ family of hash functions provides the mapping to the small length output. When a function is chosen randomly and uniformly from the family, the output is distributed randomly and uniformly over the output space.

Zheng, Matsumoto and Imai [84] define a scheme based on the composition of a pairwise independent uniformizer and a strongly universal hash function with a quasi-injection one-way function.

De Santis and Yung [24] construct hash functions from one-way functions with an almost-known preimage size. In other words, if an element of the domain is given, then with a polynomial uncertainty an estimate of the size of the preimage set is easily computable. A *regular* function is an example of such a function. (In a regular function, each image of an n-bit input has the same number of preimages of length n.)

Rompel [62] constructs a UOWHF from any one-way function. His construction is rather elaborate. Briefly, his idea is to transform any one-way function into a UOWHF through a sequence of complicated procedures. First, the one-way function is transformed into another one-way function such that for most elements of the domain except for a fraction, it is easy to find a collision. From this, another one-way function is constructed such that for most of the elements it is hard to find a collision. Subsequently, a length increasing one-way function is constructed for which it is hard to find collisions almost everywhere. Finally, this is turned into a UOWHF which compresses the input in a way that makes it difficult to find a collision (cf. Pieprzyk and Sadeghiyan [49]).

Hashing Based on Block Ciphers

To minimize the design effort for cryptographically secure hash functions, the designers of hash functions tend to base their schemes on existing encryption algorithms. For example, sequential hashing can be obtained by dividing a given message into blocks and applying an encryption algorithm on the message blocks. The message block length must be the same as the block length of the encryption algorithm. If the message length is not a multiple of the block length, then the last block is usually padded with some redundant bits. To provide a randomizing element, an initial public vector is normally used. The proof of the security of such schemes relies on the collision freeness of the underlying encryption algorithm.

In the following, let E denote an arbitrary encryption algorithm. Let $E(K, M)$ denote the encryption of message M with key K using E; let IV denote the initial vector.

Rabin [55] shows that any private-key cryptosystem can be used for hashing. Rabin's scheme is the following. First the message is divided into blocks $M_1, M_2, \ldots$ of the same size as the block length of the

encryption algorithm. In the case of DES, the message is divided into 64-bit blocks. To hash a message $M = (M_1, M_2, \ldots, M_t)$, the following computations are performed:

$$\begin{aligned} H_0 &= IV \\ H_i &= E(M_i, H_{i-1}) \quad i = 1, 2, \ldots, t \\ H(M) &= H_t \end{aligned}$$

where M_i is a message block, H_i are intermediate results of hashing, and $H(M)$ is the digest. Although Rabin's scheme is simple and elegant, it is susceptible to the so-called *birthday attack* when the size of the hash value is 64 bits.

Winternitz [81] proposes a scheme for the construction of a one-way hash function from any block cipher. In any good block cipher, given an input and an output, it should be difficult to determine the key, but from the key and the output it should be easy to determine the input. The scheme uses an operation E^* defined by:

$$E^*(K \parallel M) = E(K, M) \oplus M \, .$$

Based on the above scheme, Davies [23] proposed the following hashing algorithm:

$$\begin{aligned} H_0 &= IV \\ H_i &= E(M_i, H_{i-1}) \oplus H_{i-1} \quad i = 1, 2, \ldots, t \\ H(M) &= H_t . \end{aligned}$$

If $E(K, M)$ is DES, then it may be vulnerable to attacks based on weak keys or a key-collision search. The meet-in-the-middle attack is thwarted because $E(K, M)$ is a one-way function.

Merkle [43, 42] proposed hashing schemes based on Winternitz's construction. These schemes use DES to produce digests of size $\approx$ 128 bits.

Their construction follows a general method for constructing hash algorithms, called the *meta method*. This is the same as the serial method of Damgård [22]. The description of the method is as follows. The message is first divided into blocks of 106 bits. Each 106-bit block M_i of data is concatenated with the 128-bit block H_{i-1}. The concatenation $X_i = M_i \parallel H_{i-1}$ contains 234 bits. Each block X_i is further divided into halves, X_{i1} and X_{i2}.

$$\begin{aligned} H_0 &= IV \\ X_i &= H_{i-1} \parallel M_i \\ H_i &= E^*(00 \parallel \text{first 59 bits of}\{E^*(100 \parallel X_{1i})\} \parallel \\ &\quad \text{first 59 bits of}\{E^*(101 \parallel X_{2i})\}) \parallel \\ &\quad E^*(01 \parallel \text{first 59 bits of}\{E^*(110 \parallel X_{1i})\} \parallel \\ &\quad \text{first 59 bits of}\{E^*(111 \parallel X_{2i})\}) \\ H(M) &= H_t \, . \end{aligned}$$

In this scheme E^* is defined as in Winternitz's construction. The strings 00, 01, 100, 101, 110, and 111 above are used to prevent the manipulation of weak keys.

Hashing Functions Based on Intractable Problems

Hashing functions can also be based on one-way functions such as exponentiation, squaring, knapsack (cf. Pieprzyk and Sadeghiyan [49]), and discrete logarithm. More recently, a group-theoretic construction using the SL_2 groups has been proposed by Tillich and Zémor [74].

A scheme based on RSA exponentiation as the underlying one-way function is defined by

$$\begin{aligned} H_0 &= IV \\ H_i &= (H_{i-1} \oplus M_i)^e \bmod N \quad i = 1, 2, \ldots, t \\ H(M) &= H_t \end{aligned}$$

where the modulus N and the exponent e are public. A correcting block attack can be used to compromise the scheme by appending or inserting a carefully selected last block message to achieve a desired hash value. To immunize the scheme against this attack, it is necessary to add redundancy to the message so that the last message block cannot be manipulated (cf. Davies and Price [23]). To ensure the security of RSA, N should be at least 512 bits in length, making the implementation of the above scheme very slow.

To improve the performance of the above scheme, the public exponent can be made small. For example, squaring can be used:

$$H_i = \left(H_{i-1} \oplus M_i\right)^2 \bmod N \, .$$

It is suggested that 64 bits of every message block be set to 0, to avoid a correcting block attack.

An algorithm for hashing based on squaring is proposed in Appendix D of the X.509 recommendations of the CCITT standards on secure message handling. The proposal stipulates that 256 bits of redundancy be distributed over every 256-bit message block by interleaving every four bits of the message with 1111, so that the total number of bits in each block becomes 512. The exponentiation algorithm, with exponent two, is then run on the modified message in CBC mode (cf. Pieprzyk and Sadeghiyan [49]). In this scheme, the four most significant bits of every byte in each block are set to 1. Coppersmith [20] shows how to construct colliding messages in this scheme.

Damgård [22] describes a scheme based on squaring, which maps a block of n bits into a block of m bits. The scheme is defined by

$$\begin{aligned} H_0 &= IV \\ H_i &= \text{extract}(00111111 \parallel H_{i-1} \parallel M_i)^2 \bmod N \\ H(M) &= H_t . \end{aligned}$$

In the above scheme, the role of *extract* is to extract m bits from the result of the squaring function. To obtain a secure scheme, m should be sufficiently large so as to thwart the birthday attack; this attack will be explained later. Moreover, *extract* should select bits for which finding colliding inputs is difficult. One way to do this is to extract m bits uniformly. However, for practical reasons, it is better to bind them together in bytes. Another possibility is to extract every fourth byte. Daemen, Govaerts and Vanderwalle [21] show that this scheme can be broken.

Impagliazzo and Naor [34] propose a hashing function based on the knapsack problem. The description of the scheme is as follows. Choose at random numbers $a_1, \ldots, a_n$ in the interval $0, \ldots, N$, where n indicates the length of the message in bits, and $N = 2^\ell - 1$ where $\ell < n$. A binary message $M = M_1, M_2, \ldots, M_n$ is hashed as

$$H(M) = \sum_{i=1}^{n} a_i M_i \bmod 2^\ell \, .$$

Impagliazzo and Naor do not give any concrete parameters for the above scheme, but they have shown that it is theoretically sound.

Gibson [31] constructs hash functions whose security is conditional upon the difficulty of factoring certain numbers. The hash function is defined by

$$f(x) = a^x (\bmod n) \, ,$$

where $n = pq$, p and q are large primes, and a is a primitive element of the ring Z_n. In Gibson's hash function n has to sufficiently large to ensure the difficulty of factoring. This constraint makes the hash function considerably slower than the MD4 algorithm.

Tillich and Zémor [74] proposed a hashing scheme where the message digests are given by two-dimensional matrices with entries in the binary Galois fields $GF(2^n)$ for $130 \leq n \leq 170$. The hashing functions are parameterized by the irreducible polynomials of degree n, $P_n(X)$, over $GF(2)$; their choice is left to the user. Their scheme has several provably secure properties: detection of local modification of text; and resistance to the birthday attack as well as a few other attacks. Hashing is fast as digests are produced by matrix multiplication in $GF(2^n)$, which can be parallelized.

Messages (encoded as a binary strings) $x_1x_2\ldots$ of arbitrary length are mapped to products of a selected pair of *generators* $\{A, B\}$ of the group $SL(2, 2^n)$, as follows:

$$x_i = \begin{cases} A & \text{if } x_i = 0 \\ B & \text{if } x_i = 1. \end{cases}$$

The resulting product belongs to the (infinite) group $SL(2, GF(2)[X])$, where $GF(2)[X]$ is the ring of all polynomials over $GF(2)$. The product is then reduced modulo an irreducible polynomial of degree n (Euclidean algorithm), mapping it to an element of $SL(2, 2^n)$. The four n-bit entries of the reduced matrix give the $(3n + 1)$-bit message digest of $x_1x_2\ldots$.

Charnes and Pieprzyk [15] showed that irreducible polynomials which produce collisions for the SL_2 hash functions can be found. Other weaknesses of this scheme are explored in a later paper available from them [17]. In that paper, the weak parameters are characterized; they can be computed with the algorithms given there.

Geiselmann [30] describes an algorithm to produce potential collisions for the $SL(2, 2^n)$ hashing scheme, which is independent of the choice of the irreducible polynomials. The complexity of his algorithm is that of the discrete logarithm problem in $GF(2^n)$ or $GF(2^{2n})$. However, no collisions in the specified range of the hash function have been found using this algorithm. Some pairs of rather long colliding strings are given by Geiselmann for a toy example of $GF(2^{21})$.

Hashing Algorithms

Rivest [58] proposes a hashing algorithm called MD4. It is a software-oriented scheme that is especially designed to be fast on 32-bit machines. The algorithm produces a 128-bit output, so it is not computationally feasible to produce two messages having the same hash value. The scheme provides diffusion and confusion using three Boolean functions. The MD5 hashing algorithm is a strengthened version of MD4 [57]. MD4 has been broken by Dobbertin [26].

HAVAL stands for a one-way hashing algorithm with a variable length of output. It was designed at the University of Wollongong by Zheng, Pieprzyk and Seberry [85]. It compresses a message of an arbitrary length into a digest of either 128, 160, 192, 224 or 256 bits. The security level can be adjusted by selecting 3, 4, or 5 passes. The structure of HAVAL is based on MD4 and MD5. Unlike MD4 and MD5 whose basic operations are done using functions of three Boolean variables, HAVAL employs five Boolean functions of seven variables (each function serves a single pass). All functions used in HAVAL are highly nonlinear, 0-1 balanced, linearly inequivalent, mutually output-uncorrelated and satisfy the strict avalanche criterion (SAC). No attack on HAVAL has been reported so far.

Charnes and Pieprzyk [14] proposed a modified version of HAVAL based on five Boolean functions of five variables. The resulting hashing algorithm is faster than the five pass, seven variable version of the original HAVAL algorithm. They use the same cryptographic criteria that are used to select the Boolean functions in the original scheme. Unlike the seven variable case, the choice of the Boolean functions is fairly restricted in the modified setting. Using the shortest algebraic normal form of the Boolean functions as one of the criteria (to maximize the speed of processing), it is shown that the Boolean functions used are optimal. No attacks have been reported for the five variable version.

Attacks

The best method to evaluate a hashing scheme is to see what attacks an adversary can perform to find collisions. A good hashing algorithm produces a fixed length number which depends on all the bits of the message. It is generally assumed that the adversary knows the hashing algorithm. In a conservative approach, it is assumed that the adversary can perform an adaptive chosen message attack, where it may choose messages, ask for their digests, and try to compute colliding messages. There are several methods for using such pairs to attack a hashing scheme and to calculate colliding messages. Some methods are quite general and can be applied against any hashing scheme; for example, the so-called *birthday attack*. Other methods are applicable only to specific hashing schemes. Some attacks can be used against a wide range of hash functions. For example, the so-called *meet-in-the-middle attack* is applicable to any scheme that uses some sort of block chaining in its structure. As another example, the so-called *correcting block attack* is applicable mainly to hash functions based on modular arithmetic.

Birthday Attack

The idea behind this attack originates from a famous problem from probability theory, called the *birthday paradox*. The paradox can be stated as follows. What is the minimum number of pupils in a classroom so the probability that at least two pupils have the same birthday is greater than 0.5? The answer to this question is 23, which is much smaller than the value suggested by intuition. The justification for the paradox is as follows. Suppose that the pupils are entering the classroom one at a time. The probability that the birthday of the first pupil falls on a specific day of the year is equal to $\frac{1}{365}$. The probability that the birthday of the second pupil is not the same as the first one is equal to $1 - \frac{1}{365}$. If the birthdays of the first two pupils are different, the probability that the birthday of the third pupil is different from the first one and the second one is equal to $1 - \frac{2}{365}$. Consequently, the probability that t students have different birthdays is equal to $(1 - \frac{1}{365})(1 - \frac{2}{365}) \ldots (1 - \frac{t-1}{365})$, and the probability that at least two of them have the same birthday is

$$P = 1 - \left(1 - \frac{1}{365}\right)\left(1 - \frac{2}{365}\right) \cdots \left(1 - \frac{t-1}{365}\right) .$$

It can be easily computed that for $t \geq 23$, this probability is greater than 0.5.

The birthday paradox can be employed for attacking hash functions. Suppose that the number of bits of the hash value is n. An adversary generates r_1 variations of a bogus message and r_2 variations of a genuine message. The probability of finding a bogus message and a genuine message that hash to the same digest is

$$P \approx 1 - e^{-\frac{r_1 r_2}{2^n}}$$

where $r_2 \gg 1$ (see Ohta and Koyama [46]). When $r_1 = r_2 = 2^{\frac{n}{2}}$, the above probability is ≈ 0.63. Therefore any hashing algorithm which produces digests of length around 64 bits is insecure, since the time complexity function for the birthday attack is $\approx 2^{32}$. It is usually recommended that the hash value should be around 128 bits to thwart the birthday attack.

This method of attack does not take advantage of the structural properties of the hash scheme or its algebraic weaknesses. It applies to any hash scheme. In addition, it is assumed that the hash scheme assigns to a message a value which is chosen with a uniform probability among all the possible hash values. Note that if the structure is weak or has certain algebraic properties, the digests do not have a uniform probability distribution. In such cases it may be possible to find colliding messages with a better probability and fewer message-digest pairs.

Meet-in-the-Middle Attack

This is a variation of the birthday attack, but instead of comparing the digests, the intermediate results in the chain are compared. The attack can be made against schemes which employ some sort of block chaining in their structure. In contrast to birthday attack, a meet-in-the-middle attack enables an

attacker to construct a bogus message with a desired digest. In this attack the message is divided into two parts. The attacker generates r_1 variations on the first part of a bogus message. He starts from the initial value and goes forward to the intermediate stage. He also generates r_2 variations on the second part of the bogus message. He starts from the desired false digest and goes backward to the intermediate stage. The probability of a match in the intermediate stage is the same as the probability of success in the birthday attack.

Correcting-Block Attack

In a correcting block attack, a bogus message is concatenated with a block to produce a corrected digest of the desired value. This attack is often applied to the last block and is called *correcting last block* attack, although it can be applied to other blocks as well. Hash functions based on modular arithmetic are especially sensitive to the correcting last block attack (cf. Preneel [50]). The introduction of redundancy into the message in these schemes makes finding a correcting block with the necessary redundancy difficult. However, it makes the scheme less efficient. The difficulty of finding a correcting block depends on the nature of the redundancy introduced. For example, Coppersmith [20] shows that the redundancy built into the CCITT hashing scheme based on modular squaring results in an insecure scheme.

Biham and Shamir [11] have developed a method for attacking block ciphers, known as *differential cryptanalysis*. This is a general method for attacking cryptographic algorithms, including hashing schemes. For example, Berson [8] has applied differential cryptanalysis to MD5.

40.5 MAC

Message authentication codes provide message integrity and are one of the most important security primitives in current distributed information systems. A *message authentication code* (MAC) is a symmetric key cryptographic primitive that consists of two algorithms. A MAC *generation algorithm*, $G = \{G_k : k = 1, \ldots, N\}$ takes an arbitrary message, s, from a given collection $\mathcal{S}$ of messages and produces a *tag*, $t = G_k(s)$, which is appended to the message to produce an *authentic* message, $m = (s.t)$. A *MAC verification* algorithm, $V = \{V_k(.) : k = 1, \ldots, N\}$, takes authenticated messages of the form $(s.t)$, and produces a true or false value, depending on whether the message is authentic. The security of a MAC depends on the best chance that an active spoofer has to successfully substitute a received message $(s.G_k(s))$ for a fraudulent one, $m' = (s', t)$, so that $V_k(m')$ produces a true result. In MAC systems, the communicants share a secret key, and are therefore not distinguishable cryptographically.

The security of MACs can be studied from the point of view of unconditional or computational security.

Unconditionally secure MACs are equivalent to cartesian authentication codes. However, in MAC systems only multiple communications are of interest. In Section 40.2, A-codes that provide protection for multiple transmissions were discussed. In the next section, we present a construction for a MAC that has been the basis of all the recent MAC constructions and has a number of important properties. It is provably secure; the number of key bits required is asymptotically minimal; and it has a fast implementation.

Computationally secure MACs have arisen from the needs of the banking community, cf. Preneel et al., [52]. They are also studied under other names, such as *keyed hash functions* and *keying hash functions*. In Section "Computational Security," we review the main properties and constructions of such MACs.

Unconditionally Secure MACs

When the enemy has unlimited computational resources, attacks against MAC systems and the analysis of security are similar to that of Cartesian A-codes. The enemy observes n codewords of the form $s_i.t_i$, $i = 1, \ldots, n$, in the channel and attempts to construct a fraudulent codeword $s.t$ which is accepted by the receiver. (This is the same as spoofing of order n in an A-code.) If the communicants want to limit the enemy's chance of success to p after n message transmissions, the number of authentication functions

(number of keys) must be greater than a lower bound which depends on p. If the enemy's chance of success in spoofing of order i, $i = 1, \ldots, n$, is p_i, then at least $1/p_1 p_2 \cdots p_n$ keys are required; see Fak [28], Wegman and Carter [80] for a proof of this. For $p_i = p, i = 1, \ldots, n$, the required number of key bits is $-n \log_2 p$. That is, for every message, $-\log_2 p$ key bits are required. This is the absolute minimum for the required number of key bits.

Perfect protection is obtained when the enemy's best strategy is a random choice of a tag and appending it to the message; this strategy succeeds with probability $p = 2^{-k}$, if the size of the tag is k bits. In this case the number of required key bits for every extra message is k.

Wegman and Carter [80] give a general construction for unconditionally secure MACs that can be used for providing protection for an arbitrary number of messages.

Their construction uses *universal classes of hash functions*. Traditionally, a hash function is used to achieve fast average performance over all inputs in varied applications, such as databases. By using a universal class of hash functions it is possible to achieve provable average performance without restricting the input distribution.

Let $h : A \rightarrow B$ be a hash function mapping the elements of a set A to a set B. A *strongly universal$_n$ class* of hash function is a class of hash functions with the property that for n distinct elements $a_1, \ldots, a_n$ of A and n distinct elements $b_1, \ldots, b_n$ of B, exactly $|H|/(b^n)$ functions map a_i to b_i, for $i = 1, \ldots, n$. Strongly universal$_n$ hash functions give perfect protection for multiple messages as follows. The transmitter and the receiver use a publicly known class of strongly universal$_n$ hash functions, and a shared secret key determines a particular member of the class that they will use for their communication. Stinson [70] shows that a class of strongly universal$_2$ that maps a set of a elements to a set of b elements is equivalent to an orthogonal array $OA_\lambda(2, a, b)$ with $\lambda = |H|/b^2$. Similar results can be proved for strongly universal$_n$ classes of hash functions. Because of this equivalence, universal$_n$ hash functions are not a practically attractive solution. In particular, this proposal is limited by the constraints of constructing orthogonal arrays with arbitrary parameters. For a survey of known results on orthogonal arrays, see Beth, Jungnickel and Lenz [10].

Wegman and Carter Construction

Wegman and Carter show that, instead of strongly universal$_n$ one can always use a strongly universal$_2$ family of hash functions, together with a one time pad of random numbers. The system works as follows. Let B denote the set of tags consisting of the sequences of k bit strings. Let $\mathcal{H}$ denote a strongly universal$_2$ class of hash functions mapping $\mathcal{S}$ to B. Two communicants share a key that specifies a function $h \in \mathcal{H}$ together with a pad containing k-bit random numbers. The tag for the j^{th} message s_j is $h(s_j) \oplus r_j$, where r_j is the j^{th} number on the pad. It can be proved that this system limits the enemy's chance of success to 2^{-k} as long as the pad is random and not used repeatedly. The system requires $nk + K$ bits of key, where K is the number of bits required to specify an element of $\mathcal{H}$, n is the number of messages to be authenticated, and k is the size of the tags.

This construction has a number of remarkable properties. Firstly, for large n the key requirement for the system approaches the theoretical minimum of k bits per message. This is because for large n the number of key bits is effectively determined by nk. Secondly, the construction of MAC with provable security for multiple communications is effectively reduced to the construction of a better studied primitive, that is, strongly universal$_2$ class of hash functions. Finally, by replacing the one-time pad with a pseudorandom sequence generator, unconditional security is replaced by computational security.

Wegman and Carter's important observation is as follows. By not insisting on the minimum value for the probability of success in spoofing of order one, i.e., allowing $p_1 > 1/k$, it is possible to reduce the number of functions, and thus the required number of keys. This observation leads to the notion of almost strongly universal$_2$ class.

An *ϵ-almost universal$_2$* (or ϵ-AU$_2$) class of hash functions has the following property. For any pair $x, y \in A, x \neq y$, the number of hash functions h with $h(x) = h(y)$ is at most equal to ϵ. The *ϵ-almost*

strongly-universal$_2$ (or ϵ-ASU$_2$) hash functions have the added property that for any $x \in A$, $y \in B$ the number of functions with $h(x) = y$ is $|H|/|B|$. Using an ϵ-almost strongly universal$_2$ class of functions in the Wegman and Carter construction results in MAC systems for which the probability of success for an intruder is ϵ. Such MACs are called ϵ*-otp-secure*, see Krawczyk [38].

Stinson [72] gives several methods for combining hash functions of class AU$_2$ and ASU$_2$. The following theorem shows that an ϵ-ASU$_2$ class can be constructed from an ϵ-AU$_2$ class.

THEOREM 40.3 *[72] Suppose H_1 is an ϵ_1-AU$_2$ class of hash functions from A_1 to B_1, and suppose H_2 is an ϵ_2-ASU$_2$ class of hash functions from B_1 to B_2. Then there exists an ϵ-ASU$_2$ class H of hash functions from A_1 to B_2, where $\epsilon = \epsilon_1 + \epsilon_2$ and $|H| = |H_1| \times |H_2|$.*

This theorem further reduces the construction of MACs with provable security to the construction of ϵ-AU$_2$ class of hash functions.

Several constructions for ϵ-ASU$_2$ hash functions are given by Stinson [72]. Johansson et al. [37] establish relationships between ASU$_2$ hash functions and error correcting codes. They use geometric error correcting codes to construct new classes of ϵ-ASU$_2$ hash function of smaller size. This reduces the key size.

Krawczyk [38] shows that in the Wegman–Carter construction, ϵ-ASU$_2$ hash functions can be replaced with a less demanding class of hash functions, called ϵ*-otp-secure*. The definition of this class differs from other classes of hash functions, in that it is directly related to MAC constructions and their security, in particular, to the Wegman–Carter construction.

Let $s \in \mathcal{S}$ denote a message that is to be authenticated by a k bit tag $h(s) \oplus r$, constructed by Wegman and Carter's method. An enemy succeeds in a spoofing attack if he can find $s' \neq s$, $t' = h(s') \oplus r$, assuming that he knows H but does not know h and r. A class H of hash functions is ϵ*-otp-secure* if for any message no adversary succeeds in the above attack scenario with probability greater than ϵ.

THEOREM 40.4 *[38] A necessary and sufficient condition for a family H of hash functions to be ϵ-otp-secure is that*

$$\forall a_1 \neq a_2,\ c,\quad Pr_h\left(h\left(a_1\right) \oplus h\left(a_2\right) = c\right) \leq \epsilon\ .$$

The need for high speed MACs has increased with the progress in high speed data communication. A successful approach to the construction of such MACs uses hash function families in which the message is hashed by multiplying it by a binary matrix. Because hashing is achieved with exclusive-or operations, it can be efficiently implemented in software. An obvious candidate for such a class of hash functions, originally proposed by Wegman and Carter [13, 80], is the set of linear transformations from A to B. It is shown that this forms an ϵ-AU$_2$ class of hash functions. However the size of the key—the number of entries in the matrix—is too large, and too many operations are required for hashing. Later proposals by Krawczyk [38] and by Rogaway [61] are aimed at alleviating these problems, and have a fast software implementation. The former uses Topelitz matrices [38], while the latter uses binary matrices with only three ones per column. In both cases, the resulting family is ϵ-AU$_2$.

The design of a complete MAC usually involves a number of hash functions which are combined by methods, similar to those proposed by Stinson [72]. The role of some of the hash functions is to produce high compression (small b), while others produce the desired spread and uniformity (see Rogaway [61]).

Reducing the key size of the hash function is especially important in practical applications, because the one-time pad is replaced by the output of a pseudorandom generator with a short key (of the order of 128 bits). Hence it is desirable to have the key size of the hash function of similar order.

Computational Security

In the computationally secure approach, protection is achieved because excessive computation is required for a successful forgery. Although a hash value can be used as a checksum to detect random changes in the data, a secret key must be used to provide protection against active tampering. Methods for constructing MACs from hash functions have traditionally followed one of the following approaches: the so-called *hash-then-encrypt* and *keying a hash function.*

Hash-Then-Encrypt To construct a MAC for a message x with this method, the hash value of x is calculated and the result is encrypted using an encryption algorithm. This is similar to signature generation, where a public key algorithm is replaced by a private key encryption function.

There are a number of drawbacks to this method. First, the overall scheme is slow. This is because the two primitives used in the construction, i.e., the cryptographic hash functions and encryption functions, are designed for other purposes and have extra security properties which are not strictly required in the construction. Although this construction can produce a secure MAC, the speed of the MAC is bounded by the speed of its constituent algorithms. For example, cryptographic hash functions are designed to be one-way. It is not clear whether this is a required property in the hash-then-encrypt construction, where the output of the hash function is encrypted and one-wayness is effectively obtained through the difficulty of finding the plaintext from the ciphertext.

A serious shortcoming of this method is that existing export restrictions, which usually apply to encryption functions, are inherited by MACs constructed using this method.

Keying a Hash Function In the second approach a secret key is incorporated into a hashing algorithm. This operation is sometimes called *keying a hash function* (see Bellare, Canetti and Krawczyk [5]). This method is attractive, because of the availability of hashing algorithms and their relative speed in software implementation; these algorithms are not subject to export restrictions.

Although this scheme can be implemented more efficiently in software than the previous scheme, the objection to the superfluous properties of the hash functions remains.

The keying method depends on the structure of the hash function. Tsudik [78] proposes three methods of incorporating the key into the data. In the *secret prefix method*, $G_k(s) = H(k\|s)$, while in the *secret suffix*, we have $G_k(s) = H(s\|k)$. Finally, the *envelope method* combines the previous two methods with $G_k(s) = H(k_1\|s\|k_2)$ and $k = k_1\|k_2$.

Instead of including the key into the data, the key information can be included into the hashing algorithm. In iterative hash functions such as MD5 and SHA, the key can be incorporated into the initial vector, compression function or into the output transformation.

There have also been some attempts at defining and constructing *secure keyed hash functions* as independent primitives, namely by Berson, Gong and Lomas [9] and Bakhtiari, Safavi-Naini and Pieprzyk [1]. The former propose a set of criteria for secure keyed hash functions and give constructions using one-way hash functions. The latter argue that the suggested criteria for security is in most cases excessive; relaxing these allows constructions of more efficient secure keyed hash functions. Bakhtiari et al. also give a design of a keyed hash function from scratch. Their design is based mostly on intuitive principles and lacks a rigorous proof of security. A similar approach is taken in the design of MDx-MAC by Preneel and van Oorschot [53], which is a scheme for constructing a MAC from an MD5-type hash function. It is conjectured that if MDx is a secure hash function, then MDx-MAC is a secure MAC.

Security Analysis of Computationally Secure MACs

The security analysis of computational secure MACs has followed two different approaches. In the first approach, the security assessment is based on an analysis of some possible attacks. In the second approach, a security model is developed and used to examine the proposed MAC.

Security Analysis Through Attacks Consider a MAC algorithm that produces MACs of length m using a k bit key. In general an attack might result in a *successful forgery*, or in the *recovery of the key*. According to the classification given by Preneel and van Oorschot [54], a forgery in a MAC can be

either *existential*—the opponent can construct a valid message and MAC without the knowledge of the key pair—or *selective*—the opponent can determine the MAC for a message of his choice. Protection against the former type of attack imposes more stringent conditions than the latter type of attack. A forgery is *verifiable* if the attacker can determine with a high probability whether the attack is successful. In a *chosen text attack* the attacker is given the MACs for the messages of his own choice. In an *adaptive attack* the attacker chooses text for which he can see the result of his previous request before forming his next request. In a *key recovery* attack the aim of the attacker is to find the key. If the attacker is successful, he can perform selective forgery on any message of his choice and the security of the system is totally compromised.

For an *ideal MAC* any method to find the key is as expensive as an exhaustive search of $O(2^k)$ operations. If $m < k$, the attacker may randomly choose the MAC for a message with the probability of success equal to $1/2^m$. However, in this attack the attacker cannot verify whether his attack has been successful.

The complexity of various attacks is discussed by several authors: Tsudik [78], Bakhtiari et al. [2], Bellare et al. [6]. Preneel and van Oorschot [53, 54] propose constructions resistant to such attacks. Some attacks can be applied to all MACs obtained using a specific construction method while other attacks are limited to particular instances of the method.

Formal Security Analysis

The main attempts at formalizing the security analysis of computationally secure MACs are due to Bellare et al. [5], and Bellare and Rogaway [7]. In both papers, an attack model is firstly carefully defined and the security of a MAC with respect to that model is considered. Bellare et al. [5] use their model to prove the security of a generic construction based on pseudorandom functions, while Bellare and Rogaway [7] use their model to prove the security of a generic construction based on hash functions.

MAC from Pseudorandom Functions The formal definition of security given by Bellare et al. [7] assumes that the enemy can ask the transmitter to construct tags for messages of his choice, and also ask the receiver to verify chosen message and tag pairs. The number of these requests is limited, and a limited time t can be spent on the attack. Security of the MAC is expressed as an upper bound on the enemy's chance of succeeding in its best attack.

The construction proposed by Bellare et al. applies to any pseudorandom function. Their proposal, called XOR-MAC, basically breaks a message into blocks. For each block the output of the pseudorandom function is calculated, and the outputs are finally XORed. Two schemes based on this approach are proposed: the randomized XOR scheme and the counter-based scheme.

The pseudorandom function used in the above construction can be an encryption function, like DES, or a hash function, like MD5. It is proved that the counter based scheme is more secure than the randomized scheme, and if DES is used, both schemes are more secure than CBC MAC. Some of the desirable features of this construction are *parallelizability* and *incrementality*. The former means that message blocks can be fed into the pseudorandom function in parallel. The latter refers to the feature of calculating incrementally the value of the MAC for a message s' which differs from s in only a few blocks.

MAC from Hash Functions The model used by Bellare and Rogaway [7] is similar to the above one. The enemy can obtain information by asking queries; however, in this case queries are only addressed to the transmitter.

A family of functions $\{F_k\}$ is *(ϵ, t, q, L)-secure MAC* [6] if any adversary that is not given the key k, is limited to spend total time t, and sees the values of the function F_k computed on q messages $s_1, s_2, \cdots, s_q$ of its choice, each of length at most L, cannot find a message and tag pair (s, t), $s \neq s_i$, $i = 1, \ldots q$, such that $t = F_k(s)$ with probability better that ϵ.

Two general constructions for MAC from hash functions, the so-called NMAC (the nested construction) and HMAC (the hash-based MAC) are given and their security is formally proved.

THEOREM 40.5 *[5] If the keyed compression function f is a (ϵ_f, t, q, L)-secure MAC and the keyed iterated hash function F is (ϵ_F, t, q, L)-weakly collision-resistant, then the NMAC is ($\epsilon_f + \epsilon_F$, t, q, L)-secure MAC.*

Weak collision-resistance is a much weaker notion than the collision resistance of (unkeyed) hash functions, because the enemy does not know the secret key and finding collision is much more difficult in this case. More precisely, a family of *keyed hash functions* $\{F_k\}$ *is* (ϵ, t, q, L)*-weakly collision-resistant* if any adversary that is not given the key k, is limited to spend total time t, and sees the values of the function F_k computed on q messages $m_1, m_2, \ldots, m_q$ of its choice, each of length at most L, cannot find messages m and m' for which $F_k(m) = F_k(m')$ with probability better that ϵ.

With some extra assumptions similar results are proved for the HMAC construction.

A related construction is the *collisionful keyed hash function* proposed by Gong [33]. In his construction, the collisions are selectable and the resulting function is claimed to provide security against password guessing attacks. Bakhtiari, Safavi-Naini and Pieprzyk [3, 4] explore the security of Gong's function and a key exchange protocol based on collisionful hash functions.

Applications

The main application of a MAC is to provide protection against active spoofing (see Wegman and Carter [13]). This is particularly important in open distributed systems such as the Internet. Other applications include secure password checking and software protection. MACs can be used to construct encryption functions and have been used in authentication protocols in place of encryption functions (cf. Bird et al. [12]). An important advantage of MAC functions is that they are not subject to export restrictions. Other applications of MAC functions are to protect software against viruses (cf. Radai [56]), or to protect computer files against tampering. Integrity checking is an important service in a computer operating system which can be automated with software tools.

40.6 Digital Signatures

Digital signatures are meant to be electronic equivalents of handwritten signatures. They should preserve the main features of handwritten signatures. Obviously, it is desirable that digital signatures be as legally binding as handwritten ones. There are three elements in every signature: the signer, the document, and the time of signing.

In most cases, the document already includes a timestamp. A digital signature must reflect both the content of the document and the identity of the signer. The signer is uniquely identified by its secret key. In particular, we require the signature to be

- Unique—a given signature reflects the document and can be generated by the signer only;
- Unforgeable—it must be computationally intractable for an opponent to forge the signature;
- Easy to generate by the signer and easy to verify by recipients; and
- Impossible to deny by the signer (nonrepudiation).

A digital signature differs from a handwritten signature in that it is not physically attached to the document on a piece of paper. Digital signatures have to be related both to the signer and the document by a cryptographic algorithm. Signatures can be verified by any potential recipient. Therefore, the verification algorithm must be public. Signature verification succeeds only when the signer and document match the signature.

There are two general classes of signature schemes:

- One-time signature schemes, and
- Multiple signature schemes.

One-time signature schemes can be used to sign only one message. To sign a second message, the signature scheme has to be reinitialized; however, any signature can be verified repeatedly. Multiple signature schemes can be used to sign several messages without the necessity to re-initialize the signature scheme.

In practice, a signature scheme is required to provide a relatively short signature for a document of an arbitrary length. We sign the document by generating a signature for its digest. The hashing employed to produce the digest must be secure and collision free.

One-Time Signature Schemes

This class of signature schemes can be implemented using any one-way function. These schemes were first developed using private key cryptosystems. We follow the original notation. An encryption algorithm is used as a one-way function. To set up the signature scheme, the signer chooses a one-way function (encryption algorithm). The signer selects an index k (secret key) randomly and uniformly from the set of keys, K. The index determines an instance of the one-way function, i.e., $E_k : \Sigma^n \rightarrow \Sigma^n$ where $\Sigma = \{0, 1\}$; it is known only by the signer. Note that n has to be large enough to avoid birthday attacks.

Lamport Scheme

Lamport's scheme [40] generates signatures for n-bit messages. To sign a message, the signer first chooses randomly n key pairs:

$$(K_{10}, K_{11}), (K_{20}, K_{21}), \ldots, (K_{n0}, K_{n1}) \ . \tag{40.1}$$

The pairs of keys are kept secret and are known to the signer only. Next, the signer creates two sequences, S and R:

$$\begin{aligned} S &= \{(S_{10}, S_{11}), (S_{20}, S_{21}), \ldots, (S_{n0}, S_{n1})\} , \\ R &= \{(R_{10}, R_{11}), (R_{20}, R_{21}), \ldots, (R_{n0}, R_{n1})\} . \end{aligned} \tag{40.2}$$

The elements of S are selected randomly and the elements of R are cryptograms of S so

$$R_{ij} = E_{K_{ij}}\left(S_{ij}\right) \quad \text{for} \quad i = 1, \ldots, n \quad \text{and} \quad j = 0, 1 , \tag{40.3}$$

where E_K is the encryption function of the selected symmetric cryptosystem. S and R are stored in a read-only public register; they are known by the receivers.

The signature of a n-bit message $M = (m_1, \ldots, m_n)$, $m_i \in \{0, 1\}$ for $i = 1, \ldots, n$, is a sequence of cryptographic keys,

$$S(M) = \{K_{1i_1}, K_{2i_2}, \ldots, K_{ni_n}\} \tag{40.4}$$

where $i_j = 0$ if $m_j = 0$; otherwise $i_j = 1$, $j = 1, \ldots, n$. A receiver validates the signature $S(M)$ by verifying whether suitable pairs of S and R match each other for known keys.

Rabin Scheme

In Rabin's scheme [55], a signer begins the construction of the signature by generating $2r$ keys at random:

$$K_1, K_2, \ldots, K_{2r} \ . \tag{40.5}$$

The parameter r is determined by the security requirements. The K_i are secret and known only to the signer. Next, the signer creates two sequences which are needed by the recipients to verify the signature. The first sequence,

$$S = \{S_1, S_2, \ldots, S_{2r}\}$$

comprises of binary blocks chosen at random by the signer. The second,

$$R = \{R_1, R_2, \ldots, R_{2r}\}$$

is created using the sequence S, $R_i = E_{K_i}(S_i)$ for $i = 1, \ldots, 2r$. S and R are stored in a read-only public register.

The signature is generated using the following steps. The message to be signed M is enciphered under keys $K_1, \ldots, K_{2r}$. The cryptograms

$$E_{K_1}(M), \ldots, E_{K_{2r}}(M) \tag{40.6}$$

form the signature $S(M)$. The pair $(S(M), M)$ is sent to the receivers.

To verify the signature, a receiver selects randomly a $2r$-bit sequence σ of r-ones and r-zeros. A copy of σ is forwarded to the signer. Using σ, the signer forms an r-element subset of the keys with the property that K_i belongs to the subset if and only if the ith element of the $2r$-bit sequence is '1'; $i = 1, \ldots, 2r$. The subset of keys is then communicated to the receiver. To verify the key subset, the receiver generates and compares r suitable cryptograms of S with the originals kept in the public register.

Matyas–Meyer Scheme

Matyas and Meyer [41] propose a signature scheme based on the DES algorithm. However, any one-way function can be used in the scheme.

The signer first selects a random matrix $U = [u_{i,j}]$ $i = 1, \ldots, 30$, $j = 1, \ldots, 31$ and $u_{i,j} \in \Sigma^n$. Using U, a 31×31 matrix $KEY = [k_{i,j}]$ is constructed for $k_{i,j} \in \Sigma^n$. The first row of KEY matrix is chosen at random, the other rows are

$$k_{i+1,j} = E_{k_{i,j}}\left(u_{i,j}\right)$$

for $i = 1, \ldots, 30$ and $j = 1, \ldots, 31$. Finally, the signer installs in a public registry the matrix U and the vector $(k_{31,1}, \ldots, k_{31,31})$ (the last row of KEY).

To sign a message $m \in \Sigma^n$ the cryptograms

$$c_i = E_{k_{31,i}}(m) \text{ for } i = 1, \ldots, 31$$

are computed. The cryptograms are considered as integers and ordered according to their values so $c_{i_1} < c_{i_2} < \cdots < c_{i_{31}}$. The signature of m is the sequence of keys

$$SG_k(m) = \left(k_{i_1,1}, k_{i_2,2}, \ldots, k_{i_{31},31}\right) .$$

The verifier takes the message m, recreates the cryptograms c_i and orders them in increasing order. Next, the signature-keys are put into the "empty" matrix KEY in the entries indicated by the ordered sequence of c_i's. The verifier then repeats the signer's steps and computes all keys below the keys of the signature. The signature is accepted if the last row of KEY is identical to the row stored in the registry.

Signature Schemes Based on Public-Key Cryptosystems

RSA Signature Scheme

First, a signer sets up the RSA system [59] with the modulus $N = p \times q$, where the two primes p and q are fixed. Next a random decryption key $d \in Z_N$ is chosen; the encryption key e is

$$e \times d \equiv 1 \pmod{(p-1, q-1)} .$$

The signer publishes both the modulus N and the decryption key d.

Given a message $M \in Z_N$, the signature generated by the signer is

$$S \equiv M^e \pmod{N} .$$

Since the decryption key is public, anyone can verify whether

$$M \equiv S^d \pmod{N} .$$

The signature is considered to be valid if this congruence is satisfied. RSA signatures are subject to various attacks which exploit the commutativity of exponentiation.

ElGamal Signature Scheme

The signature scheme due to ElGamal [27] is based on the discrete logarithm problem. The signer chooses a finite field $GF(p)$ for a sufficiently large prime p. A primitive element $g \in GF(p)$ and a random integer $r \in GF(p)$ are fixed. Next the signer computes

$$K \equiv g^r (\bmod p)$$

and announces K, g and p. To sign a message $M \in GF(p)$, the signer selects a random integer $R \in GF(p)$ such that gcd $(R, p-1) = 1$ and calculates

$$X \equiv g^R (\bmod p) .$$

Using this data following congruence is solved

$$M \equiv r \times X + R \times Y (\bmod p - 1)$$

for Y using Euclid's algorithm. The signature of M is the triple (M, X, Y). Note that r and R are kept secret by the signer. The recipient of the signed message forms

$$A \equiv K^X X^Y (\bmod p)$$

and accepts the message M as authentic if $A \equiv g^M \pmod p$. It is worth noting that knowledge of the pair (X, Y) does not reveal the message M. As a matter of fact, there are many pairs matching the message—for every pair (r, R) there is a pair (X, Y).

Since discrete exponent systems can be based on any cyclic group, the ElGamal signature scheme can be extended to this setting. A modification of ElGamal's signature was proposed as a Digital Signature Standard (DSS) in 1991 [45].

Special Signatures

Sometimes additional conditions are imposed upon digital signatures. Blind signatures are useful in situations where the message to be signed should not be revealed to the signer. Unlike typical digital signatures, the undeniable versions require the participation of the signer in order to verify the signature. Fail-stop signatures are used whenever there is a need for protection against a very powerful adversary. As these signatures require interactions amongst the parties involved, the signatures are sometimes called *signature protocols.*

Blind Signatures

The concept of blind signatures was introduced by Chaum [18]. They are applicable to situations where the holder of a message M needs to get M signed by a signer (which could be a public registry) without revealing the message. This can be done with the following steps.

- The holder of the message first encrypts it.
- The holder sends a cryptogram of the message to the signer.
- The signer generates the signature for the cryptogram and sends it back to the holder.
- The holder decodes the encryption and obtains the signature of the message.

This scheme works if the encryption and signature operations commute, for example, the RSA scheme can be used to implement blind signatures.

Assume that the signer has set up a RSA signature scheme with modulus N and public decryption key d. The holder of the message M selects at random an integer $k \in Z_N$ and computes the cryptogram

$$C \equiv M \times k^d (\bmod N) .$$

The cryptogram C is now sent to the signer who computes the blind signature

$$S_C \equiv \left(M \times k^d\right)^e \ (\mathrm{mod} N) \ .$$

The blind signature S_C is returned to the holder who computes the signature for M as follows:

$$S_M \equiv S_C \times k^{-1} \equiv M^e (\mathrm{mod}\ N) \ .$$

It is not necessary to have special signature schemes to generate blind signatures. It is enough for the holder of the message to use a secure hash function $h()$. To get a (blind) signature from the signer, the holder first compresses the message M using $h()$. The digest $D = h(M)$ is sent to the signer. After signing the digest, the signature $SG_k(D)$ is communicated to the holder who attaches the message M to the signature $SG_k(D)$. Note that the signer cannot recover the message M from the digest, since $h()$ is a one-way hash function. Also the holder cannot cheat by attaching a "false" message unless collisions for the hash function can be found.

Undeniable Signatures

The concept of undeniable signatures is due to Chaum and van Antwerpen [19]. The characteristic feature of undeniable signatures is that signatures cannot be verified without the cooperation of the signer. Assume we have selected a large prime p and a primitive element $g \in GF(p)$. Both p and g are public. The signer randomly selects its secret $k \in GF(p)$ and announces $g^k \pmod p$. For a message M, the signer creates the signature

$$S \equiv M^k (\mathrm{mod}\ p) \ .$$

Verification needs the cooperation of the verifier and signer, and proceeds as follows.

- The verifier selects two random numbers $a, b \in GF(p)$ and sends $C \equiv S^a (g^k)^b \pmod p$ to the signer.
- The signer computes k^{-1} such that $k \times k^{-1} \equiv 1 \pmod{p-1}$ and returns $d = C^{k^{-1}} \equiv M^a \times g^b \pmod p$ to the verifier.
- The verifier accepts or rejects the signature as genuine depending on whether $d \equiv M^a \times g^b \pmod p$.

There are two possible ways in which a verification can fail. Either the signer has tried to disavow a genuine signature or the signature is indeed false. The first possibility is prevented by incorporating a disavowal protocol. The protocol requires two runs for verification. In the first run, the verifier randomly selects two integers $a_1, b_1 \in GF(p)$ and sends $C_1 \equiv S^{a_1}(g^k)^{b_1} \pmod p$ to the signer. The signer returns $d_1 = C_1^{k^{-1}}$ to the verifier. The verifier checks whether

$$d_1 \neq M^{a_1} \times g^{b_1} (\mathrm{mod}\ p) \ .$$

If the congruence is not satisfied, the verifier repeats the process using a different pair $a_2, b_2 \in GF(p)$. The verifier concludes that S is a forgery if and only if

$$\left(d_1 g^{-b_1}\right)^{a_2} \equiv \left(d_2 g^{-b_2}\right)^{a_1} (\mathrm{mod}\ p) \ ;$$

otherwise, the signer is cheating.

Fail-Stop Signatures

The concept of fail-stop signatures was introduced by Pfitzmann and Waidner [48]. Fail-stop signatures protect signatures against a powerful adversary. As usual the signature is produced by a signer who holds a particular secret key. There are, however, many other keys which can be used to produce the same signature and which thus work with the original public key. There is a high probability that the key chosen by the adversary differs from the key held by the signer. Fail-stop signatures provide signing and verification algorithms as well as an algorithm to detect forgery.

Let k be a secret key known to the signer only and K be the public key. The signature on a message M is denoted as $s = SG_k(M)$. A fail-stop signature must satisfy the following conditions:

- An opponent with unlimited computational power can forge a signature with a negligible probability. More precisely, an opponent who knows the pair $(s = SG_k(M), M)$ and the signer's public key K, can create a collection of all keys $K_{s,M}$ such that $k^* \in K_{s,M}$ if and only if $s = SG_{k^*}(M) = SG_k(M)$. The size of $\mathcal{K}_{s,M}$ has to increase exponentially as a function of the security parameter n. Not knowing the secret k, the opponent can only randomly choose an element from $K_{s,M}$. Let this element be k^*. If the opponent signs another message $M^* \neq M$, it is a requirement that $s^* = SG_{k^*}(M^*) \neq SG_k(M^*)$ with a probability close to one.
- There is a polynomial-time algorithm that produces a proof of forgery as output, when given the following inputs: a secret key k, a public key K, a message M, a valid signature s, and a forged signature s^*.
- A signer with polynomially bounded computing power cannot construct a valid signature that it can later deny by proving it to be a forgery.

Clearly, after the signer has provided a proof of forgery, the scheme is compromised and is no longer used. This is why it is called "fail-stop."

40.7 Research Issues and Summary

In this chapter we discussed authentication, hashing, message authentication codes (MACs), and digital signatures. We have presented the fundamental ideas underlying each topic and indicated the current research developments in these topics. This is reflected in our list of references.

We shall now summarize the topics covered in this chapter.

Authentication deals with the problem of providing assurance to a receiver that a communicated message originates from a particular transmitter, and that the received message has the same content as the transmitted message. A typical and widely used application of authentication occurs in computer networks. Here the problem is to provide a protocol to establish the identity of two parties wishing to communicate or make transactions via the network. Motivated by such applications, the theory of authentication codes has developed into a mature area of research, drawing from several areas of mathematics.

Hashing algorithms provide a relatively short digest of a much longer input. Hashing must satisfy the critical requirement that the digests of two distinct messages are distinct. A widely used type of hashing functions are constructed from block encryption ciphers. They have numerous applications in cryptology. Algebraic methods have also been proposed as a source of good hashing functions. These offer some provable security properties.

Message authentication codes or (MACs) are symmetric key primitives providing message integrity against active spoofing, by appending a cryptographic checksum to a message that is verifiable only by the intended recipient of the message. Message authentication is one of the most important ways of ensuring the integrity of information communicated by electronic means. This is especially relevant in the rapidly developing sphere of electronic commerce.

Digital signatures are the electronic equivalents of handwritten signatures. They are designed so as to preserve the essential features of handwritten signatures. They can be used to sign electronic documents and have potential application in legal contexts.

40.8 Defining Terms

Authentication: One of the main two goals of cryptography (the other is secrecy). An authentication system ensures that messages transmitted over a communication channel are authentic.

Cryptology: The art/science of design and analysis of cryptographic systems.

Digital signatures: An asymmetric cryptographic primitive that is the digital counterpart of a signature and links a document to a unique person.

Encryption algorithm: Transforms an input text by "mixing" it with a randomly chosen bit string—the key—to produce the cipher text. In a symmetric encryption algorithm, the plain text can be recovered by applying the key to the cipher text.

Hashing: Hashing is accomplished by applying a function to an arbitrary length message to create a digest/hash value, which is usually of fixed length.

Key: An input provided by the user of a cryptographic system. This piece of information is kept secret and is the source of security in a cryptographic system. Sometimes a part of key information is made public, in which case the secret part is the source of security.

Message authentication codes: A symmetric cryptographic primitive that is used for providing authenticity.

Plain text, cipher text: The cipher text is the "scrambled" version of an original source—the plain text. It is assumed that the scrambled text, produced by an encryption algorithm, can be inspected by persons not having the key and not reveal the content of the source.

Acknowledgments

We thank Anish Mathuria for all his comments and suggestions, which have greatly helped us improve our exposition.

41.1 Introduction

In this chapter we continue our exposition of the crypto topics that was begun in the previous chapter. This chapter covers secret sharing, threshold cryptography, signature schemes, and finally quantum key distribution and quantum cryptography. As in the previous chapter, we have focused only on the essentials of each topic. We have included in the reference list sufficient items that can be consulted for further details.

First we give a synopsis of the topics that are discussed in this chapter.

Secret sharing is concerned with the problem of how to distribute a secret among a group of participating individuals, or entities, so that only predesignated *collections* of individuals are able to recreate the secret by collectively combining the parts of the secret that were allocated to them. There are numerous applications of secret sharing schemes in practice. One example of secret sharing occurs in banking. For instance, the combination to a vault may be distributed in such a way that only specified collections of employees can open the vault by pooling their portions of the combination. In this way the authority to initiate an action, e.g., the opening of a bank vault, is divided for the purposes of providing security and for added functionality such as auditing if required.

Threshold cryptography is a relatively recently studied area of cryptography. It deals with situations where the authority to initiate or perform cryptographic operations is distributed amongst a group of individuals. Many of the standard operations of single-user cryptography have counterparts in threshold cryptography.

Signature schemes deal with the problem of generating and verifying (electronic) signatures for documents. A subclass of signature schemes is concerned with the shared-generation and shared-verification of signatures, where a collaborating group of individuals is required to perform these actions.

A new paradigm of security has recently been introduced into cryptography with the emergence of the ideas of quantum key distribution and quantum cryptography. While classical cryptography employs various mathematical techniques to restrict eavesdroppers from learning the contents of encrypted messages, in quantum cryptography the information is protected by the laws of physics.

41.2 Secret Sharing

Introduction

Secret sharing is concerned with the problem of distributing a secret among a group of participating individuals, or entities, so that only predesignated collections of individuals are able to recreate the secret by collectively combining their *shares* of the secret.

The earliest and the most widely studied type of secret sharing schemes are called (t, n)-*threshold schemes*. In these schemes the *access structure*—a specification of the participants authorized to recreate the secret—comprises all the possible t-element subsets selected from a n-element set.

The problem of *realizing*, i.e., implementing secret sharing schemes for threshold structures was solved independently by Blakley [12] and Shamir [75] in 1979. Shamir's solution is based on the property of polynomial interpolation in finite fields; Blakley formulated and solved the problem in terms of finite geometries.

In a (t, n)-threshold scheme, each of the n participants holds some *shares* (also called *shadows*) of the secret. The parameter $t \leq n$ is called the *threshold* value. A fundamental property of a (t, n)-threshold scheme is that the secret can only be recreated if at least t shareholders combine their shares, but less than t shareholders cannot recreate the secret. The fact that the key can be recovered from the combined shares of any t-sized subset is a property which makes threshold schemes very useful in key management. Threshold schemes tolerate the invalidation of up to $n - t$ shares—the secret can still be recreated from the remaining intact shares.

Secret sharing schemes are also used to control the authority to perform critical actions. For example, a bank vault can be opened only if say, any two out of three trusted employees of the bank agree to do so by combining their partial knowledge of the vault combination. In this case, even if any one of the three employees is not present at any given time the vault can still be opened, and no single employee has sufficient information about the combination to open the vault.

Secret sharing schemes that do not reveal any information about the shared secret to unauthorized individuals are called *perfect*. This notion will be formally defined in "Models of Secret Sharing." In this survey we discuss both perfect and *nonperfect* schemes, as the latter schemes are proving to be useful in various secret sharing applications.

Besides the (t, n)-threshold structures, more general access structures are encountered in the theory of secret sharing. These will be considered in "General Access Structures." General access structures apply to situations where the trust-status of the participants is not uniform. For example, in the bank scenario described earlier, it might be considered more secure to authorize either the bank manager, or any two out of three senior employees to open the vault.

Since Blakley's and Shamir's papers have appeared, the study of secret sharing has developed into an active area of research in cryptography. The fundamental problem of the theory and practice of secret sharing deals with the issue of how to implement secret sharing schemes for arbitrary access structures.

We shall describe later some of the solutions to this problem. Simmons [79] gives numerous examples of practical situations which require secret sharing schemes. He also gives a detailed account of the geometric approach to secret sharing. Stinson's [84] survey is broader and more condensed.

Simmons [78] discusses secret sharing schemes with extended capabilities. He argues that there are realistic applications in which schemes with extended capabilities are required. We assume there exists a key distribution center (KDC) that is trusted unconditionally.

Models of Secret Sharing

A common model of secret sharing has two phases. In the *initialization phase*, a trusted entity—the *dealer*—distributes shares of a secret to the participants via secure means. In the *reconstruction phase* the authorized participants submit their shares to a *combiner*, who reconstructs the secret on their behalf. It is assumed that the combiner is an algorithm which only performs the task of reconstructing the secret. We denote the sets of all possible secrets and shares by $\mathcal{K}$ and $\mathcal{S}$ respectively; the set of participants in a scheme is denoted by $\mathcal{P}$. Secret sharing schemes can be modeled using the information theory concept of *entropy* (cf. [45]). This approach was initiated by Karnin, Greene and Hellman [54] and developed further by Capocelli et al. [23].

DEFINITION 41.1 A secret sharing scheme is a collection of two algorithms. The first (the dealer) is a probabilistic mapping

$$\mathcal{D} : \mathcal{K} \to \mathcal{S}_1 \times \mathcal{S}_2 \times \ldots \times \mathcal{S}_n$$

where $\mathcal{S}_i \subset \mathcal{S}$ $(i = 1, 2, \ldots, n)$ and $\mathcal{S}_i$ is a subset of shares which is used to generate a share for the participant $P_i \in \mathcal{P}$. The second (the combiner) is a function

$$\mathcal{C} : \mathcal{S}_{i_1} \times \mathcal{S}_{i_2} \times \ldots \times \mathcal{S}_{i_t} \to \mathcal{K}$$

such that if the corresponding subset of participants $\{P_{i_1}, P_{i_2}, \ldots, P_{i_t}\}$ belongs to the access structure Γ, it produces the secret $K \in \mathcal{K}$, i.e.,

$$H\left(K \mid P_{i_1}, P_{i_2}, \ldots, P_{i_t}\right) = 0\,. \tag{41.1}$$

The combiner fails to recompute the secret if the subset of participants does not belong to the access structure Γ, i.e.,

$$H\left(K \mid S_l\right) \geq 0 \tag{41.2}$$

for $S_l = \{s_{i_1}, s_{i_2}, \ldots, s_{i_l}\}$ and $S_l \notin \Gamma$.

In Eq. (41.1), $H(K \mid P_{i_1}, P_{i_2}, \ldots, P_{i_t})$ is calculated with respect to the shares of the participants. A secret sharing scheme is called *perfect* if $H(K \mid S_l) = H(K)$ for any unauthorized subset of participants, i.e., not belonging to an access structure Γ (cf. "General Access Structures").

The following result is proved by Karnin et al. [54].

THEOREM 41.1 *A necessary condition for a perfect threshold scheme is that for each share s_i, the inequality $H(s_i) \geq H(K)$ holds.*

Most of the secret sharing schemes which we discuss satisfy this inequality, but we will also consider in the section on "Nonperfect Schemes" schemes that do not satisfy this inequality; these are called *nonperfect* schemes.

The Matrix Model

A matrix representation of perfect secret sharing schemes was introduced by Brickell and Stinson [21]. The matrix model is often used in theoretical investigations of secret sharing. In this model a perfect secret sharing scheme is formulated as a matrix M that is known by all the participants $\mathcal{P}$ in the scheme. The $|\mathcal{P}| + 1$ columns of M are indexed as follows. The first column corresponds to the dealer $\mathcal{D}$, the remaining columns are indexed by the remaining participants in $\mathcal{P}$. Each row of M contains one of the possible keys K which is to be shared in column $\mathcal{D}$, and the shares of K are located in the remaining columns. When the dealer wants share K, a row r which has K in the $\mathcal{D}$-column is chosen uniformly and randomly. The dealer distributes the shares of K to each participant using the matrix M, i.e., participant P_j receives the entry $M_{r,j}$ as his share.

The general requirements of a perfect secret scheme translate into the following combinatorial conditions in the matrix model, cf. Stinson [84], and Blundo et al. [15]. Suppose that Γ is an access structure.

1. If $\mathcal{B} \in \Gamma$ and $M(r, P) = M(r', P)$ for all $P \in \mathcal{B}$, then $M(r, \mathcal{D}) = M(r', \mathcal{D})$.
2. If $\mathcal{B} \notin \Gamma$, then for every possible assignment f of shares to the participants in $\mathcal{B}$, say $f = (f_P : P \in \mathcal{B})$, a nonnegative integer $\lambda(f, \mathcal{B})$ exists such that

$$|\{r : M(r, P) = f_P \ \forall P \in \mathcal{B},\ M(r, D) = K\}| = \lambda(f, \mathcal{B})$$

is independent of the value of K.

Information Rate

The *information rate* of secret sharing schemes was studied by Brickell and Stinson [21]. It is a measure of the amount of information that the participants need to keep secret in a secret sharing scheme. The *information rate* of a participant P_i in a secret sharing scheme with $|S_i|$ shares is

$$\rho_i = \frac{\log_2 |\mathcal{K}|}{\log_2 |S_i|}.$$

The information rate of the scheme, denoted ρ, is defined to be the minimum of the ρ_i.

A proof of the fact that $\rho \leq 1$ is given by Stinson [84]. This result motivates the definition of *ideal* secret sharing schemes.

DEFINITION 41.2 A perfect secret sharing scheme is called *ideal* if $\rho = 1$; that is, if the size of each participants share, measured in the number of bits, equals the size of the secret.

We now define another measure used to quantify the comparison between secret sharing schemes (cf. "General Access Structures").

DEFINITION 41.3 $\rho^*(\Gamma)$ is the maximum value of ρ for any perfect secret sharing scheme realizing the access structure Γ.

For any access structure it is desirable to implement a secret sharing scheme with information rate close to 1. This minimizes the amount of information that needs to be kept secret by the participants, which means that there is a greater chance of the scheme remaining secure. For example, a (t, n)-threshold scheme implemented as in Shamir's method is ideal, but when the scheme is modified to prevent *cheating* as proposed by Tompa and Woll [87], it is no longer ideal (cf. "The Problem of Cheaters").

Some Known Schemes

We now describe several well-known threshold secret sharing schemes.

Blakley's Scheme

Blakley [12] implements threshold schemes using *projective spaces* over finite fields $GF(q)$. A projective space $PG(t, q)$ is defined from the corresponding $t+1$-dimensional vector space $V(t+1, q)$ by omitting the zero vector of $V(t+1, q)$ and identifying two vectors v and v' satisfying the relation $v = \lambda v'$, where λ is a nonzero element of $GF(q)$. This defines an equivalence relation on $V(t+1, q)$. The set of equivalence classes, i.e., the lines through the origin of $V(t+1, q)$, are the points of $PG(t, q)$; there are $(q^t - 1)/(q - 1)$ such points. Similarly, each k-dimensional subspace of $V(t+1, q)$ corresponds to a $(k-1)$-dimensional subspace of $PG(t, q)$. Every point of $PG(t, q)$ lies on $(q^t - 1)/(q - 1)$ $(t-1)$-dimensional subspaces which are called the *hyperplanes* of $PG(t, q)$.

To realize a (t, n)-threshold scheme, the secret is represented by a point p chosen randomly from $PG(t, q)$; each point p belongs to $(q^t - 1)/(q - 1)$ hyperplanes. The shares of the secret are the n hyperplanes, which are randomly selected and distributed to the participants. If q is sufficiently large and n is not too large, then the probability that any t of the hyperplanes intersect in some point other than p is close to zero; cf. Blakley [12]. Thus generally the secret can be recovered from any t of the n shares. The secret cannot be recovered from the knowledge of less than t hyperplanes, as these will intersect only in some subspace containing p. This scheme is not perfect, since a coalition of unauthorized insider participants has a greater chance of guessing the secret than an unauthorized group of outsider participants.

Blakley's geometric solution to the secret sharing problem has grown into an active area of research. We will cover some of these developments in this survey.

Simmons' Scheme

Simmons formulates secret sharing schemes in terms of *affine spaces* instead of projective spaces. The reasons for using affine spaces instead of projective spaces are explained by Simmons [79]. (There is a correspondence between projective spaces and affine spaces, cf. Beth, Jungnickel and Lenz [9].) Briefly, an affine space $AG(n, q)$ consist of points—the vectors of $V(n, q)$, and a hierarchy of l-dimensional subspaces for $l \leq n$ and their *cosets*. These correspond to the equivalence classes in projective geometry mentioned above, and are called the *flats* of $AG(n, q)$. The equivalence classes of lines, planes, etc., of $AG(t, q)$ are the 1-dimensional, 2-dimensional, etc., flats. A *hyperplane* is a flat of co-dimension one. To realize a (t, n)-threshold scheme in $AG(t, q)$, the secret is represented by a point p chosen randomly from $AG(t, q)$, which lies on a publicly known line V_d (lines have q points). A hyperplane V_i of the *indicator variety* is selected so that V_i intersects V_d in a single point p. The shares of the secret are the subsets of points of V_i. An authorized subset of participants, which spans V_i, enables reconstruction of the secret. If an unauthorized subset of participants attempts to reconstruct the secret, their shares will only span a flat which intersects V_d in the empty set. Thus they gain no information about the secret. The precise amount of information gained by the unauthorized participants about the secret can be expressed in terms of the defining parameters of $AG(n, q)$. These schemes are perfect. Simmons [79] gives a detailed explanation of the implementation of secret sharing schemes using projective and affine spaces.

Shamir's Scheme

Shamir's [75] scheme realizes (t, n)-access structures using on polynomial interpolation over finite fields. In his scheme the secrets $\mathcal{S}$ belong to a prime power finite field $GF(q)$, which satisfies $q \geq n + 1$. In the initialization phase, the dealer $\mathcal{D}$ chooses n distinct nonzero elements $\{x_1, \ldots, x_n\}$ from $GF(q)$ and allocates these to participants $\{P_1, \ldots, P_n\}$. This correspondence is publicly known, and creates undesirable side effects if any of the participants are dishonest; see Section "The Problem of Cheaters." However for now, we will assume that all the participants obey faithfully the protocol for reconstructing the secret.

Fix a random element of $GF(q)$ as the secret K. The shares of K are created using the following protocol.

(a) $\mathcal{D}$ chooses $a_1, a_2, \ldots, a_{t-1}$ from $GF(q)$ randomly, uniformly, and independently.

(b) Let $a(x)$ be a polynomial of degree at most $t-1$, defined as $a(x) = K + a_1 x + a_2 x^2 + \cdots + a_{k-1} x^{k-1}$.

(c) The shares of the secret key are $y_i = a(x_i)$, for $1 \leq i \leq n$.

With the above data, if any t out of the n participants $\{x_{i_1}, \ldots, x_{i_t}\}$ combine their shares $\{y_{i_1}, \ldots, y_{i_t}\}$, then using Lagrangian interpolation, there is a unique polynomial of degree at most $t-1$ passing through the points: $\{(x_{i_1}, y_{i_1}), \ldots, (x_{i_t}, y_{i_t})\}$. So the combined shares of the t participants can be used to recreate the polynomial $a(x)$, and hence the secret, which is $K = a(0)$.

The relation between the secret and the shares is obtained from Lagrange's interpolation formula as

$$K = \sum_{j=1}^{t} y_{i_j} b_j \,, \tag{41.3}$$

where the b_j are defined as

$$b_j = \prod_{\substack{1 \leq k \leq t, \\ k \neq j}} \frac{x_{i_k}}{x_{i_k} - x_{i_j}} \,.$$

Shamir's scheme is computationally efficient in terms of the computational effort required to create the shares and to recover the secret. Also the share size is optimal in an information theoretic sense, cf. Definition 41.2.

The reconstruction phase in Shamir's scheme can also be considered as a system of linear equations, which are defined by the shares K_i. If t shares are submitted to the combiner, the system of linear equations

$$y_{i_j} = K + a_1 x_{i_j} + a_2 x_{i_j}^2 + \cdots + a_{k-1} x_{i_j}^{k-1}, \;\; j = 1, \ldots t$$

can be solved for the unknowns $K, a_1, a_2, \ldots, a_{t-1}$, because the determinant of this system of equations is a nonsingular Vandermonde determinant. (The $\{x_1, \ldots, x_n\}$ are pair-wise distinct.) However, if $t-1$ participants try to reconstruct the secret, they face the problem of solving $t-1$ linear equations in t unknowns. This system of equations has one degree of freedom. Consequently, $t-1$ participants do not obtain any information about the secret, as K was selected uniformly and randomly from $GF(q)$. Shamir's system is perfect.

A (t, t) Threshold Scheme

Karnin et al. [54] describe a secret sharing scheme which realizes (t, t)-access structures. The interest in such schemes is that they can be used as the basis for other cryptographic constructions.

In their scheme, the set of secrets $\mathcal{S}$ is the ring of residue classes Z_m, where m is any integer. (In applications m is large.) The secret K is shared using the following algorithm.

(a) $\mathcal{D}$ secretly chooses randomly, uniformly, and independently $t-1$ elements $y_1, y_2, \ldots, y_{t-1}$ from Z_m; y_t is defined as

$$y_t = K - \sum_{i=1}^{t-1} y_i \bmod m \,.$$

(b) Participant P_i for $1 \leq i \leq t$ receives the share y_i from $\mathcal{D}$.

The above system is perfect, as the following argument shows. The set of shares of $l < t$ participants attempting to reconstruct the secret either contains the share $y_t = K - \sum_{i=1}^{t-1} y_i \bmod m$, or not. In both cases the (unauthorized) participants lack the necessary information to determine K. Shamir's scheme with $t = n$ provides an alternative construction of (t, t)-threshold schemes, using the fields $GF(q)$ instead of Z_m.

Threshold Schemes and Discrete Logarithms

The *discrete logarithm* has been widely employed in the literature to transform threshold schemes into conditionally secure schemes with extra properties. This idea is exploited in the papers by Benaloh [1], Beth [10], Charnes, Pieprzyk and Safavi-Naini [27], Charnes and Pieprzyk [28], Lin and Harn [58], Langford [56], and Hwang and Chang [50].

It is a consequence of the linearity of Eq. (41.3) that Shamir's scheme can be modified to obtain schemes having enhanced properties such as *disenrollment* capability, in which shares from one or more participants can be made incapable of forming an updated secret. (The formal analysis of schemes with this property was given by Blakley et al. [13].) Let $a(x)$ be a polynomial and let $a(i)$ be the shares as in Shamir's scheme. In the modified threshold scheme proposed by Charnes, Pieprzyk and Safavi-Naini [27], $g^{a(0)}$ is the secret and the shares are $s_i = g^{c_i}, c_i = a(i)$. A generator g of the cyclic group of the field $GF(2^n)$ is chosen so that $2^n - 1$ is a Mersenne prime.

The modified (t, n)-threshold schemes are capable of disenrolling participants whose shares have been compromised either through loss or theft, and still maintain the original threshold level. In the event that some of the original shares are compromised, the KDC can issue using a public authenticated channel a new generator g' of the cyclic group of $GF(2^n)$. The shareholders can calculate their new shares $s_i{}'$ from the initial secret data according to

$$s_i{}' = g'^{c_i} .$$

Hwang and Chang [50] used a similar setting to obtain *dynamic* threshold schemes.

Threshold schemes with disenrollment capability, without the assumption of the intractability of the discrete logarithm problem, can be based on *families* of threshold schemes. The properties of these schemes are studied in a paper by Charnes, Pieprzyk and Safavi-Naini [26]; here we provide the basic definition.

DEFINITION 41.4 A threshold scheme family (TSF) is defined by an $(m \times n)$ matrix of shares $[s_{i,j}]$ such that

1. Any row $(s_{i,1}, s_{i,2}, \ldots, s_{i,n})$ represents an instance of $TS_{r_i}(t_i, n)$ where $i = 1, \ldots, m$.
2. Any column $(s_{1,j}, s_{2,j}, \ldots, s_{m,j})$ represents an instance of $TS_{c_j}(t_j, m)$ where $j = 1, \ldots, n$.

A family of threshold schemes in which all rows and all columns are ideal schemes is called an *ideal threshold scheme family*, or ITS family for short. In these schemes it is possible to alter dynamically the threshold values by moving from one level of the matrix to another.

Lin and Harn [58] and Langford [56] use the discrete logarithm to transform Shamir's scheme into a conditionally secure scheme which does not require a trusted KDC. A similar approach is used by Langford [56] to obtain a *threshold signature* scheme. Beth [10] describes a protocol for *verifiable secret sharing* for general access structures based on geometric schemes. The discrete logarithm problem is used to encode the secret and the shares so that they can be publicly announced for verification purposes.

It should be noted that the definition of disenrollment given by Charnes et al. [27] is not the same as that of Blakley et al. [13]. Blakley et al. establish a lower bound on the number of bits required to encode the shares in schemes with disenrollment. Their bound shows that this number grows linearly with the number of disenrollments. They also present two geometric (t, n)-threshold schemes which meet this bound.

It is interesting to note that Benaloh [1] uses the discrete logarithm to transform Shamir's scheme, but for a very different purpose. One of the properties of the discrete logarithm is that the sum of the discrete logarithms of the shares of a secret is equal to the discrete logarithm of the product of the shares of the secret. This property has an application in secret-ballot elections (cf. Benaloh [1]) where, in contrast with schemes mentioned above, the discrete logarithm problem is required to be tractable.

The *homomorphic* property introduced by Benaloh [1] has prompted the question whether similar schemes can be set up in noncommutative groups—other than the additive and multiplicative groups of

finite fields. Frankel and Desmedt [44] prove that perfect homomorphic threshold schemes cannot be set up in non-commutative groups. It is an open problem to find useful applications of homomorphic schemes in abelian groups.

Error Correcting Codes and Secret Sharing

McEliece and Sarwate [61] observe that Shamir's scheme is closely related to Reed–Solomon codes [62]. The advantage of this formulation is that the error correcting capabilities of the Reed–Solomon codes can be translated into desirable secret sharing properties.

Let $(\alpha_0, \alpha_1, \ldots, \alpha_{q-1})$ be a fixed list of the nonzero elements of a finite field $GF(q)$ containing q elements. In a Reed–Solomon code, an information word $\mathbf{a} = (a_0, a_1, \ldots, a_{k-1})$, $a_i \in GF(q)$, is encoded into the codeword $\mathbf{D} = (D_1, D_2, \ldots, D_{r-1})$, where $D_i = \sum_{j=0}^{k-1} a_j \alpha_i{}^j$. In this formulation the secret is $a_0 = -\sum_{i=1}^{r-1} D_i$ and the shares distributed to the participants are the D_i.

In the above formulation of threshold schemes, algorithms such as the errors-and-erasures decoding algorithm can be used to correct t out of s shares where $s - 2t \geq k$ in a (k, n)-threshold scheme, if for some reason these shares were corrupted. The algorithm will also locate which invalid shares D_i were submitted, either as a result of deliberate tampering or as a result of storage degradation.

Karnin et al. [54] realize threshold schemes using linear codes. Massey [59] introduced the concept of *minimal codewords*, and proved that the access structure of a secret sharing scheme based on a $[n, k]$ linear code is determined by the minimal codewords of the *dual* code. To realize a (t, n)-threshold scheme, a linear $[n+1, t; q]$ code $\mathcal{C}$ over $GF(q)$ is selected. If G is the generator matrix of $\mathcal{C}$ and $s \in GF(q)$ is the secret, then the *information vector* $\mathbf{s} = (s_0, s_1, \ldots, s_{t-1})$ is any vector satisfying $s = \mathbf{s} \cdot \mathbf{g}^T$, where $\mathbf{g}^T$ is the first column vector of G. The codeword corresponding to $\mathbf{s}$ is $\mathbf{s}G = (t_0, t_1, \ldots, t_n)$. Each participant in the scheme receives t_i as its share and t_0 is the secret. To recover the secret, first the linear dependency between $\mathbf{g}$ and the other column vectors in the (public) generator matrix G is determined. If $\mathbf{g} = \sum x_j \mathbf{g}_j$ is the linear relation, the secret is given by $\sum x_j t_{i_j}$, where $\{t_{i_1}, t_{i_2}, \ldots, t_{i_t}\}$ is a set of t shares.

Renvall and Ding [69] consider the access structures of secret sharing schemes based on linear codes as used by McEliece and Sarwate and Karnin et al. They determine the access structures that arise from $[n+1, k, n-k+2]$ MDS codes—codes which achieve the *singleton bound* [62]. Bertilsson and Ingemarsson [8] use linear block codes to realize secret sharing schemes for general access structures. Their algorithm takes a description of an access structure by a monotone Boolean formula Γ, and outputs the generator matrix of a linear code which realizes Γ.

Combinatorial Structures and Secret Sharing

There are various connections between combinatorial structures and secret sharing, cf. [9]. Stinson and Vanstone [85], and Schellenberg and Stinson [72] study threshold schemes based on *combinatorial designs*. Stinson [84] uses *balanced incomplete blocks designs* to obtain general bounds on the information rate ρ^* of schemes with access structure based on graphs (cf. "Ideal and Other Schems").

Street [83] surveys *defining* sets for t-designs and *critical sets* for Latin squares, with the view of applying these concepts to multilevel secret sharing schemes, in which a hierarchical structure can be imposed on the shares. To illustrate these methods, we give an example of a (2, 3)-threshold scheme based on a small Latin square, cf. Chaudhry and Seberry [31]. For an example of a scheme with a hierarchical share structure, cf. Street [83].

Let $(i, j; k)$ denote that the value k is in position (i, j) of the Latin square

$$L = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \\ 3 & 1 & 2 \end{pmatrix}.$$

The shares of the secret, which is L, are: $S = \{(2, 1; 1), (3, 2; 1), (1, 3; 3)\}$.

More recently, critical sets in *Room squares* have been used to realize multilevel secret sharing schemes, cf. Chaudhry and Seberry [31]. Some other approaches to multilevel schemes are considered in the papers by Beutelspacher [11] and Cooper et al. [33]. The schemes based on Latin and Room squares are examples of nonperfect schemes which will be discussed in the section on "Nonperfect Schemes."

The Problem of Cheaters

So far we have assumed that the participants in a secret sharing scheme are honest and obey the reconstruction protocol. However, there are conceivable situations where a dishonest clique of participants (assuming an honest KDC) may attempt to defraud the honest participants by altering the shares they were issued.

In the McEliece and Sarwate formulation of Shamir's scheme, invalid shares can be identified. Schemes with this capability are said to have the *cheater identification* property. A weaker capability ascertains that invalid shares were submitted in the reconstruction phase without necessarily locating the source of these shares; this is called *cheater detection*.

Tompa and Woll [87] show that public knowledge of the ordinates in Shamir's scheme allows a clique of dishonest participants to modify their shares resulting in an invalid secret K' being recreated. Suppose that participants $i_1, i_2, \ldots, i_t$ agree to pool their shares in order to recreate the secret. A dishonest participant, say i_1, can determine a polynomial $\Delta(x)$ of degree at most $t-1$ from $\Delta(0) = -1$ and $\Delta(i_2) = \Delta(i_3) = \ldots = \Delta(i_t) = 0$ using Lagrangian interpolation. Instead of the share originally issued by the dealer, the cheater submits the modified share $a(i_1) + \Delta(i_1)$. Lagrangian interpolation of points using the modified share will result in the polynomial $a(x) + \Delta(x)$ being recreated, instead of the intended polynomial $a(x)$. Now the constant term is $a(0) + \Delta(0) = K - 1$, a legal but incorrect secret. The honest participants believe that the secret is $K - 1$, but the cheater privately recovers the correct secret as $K = (K-1) + 1$.

To prevent this type of cheating, Tompa and Woll define the shares in their scheme as (x_1, d_1), $(x_2, d_2), \ldots$ (x_n, d_n). The dealer chooses randomly and uniformly a permutation $(x_1, x_2, \ldots, x_n)$ of n distinct elements from $\{1, 2, \ldots, q-1\}$, and $d_i = a(x_i)$. The modified scheme resists the above attack for up to $t-1$ cheaters. The expected running time of the scheme is polynomial in $k, n, \log s$ and $\log(1/\epsilon)$, where ϵ is a designated security parameter of the scheme and the secret k is chosen from $\{0, 1, \ldots, s-1\}$. But the participants need to keep secure two shares instead of the usual single share.

Brickell and Stinson [20] modified Blakley's geometric (t, n)-scheme and obtained a scheme in which cheaters can be detected and identified. Blakley et al. [13] proved that this scheme is capable of disenrolling participants; cf. "Threshold Schemes and Discrete Logarithms." To set up the scheme, the dealer performs certain computations such as checking that the shadows are in *general position*. It is an open problem whether these computations can be done efficiently as the numbers of participants increase.

The problem of secret sharing without the usual assumptions about the honesty of the participants, or even the KDC has been considered in the literature. For example, in verifiable secret sharing it is not assumed that the dealer is honest. This problem is studied by Chor et al. [32]. The problem is how to convince the participants in a (t, n)-threshold scheme, that every subset of t shares of a share set $\{s_1, s_2, \ldots, s_n\}$ defines the same secret. This is called t-consistency. In Shamir's scheme, t-consistency is equivalent to the condition that interpolation on the points $(1, s_1)$, $(2, s_2), \ldots, (n, s_n)$ yields a polynomial of degree at most $t-1$. As application of homomorphic schemes, Benaloh [1] gives an *interactive proof* that Shamir's scheme is t-consistent.

General Access Structures

A complete discussion of secret sharing requires the notion of a general *access structure*.

Ito, Saito and Nishizeki [52] describe a method to realize secret sharing schemes for general access structures. They observe that for most applications of secret sharing it suffices to consider *monotone* access structures (MAS), defined as follows.

DEFINITION 41.5 Given a set $\mathcal{P}$ of n participants ($|\mathcal{P}| = n$), a monotone access structure on $\mathcal{P}$ is a family of subsets $\mathcal{A} \subseteq 2^{\mathcal{P}}$ such that

$$\mathcal{A} \subseteq \mathcal{A}' \subseteq \mathcal{P} \Rightarrow \mathcal{A}' \in \mathcal{A} \tag{41.4}$$

The intersection $\mathcal{A}_1 \cap \mathcal{A}_2$, and the union $\mathcal{A}_1 \cup \mathcal{A}_2$ of two monotone access structures is a monotone access structure. If $\mathcal{A}$ is a monotone access structure, then $2^{\mathcal{P}} \setminus \mathcal{A} = \bar{\mathcal{A}}$ is not a MAS. Any MAS can be expressed equivalently by a monotone Boolean function. Conversely, any Boolean expression without negations represents a MAS.

In view of the above observations, we consider the *minimal* authorized subsets of an access structure $\mathcal{A}$ on $\mathcal{P}$. A set $B \in \mathcal{A}$ is minimal authorized, if for each proper subset A of B, it is the case that $A \notin \mathcal{A}$. The set of minimal authorized subsets of $\mathcal{A}$ is called the *basis*. An access structure $\mathcal{A}$ is the unique *closure* of the *basis*, i.e., all subsets of $\mathcal{P}$ that are supersets of the basis elements.

Some examples of inequivalent access structures on four participants are given by the following monotone formulae: $\Gamma_1 = P_1P_2P_3 + P_1P_2P_4 + P_1P_3P_4 + P_2P_3P_4$—a $(3, 4)$-threshold scheme; $\Gamma_2 = P_1P_2 + P_3P_4$; $\Gamma_4 = P_1P_2 + P_2P_3 + P_3P_4$. In these formulae, the P_i's represent the participants in the scheme (sometimes the literals A, B, etc., are used). The authorized subsets in the access structure are specified precisely by these formulae. For example, Γ_2 stipulates that either P_1 AND P_2 OR P_3 AND P_4 are the authorized subsets. (It is known that no threshold scheme can realize the access structure defined by Γ_2. For a proof, cf. Benaloh and Leichter [2].)

The inequivalent access structures on three and four participants, and the information rates of secret sharing schemes realizing these structures are given by Simmons, Jackson and Martin [80] and by Stinson [84]. The information rates of all inequivalent access structures on five participants are discussed by Martin and Jackson [60]. It should be remarked that a practical examination of access structures is probably limited to five participants. For more than five participants, the number of equivalence classes of monotone Boolean formulae becomes too great to consider. However, Martin and Jackson [60] provide inductive methods using which the information rates of an access structure Γ is related to the information rates of smaller access structures that are "embedded" in Γ.

Secret sharing schemes for nonmonotone access structures have also been investigated, cf. Simmons [79].

Realizing General Access Structures

Ito et al. [52] were the first to show how to realize secret sharing schemes for general access structures. Benaloh and Leichter [2] simplified the method of Ito et al.

They show that any monotone access structure can be recognized by a *monotone* Boolean circuit. In a monotone circuit, each variable corresponds to an element of $\mathcal{P}$. The circuit outputs a true value only when the set of variables which take a true value corresponds to an authorized subset of $\mathcal{P}$, i.e., belongs to the access structure. Monotone circuits are described by Boolean formulae which involve only AND and OR operators. Using Benaloh and Leichter's method, one can realise any access structure as a composite of subsecrets. The subsecrets are shared across AND gates by (t, t)-threshold schemes for appropriate t, and all the inputs to the OR gates have the same value.

Simmons, Jackson and Martin [80] show how *cumulative arrays*, first studied by Ito et al. [52], can be used to realize geometric secret sharing schemes for general access structures.

DEFINITION 41.6 A cumulative array $C_{\mathcal{A}} = (\mathcal{S}, f)_{\mathcal{A}}$ for the access structure $\mathcal{A}$ is a pair comprising of the share set $\mathcal{S} = \{s_1, s_2, \ldots\}$, and the dealer function $f : \mathcal{P} \to 2^{\mathcal{S}}$ which assigns subset of shares to each participant.

As an example, consider the following access structure:

$$\mathcal{A} = \text{ closure } \{\{P_1, P_2\}, \{P_2, P_3\}, \{P_3, P_4\}, \{P_1, P_4\}\} ,$$

where $\mathcal{P} = \{P_1, P_2, P_3, P_4\}$. Let $\mathcal{S} = \{s_1, s_2\}$. A cumulative array for this access structure is $f(P_1) = s_1$, $f(P_2) = s_2$, $f(P_3) = s_1$, and $f(P_4) = s_2$.

Perfect geometric secret sharing schemes are obtained from cumulative arrays as follows. Choose a projective space $V_i = PG(m-1, q)$, where m is the number of columns in the cumulative array. In V_i, let $\{s_i, \ldots, s_m, K\}$ be $m+1$ points such that no m points lie on a hyperplane of V_i – the points are in general position. A domain variety V_d is chosen so that $V_i \bigcap V_d = \{K\}$. The set of shares in the geometric scheme is $\{s_i, \ldots, s_m\}$ and K is the secret. The shares are distributed using the cumulative array: participant P_i receives share s_j if and only if the (i, j) entry of the array is one. Note that it could be difficult to verify the general position hypothesis for large m, cf. Brickell and Stinson [20]. Jackson and Martin [53] show that any geometric secret sharing scheme realizing an access structure is "contained" in the cumulative array, which realizes the access structure.

For any access structure $\mathcal{A}$ on the set $\mathcal{P}$, there is a unique minimal cumulative array. Thus to implement geometric secret sharing schemes with the minimal number of shares, we need only consider minimal cumulative arrays. It remains only to have a means by which the minimal cumulative array can be calculated given an arbitrary monotone Boolean function Γ. Such a method was first given by Simmons, Jackson and Martin [80]. It relies on minimizing the Boolean expression which results when the AND and OR operators in Γ are exchanged.

An alternative method for calculating minimal cumulative arrays is described by Charnes and Pieprzyk [29]. Their method has the advantage that the complete truth table of Γ is not required for some Γ, thereby avoiding an exponential time computation. For general Boolean expressions, as the number of variables increases the time complexity of the above method and the method given by [80] is the same.

To describe the method of Charnes and Pieprzyk [29], we require the following.

DEFINITION 41.7 [29] The *representative matrix* M_Γ of a monotone Boolean function $\Gamma(P_1, P_2, \ldots, P_n)$, expressed as a disjunctive sum of r products of n variables, is an $n \times r$ matrix with rows indexed by the P_i and columns by the product terms of the P_i. The (i, j)-entry is one if P_i occurs in the jth product, and is zero otherwise.

For example, if $\Gamma = P_1P_2 + P_2P_3 + P_3P_4$, then M_Γ is the following matrix:

	P_1P_2	P_2P_3	P_3P_4
P_1	1	0	0
P_2	1	1	0
P_3	0	1	1
P_4	0	0	1

Suppose that $\Gamma(P_1, P_2, \ldots, P_n)$ is a monotone formula expressed in *minimal disjunctive form*, i.e., a disjunctive sum of products of the P_i and no product term is contained in any other. Let M_Γ be its representative matrix.

DEFINITION 41.8 [29] A subset $\{P_l, P_m, \ldots\}$ of the variables of $\Gamma(P_1, P_2, \ldots, P_n)$ is a *relation set* if $P_lP_m \ldots$ is represented in M_Γ by the all ones vector.

In the representative matrix above, $\{P_1, P_3\}$, $\{P_2, P_3\}$, and $\{P_2, P_4\}$ are the *minimal* representative

sets, i.e., not contained in any other representative set. The Boolean formula derived from these sets is $P_1P_3 + P_2P_3 + P_2P_4$.

THEOREM 41.2 *[29] Let $\Gamma(P_1, P_2, \ldots, P_n)$ be a monotone formula and M_Γ its representative matrix. Let $\mathcal{R}$ be the collection of minimal relation sets of M_Γ. Then the representative matrix whose rows are indexed by the variables P_i and columns by product terms derived from $\mathcal{R}$ is the minimal cumulative array for $\mathcal{A}$.*

Thus, using the above theorem the matrix

	P_1P_3	P_2P_3	P_2P_4
P_1	1	0	0
P_2	0	1	1
P_3	1	1	0
P_4	0	0	1

is the minimal cumulative array for $\Gamma = P_1P_2 + P_2P_3 + P_3P_4$. To realize Γ as a geometric scheme, we require a projective space $V_i = PG(2, q)$. The secret $K \in V_d$, and the shares $\{s_1, s_2, s_3\}$ are points chosen in general position in V_i. The cumulative array specifies the distribution of the shares: P_1 receives share $\{s_1\}$; P_2 receives shares $\{s_2, s_3\}$; P_3 receives shares $\{s_1, s_2\}$; P_4 receives share $\{s_3\}$. It can be easily verified that only the authorized subsets of participants can recreate the secret, e.g., the combined shares of P_1 and P_2 span V_i, hence these participants can recover the secret as $V_i \cap V_d = \{K\}$. But unauthorized participants, e.g., P_1 and P_3, cannot recover the secret.

An algorithm for calculating cumulative arrays, based on Theorem 41.2, is described by Charnes and Pieprzyk [29]. This algorithm is efficient for those Γ which have columns containing many zeros in M_Γ. Thus in the previous example, the combinations $\{P_1, P_2\}$, $\{P_1, P_4\}$ and $\{P_3, P_4\}$ cannot produce relation sets and can be ignored. Further computational economy is obtained if the Boolean formula has a large degree of symmetry.

Ideal and Other Schemes

Brickell [18] gives a vector space construction for realizing ideal secret sharing schemes for certain types of access structures, Γ. Let ϕ be a function

$$\phi : \mathcal{P} \cup \{\mathcal{D}\} \rightarrow GF(q)^d$$

with the property that $\phi(D)$ can be expressed as a linear combination of the vectors in $< \phi(P_i) : P_i \in B >$ if and only if B is an authorized subset, i.e. $B \in \Gamma$. Then, for any such ϕ, the distribution rules (cf. "The Matrix Model") are for any vector $\mathbf{a} = (a_1, \ldots, s_d)$ in $GF(q)^d$, a distribution rule is given by the inner product of $\mathbf{a}$ and $\phi(x)$ for every $x \in \mathcal{P} \cup \{\mathcal{D}\}$. Under the above conditions, the collection of distribution rules is an ideal secret sharing scheme for Γ. A proof of this result can be found in a paper by Stinson [84].

Shamir's (t, n)-threshold scheme is an instance of the vector space construction. Access structures $\Gamma(G)$, whose basis is the edge set of certain undirected graphs, can also be realized as ideal schemes by this construction. In particular the access structure $\Gamma(G)$, where $G = (V, E)$ is a *complete multigraph* can be realized as an ideal scheme. A proof of this is given by Stinson [84].

A relation between ideal secret sharing schemes and *matroids* was established by Brickell and Davenport [19]. The matroid theory counterpart of a minimal linearly dependent set of vectors in a vector space is called a *circuit*. A *coordinatizable* matroid is one that can be mapped into a vector space over a field in a way that preserves linear independence. Brickell and Davenport [19] prove the following theorem about coordinatizable matroids.

THEOREM 41.3 *[19] Suppose the connected matroid $\mathcal{M} = (X, \mathcal{I})$ is coordinatizable over a finite field. Let $x \in X$ and let $\mathcal{P} = X \setminus \{x\}$. Then there exists an ideal scheme for the connected access structure having basis $\Gamma_0 = \{C \setminus \{x\} : x \in C \in \mathcal{C}\}$, where $\mathcal{C}$ denotes the set of circuits of $\mathcal{M}$.*

There are limits to the access structures that can be realized as ideal secret sharing schemes. This was first established by Benaloh and Leichter [2]. They proved that the access structure on four participants specified by the monotone formula $\Gamma = P_1P_2 + P_2P_3 + P_3P_4$ cannot be realized by an ideal scheme. The relation between the size of the shares and the secret for Γ was made precise by Capocelli et al. [23]. They proved the following information theoretic bound.

THEOREM 41.4 *For the access structure $\Gamma = closure\{\{P_1, P_2\}, \{P_2, P_3\}, \{P_3, P_4\}\}$ on four participants $\{P_1, P_2, P_3, P_4\}$, the inequality $H(P_2) + H(P_3) \geq 3H(K)$ holds for any secret sharing scheme realizing Γ.*

From this theorem it follows that the information rate ρ of any secret sharing scheme realizing Γ satisfies the bound $\rho \leq \frac{2}{3}$. Bounds are also derived by Capocelli et al. [23] for the maximum information rate ρ^* of access structures $\Gamma(G)$, where the graph G is a *path* P_n ($n \geq 3$); a *cycle* C_n, $n \geq 6$, for n even and $n \geq 5$, for n odd; or any *tree* T_n.

Realizing Schemes Efficiently

In view of bounds on the information rates of secret sharing schemes, it is natural to ask whether there exist schemes whose information rates equal the known bounds. For example, for $\Gamma = P_1P_2 + P_2P_3 + P_3P_4$ one is interested in realizations of Γ with $\rho = \frac{2}{3}$.

Stinson [84] used a general method, called *decomposition construction*, to build larger schemes starting from smaller ideal schemes. In this method, the basis Γ_0 of an access structure is decomposed into smaller access structures, as $\Gamma_0 = \cup\Gamma_k$, where the Γ_k are the basis of the constituent access structures which can be realized as ideal schemes. From such decompositions of access structures, Stinson [84] derives a lower bound: $\rho^*(\Gamma) \geq \ell/R$, where ℓ and R are two quantities defined in terms of the ideal decomposition of Γ_0. The decomposition construction and its precursor, the graph decomposition construction (cf. Blundo et al. [15]), can be formulated as linear programming problems in order to derive the best possible information rates that are obtainable using these constructions.

Other ways of realizing schemes with optimal or close to optimal information rates are considered by Charnes and Pieprzyk [30]. Their method combines multiple copies of cumulative arrays using the notion of *composite shares*—combinations of the ordinary shares in cumulative arrays. This procedure is stated as an algorithm that outputs a cumulative array with the best information rate. It is not clear how efficient this algorithm is as the numbers of participants increases. However, the optimal information rates for access structures on four participants given by Stinson [84] can be attained by combining cumulative arrays.

Nonperfect Schemes

It is known that in nonperfect schemes the size of the shares is less that the size of the secret, i.e., $H(s_i) < H(K)$. Because of this inequality, a nonperfect scheme can be used to disperse a computer file to n sites, in such a way that the file can be recovered from its images that are held at any t of the sites ($t \leq n$). Moreover, this can be done so that the size of the images is less than the size of the original file, resulting in an obvious saving of disk space. Making backups of computer files using this method provides insurance against the loss or destruction of valuable data. For details, cf. Karnin et al. [54].

A formal analysis of nonperfect secret sharing schemes is given by Ogata, Kurosawa and Tsujii [66]. Their analysis characterizes, using information theory, secret sharing schemes in which the participants *not*

belonging to an access structure do gain some information about the secret. This condition is precluded in perfect secret sharing schemes.

Ogata et al. [66] define a nonperfect scheme in terms of a triple of access sets $(\Gamma_1, \Gamma_2, \Gamma_3)$, which partition the set of all subsets of the participants $\mathcal{P}$. Γ_1 is the family of access subsets, Γ_2 is the family of semi-access subsets and Γ_3 is the family of non-access subsets. The participants belonging to the semi-access subsets are able to obtain some, but not complete information about the secret. The participants which belong to the non-access subsets gain no information about the secret.

The *ramp schemes* of Blakley and Meadows [14] are examples of nonperfect schemes where the access structure consists of semi-access subsets. Another way of viewing ramp schemes is that the collective uncertainty about a secret gradually decreases as more participants join the collective.

Ogata et al. [66] prove a lower bound on the size of the shares in nonperfect schemes. They also characterize nonperfect schemes for which the size of the shares is $|K|/2$.

Ogata and Kurosawa [65] establish a general lower bound for the sizes of shares in nonperfect schemes. They show that there is an access hierarchy for which the size of the shares is strictly larger than this bound. It is in general a difficult problem to realize nonperfect secret sharing schemes with the optimum share size, as in the case of perfect schemes.

41.3 Threshold Cryptography

There are circumstances where an action requires to be executed by a group of people. For example, to transfer money from a bank a manager and clerk need to concur. A bank vault can be opened only if three high ranking bank employees cooperate. A ballistic missile can be launched if two officers authorize the action.

Democratic groups usually exhibit a flat relational structure where every member has equal rights. On the other hand, in hierarchical groups, the privileges of group members depend on their position in the hierarchy. A member on the level $i - 1$ inherits all the privileges from the level i, as well as additional privileges specific to its position.

Unlike single-user cryptography, threshold or society-oriented cryptography allows groups to perform cryptographic operations such as encryption, decryption, signature, etc. A trivial implementation of group-oriented cryptography can be achieved by concatenating secret sharing schemes and a single user cryptosystem. This arrangement is usually unacceptable as the cooperating subgroup must first recover the cryptographic key. Having access to the key can compromise the system, as its use is not confined to the requested operation. Ideally, the cooperating participants should perform their private computations in one go. Their partial results are then sent to a so-called *combiner* who calculates the final result. Note that at no point is the secret key exposed.

A group-oriented cryptosystem is usually set up by a *dealer* who is a trusted authority. The dealer generates all the parameters, distributes elements via secure channels if the elements are secret, or broadcasts the parameters if they need not be protected. After setting up a group cryptosystem, the dealer is no longer required, as all the necessary information has been deposited with the participants of the group cryptosystem.

If some participants want to cooperate to perform a cryptographic operation, they use a combiner to perform the final computations on behalf of the group. The final result is always correct if the participants belong to the access structure and follow the steps of the algorithm. The combiner fails if the participants do not belong to the access structure, or if the participants do not follow the algorithm (that is, they cheat). The combiner need not be trusted; it suffices to assume that it will perform some computations reliably but not necessarily all.

The *access structure* is the collection of all subsets of participants authorized to perform an action. An example is a (t, n)-threshold scheme, where any t out of n participants are authorized subsets ($t \leq n$).

Threshold cryptography provides tools for groups to perform the following tasks:

- Threshold encryption—a group generates a valid cryptogram which can later be decrypted by a single receiver;
- Threshold decryption—a single sender generates a valid cryptogram which can be decrypted by a group;
- Threshold authentication—a group of senders agrees to co-authenticate the message so the receiver can decide whether the message is authentic or not;
- Threshold signature (multisignature)—a group signs a message which is later validated by a single verifier;
- Threshold pseudorandom generation.

Threshold Encryption

Public-key cryptography can be used as a basis for simple group encryption. Assume that a receiver wants to have a communication channel from a group of n participants $\mathcal{P} = \{P_1, \ldots, P_n\}$. Further suppose that the receiver can decrypt a cryptogram only if all participants cooperate, i.e., a (n, n)-threshold encryption system. Group encryption works as follows.

Assume that the group and the receiver agree to use the RSA cryptosystem with the modulus $N = pq$. The receiver first computes a pair of keys: one for encryption e and the other for decryption d, where $e \times d \equiv 1 \bmod (p-1)(q-1)$. Both keys are secret. The factors p and q are known by the receiver only. The encryption key is communicated to the dealer (via a secure channel). The dealer selects $n-1$ shares e_i of the encryption key at random from the interval $[0, e/n]$. The last share is

$$e_n = e - \sum_{i=1}^{n-1} e_i \ .$$

Each share e_i is communicated to participant P_i via a secure channel $(i = 1, \ldots, n)$.

Now if the group wants to send a message m to the receiver, each participant P_i prepares its partial cryptogram $c_i \equiv m^{e_i} \bmod N$ $(i = 1, \ldots, n)$. After collecting n partial cryptograms, the receiver can recover the message $m \equiv (\prod_{i=1}^{n} c_i)^d \bmod N$. Note that the receiver also plays the role of a combiner. Moreover, the participants need not reconstruct the secret encryption key e and at no stage of decryption is the encryption key revealed—this is a characteristic feature of threshold cryptography.

Many existing secret-key algorithms such as the DES [64], LOKI [22], FEAL [76], or the Russian GOST [82], are not homomorphic. These algorithms cannot be used for threshold encryption. The homomorphic property is necessary in order to generate shares of the key so that partial cryptograms can be combined into a cryptogram for the correct message, cf. [1].

Threshold encryption has not received a great deal of attention, perhaps because of its limited practical significance.

Threshold Decryption

Hwang [49] proposes a cryptosystem for group decryption based on the discrete logarithm problem. In his system it is assumed that the sender knows the participants of the group. The sender encrypts the message using a predetermined (either private or public key) cryptosystem with a secret key known to the sender only. The sender then distributes the secret key among the group of intended receivers using Shamir's (t, n)-threshold scheme. Any t cooperating participants can recover the decryption key and decrypt the cryptogram. In Hwang's scheme, key distribution is based on the Diffie–Hellman [39] protocol. Thus the security of his scheme is equivalent to the security of the discrete logarithm problem. However, the main problem with the above solution is that the key can be recovered by a straightforward application of secret sharing. This violates the fundamental requirement that the decryption key must never be revealed to the group (or combiner).

We consider now an implementation of a scheme for (t, n)-threshold decryption. The group decryption used here is based on the ElGamal public-key cryptosystem [41] and is described by Desmedt and Frankel [35].

The system is set up by the dealer $\mathcal{D}$ who first chooses a Galois field $GF(q)$ such that $q-1$ is a Mersenne prime and $q = 2^{\ell}$. Further $\mathcal{D}$ selects a primitive element $g \in GF(q)$ and a nonzero random integer $s \in GF(q)$. The dealer computes $y = g^s \bmod q$ and publishes the triple (g, q, y) as the public parameters of the system. The dealer then uses Shamir's (t, n)-threshold scheme to distribute the secret s among the n shareholders in such a way that for any subset $\mathcal{B}$ of t participants, the secret $s = \sum_{P_i \in \mathcal{B}} s_i \bmod (q-1)$ (all calculations are performed in $GF(q)$).

Suppose that user A wants to send a message $m \in GF(q)$ to the group. A first chooses at random an integer $k \in GF(q)$ and computes the cryptogram $c = (g^k, my^k)$ for the message m.

Assume that $\mathcal{B}$ is an authorized subset, so it contains at least t participants. The first stage of decryption is executed separately by each participant $P_i \in \mathcal{B}$. P_i takes the first part of the cryptogram and computes $(g^k)^{s_i} \bmod q$. The result is sent to the combiner, who computes $y^k = g^{ks} = \prod_{i \in \mathcal{B}} g^{ks_i}$, and decrypts (using the multiplicative inverse y^{-k}) the cryptogram

$$m \equiv my^k \times y^{-k} \bmod p \, .$$

Group decryption can also be based on a combination of the RSA cryptosystem [70] and Shamir's threshold scheme. The scheme described by Desmedt and Frankel [36] works as follows. The dealer D computes the modulus $N = pq$, where p, q are strong primes, that is, $p = 2p' + 1$ and $q = 2q' + 1$ (where p' and q' are large and distinct primes). The dealer selects at random an integer e such that e and $\lambda(N)$ are coprime ($\lambda(N)$ is the least common multiple of two integers $p-1$ and $q-1$, so $\lambda(N) = 2p'q'$). Next D publishes e and N as the public parameters of the system, but keeps p, q, and d secret (d satisfies the congruence $ed = 1 \bmod \lambda(N)$). It is clear that computing d is easy for the dealer who knows $\lambda(N)$, but is difficult—equivalent to the factoring of N—to someone who does not know $\lambda(N)$. The dealer then uses Shamir's scheme to distribute the secret $s = d - 1$ amongst n participants. The shares are denoted s_i and any t co-operating participants (the set $\mathcal{B}$) can retrieve the secret. We have,

$$s = \sum_{i \in \mathcal{B}} s_i \bmod \lambda(N) \, .$$

Group decryption of the cryptogram $c \equiv m^e \bmod N$ starts from individual computations. Each $P_i \in \mathcal{B}$ calculates its partial cryptogram $c^{s_i} \bmod N$. All the partial cryptograms are sent to the combiner who recovers the message

$$m = \prod_{i \in \mathcal{B}} c^{s_i} \times c \equiv c^{\left(\sum_{i \in \mathcal{B}} s_i + 1\right)} \equiv c^d \equiv \left(m^e\right)^d \bmod N \, .$$

Again the secret $s = d - 1$ is never exposed during the decryption.

Ghodosi, Pieprzyk, and Safavi-Naini [46] proposed a solution to the problem of group decryption which does not require a dealer. It uses the RSA cryptosystem and Shamir's threshold scheme. The system works under the assumption that all participants from $\mathcal{P} = \{P_1, \ldots, P_n\}$ have their entries in a public registry (white pages). The registry provides the public parameters of a given participant. A participant P_i has as its RSA entry N_i, e_i in the registry, and this entry cannot be modified by an unauthorized person.

The sender first selects the group $\mathcal{P} = \{P_1, \ldots, P_n\}$. For the message m $(0 < m < \prod_{i=1}^{n} N_i)$, the sender computes

$$m_i \equiv m \bmod N_i$$

for $i = 1, \ldots, n$. Next the sender selects at random a polynomial $f(x)$ of degree at most t over $GF(p)$, where $p < \min_i N_i$. Let

$$f(x) = a_0 + a_1 x + \cdots + a_{t-1} x^{t-1} \, .$$

The sender computes $c_i = f(x_i)$ for public x_i, $k = f(0)$, $c_i^{e_i} \bmod N_i$, and $m_i^k \bmod N_i$ $(i = 1, \ldots, n)$. Finally, the sender merges $c_i^{e_i} \bmod N_i$ into C_1 and $m_i^k \bmod N_i$ into C_2 using the Chinese Remainder Theorem. The sender broadcasts the tuple (N, p, t, C_1, C_2) as the cryptogram.

The participants check whether they are the intended recipients, by finding the gcd (N_i, N) for instance. Note that the sender can give the list of all participants instead of the modulus N. A participant P_i first recovers the pair $(c_i^{e_i} \bmod N_i)$ and $(m_i^k \bmod N_i)$ from C_1 and C_2, respectively. Using its secret key d_i, the participant retrieves c_i. The c_i are now broadcast so that each participant can reconstruct $f(x)$ and find $k = f(0)$. Note that none of the participants can cheat, as it can be readily verified whether c_i' satisfies the congruence

$$c_i'^{e_i} \equiv C_1 \bmod N_i \ .$$

Knowing k, each participant finds the message $m_i \equiv C_2^{k^{-1}} \bmod N_i$. Although k is public, only participant P_i can find $k^{-1} \times k \bmod (p_i - 1)(q_i - 1)$ from his knowledge of the factorization of $N_i = p_i q_i$. Lastly, all the partial messages are communicated to the combiner who recovers the message m by the Chinese Remainder Theorem.

41.4 Signature Schemes

A signature scheme consists of two algorithms: signature generation and signature verification. Each of these algorithms can be collaboratively performed. A shared-generation scheme allows a group of signers to collaboratively sign a document. In a signature scheme with shared verification, the signature verification requires collaboration of a group. We examine the two types of systems and note that the two can be combined if necessary.

Shared Generation Schemes

In these schemes a signer group P of n participants has a public/private key pair. The private part is shared among members of the group such that each member has part of the private key that is not known to anyone else. The signature scheme is usually based on one of the well known signature schemes such as ElGamal, Schnorr, RSA, and Fiat–Shamir.

The group is created with an access structure that determines the authorized groups of signers. A special case of shared-generation schemes are the *multisignature* schemes, in which collaboration of all members in P is necessary. Most systems proposed for shared generation are of the multisignature type, or its generalization, (t, n)*-threshold signature*. In the latter type of signature each subgroup p, $p \subset P$ of size t, can generate the signature.

A shared-generation scheme can be *sequential* or *simultaneous*. In a sequential scheme each member of the group signs the message and forwards it to the next group member. In some schemes, after the first signer the message is not readable and all subsequent signers must blindly sign the message. In a simultaneous scheme, each group member forms a partial signature which is sent to a combiner who forms the final signature.

There are a number of issues that differentiate shared-generation systems.

1. Mutually trusted party: a system may need a mutually trusted party who is usually active during the key generation phase; it chooses the group secret key and generates secrets for all group members. In systems without a trusted party, each signer produces his secret key and participates in a protocol with other signers to generate the group public key.
2. The security of most signatures schemes is based on the intractability of one of the following problems: discrete logarithm or integer factorization. Shared-generation schemes based on ElGamal and Schnorr signature schemes use the former, while those based on RSA and Fiat–Shamir use the later.

3. Using many/few interactions for producing signature. The amount of interaction between the signers and the trusted third party varies in different schemes.

There are properties—some essential and some desirable—that a shared-generation scheme must satisfy. The *essential* properties are as follows:

A1 Signature generation must require collaboration of all members of the authorized group and no signer in the group should be able to deny his signature. Verification must be possible by any outsider.

A2 An unauthorized group should not be able to forge the signature of an authorized group. It should not also be possible for an authorized group to forge the signature of another authorized group.

A3 No secret information should be derivable from the released group and partial signatures.

The *desirable* properties are as follows:

1. Each signer must have the same power and be able to see the message that he is signing.
2. The order of signing in a sequential scheme should not be fixed.
3. The size of the multisignature should be comparable to, preferably the same as, the size of the individual signature.

For a (t, n) threshold signature scheme (A1) and (A2) reduce to

B1 From any t partial signature the group signature should be easily derivable.

B2 Knowledge of $t-1$ or fewer partial signatures should not reduce the chance of forgery of an unauthorized group.

Constructions

The earliest proposals for shared-generation schemes are by Itakura [51] and by Boyd [16]. Boyd's scheme is a (n, n)-threshold group signature based on RSA, in which if $n > 2$, most participants must blindly sign the message.

Threshold RSA Signature

Desmedt and Frankel [36] construct a simultaneous threshold (t, n) RSA signature that requires a trusted third party to generate and distribute the group public key and the secret keys of the signers.

Their scheme works as follows. In the initialization stage, a trusted KDC (dealer) selects at random a polynomial of degree $t-1$: $f(x) = a_0 + a_1 x + a_2 x^2 + \cdots + a_{t-1}x^{t-1}$. The group secret key k is fixed as $a_0 = f(0)$. The dealer gives $y_i = f(x_i)$ to participant P_i, for each i, via a secure channel. The computations are performed in $Z_{\lambda(N)}$, where $\lambda = 2p'q'$ and $p = 2p' + 1$, $q = 2q' + 1$. To sign a message m $(0 \le m < N)$ each participant $P_i \in B$ calculates its partial signature $s_i = m^{k_i} \bmod N$ and transmits the result to the combiner. The combiner computes the signature S of the message m according to the following:

$$S = m \times \prod_{P_i \in B} s_i = m \times \prod_{\substack{P_i \in B \\ i=1}}^{t} m^{k_i} = m \times m^{d-1} = m^d \bmod N .$$

The signature verification is similar to the conventional RSA signature scheme.

Threshold Signature Based on Discrete Logarithm

Ohta and Okamoto [67] propose a sequential multisignature scheme based on the Fiat–Shamir signature scheme. In their scheme, the order of signing is not restricted but the scheme requires a trusted center for key generation.

A variation of group signature is *undeniable group signature*, in which verification requires collaboration of signers. The signature scheme has a "commitment phase" during which t group members work together to sign a message, and a "verification phase" during which all signers work together to prove validity of the signature to an outsider. Harn and Yang [48] propose two (t, n)-threshold schemes, with $t = 1$ and $t = n$. Their schemes do not require a trusted third party and the algorithm is based on the discrete logarithm problem.

Harn [47] proposes three simultaneous multisignature schemes, based on the difficulty of discrete logarithm. Two of these schemes do not require a trusted third party. We briefly review one of the schemes. We use the notation of Harn [47].

Let KDC denote the key distribution center. The KDC selects

1. p, a large prime, in the range $2^{511} \leq p \leq 2^{512}$
2. q, a prime divisor of $p - 1$
3. $\{a_i, i = 0, \ldots, t-1\}$, and $f(x) = a_0 + a_1 x + \cdots + a_{t-1}x^{t-1} \pmod{q}$ where $0 < a_i < q$
4. α, where $\alpha = h^{(p-1)/q} \pmod{p} > 1$. α is a generator with order q in GF(p); p, q and α are made public.

The KDC computes the group public key $y = \alpha^{f(0)} \bmod p$, where $f(0)$ is the group secret key. The KDC also computes public keys for all group members as

$$y_i = \alpha^{f(x_i)} \pmod{p}, \quad \text{for} \quad i = 1, 2, \ldots, n$$

where $f(x_i) \bmod q$ is the share of participant i from the group secret key. (Note that, since α is a generator with order q in $GF(p)$, $\alpha^r \bmod p = \alpha^{r \bmod q}$, for any nonnegative integer r.)

In order to generate the group signature on a message m, each participant of a group B ($|B| \geq t$) randomly selects an integer, $k_i \in [1, q-1]$, and computes a public value, $r_i = \alpha^{k_i} \bmod p$ and broadcasts r_i to all members in B. Knowing all the r_i ($i \in B$), each member of the group B computes

$$r = \prod_{i \in B} r_i \pmod{p}.$$

Participant i computes his partial signature as

$$s_i = m' \times f(x_i) \times \left(\prod_{\substack{i,j \in B \\ i \neq j}} \frac{x_j}{(x_i - x_j)} \right) - k_i \times r \pmod{p}$$

where $H(m) = m'$ (H is a one-way and collision free hash function) and transmits (r_i, s_i) to a designated combiner.

Once the combiner receives the partial signature (r_i, s_i), it is verified using

$$y_i^{(m')^{\left(\prod_{\substack{i,j \in B \\ i \neq j}} \frac{x_j}{(x_i - x_j)}\right)}} = \alpha^{s_i} r_i^r \pmod{p}.$$

If all the partial signatures are verified, then the combiner calculates the group signature (r, s) on message m, where $s = \sum_{i \in B} s_i \pmod{q}$.

An outsider who receives the signature (r, s) on the message m can verify the validity of the signature using the check $y^{m'} = \alpha^s r^r \pmod{p}$. This check works because

$$f(0) = \sum_{i \in B} f(x_i) \prod_{\substack{i,j \in B \\ i \neq j}} \frac{x_j}{(x_i - x_j)} \pmod{q}$$

and thus,

$$\begin{aligned} y^{m'} &= \left(\alpha^{f(0)}\right)^{m'} = (\alpha^{\left(\sum_{i \in B} f(x_i) \prod_{\substack{i,j \in B \\ i \neq j}} \frac{x_j}{(x_i - x_j)}\right)^{m'}} \\ &= \prod_{i \in B} y_i^{(m') (\prod_{\substack{i,j \in B \\ i \neq j}} \frac{x_j}{(x_i - x_j)})} = \prod_{i \in B} \left(r_i^r a_i^s\right) = r^r \alpha^s \ . \end{aligned}$$

An interesting security problem in these schemes, as discussed by Desmedt and Frankel [36] and by Harn [47], is that if more than t signers collaborate they can find the secrets of the system with a high probability, and thus identify the rest of the shareholders. Possible solutions to this problem in the case of discrete logarithm based schemes can be found in a paper by Li, Hwang and Lee [57].

A concept related to threshold signature is t-resilient digital signatures. In these schemes, n members of a group can collaboratively sign a message even if there are t dishonest members. Moreover no subset of t dishonest members can forge a signature.

Desmedt [34] shows that a t-resilient signature scheme with no trusted center can be constructed for any signature scheme using a general multiparty protocol. Cerecedo, Matsumoto and Imai [24] present efficient protocols for the shared generation of signatures based on the discrete logarithm problem, Schnorr's scheme and variants of the ElGamal scheme. Their protocols are based on an efficient multiparty protocol for shared computation of products and they do not need a trusted party. Park and Kurosawa [68] discuss a (t, n)-threshold scheme based on the discrete logarithm, more precisely a version of Digital Signature Standard (DSS), which does not require multiplication and only uses linear combination for combination of shares.

Chang and Liou [25] and Langford [56] propose other signature schemes based on the discrete logarithm problem.

Shared Verification of Signatures

Signature schemes with shared verification are not commonly found in the literature.

De Soete, Quisquater and Vedder [81] propose a system for shared verification of signatures. But their system is not really a signature scheme in the sense that it does not produce a signature for every message. Each user has a secret that enables him to verify himself to others. It requires at least two verifiers for the secret to be verified.

Laih and Yen [55] argue that in some cases it might be necessary to sign a message such that only specified groups of participants can verify the signed message. The main requirements of such schemes are:

1. A can sign any message M for any specified group B.
2. Only the specified group can validate the signature of A. No other group, except B, can validate the signature of A on M.
3. B should not be able to forge A's signature on M for another user C even if B and C conspire.
4. No one should be able to forge A's signature on another message M'.

5. If A disavows his signature, it must be possible for a third party to resolve the dispute between A and B.

The scheme proposed by Laih and Yen [55] is based on Harn's scheme, which is an efficient ElGamal type shared-generation scheme. In the proposed scheme a group of signers can create a digital shared-generation scheme for a specified group, who can collectively check the validity of the signature. The secret key of the users is chosen by the users themselves and each group has a public key for signature generation or verification. Since the private key of the verifiers is not known, dispute settlement by a third party requires an extra protocol between the third party and the verifiers.

41.5 Quantum Key Distribution—Quantum Cryptography

While classical cryptography employs various mathematical techniques to restrict eavesdroppers from learning the contents of encrypted messages, in quantum mechanics the information is protected by the laws of physics. In classical cryptography absolute security of information cannot be guaranteed. However on the quantum level there is a law called the Heisenberg uncertainty principle. This states that even the most refined measurement on a quantum object cannot reveal everything about the object before the measurement was made. This is because the object may be altered by simply taking the measurement. The Heisenberg uncertainty principle and quantum entanglement can be exploited in a system of secure communication, often referred to as "quantum cryptography" [6]. Quantum cryptography provides means for two parties to exchange a enciphering key over a private channel with complete security of communication.

There are at least three main types of quantum cryptosystems for the key distribution:

- *BB protocol*: Cryptosystems with encoding based on two noncommuting observables proposed by Wiesner [89], and by Bennett and Brassard [5].
- *EPR-type*: Cryptosystems with encoding built upon quantum entanglement and the Bell Theorem proposed by Ekert [42].
- *B-type*: Cryptosystems with encoding based on two non-orthogonal state vectors proposed by Bennett [3].

A *BB* quantum cryptosystem can be explained using the following simple example. The system includes a transmitter, Alice, and a receiver, Bob. Alice may use the transmitter to send photons in one of four polarizations: 0, 45, 90, or 135 degrees. Bob at the other end uses the receiver to measure the polarization. According to the laws of quantum mechanics, Bob's receiver can distinguish between rectilinear polarizations (0 and 90), or it can quickly be reconfigured to discriminate between diagonal polarizations (45 and 135); it can never, however, distinguish both types. The key distribution requires several steps. Alice sends photons with one of the four polarizations which are chosen at random. For each incoming photon, Bob chooses at random the type of measurement: either the rectilinear type or the diagonal type. Bob records the results of the measurements but keeps them secret. Subsequently Bob publicly announces the type of measurement (but not the results) and Alice tells the receiver which measurements were of the correct type. Alice and Bob (the sender and the receiver) keep all cases in which Bob's measurements were of the correct type. These cases are then translated into bits (1's and 0's) and thereby become the key. An eavesdropper is bound to introduce errors to this transmission because he/she does not know in advance the type of polarisation of each photon and quantum mechanics does not allow him/her to acquire sharp values of two non-commuting observables (here rectilinear and diagonal polarisations). The two legitimate users of the quantum channel, Alice and Bob, test for eavesdropping by revealing a random subset of the key bits and checking (in public) the error rate. Although they cannot prevent eavesdropping, they will never be fooled by an eavesdropper because any effort to tap the channel, however subtle and sophisticated, will be detected. Whenever they are not happy with the security of the channel they can try to set up the key

distribution again. The mechanism of *privacy amplification* is used to finally distill a secret key between Alice and Bob from these interactions, cf. Bennett, Brassard and Robert [7].

The basic idea of cryptosystems of *EPR*-type is as follows. A sequence of correlated particle pairs is generated, with one member of each pair being detected by Alice and the other by Bob (for example, a pair of so-called Einstein–Podolsky–Rosen photons, whose polarizations are measured by Alice and Bob). An eavesdropper on this communication would have to detect a particle to read the signal, and retransmit it in order for his/her presence to remain unknown. However, the act of detection of one particle of a pair destroys its quantum correlation with the other. Thus Alice and Bob can easily verify whether this has been done, without revealing the results of their own measurements, by communication over an open channel.

In our example we will consider two types of measurement: we consider \ and / to be one type (diagonal) and | and − to be the other (rectilinear).

1. Alice's polarization	|	\	−	|	/	−	−	−	−	\	/
2. Bits Alice sent	0	0	1	0	0	1	1	1	0	1	1
3. Bob's polarization	|	\	|	\	|	|	/	|	−	\	−
4. Bits Bob registered	0	0	1	1	0	1	0	1	0	1	1
5. Alice states publicly whether Bob's polarization was correct or not	Yes	Yes	Yes	No	No	Yes	No	Yes	Yes	Yes	No
6. Alice's remaining bits	0	0	1	*x*	*x*	1	*x*	1	0	1	*x*
7. Bob's remaining bits *x* means discard	0	0	1	*x*	*x*	1	*x*	1	0	1	*x*
8. Alice and Bob	0	0	1	*x*	*x*	1	*x*	1	0	1	*x*
compare bits	0	0	1	*x*	*x*	1	*x*	1	0	1	*x*
chosen at random	OK							OK		OK	
9. Alice's remaining bits	*x*	0	1	*x*	*x*	1	*x*	*x*	0	*x*	*x*
10. Bob's remaining bits	*x*	0	1	*x*	*x*	1	*x*	*x*	0	*x*	*x*
11. The key		0	1			1			0		

Shor's Quantum Factoring Algorithm

Mathematicians have tried hard to solve the key distribution problem, and in the 1970s a clever mathematical discovery called "public key" systems gave an elegant solution. Public-key cryptosystems avoid the key distribution problem, but unfortunately their security depends on unproven mathematical assumptions, such as the difficulty of factoring large integers (RSA, the most popular public key cryptosystem, gets its security from the difficulty of factoring large numbers). An enemy who knows your public key can in principle calculate your private key because the two keys are mathematically related; however, the difficulty of computing the private key from the respective public key is exactly that of factoring big integers.

Difficulty of factoring grows rapidly with the size, i.e., number of digits, of the number we want to factor. To see this, take a number N with ℓ decimal digits ($N \approx 10^{\ell}$) and try to factor it by dividing it by $2,\ 3,\ \ldots, \sqrt{N}$ and checking the remainder. In the worst case approximately $\sqrt{N} \approx 10^{\ell/2}$ divisions may be needed to solve the problem—an exponential increase as a function of ℓ. Now imagine computer capable of performing 10^{10} divisions per second. The computer can then factor any number N, using the trial division method, in about $\sqrt{N}/10^{10}$ seconds. Take a 100-digit number N, so that $N \approx 10^{100}$. The computer will factor this number in about 10^{40} seconds, much longer than 10^{17} seconds—the estimated age of the universe!

It seems that factoring big numbers will remain beyond the capabilities of any realistic computing devices and unless mathematicians or computer scientists come up with an efficient factoring algorithm public-key cryptosystems will remain secure. Or will they? As it turns out we know that this is not the case; the classical, purely mathematical, theory of computation is not complete simply because it does not describe all physically possible computations. In particular it does not describe computations that can be performed by quantum devices. Indeed, recent work in quantum computation shows that a quantum computer can factor much faster than any classical computer.

Quantum computers can compute faster because they can accept as input not just one number, but a coherent superposition of many different numbers, and subsequently perform a computation (a sequence of unitary operations) on all of these numbers simultaneously. This can be viewed as a massive parallel computation, but instead of having many processors working in parallel we have only one quantum processor performing a computation that affects all components of the state vector. To see how it works let us describe Shor's factoring using a quantum computer composed of two quantum registers.

Consider two quantum registers, each register being composed of a certain number of two-state quantum systems which we call "qubits" (quantum bits). We take the first register and place it in a quantum superposition of all the possible integer numbers it can contain. This can be done by starting with all qubits in the 0 states and applying a simple unitary transformation to each qubit which creates a superposition of 0 and 1 states:

$$|0\rangle \longrightarrow \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \,. \tag{41.5}$$

Imagine a two-qubit register, for example. After this procedure the register will be in a superposition of all four numbers it can contain,

$$\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) = \frac{1}{2}(|00\rangle + |01\rangle + |10\rangle + |11\rangle) \tag{41.6}$$

where 00 is binary for 0, 01 binary for 1, 10 binary for 2 and finally 11 which is binary for 3.

Then we perform an arithmetical operation that takes advantage of quantum parallelism by computing the function $F_N(x)$ for each number x in the superposition. The values of $F_N(x)$ are placed in the second register so that after the computation the two registers become entangled:

$$\sum_x |x\rangle|F_N(x)\rangle \tag{41.7}$$

(we have ignored the normalization constant). Now we perform a measurement on the second register. The measurement yields a randomly selected value $F_N(k)$ for some k. The state of the first register immediately after the measurement, due to the periodicity of $F_N(k)$, is a coherent superposition of all states $|x\rangle$ such that $x = k,\ k+r,\ k+2r,\ \ldots$, i.e., all x for which $F_N(x) = F_N(k)$. The value k is randomly selected by the measurement: therefore, the state of the first register is subsequently transformed via a unitary operation which sets any k to 0 (i.e., $|k\rangle$ becomes $|0\rangle$ plus a phase factor) and modifies the period from r to a multiple of $1/r$. This operation is known as the quantum Fourier transform. The first register is then ready for the final measurement and yields an integer which is the best whole approximation of a multiple of $1/r$. From this result r, and subsequently factors of N, can be easily calculated (see below). The execution time of the quantum factoring algorithm can be estimated to grow as a quadratic function of ℓ, and numbers 100 decimal digits long can be factored in a fraction of a second!

When the first quantum factoring devices are built, the security of public-key cryptosystems will vanish. The mathematical solution to the key distribution problem is shattered by the power of quantum computation. Does it leave us without any means to protect our privacy? Fortunately quantum mechanics after destroying classical ciphers comes to rescue our privacy and offers its own solution to the key distribution problem.

The main reference for this brief account of quantum cryptanalysis is the paper by Shor [77]. A comprehensive exposition of Shor's algorithm for factoring on a quantum computer, together with some

relevant background in number theory, computational complexity theory and quantum computation including remarks about possible experimental realizations has been prepared for the Review of Modern Physics by Artur Ekert and Richard Jozsa and can be obtained via electronic (postscript file) or postal service.

Factoring

Quantum factoring of an integer N is based on calculating the period of the function $F_N(x) = a^x \pmod N$. We form the increasing powers of a until they start to repeat with a period we denote r. Once r is known the factors of N can be found using the Euclidean algorithm to find the greatest common divisor of $a^{r/2} \pm 1$ and N.

Suppose we want to factor 91. Let us take a number at random, say 28, and raise it to the powers 2, 3, ... After 12 iterations we find we have the number 28 repeated and so we use $r = 12$. Hence we want to find gcd(91, $28^6 \pm 1$), which we find to be 1 and 13, respectively. From here we can factorize 91. Classically, calculating r is as difficult as trying to factor N and the execution time is exponential in the number of digits in N. Quantum computers can find r in time which grows only as a quadratic function of the number of digits of N.

Practicalities

The idea of a quantum computer is simple, however its realization is not. Quantum computers require a coherent, controlled evolution for a period of time which is necessary to complete the computation. Many view this requirement as an insurmountable experimental problem; however, others believe that technological progress will sooner or later make such devices feasible. In an ordinary, classical computer, all the bits have a definite state at a given instant in time, say 0 1 1 0 0 0 1 0 1 0 .... However, in a quantum computer the state of the bits is described by a wave equation such as

$$\Psi = a|0\,1\,1\,0\,0\,0\,1\,0\,1\ \ldots\rangle + b|1\,1\,1\,0\,0\,0\,0\,0\,1\ \ldots\rangle\,. \tag{41.8}$$

The coefficients a, b, ... are complex numbers and the probability that the computer is in state 0 1 1 0 0 0 1 0 1 ... is $|a|^2$, that it is in the state 1 1 1 0 0 0 0 0 1 ... is $|b|^2$, and so on. However, describing the state of the computer by a wave function does not merely imply the ordinary uncertainties that we describe using probabilities. For instance, the phases of the complex coefficients a, b, ... have genuine significance: they can describe interference between different states of the computer, which is very useful for quantum computation. The quantum wave function declares that the computer exists in all of its states simultaneously so long as that state is not measured; when we do choose to measure it, a particular state will be observed with the prescribed probability.

DiVincenzo [40] shows how to construct the quantum analogue of the one-bit NOT, or inverter gate, with spectroscopic techniques that have been well known in physics for over 50 years. He then shows that the 1956 Feher procedure for polarization transfer in electron-nucleus double resolution has the protocol for making the two-qubit (quantum bit) XOR gate implicit within it. Finally he shows how the three-qubit AND operation can be performed using three XOR gates and four single-qubit rotations.

In practice we do not know how to "wire up" the components of the XOR gates, and so a quantum computer is still just a theoretical possibility. However, if a quantum computer could be built it would be the end of classical cryptography as we know it.

The field of quantum cryptography was pioneered by Stephen Wiesner [89]. Around 1970 at Columbia University in New York he showed how quantum effects could in theory be use to produce "quantum bank notes" that are immune to counterfeiting. The first feasible cryptosystems were designed between 1982 and 1984 by the American physicist Charles H. Bennett of IBM's Thomas J. Watson Research Center in Yorktown Heights in the U.S. and by the Canadian expert in cryptography, Gilles Brassard from the University of Montreal [5]. In 1989 David Deutsch and Artur Ekert [37, 38] at Oxford University developed

the idea along slightly different lines. Their system is based on another aspect of quantum theory called quantum correlation.

In the early 1980s, secure quantum key distribution based on both the Heisenberg uncertainty principle and quantum correlations evolved into a testable system for practical use, though this is by no means easy to set up. The first apparatus, constructed by Bennett, Brassard and colleagues in 1989 [4] at IBM's research center, was capable of transmitting a secret key over a distance of approximately 30 centimeters.

Since then, other researchers have looked at systems based on correlations of another quantum property of light, called phase. Phase is measure of how far a photon has gone in its cycle of vibration. Information about the key is encoded in this property of phase instead of polarization. This has the advantage that with current technology, phase is easier to handle over a long distance. Since 1991 John Rarity and Paul Tapster of Britain's [43, 86, 88] Defense Research Agency in Malvern have been developing a system to increase the transmission distance. They have designed and tested an optical system good enough to transmit photons that stay correlated in phase over several hundred meters. Rarity and Tapster believe the distances could increase to several kilometers, once advances in technology give new optical fibers and semiconductor photo detectors that allow better transmission and detection, and thereby reduce background errors.

In theory, cryptosystems based on quantum correlations should also allow quantum keys to be stored, by storing photons without performing any measurements. At present, however, photons cannot be kept correlated longer than a small fraction of a second, so they are not a good medium for information storage. But a fraction of a second is long enough for a photon to cover a long distance, so photons are suitable for sending information and for key distribution.

41.6 Research Issues and Summary

In this chapter we discussed secret sharing, threshold cryptography, signature schemes, and finally quantum key distribution and quantum cryptography. As in the previous chapter, we have focused only on the essentials. The list of references expands our exposition by listing items that represent the current research activity in these topics. We give a brief summary of our exposition.

The central problem in secret sharing is how to distribute parts of a secret, to a group individuals, in such a way that only the predesignated individuals can recreate the secret. As well as having direct application in key management, secret sharing schemes are also components of other cryptographic constructions.

Threshold cryptography is concerned with situations where the authority to initiate or perform cryptographic operations is distributed amongst a group of individuals. Many standard constructions of single-user cryptography have counterparts in threshold cryptography.

A signature scheme is an algorithm for generating and verifying (electronic) signatures for documents. A subclass of signature schemes deals with the shared-generation and shared-verification of signatures, where a collaborating group of individuals is required to perform these actions.

A new paradigm of security has recently been introduced into cryptography with the emergence of the ideas of quantum key distribution and quantum cryptography. As opposed to classical cryptography, where various mathematical techniques are used to restrict eavesdroppers from learning the contents of encrypted messages, in quantum key distribution the information is protected by the uncertainty principle of quantum mechanics. A non-Turing model of computation can be also be based on the formalism of quantum mechanics. Various computations, notably the factorization of integers into primes, could be done on such machines with unprecedented parallelism.

41.7 Defining Terms

Access structure: A formal specification of the participants in a secret-sharing scheme which are able to recreate a shared key from their portions of the key.

Geometric secret sharing: A realization of a secret-sharing scheme using finite geometry. Usually either affine or projective geometries are used.

Group cryptosystems: A recent development where cryptographic operations are performed by groups instead of individuals.

Perfect secret sharing: In such a scheme it is impossible to deduce any partial information about a shared key from less than the critical number of shares of the key.

Quantum computation: A theoretical model of computer based on the principles of quantum mechanics. It is known that factoring of integers could be done in polynomial time on such a machine.

Quantum cryptosystem: Methods of securely exchanging private keys across an insecure channel in which the principles of quantum mechanics are used.

Secret sharing: Protecting a secret key by distributing it in such a way that only the authorized individuals can recreate the key.

Signature schemes: An algorithm that generates and verifies a cryptographic signature.

Threshold scheme: A secret-sharing scheme with a uniform access structure in which any collection of shareholders greater than a given threshold can recreate the secret.

Acknowledgments

We thank Anish Mathuria and Hossein Ghodosi for all their comments and suggestions, which have greatly helped us improve our exposition.

Cryptanalysis

Samuel S. Wagstaff, Jr.
Purdue University

42.1 Introduction

A *cipher* is a secret way of writing in which plaintext is enciphered into ciphertext under the control of a key. Those who know the key can easily decipher the ciphertext back into the plaintext. *Cryptanalysis* is the study of breaking ciphers, that is, finding the key or converting the ciphertext into the plaintext without knowing the key.

For a given cipher, key and plaintext, let M, C, and K denote the plaintext, the corresponding ciphertext and the key, respectively. If E_K and D_K represent the enciphering and deciphering functions when the key is K, then we may write $C = E_K(M)$ and $M = D_K(C)$. For all M and K we must have $D_K(E_K(M)) = M$.

There are four kinds of cryptanalytic attacks. All four kinds assume that the forms of the enciphering and deciphering functions are known.

1. Ciphertext only: Given C, find K or at least M for which $C = E_K(M)$.
2. Known plaintext: Given M and the corresponding C, find K for which $C = E_K(M)$.
3. Chosen plaintext: The cryptanalyst may choose M. He is told C and must find K for which $C = E_K(M)$.
4. Chosen ciphertext: The cryptanalyst may choose C. He is told M and must find K for which $C = E_K(M)$.

The ciphertext only attack is hardest. To carry it out, one may exploit knowledge of the language of the plaintext, its redundancy, or its common words.

An obvious known plaintext attack is to try all possible keys K and stop when one is found with $C = E_K(M)$. This is feasible only when the number of possible keys is small.

The chosen plaintext and ciphertext attacks may be possible when the enemy can be tricked into enciphering or deciphering some text or after the capture of a cryptographic chip with an embedded key.

The cryptanalyst has *a priori* information about the plaintext. For example, he knows that a string like "the" is more probable than the string "wqx." One goal of cryptanalysis is to modify the *a priori* probability distribution of possible plaintexts to make the correct plaintext more probable than the incorrect ones, although not necessarily certain. Shannon's [20] information theory is used to formalize this process. It estimates, for example, the *unicity distance* of a cipher, which is the shortest length of ciphertext needed to make the correct plaintext more probable than the incorrect ones.

42.2 Types of Ciphers

There is no general method of attack on all ciphers. There are many *ad hoc* methods that work on just one cipher or, at best, one type of cipher. We will list some of the kinds of ciphers and describe what methods one might use to break them. In the later sections we will describe some of the more sophisticated methods of cryptanalysis.

Ciphers may be classified as **transposition ciphers, substitution ciphers** or product ciphers.

Transposition ciphers rearrange the characters of the plaintext to form the ciphertext. For example, enciphering may consist of writing the plaintext into a matrix row-wise and reading out the ciphertext column-wise. More generally, one may split the plaintext into blocks of fixed length L and encipher by applying a given **permutation,** the key, to each block. It is easy to recognize transposition ciphers, because the frequency distribution of ciphertext letters is the same as the usual distribution of letters in the language of the plaintext. One may guess the period length L from the message length and the spacing between repeated strings. Once L is guessed, the permutation may be constructed by trial and error using the frequency distribution of pairs or triples of letters.

In a *simple substitution cipher,* the key is a fixed permutation of the alphabet. The ciphertext is formed from the plaintext by replacing each letter by its image under the permutation. These ciphers are broken by trial and error, comparing the frequency distribution of the ciphertext letters with that of the plaintext letters. For example, "e" is the most common letter in English. Therefore, the most frequent ciphertext letter probably is the image of "e." The frequency distribution of pairs or triples of letters helps, too. The pair "th" is common in English. Hence, a pair of letters with high frequency in the ciphertext might be the image of "th."

A *homophonic substitution cipher* uses a ciphertext alphabet larger than the plaintext alphabet, to confound the frequency analysis just described. The key is an assignment of each plaintext letter to a subset of the ciphertext alphabet, called the **homophones** of the plaintext letter. The homophones of different letters are disjoint sets and the size of the homophone set is often proportional to the frequency of the corresponding letter in ordinary plaintext. Thus "e" would have the largest homophone set. Plaintext is enciphered by replacing each letter by a *random* element of its homophone set. As a result, a frequency analysis of single ciphertext letters will find that they have a uniform distribution, which is useless for cryptanalysis. Homophonic substitution ciphers may be broken by analysis of the frequency distribution of pairs and triples of letters.

Polyalphabetic substitution ciphers use multiple permutations (called *alphabets*) of the plaintext alphabet onto the ciphertext alphabet. The key is a description of these permutations. If the permutations repeat in a certain sequence, as in the Beaufort and Vigenère ciphers, one may break the cipher by first determining the number d of different alphabets and then solving d interleaved simple substitution ciphers. Either the Kasiski method or the Index of Coincidence may be used to find d.

The Kasiski method looks for repeated ciphertext strings in the hope that they may be encipherments of the same plaintext word which occurs each time at the same place in the cycle of alphabets. For example, if the ciphertext "wqx" occurs twice, starting in positions i and j, then probably d divides $j - i$. When several repeated pairs are found, d may be the greatest common divisor of a subset of the differences in their starting points.

The Index of Coincidence (IC) (see Friedman [11]) measures frequency variations of letters to estimate the size of d. Let $\{a_1, \ldots, a_n\}$ be the alphabet (plaintext or ciphertext). For $1 \leq i \leq n$, let F_i be the frequency of occurrence of a_i in a ciphertext of length N. The Index of Coincidence is given by the formula

$$IC = \binom{N}{2}^{-1} \sum_{i=1}^{n} \binom{F_i}{2}.$$

Then IC is the probability that two letters chosen at random in the ciphertext are the same letter. One can estimate IC theoretically in terms of d, N and the usual frequency distribution of letters in plaintext. For English, $n = 26$ and the expected value of IC is

$$\frac{1}{d}\left(\frac{N-d}{N-1}\right)(0.066) + \left(\frac{d-1}{d}\right)\left(\frac{N}{N-1}\right)\frac{1}{26}.$$

One estimates d by comparing IC, computed from the ciphertext, with its expected value for various d.

These two methods of finding d often complement each other in that the Index of Coincidence tells the approximate size of d, while the Kasiski method gives a number that d divides. For example, the Index of Coincidence may suggest that d is 5, 6, or 7 and the Kasiski method may predict that d probably divides 12. In this case $d = 6$.

Rotor machines, like the German Enigma, and Hagelin machines are hardware devices that implement polyalphabetic substitution ciphers with very long periods d. They can be cryptanalyzed using group theory. See Barker [1], Kahn [13] and Konheim [14]. The UNIX `crypt(1)` command uses a similar cipher. See Reeds and Weinberger [19] for its cryptanalysis.

A *one-time pad* is a polyalphabetic substitution cipher whose alphabets do not repeat. They are selected by a random sequence which is the key. The key is as long as the plaintext. If the key sequence is truly random and if it is used only once, then this cipher is unbreakable. However, if the key sequence is itself ordinary text, as in a running-key cipher, the cipher can be broken by frequency analysis, beginning with the assumption that usually in each position both the plaintext letter and key letter are letters which occur with high frequency. Frequency analysis works also when a key is reused to encipher a second message. In this case one assumes that in each position the plaintext letters from both messages are letters which occur with high frequency.

A *polygram substitution cipher* enciphers a block of several letters together to prevent frequency analysis. For example, the Playfair cipher enciphers pairs of plaintext letters into pairs of ciphertext letters. It may be broken by analyzing the frequency of pairs of ciphertext letters. See Hitt [12] for details. The Hill cipher treats a block of plaintext or ciphertext letters as a vector and enciphers by matrix multiplication. If the vector dimension is 2 or 3, then the cipher may be broken by frequency analysis of pairs or triples of letters. A known plaintext attack on a Hill cipher is an easy exercise in linear algebra. (Compare with linear feedback shift registers in the next section.)

The Pohlig–Hellman cipher and most public key ciphers are polygram substitution ciphers with a block size several hundred characters long. The domain and range of the substitution mapping is so large that the key must be a compact description of this function, such as exponentiation modulo a large number. See the sections on knapsacks, RSA, integer factoring, and discrete logarithms below for cryptanalysis of such ciphers.

A *product cipher* is a cipher formed by composing several transposition and substitution ciphers. A classic example is the data encryption standard, which alternates transposition and substitution ciphers in 16 rounds. See Diffie and Hellman [9] for general cryptanalysis of DES. See the section on differential cryptanalysis below for a powerful attack on DES and similar product ciphers.

Ciphers are also classified as block or stream ciphers. All ciphers split long messages into blocks and encipher each block separately. Block sizes range from one bit to thousands of bits per block.

- A *block cipher* enciphers each block with the same key.
- A *stream cipher* has a sequence or stream of keys and enciphers each block with the next key. The **key stream** may be periodic, as in the Vigenère cipher or a linear feedback shift register, or not periodic, as in a one-time pad. Ciphertext is often formed in stream ciphers by exclusive-oring the plaintext with the key.

42.3 Linear Feedback Shift Registers

A linear feedback shift register is a device that generates a key stream for a stream cipher. It consists of an n-bit shift register and an XOR gate. Let the shift register hold the vector $R = (r_0, r_1, \ldots, r_{n-1})$. The inputs to the XOR gate are several bits selected (tapped) from fixed bit positions in the register. Let the 1 bits in the vector $T = (t_0, t_1, \ldots, t_{n-1})$ specify the tapped bit positions. Then the output of the XOR gate is the scalar product $TR = \Sigma_{i=0}^{n-1} t_i r_i \bmod 2$, and this bit is shifted into the shift register. Let $R' = (r'_0, r'_1, \ldots, r'_{n-1})$ be the contents of the register after the shift. Then $r'_i = r_{i-1}$ for $1 \le i < n$ and $r'_0 = TR$. In other words, $R' \equiv HR \bmod 2$, where H is the $n \times n$ matrix with T as its first row, 1s just below the main diagonal and 0s elsewhere.

$$H = \begin{pmatrix} t_0 & t_1 & \ldots & t_{n-2} & t_{n-1} \\ 1 & 0 & \ldots & 0 & 0 \\ 0 & 1 & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & 0 & 0 \\ 0 & 0 & \ldots & 1 & 0 \end{pmatrix}$$

The bit r_{n-1} is shifted out of the register and into the key stream. One can choose T so that the period of the bit stream is $2^n - 1$, which is the maximum possible period. If n is a few thousand, this length may make the cipher appear secure, but the linearity makes it easy to break.

Suppose $2n$ consecutive key bits $k_0, \ldots, k_{2n-1}$ are known. Let X and Y be the $n \times n$ matrices

$$X = \begin{pmatrix} k_{n-1} & k_n & \ldots & k_{2n-2} \\ k_{n-2} & k_{n-1} & \ldots & k_{2n-3} \\ \vdots & \vdots & \ddots & \vdots \\ k_0 & k_1 & \ldots & k_{n-1} \end{pmatrix}$$

$$Y = \begin{pmatrix} k_n & k_{n+1} & \ldots & k_{2n-1} \\ k_{n-1} & k_n & \ldots & k_{2n-2} \\ \vdots & \vdots & \ddots & \vdots \\ k_1 & k_2 & \ldots & k_n \end{pmatrix}$$

From $R' \equiv HR \bmod 2$ it follows that $Y \equiv HX \bmod 2$, so H may be computed from $H \equiv YX^{-1} \bmod 2$. The inverse matrix $X^{-1} \bmod 2$ is easy to compute by Gaussian elimination or by the Berlekamp–Massey algorithm for n up to at least 10^4. The tap vector T is the first row of H and the initial contents R of the shift register are $(k_{n-1}, \ldots, k_0)$.

See Ding, Xiao and Shan [10] for more information about linear feedback shift registers and variations of them.

42.4 Meet in the Middle Attacks

One might think that a way to make block ciphers more secure is to use them twice with different keys. If the key length is n bits, a brute force known plaintext attack on the basic block cipher would take up to 2^n encryptions. It might appear that the double encryption $C = E_{K_2}(E_{K_1}(M))$, where K_1 and K_2 are independent n-bit keys, would take up to 2^{2n} encryptions to find the two keys. The *meet-in-the-middle attack* is a known plaintext attack which trades time for memory and breaks the double cipher using only about 2^{n+1} encryptions, and space to store 2^n blocks and keys. Let M_1 and M_2 be two known plaintexts, and let C_1 and C_2 be the corresponding ciphertexts. (A third pair may be needed.) For each possible key K store the pair $(K, E_K(M_1))$ in a file. Sort the 2^n pairs by second component. For each possible key K compute $D_K(C_1)$ and look for this value as the second component of a pair in the file. If it is found, the current key might be K_2 and the key in the pair found in the file might be K_1. Check whether $C_2 = E_{K_2}(E_{K_1}(M_2))$ to determine whether K_1 and K_2 really are the keys.

In the case of DES, $n = 56$ and the meet-in-the-middle attack requires enough memory to store 2^{56} plaintext-ciphertext pairs, more than is available now. But some day there may be enough memory to make the attack feasible.

42.5 Differential and Linear Cryptanalysis

Differential cryptanalysis is an attack on DES and some related ciphers which is faster than exhaustive search. It requires about 2^{47} steps rather than the 2^{55} steps needed on average to test all keys.

Note: Although there are 2^{56} keys for DES, one can test both a key K and its complement $\overline{K}$ with a single DES encipherment using the equivalence

$$C = \mathrm{DES}_K(M) \iff \overline{C} = \mathrm{DES}_{\overline{K}}(\overline{M}) .$$

The adjective "differential" here refers to a difference modulo 2 or XOR. The basic idea of differential cryptanalysis is to form many input plaintext pairs M, M^* whose XOR $M \oplus M^*$ is constant and study the distribution of the output XORs $\mathrm{DES}_K(M) \oplus \mathrm{DES}_K(M^*)$. The XOR of two inputs to DES, or a part of DES, is called the *input XOR* and the XOR of the outputs is called the *output XOR*.

DES (see Chapter 38) consists of permutations, XORs and F functions. The F functions are built from expansion (48 bits from 32 bits), S-boxes and permutations. It is easy to see that permutations P, expansions E, and XOR's satisfy these equations:

$$\begin{aligned} P(X) \oplus P(X^*) &= P(X \oplus X^*), \\ E(X) \oplus E(X^*) &= E(X \oplus X^*) \end{aligned}$$

and

$$(X \oplus K) \oplus (X^* \oplus K) = X \oplus X^* .$$

These operations are *linear* (as functions on vector spaces over the field with 2 elements). In contrast, S-boxes are *nonlinear*. They do not preserve XORs:

$$S(X) \oplus S(X^*) \neq S(X \oplus X^*) .$$

Indeed, if one tabulates the distribution of the four-bit output XOR of an S-box as a function of the six-bit input XOR, one obtains an irregular table. We show a portion of this table for the S-box S_1 (Table 42.1).

The row and column labels are hexadecimal numbers. All counts are even numbers since a pair (X, X^*) is counted in an entry if and only if (X^*, X) is counted. Note also that if the input XOR is 0, then the output XOR is 0, too. Hence the first row (0H) has the entry 64 in column 0H and 0 counts for the other

TABLE 42.1 XOR Distribution for S-box S_1

Input	Output XOR										
XOR	0H	1H	2H	3H	4H	5H	6H	7H	...	EH	FH
0H	64	0	0	0	0	0	0	0	...	0	0
1H	0	0	0	6	0	2	4	4	...	2	4
2H	0	0	0	8	0	4	4	4	...	4	2
3H	14	4	2	2	10	6	4	2	...	2	0
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
34H	0	8	16	6	2	0	0	12	...	0	6
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
3FH	4	8	4	2	4	0	2	4	...	2	2

15 columns. The other rows have no entry greater than 16 and 20% to 30% 0 counts. The average entry size is $64/16 = 4$. The 64 rows for each S-box are all different.

Here is an overview of the differential cryptanalysis of DES. Encipher many plaintext pairs having a fixed XOR and save the ciphertext pairs. The input to the F function in the last round is $R_{15} = L_{16}$, which can be computed from the ciphertext by undoing the final permutation. Thus we can find the input XOR and output XOR for each S-box in the last round. Consider one S-box. If we knew the output E of expansion and the input X to the S-box, we could compute 6 bits (K) of the key used here by $K = E \oplus X$, since the F function computes $X = E \oplus K$. For each of the 64 possible 6-bit blocks K of the key, count the number of pairs that result with the known output XOR using this key value in the last round. Compare this distribution with the rows of the XOR table for the S box. When enough pairs have been enciphered, the distribution will be similar to a unique row, and this will give six of the 48 key bits used in the last round. After this has been done for all eight S boxes, one knows 48 of the 56 key bits. The remaining 8 bits can be found quickly by trying the 256 possibilities.

The input XORs to the last round may be specified by using as plaintext XORs certain 64-bit patterns which, with a small positive probability, remain invariant under the first 15 rounds. Plaintext pairs which produce the desired input to the last round are called *right pairs.* Other plaintext pairs are called *wrong pairs.* In the statistical analysis, right pairs predict correct key bits while wrong pairs predict random key bits. When enough plaintext pairs have been analyzed, the correct key bits overcome the random bits by becoming the most frequently suggested values.

The description above gives the *chosen* plaintext attack on DES. A *known* plaintext attack may be performed as follows. Suppose we need m plaintext pairs to perform a chosen plaintext attack. Let $2^{32}\sqrt{2m}$ random known plaintexts be given together with their corresponding ciphertexts. Consider all $(2^{32}\sqrt{2m})^2/2 = 2^{64}m$ possible (unordered) pairs of known plaintext. Since the block size is 64 bits, there are only 2^{64} possible plaintext XOR values. Hence there are about $2^{64}m/2^{64} = m$ pairs giving each plaintext XOR value. Therefore, it is likely that there are m pairs with each of the plaintext XOR's needed for a chosen plaintext attack.

Although we have described the attack for ECB mode, it works also for the other modes (CBC, CFB, and OFB) because it is easy to compute the real input and output of DES from the plaintext and ciphertext in these modes.

The linearity of parts of the DES algorithm mentioned earlier is the basis for Matsui's [16] linear cryptanalysis. In this known plaintext attack on DES, one XOR's together certain plaintext and ciphertext bits to form a linear approximation for the XOR of certain bits of the key. This approximation will be correct with some probability p. Irregularity in the definition of the S-boxes allows one to choose bit positions from the plaintext, ciphertext and key for which the XOR approximation is valid with probability $p \neq 1/2$. This bias can be amplified by computing the XOR of the key bits for many different known plaintext-ciphertext pairs. When enough XOR's of key bits have been guessed, one can compute the key

bits by solving a system of linear equations over the field with 2 elements. Linear cryptanalysis of DES requires about 2^{43} known plaintext-ciphertext pairs to determine the 56-bit key.

Differential and linear cryptanalysis apply also to many substitution/ permutation ciphers similar to DES. These include FEAL, LOKI, Lucifer, and REDOC-II. The same methods can break some hash functions like Snefru and N-hash, by producing two messages with the same hash value.

See Biham and Shamir [3] and [4] for more information about differential cryptanalysis. See Matsui [16] for the details of linear cryptanalysis.

42.6 Knapsack Ciphers

We describe a variation of Shamir's attack on the Merkle–Hellman knapsack. A similar attack will work for almost all known knapsacks, including iterated ones. The only public key knapsack not yet broken is that of Chor and Rivest [6].

Let the public knapsack weights be the positive integers a_i for $1 \le i \le n$. An n-bit plaintext block $x_1, \ldots, x_n$ is enciphered as $E = \Sigma_{i=1}^{n} a_i x_i$.

Let the secret superincreasing knapsack weights be s_i for $1 \le i \le n$, where $\Sigma_{i=1}^{j} s_i < s_{j+1}$ for $1 \le j < n$. Let the secret modulus M and multiplier W satisfy $1 < W < M$, $\gcd(W, M) = 1$ and $M > \Sigma_{i=1}^{n} s_i$. Then $a_i \equiv W^{-1} s_i \bmod M$ or $W a_i \equiv s_i \bmod M$ for $1 \le i \le n$.

To attack this cryptosystem, rewrite the last congruence as $W a_i - M k_i = s_i$ for $1 \le i \le n$, where the k_i are unknown nonnegative integers. Divide by $M a_i$ to get

$$\frac{W}{M} - \frac{k_i}{a_i} = \frac{s_i}{M a_i} .$$

This equation shows that, at least for small i, the fraction k_i/a_i is a close approximation to the fraction W/M. The inequalities $\Sigma_{i=1}^{j} s_i < s_{j+1}$ and $\Sigma_{i=1}^{n} s_i < M$ imply $s_i \le 2^{-n+i} M$. For almost all W we have $a_i \ge M/n^2$. Hence,

$$\frac{W}{M} - \frac{k_i}{a_i} = \frac{s_i}{M a_i} \le \frac{2^{-n+i}}{a_i} \le \frac{2^{-n+i} n^2}{M} .$$

We expect that all k_i and all a_i are about the same size as M, so that

$$\frac{k_i}{k_1} - \frac{a_i}{a_1} = \mathrm{O}(2^{-n+i} n^2 / M) .$$

This says that the vector $(a_2/a_1, \ldots, a_n/a_1)$, constructed from the public weights, is a very close approximation to the vector $(k_2/k_1, \ldots, k_n/k_1)$, which involves numbers k_i from which one can compute the secret weights s_i. Given a vector like $(a_2/a_1, \ldots, a_n/a_1)$, one can find close approximations to it, like $(k_2/k_1, \ldots, k_n/k_1)$, by integer programming or the Lenstra–Lenstra–Lovasz Theorem. After k_1 is found, M and W are easily determined from the fact that k_1/a_1 is a close approximation to W/M. Finally, Shamir showed that if W^*/M^* is any reasonably close approximation to W/M, then W^* and M^* can be used to decrypt every ciphertext.

See Brickell and Odlyzko [2] for more information about breaking knapsacks.

42.7 Cryptanalysis of RSA

Suppose an RSA cipher (see Rivest, Shamir and Adleman [18]) is used with public modulus $n = pq$, where $p < q$ are large secret primes, public enciphering exponent e and secret deciphering exponent d.

Most attacks on RSA try to factor n. One could read the message without factoring n if the sender of the enciphered message packed only one letter per plaintext block. Then the number of different ciphertext

blocks would be small (the alphabet size) and the ciphertext could be cryptanalyzed as a simple substitution cipher.

Here are four cases in which $n = pq$ might be easy to factor.

(1) If p and q are too close, that is, if $q - p$ is not much larger than $n^{1/4}$, then n can be factored by Fermat's Difference of Squares method. It finds x and y so that $n = x^2 - y^2 = (x - y)(x + y)$, as follows. Let $m = \lceil \sqrt{n} \rceil$. Write $x = m$. If $z = x^2 - n$ is a square y^2, then $p = x - y$, $q = x + y$ and we are done. Otherwise, add $2m + 1$ to z and add 2 to m. Then test whether $z = (x + 1)^2 - n$ is a square, and so on. Most z can be eliminated quickly because squares must lie in certain congruence classes. For example, squares must be $\equiv 0, 1, 4$, or $9 \bmod 16$, which eliminates three out of four possible values for z. If $p = k\sqrt{n}$, where $0 < k < 1$, then this algorithm tests about $((1 - k)^2/(2k))\sqrt{n}$ z's to discover p. The Difference of Squares method normally is not used at all to factor large integers. Its only modern use is to insure that no one forms an RSA modulus by multiplying two 100-digit primes having the same high order 45 digits, say. Riesel [17] has a nice description of Fermat's Difference of Squares Method.

(2) If either $p - 1$ or $q - 1$ has a small ($< 10^9$, say) largest prime factor, then n can be factored easily by Pollard's $p - 1$ factoring algorithm. The idea of this method is that if $p - 1$ divides Q and p does not divide b, then p divides $b^Q - 1$. This assertion follows from Fermat's little theorem. Typically, Q is the product of all prime powers below some limit. The method is feasible when this limit is as large as 10^9. If $Q = \prod_{i=1}^{k} q_i$, when q_i are prime powers, then one computes

```
x = b
for i = 1 to k
     x = x^q_i mod n
     if g = gcd(x-1, n) > 1, stop with factor g of n
end
```

This method and the following one have analogues in which $p - 1$ and $q - 1$ are replaced by $p + 1$ and $q + 1$. See Riesel [17] for more details of Pollard's $p - 1$ method. See Williams [21] for details of the $p + 1$ method.

(3) The number $g = \gcd(p - 1, q - 1)$ divides $n - 1$ and may be found by factoring $n - 1$, which may be much easier than factoring n. When g is small, as usually happens, it is not useful for finding p or q. But when g is large, it may help to find p or q. In that case, for each large factor $g < \sqrt{n}$ of $n - 1$ one can seek a factorization $n = (ag + 1)(bg + 1)$.

(4) If n is small, $n < 10^{150}$, say, then one can factor n by a general factoring algorithm like those described in the next section.

42.8 Integer Factoring

We outline the quadratic sieve (QS) and the number field sieve (NFS), which are currently the two fastest known integer factoring algorithms that work for any composite number, even an RSA modulus.

Both of these methods factor the odd composite positive integer n by finding integers x, y so that $x^2 \equiv y^2 \bmod n$ but $x \not\equiv \pm y \bmod n$. The first congruence implies that n divides $(x - y)(x + y)$, while the second congruence implies that n does not divide $x - y$ or $x + y$. It follows that at least one prime factor of n divides $x - y$ and at least one prime factor of n does not divide $x - y$. Therefore, $\gcd(n, x - y)$ is a proper factor of n. (This analysis fails if n is a power of a prime, but an RSA modulus would never be a prime power because it would be easy to recognize.)

However, these two factoring methods ignore the condition $x \not\equiv \pm y \bmod n$ and seek many random solutions to $x^2 \equiv y^2 \bmod n$. If n is odd and not a prime power, at least half of all solutions with $y \not\equiv 0 \bmod n$ satisfy $x \not\equiv \pm y \bmod n$ and factor n. Actually, if n has k different prime factors, the probability of successfully factoring n is $1 - 2^{1-k}$, for each random congruence $x^2 \equiv y^2 \bmod n$ with $y \not\equiv 0 \bmod n$.

In QS, many congruences (called relations) of the form $z^2 \equiv q \bmod n$ are produced with q factored completely. One uses linear algebra over the field GF (2) with two elements to pair these primes and find a subset of the relations in which the product of the qs is a square, y^2, say. Let x be the product of the zs in these relations. Then $x^2 \equiv y^2 \bmod n$, as desired.

The linear algebra is done as follows: Let $p_1, \ldots, p_r$ be all of the primes which divide any q. Write the relations as

$$z_i^2 \equiv q_i = \prod_{j=1}^{r} p_j^{e_{ij}} \bmod n, \text{ for } 1 \le i \le s \ ,$$

where $s > r$. Note that $\prod_{j=1}^{r} p_j^{f_j}$ is the square of an integer if and only if every $f_i \equiv 0 \bmod 2$. Suppose $(t_1, \ldots, t_s)$ is not the zero vector in the s-dimensional vector space $GF(2)^s$, but does lie in the null space of the matrix $[e_{ij}]$, that is, $\Sigma_{i=1}^{s} e_{ij} t_i = 0$ in $GF(2)$. Then

$$\prod_{\substack{i=1 \\ t_i=1}}^{s} q_i = \prod_{j=1}^{r} \prod_{\substack{i=1 \\ t_i=1}}^{s} p_j^{e_{ij}} \ .$$

The exponent on p_j in this double product is $\Sigma_{i=1}^{s} e_{ij} t_i$, which is an even integer since the t vector is in the null space of the matrix. Therefore,

$$\prod_{\substack{i=1 \\ t_i=1}}^{s} q_i$$

is a square because every one of its prime factors appears raised to an even power. Call this square y^2 and let

$$x = \prod_{\substack{i=1 \\ t_i=1}}^{s} z_i \ .$$

Then $x^2 \equiv y^2 \bmod n$.

In QS, the relations $z^2 \equiv q \bmod n$ with q factored completely are produced as follows: Small primes $p_1, \ldots, p_r$ for which n is a quadratic residue (square) are chosen as the *factor base.* Choose many pairs a, b of integers with $a = c^2$ for some integer c, $b^2 \equiv n \bmod a$ and $|b| \le a/2$. Then the quadratic polynomial

$$Q(t) = \frac{1}{a}[(at+b)^2 - n] = at^2 + 2bt + \frac{b^2 - n}{a}$$

will take integer values at every integer t. If a value of t is found for which the right-hand side is factored completely, a relation $z^2 \equiv q \bmod n$ is produced, with $z \equiv (at+b)c^{-1} \bmod n$ and $q = Q(t) = \prod_{j=1}^{r} p_j^{f_j}$, as desired. No trial division by the primes in the **factor base** is necessary. A **sieve** factors millions of $Q(t)$'s at once. Let t_1 and t_2 be the two solutions of

$$(at+b)^2 \equiv n \bmod p_i \text{ in } 0 \le t_1, t_2 < p_i \ .$$

(A prime p is put in the factor base for QS only if this congruence has solutions, that is, only if n is a quadratic residue modulo p.) Then all solutions of $Q(t) \equiv 0 \bmod p_i$ are $t_1 + kp_i$ and $t_2 + kp_i$ for $k \in \mathbf{Z}$. In most implementations, $Q(t)$ is represented by one byte `Q[t]` and $\log p_i$ is added to this byte to avoid division of $Q(t)$ by p_i, a slow operation. The two inner loops are

```
t = t_1
while t < upper_limit
     Q[t] = Q[t] + log p_i
     t = t + p
end
```

and a similar loop for the other root of the quadratic congruence. After the sieve completes, one harvests the relations $z^2 \equiv q \bmod n$ from those t for which `Q[t]` exceeds a threshold. Only at this point is $Q(t)$ formed and factored, the latter operation being done by trial division with the primes in the factor base.

The time QS takes to factor n is about

$$\exp((1+\epsilon(n))(\log n)^{1/2}(\log\log n)^{1/2}) ,$$

where $\epsilon(n) \to 0$ as $n \to \infty$.

We begin our outline of the NFS by describing the special number field sieve (SNFS), which factors numbers of the form $n = r^e - s$, where r and $|s|$ are small positive integers. It uses some algebraic number theory. Choose a small positive integer d, the degree of an extension field. Let k be the least positive integer for which $kd \geq e$. Let $t = sr^{kd-e}$. Let f be the polynomial $X^d - t$. Let $m = r^k$. Then $f(m) = r^{kd} - sr^{kd-e} = r^{kd-e}n$ is a multiple of n. The optimal degree for f is $((3+\epsilon(e))\log n/(2\log\log n))^{1/3}$ as $e \to \infty$ uniformly for r, s in a finite set, where $\epsilon(e) \to 0$ as $e \to \infty$.

Let α be a zero of f. Let $K = \mathbf{Q}(\alpha)$. Assume f is irreducible. The degree of K over $\mathbf{Q}$ is d. Let Q_n denote the ring of rational numbers with denominator **coprime** to n. The subring $Q_n[\alpha]$ of K consists of expressions $\Sigma_{i=0}^{d-1}(s_i/t_i)\alpha^i$ with $s_i, t_i \in \mathbf{Z}$ and $\gcd(n, t_i) = 1$. Define a ring homomorphism $\phi : Q_n[\alpha] \to \mathbf{Z}/n\mathbf{Z}$ by the formula $\phi(\alpha) = (m \bmod n)$. Thus $\phi(a + b\alpha) \equiv a + bm \bmod n$.

For $0 < a \leq A$ and $-B \leq b \leq B$, SNFS uses a sieve (as in QS) to factor $a + bm$ and the norm of $a + b\alpha$ in $\mathbf{Z}$. The norm of $a + b\alpha$ is $(-b)^d f(-a/b)$. This polynomial of degree d has d roots modulo p which must be sieved, just like the two roots of $Q(t)$ in QS. A pair (a, b) is saved in a file if $\gcd(a, b) = 1$, and $a + bm$ and the norm of $a + b\alpha$ both have only small prime factors (ones in the factor base, say).

We use linear algebra to pair the prime factors just as in QS, except that now we must form squares on *both* sides of the congruences. The result is a non-empty set S of pairs (a, b) of coprime integers such that

$$\prod_{(a,b)\in S} (a + bm) \text{ is a square in } \mathbf{Z} ,$$

and

$$\prod_{(a,b)\in S} (a + b\alpha) \text{ is a square in } Q_n[\alpha] .$$

Let the integer x be a square root of the first product. Let $\beta \in Q_n[\alpha]$ be a square root of the second product. We have $\phi(\beta^2) \equiv x^2 \bmod n$, since $\phi(a + b\alpha) \equiv a + bm \bmod n$. Let y be the integer for which $\phi(\beta) \equiv y \bmod n$. Then $x^2 \equiv y^2 \bmod n$, which will factor n with probability at least $1/2$.

In the general NFS, we must factor an arbitrary n for which no obvious polynomial is given. The key properties required of the polynomial are that it is irreducible, that it has moderately small coefficients so that the norm of α is small, and that we know a non-trivial root m modulo n of it. Research in good polynomial selection is still in progress. One simple choice is to let m be some integer near $n^{1/d}$ and write n in radix m as $n = c_d m^d + \cdots + c_0$, where $0 \leq c_i < m$. Then use the polynomial $f(X) = c_d X^d + \cdots + c_0$. With this choice, the time needed by NFS to factor n is

$$\exp(((64/9)^{1/3} + \epsilon(n))(\log n)^{1/3}(\log\log n)^{2/3}) ,$$

where $\epsilon(n) \to 0$ as $n \to \infty$. QS is faster than NFS for factoring numbers up to a certain size, and NFS is faster for larger numbers. This crossover size is between 100 and 150 decimal digits, depending on the implementation and the size of the coefficients of the NFS polynomial.

See Riesel [17] for a description of the quadratic sieve and number field sieve factoring algorithms. See also Lenstra and Lenstra [15] for more information about NFS.

42.9 Discrete Logarithms

The Diffie–Hellman key exchange, the ElGamal public key cryptosystem, the Pohlig–Hellman private key cryptosystem and the **digital signature algorithm** could all be broken if we could compute discrete logarithms quickly, that is, if we could solve the equation $a^x = b$ in a large finite field. For convenience of computation, usually the finite field is either the integers modulo a prime p or the field with 2^n elements.

Consider first the exponential congruence $a^x \equiv b \bmod p$. By analogy to ordinary logarithms, we may write $x = \log_a b$ when p is understood from the context. These *discrete logarithms* enjoy many properties of ordinary logarithms, such as $\log_a bc = \log_a b + \log_a c$, except that the arithmetic with logarithms must be done modulo $p-1$ because $a^{p-1} \equiv 1 \bmod p$. Neglecting powers of $\log p$, the congruence may be solved in $O(p)$ time and $O(1)$ space by raising a to successive powers modulo p and comparing each with b. It may also be solved in $O(1)$ time and $O(p)$ space by looking up x in a precomputed table of pairs $(x, a^x \bmod p)$ sorted by the second coordinate. Shanks' "giant step–baby step" algorithm solves the congruence in $O(\sqrt{p})$ time and $O(\sqrt{p})$ space as follows. Let $m = \lceil \sqrt{p-1} \rceil$. Compute and sort the m ordered pairs $(j, a^{mj} \bmod p)$, for j from 0 to $m-1$, by the second coordinate. Compute and sort the m ordered pairs $(i, ba^{-i} \bmod p)$, for i from 0 to $m-1$, by the second coordinate. Find a pair (j, y) in the first list and a pair (i, y) in the second list. This search will succeed because every integer between 0 and $p-1$ can be written as a two-digit number ji in radix m. Finally, $x = mj + i \bmod p-1$.

There are faster ways to solve $a^x \equiv b \bmod p$ using methods similar to the two integer factoring algorithms QS and NFS. Here is the analogue for QS. Choose a factor base of primes $p_1, \ldots, p_k$. Perform the following precomputation which depends on a and p but not on b. For many random values of x, try to factor $a^x \bmod p$ using the primes in the factor base. Save at least $k+20$ of the factored residues:

$$a^{x_j} \equiv \prod_{i=1}^{k} p_i^{e_{ij}} \bmod p \text{ for } 1 \le j \le k+20 ,$$

or equivalently

$$x_j \equiv \sum_{i=1}^{k} e_{ij} \log_a p_i \bmod p-1 \text{ for } 1 \le j \le k+20 .$$

When b is given, perform the following main computation to find $\log_a b$. Try many random values for s until one is found for which $ba^s \bmod p$ can be factored using only the primes in the factor base. Write it as

$$ba^s \equiv \prod_{i=1}^{k} p_i^{c_i} \bmod p$$

or

$$(\log_a b) + s \equiv \sum_{i=1}^{k} c_i \log_a p_i \bmod p-1 .$$

Use linear algebra as in QS to solve the linear system of congruences modulo $p-1$ for $\log_a b$. One can prove that the precomputation takes time

$$\exp((1+\epsilon(p))\sqrt{\log p \log\log p}) ,$$

where $\epsilon(p) \to 0$ as $p \to \infty$, while the main computation takes time

$$\exp((0.5+\epsilon(p))\sqrt{\log p \log\log p}) ,$$

where $\epsilon(p) \to 0$ as $p \to \infty$.

There is a similar algorithm for solving congruences of the form $a^x \equiv b \bmod p$ which is analogous to NFS and runs faster than the above for large p.

There is a method of Coppersmith [5] for solving equations of the form $a^x = b$ in the field with 2^n elements which is practical for n up to about 1000. Empirically, it is about as difficult to solve $a^x = b$ in the field with p^n elements as it is to factor a general number about as large as p^n. As these are the two problems which must be solved in order to break the RSA and the ElGamal cryptosystems, it is not clear which of these systems is more secure.

42.10 Research Issues and Summary

This article presents an overview of some of the many techniques of breaking ciphers. This subject has a long and rich history. We gave some historical perspective by mentioning some of the older ciphers whose cryptanalysis is well understood. Most of this article deals with the cryptanalysis of ciphers still being used today, such as DES, RSA, Pohlig–Hellman, etc. We still do not know how to break these ciphers quickly, and research into methods for doing this continues today.

New cryptosystems are invented frequently. Most are broken quickly. For example, research continues on multistage knapsacks, some of which have not been broken yet, but probably will be soon. Some variations of differential cryptanalysis being studied now include higher-order differential cryptanalysis and a combination of linear and differential cryptanalysis. Some recent advances in integer factoring algorithms include the use of several primes outside the factor base in QS, the self-initializing QS, faster computation of the square root (β) in the NFS, better methods of polynomial selection for the general NFS, and the lattice sieve variation of the NFS. Most of these advances apply equally to computing discrete logs. A promising source of new cryptosystems is the theory of elliptic curves, in which adding a point to itself many times corresponds to exponentiation in RSA, Pohlig–Hellman, and similar cryptosystems. Cryptanalysis of elliptic curve ciphers is harder than that of exponentiation ciphers because the group structure of an elliptic curve is more complicated than that of the multiplicative group of integers modulo n.

We have omitted discussion of many important ciphers in this short article. Even for the ciphers which were mentioned, the citations are far from complete. See the "Further Information" section below for general references.

42.11 Defining Terms

Breaking a cipher: Finding the key to the cipher by analysis of the ciphertext or, sometimes, both the plaintext and corresponding ciphertext.

Coprime: Relatively prime. Refers to integers having no common factor greater than 1.

Differential Cryptanalysis: An attack on ciphers like DES that tries to find the key by examining how certain differences (XORs) of plaintext pairs affect differences in the corresponding ciphertext pairs.

Digital signature algorithm: A public-key algorithm for signing or authenticating messages. It was proposed by the National Institute of Standards and Technology in 1991.

Factor base: A fixed set of small primes, usually all suitable primes up to some limit, used in factoring auxiliary numbers in the quadratic and number field sieves.

Homophone: One of several ciphertext letters used to encipher a single plaintext letter.

Key stream: A sequence of bits, bytes, or longer strings used as keys to encipher successive blocks of plaintext.

Permutation or transposition cipher: A cipher that enciphers a block of plaintext by rearranging the bits or letters.

Quadratic residue modulo m: A number r that is coprime to m and for which there exists an x so that $x^2 \equiv r \bmod m$.

Sieve: A number theoretic algorithm in which, for each prime number p in a list, some operation is performed on every pth entry in an array.

Substitution cipher: A cipher that enciphers by replacing letters or blocks of plaintext by ciphertext letters or blocks under the control of a key.

XOR: Exclusive-or or sum of bits modulo 2.

Further Information

Research on cryptanalysis is published often in the journals *Journal of Cryptology, Cryptologia* and *Computers and Security.* Such research appears occasionally in the journals *Algorithmica, AT&T Technical Journal, Communications of the ACM, Electronics Letters, Information Processing Letters, IBM Journal of Research and Development, IEEE Transactions on Information Theory, IEEE Spectrum, Mathematics of Computation* and *Philips Journal of Research.*

Several annual or semiannual conferences with published proceedings deal with cryptanalysis. CRYPTO has been held since 1981 and has published proceedings since 1982. See CRYPTO '82, CRYPTO '83, etc. EUROCRYPT has published its proceedings in 1982, 1984, 1985, 1987, 1988, etc. The conference AUSCRYPT is held in even numbered years beginning in 1990, while ASIACRYPT is held in odd numbered years beginning in 1991.

Kahn [13] gives a comprehensive history of cryptology up to 1967. Public key cryptography was launched by Diffie and Hellman [8]. Denning [7] and Konheim [14] have lots of information about and examples of old ciphers and some information about recent ones.

Pseudorandom Sequences and Stream Ciphers

Andrew Klapper
University of Kentucky

43.1 Introduction

This chapter concerns the generation of **pseudorandom sequences** and the role of these sequences in **stream ciphers.** Pseudorandom sequences are also used in various probabilistic algorithms that arise in cryptography. In this latter context, however, the role of pseudorandomness is essentially the same as in other probabilistic algorithms and we leave this aspect of pseudorandomness to other chapters.

The only completely secure cryptosystem is the **one-time pad.** In this private key system the message alphabet is the integers modulo an integer m. The *key* or *keystream* is a sequence of symbols from the message alphabet generated uniformly independently at random. The key is known to both the sender and receiver. To encrypt a message, the key is added to the message symbol by symbol modulo m. From the point of view of Shannon's **information theory** this system is unconditionally secure. That is, an adversary who knows any subset of the symbols of the key (or, equivalently, any set of known plaintext/ciphertext pairs) can determine any other symbol of the message with probability no better than guessing. Such a system is further advantageous because encryption is as fast as the method of generating the random symbols. The drawback is that sharing the key between the sender and the receiver is no easier than sharing the message, since the key is as large as the message. Thus the one-time pad is only practical when the sender and receiver have access to a secure channel at some point (when they can share the key) and plan to use an insecure channel to share a message at some later time. Such situations are rare.

A stream cipher uses a pseudorandom sequence as the keystream in place of a truly random one. By pseudorandom we mean that the key is apparently random by various criteria that are related to the effectiveness of the system. Since the actual encryption is simple and well understood, the issues surrounding the effectiveness of a stream cipher have to do mainly with the generation of keys. The symbols of the key must be difficult to determine from a subset of the symbols and the key must be

efficiently generated. There is widespread belief in the cryptographic community that stream ciphers are less secure than either well-designed block ciphers or public key systems. Thus they are considered practical only if they achieve much higher speed. We stress, however, that the relative security of types of cryptosystems is largely a matter of belief, often depending on unproved complexity theoretic assumptions.

Stream ciphers can be implemented either in hardware, which has the advantage of speed of execution, or in software, which has the advantages of speed of implementation and portability. The choice often affects the choice of message alphabet. A binary alphabet is typically used in hardware implementations. An alphabet of size 256 is often used in software implementations. In much of this chapter we treat the case of stream ciphers based on binary sequences, since this case has been more extensively studied. In many instances the analysis is considerably simpler with binary sequences. Also, hardware implementations are essentially finite state devices. Their output sequences are thus eventually periodic and this is often an assumption about the sequences used in stream ciphers.

As with most cryptography there are two aspects to the study of stream ciphers: their design and their cryptanalysis. Of course there is a relationship. Stream ciphers must be designed to resist any general cryptanalytic attacks and the cryptanalysis of a system depends on its design.

Classification and Modes of Stream Ciphers

In the greatest generality a stream cipher is a parametrized non-terminating finite automaton with output. More precisely, it consists of

1. A *state space* $\mathcal{A}$, a key space $\mathcal{K}$, and a message alphabet $\mathcal{M}$;
2. A *state change function* $F : \mathcal{K} \times \mathcal{A} \times \mathcal{M} \to \mathcal{A}$; and
3. An *output function* $g : \mathcal{K} \times \mathcal{A} \times \mathcal{M} \to \mathcal{M}$.

For a given message sequence $x_0, x_1, \cdots \in \mathcal{M}$, initial state $\alpha_0 \in \mathcal{A}$, and key $k \in \mathcal{K}$, the stream cipher generates a state sequence and output (i.e., ciphertext) sequence by

$$\begin{aligned} \alpha_{i+1} &= F(k, \alpha_i, x_i) \\ y_i &= g(k, \alpha_i, x_i) \ . \end{aligned}$$

Most commonly

$$g(k, \alpha, x) = x + h(k, \alpha) \bmod m \ ,$$

where $\mathcal{M}$ is the integers modulo an integer m. In this case the sequence $z_i = h(k, \alpha_i)$ is called the keystream and the pair (F, h) is called a **keystream generator.**

Keystream generators may be classified as *synchronous* or *self-synchronizing.* In a self-synchronizing generator the state depends on the previous few output symbols,

$$\alpha_{i+1} = F\left(y_i, \cdots, y_{i-r+1}\right) \ .$$

In effect the state consists of the previous r output symbols. The advantage of such a system is that if symbols are lost, then the receiver can resynchronize after r output symbols have been received. The disadvantage is that distorted symbols cause error propagation for r symbols.

In a synchronous generator the keystream is independent of the message sequence. That is, $F : \mathcal{K} \times \mathcal{A} \to \mathcal{A}$. Synchronous generators are unable to recover from lost symbols without resetting to an initial state. However, an external mechanism can be added to solve the synchronization problem. Distorted symbols result in no error propagation. Nonetheless, in most applications using noisy channels it is likely that an underlying error correction mechanism will be used. Synchronous generators are the most commonly used stream ciphers.

Synchronous generators are often restricted to one of two special cases. In *counter mode,* $\alpha_{i+1} = F(\alpha_i)$ and $z_i = h(k, \alpha_i)$. An example of a counter mode generator is the *cyclotomic generator,* described below.

In *output feedback mode*, $\alpha_{i+1} = F(k, \alpha_i)$ and $z_i = h(\alpha_i)$. Most of the feedback register based generators described in this article run in output feedback mode.

43.2 Underlying Principles

The mathematical tools used to study cryptographically strong pseudorandom sequences are algebra, information theory, and probability theory. In this section various formalizations of the notion of randomness are described. We also describe the structure and analysis of **linear feedback shift registers.** These are fundamental building blocks in the design of keystream generators. Of particular importance in this analysis is the theory of finite fields [22, 23].

Randomness

There are several different notions of randomness that have been applied to sequences. These include *information theoretic randomness, statistical randomness, unpredictability* (a complexity theoretic notion), and *Kolmogorov complexity.* The first three have the greatest relevance for cryptography, and we describe them in more detail next.

Information Theoretic Randomness

The mathematical analysis of cryptographic systems was initiated by Shannon's invention of information theory [37]. Shannon's approach was to analyze the information that can be derived about a system by an adversary who has unlimited computational resources. The analysis is probabilistic. The cryptanalyst has a known ciphertext and knows the probability distribution of plaintexts, keys, and ciphertexts. The *a priori* distribution on the plaintexts arises by assuming they lie in some restricted class of strings such as a natural language. By conditioning this distribution on the known ciphertext, a new distribution on plaintext is determined. The cryptanalyst is successful if one plaintext has conditional probability close to one.

Let X be a discrete random variable whose distribution is given by $p_i = Pr(X = i)$. The **entropy** of X is defined by

$$H(X) = -\sum_{i, p_i \neq 0} p_i \log(p_i) \ .$$

The entropy is a measure of uncertainty about X. Shannon gave a set of properties that the uncertainty intuitively should have and proved that the so-defined entropy function is the unique function that has them. For any X, $H(X) \leq \log(n)$, with equality if and only if $p_i = 1/n$ for all i. The notion of entropy also plays a role in compression. It is a lower bound on the average number of bits required to encode a finite set. An introduction to information theory and its role in coding theory and cryptography can be found in the book by Welsh [38].

If X and Y are two random variables, the notion of entropy extends naturally to the joint entropy $H(X, Y)$, the conditional entropy $H(X|Y)$ (the uncertainty about X if Y is known), and the mutual information

$$I(X; Y) = H(X) - H(X|Y)$$

between X and Y (the information common to X and Y). If $I(X; Y) = 0$, then X and Y are independent, so Y reveals nothing about X. Conversely, if $I(X; Y) = H(X)$, i.e., is maximal, then $H(X|Y) = 0$ so there is no uncertainty about X when Y is known.

Now consider the case of a cryptosystem. Suppose that $X^n = x_1, x_2, \cdots, x_n$ is an n-bit plaintext, K is a key, and $Y^n = y_1, y_2, \cdots, y_n$ is the corresponding n-bit ciphertext. In general,

$$H\left(K|Y^n\right) = H\left(X^n|Y^n\right) + H\left(K|X^n, Y^n\right) \ .$$

If $I(X^n; Y^n) = 0$, then the ciphertext reveals nothing of the plaintext and the system is said to have *perfect secrecy.* In this case

$$H(K) \geq H\left(K|Y^n\right) \geq H\left(X^n|Y^n\right) = H\left(X^n\right) .$$

Thus the uncertainty about the key must be at least as great as the uncertainty about the plaintext. It follows that the average length of the minimal length encoding of the key must be at least as great as that of the plaintext. That is, to achieve perfect secrecy the key must be as long as the plaintext. This is a fundamental limit on the power of private key encryption.

At the other extreme, if $I(X^n; Y^n)$ is asymptotic to $H(X^n)$, then for long enough plaintexts knowledge of the ciphertext essentially determines the plaintext and the system can be broken (although it still may require an exhaustive search to find the plaintext).

In the intermediate cases $0 < I(X^n; Y^n) < rH(X^n)$ for some positive constant $r < 1$. For arbitrarily long messages there is some uncertainty about the plaintext. It follows that

$$H\left(K|Y^n\right) > (1-r)H\left(X^n\right)$$

is bounded away from zero. Such a cryptosystem is called *ideally secure.* This means that the key can never be determined from the ciphertext with perfect certainty. However, the uncertainty may be small enough that significant portions of the plaintext are revealed.

Shannon also defined a measure of how much ciphertext is necessary to determine the key. The *unicity distance* n_u is the minimum length n such that $H(K|Y^n) \sim 0$. Under reasonable assumptions, we have

$$n_u = \frac{H(K)}{1-h} ,$$

where h is the information rate of the plaintext (so $1-h$ is the redundancy).

Statistical Randomness

A sequence is statistically random if various statistical properties are close to those of a truly random sequence. The failure of these properties to hold does not necessarily lead directly to a cryptanalytic attack. However, such failure is reason for concern that an attack may be found in the future. Following are some of the randomness criteria that have been considered for periodic binary sequences. Let $\mathbf{a} = a_0, a_1, a_2, \cdots$ denote such a sequence. Its period, denoted $\rho(\mathbf{a})$, is the least positive integer n such that $a_i = a_{i+n}$ for every i. The period of a keystream must be large.

Balance: A sequence is **balanced** if the number of occurrences of 0 equals the number of occurrences of 1 in each period. In the extreme, a highly unbalanced sequence allows a cryptanalyst to read most of a message either directly or by complementing all bits. In less extreme cases, unbalanced sequences have been shown to leak essential information [18]. Of course if $\rho(\mathbf{a})$ is odd, then $\mathbf{a}$ cannot be perfectly balanced.

Subsequence Distribution: If r is any integer, we can count the number of occurrences of each binary r-tuple $b_0, \cdots, b_{r-1}$ in a period of $\mathbf{a}$ (more precisely, we count the number of indices i such that $0 \leq i \leq n-1$, and $a_i = b_0, a_1 = b_{i+1}, \cdots a_{i_r-1} = b_{r-1}$). It is desirable that the distribution of occurrences be close to uniform. A sequence of period 2^r such that every binary r-tuple occurs exactly once in a period is known as a *de Bruijn sequence.*

Autocorrelations: The **autocorrelation with shift** τ of $\mathbf{a}$ is defined as

$$A_{\mathbf{a}}(\tau) = \sum_{i=0}^{\rho(\mathbf{a})-1} (-1)^{a_i + a_{i+\tau}} ,$$

or, equivalently, the number of bits in one period of $\mathbf{a}$ and a τ shift of $\mathbf{a}$ that are equal minus the number of bits that are not equal. If $\mathbf{a}$ is independent of its τ shift, then the autocorrelation

is zero, while if for each i, a_i determines $a_{i+\tau}$, then the autocorrelation is plus or minus $\rho(\mathbf{a})$. Thus the autocorrelation measures the extent to which a sequence is independent of its shifts. The failure of the autocorrelation to be close to zero can sometimes be used to derive essential information about a cryptosystem.

Run Property: A *run* in a sequence is a maximal subsequence consisting of only zeros or only ones. A binary sequence can be thought of as a series of runs of varying lengths. A sequence has the *run property* if the distribution of runs is close to what would be expected of a truly random sequence. If a run starts at position i, then it has length r with probability 2^{-r}.

Nonlinearity: Generally, linearity can be exploited in constructing cryptanalytic attacks. Thus, loosely speaking, the sequence should not exhibit linear structure. This statement can be interpreted in various ways. For example, the sequence defines a function from its set of indices to $\{0, 1\}$. Whenever we interpret the index set as an algebraic structure (say, modular integers or a finite field), this function should be highly nonlinear. Various approaches have been taken to defining the degree to which such a function is nonlinear.

A Boolean function f on n bits satisfies the **strict avalanche criterion** (or SAC) if $f(\bar{x}) + f(\bar{x} + \bar{y})$ is a balanced function of $\bar{x}$ for every $\bar{y}$ with $||\bar{y}|| = 1$. Here $||\bar{y}||$ denotes the number of ones in $\bar{y}$, known as its Hamming weight. That is, changing any single bit of the input to f gives a function that is uncorrelated with f. The function f satisfies $SAC(k)$ if holding any k bits constant results in a function that satisfies SAC. Preneel et al. gave conditions under which various $SAC(k)$ hold [28]. More generally, f satisfies the *propagation criterion of degree k* if $f(\bar{x}) + f(\bar{x} + \bar{y})$ is a balanced function of $\bar{x}$ for every $\bar{y}$ with $1 \leq ||\bar{y}|| \leq k$.

The *Walsh transform of f* is defined as

$$\hat{F}(\bar{w}) = \sum_{\bar{x}} (-1)^{f(\bar{x}) + \bar{w} \cdot \bar{x}} .$$

Parseval's theorem says that

$$\sum_{\bar{w}} \left(\hat{F}(\bar{w}) \right)^2 = 2^{2n} .$$

A function is *bent* if each Walsh transform achieves exactly the average value implied by Parseval's theorem,

$$\left| \hat{F}(\bar{w}) \right| = 2^{n/2}$$

for every w [30]. That is, the maximum correlation of f with a linear function is as small as possible.

The notions of **correlation immunity** and the degree of *algebraic nonlinearity* are described in subsequent sections.

Unpredictability

In a very different attempt to define a notion of randomness suitable for cryptography, Yao [39] and Blum and Micali [3] considered what would make it effectively impossible for an adversary to determine the next bit of a sequence if a prefix were known. The adversary in their model is assumed to have limited resources, so their definition of unpredictability is complexity theoretic.

In Blum and Micali's model a generator G inputs a security parameter n and a random number $0 \leq i < 2^n$ and outputs a pseudorandom bit sequence $\mathbf{a}$. Such a generator is a **cryptographically strong pseudorandom bit generator** or CSPRB generator if the following hold.

1. The bits a_j are easy to generate. That is, it should take time polynomial in n to output the jth bit.

2. The bits are unpredictable. Given G, n, and $a_0, \cdots, a_{j-1}$, but not i, it should be computationally infeasible to predict a_j with probability significantly greater than 1/2.

More precisely, suppose the output from G has length $p(n)$ if n is the security parameter. A predicting family is a polynomial (in n) size family of circuits

$$C = \left\{ C_n^j : j < p(n) \right\}$$

such that each C_n^j has j inputs and one output. If the input is $a_0, \cdots, a_{j-1}$, and the output is d, let $P_{j,i}$ be the probability that $d = a_j$. Then G passes the **next bit test** C if for every polynomial $q(n)$, every large enough n, every $j < p(n)$, and every $i < 2^n$,

$$P_{j,i} < \frac{1}{2} + \frac{1}{q(n)} .$$

A generator is *perfect* if it passes all polynomial size next bit tests. A different, but equivalent, formulation was given by Yao. In the subsection on universal security in Section 43.3, we describe Blum and Micali's construction of a generator that passes the next bit test assuming the hardness of the discrete log problem.

Feedback Shift Registers

Many devices that are proposed for generating cryptographically strong pseudorandom sequences are based on linear feedback shift registers or LFSRs for short [14]. An LFSR of length r has an r-bit state vector that is updated by shifting by one position and filling the vacated position by a linear function of the previous state. More specifically, if we let the state be $\bar{a} = (a_0, \cdots, a_{r-1})$, $a_i \in \{0, 1\}$, then there is a linear *feedback function*

$$f(\bar{a}) = \left(\sum_{i=0}^{r-1} c_i a_i \right) \bmod 2 ,$$

where each c_i is a bit. The state is updated by replacing $\bar{a}$ with $(a_1, \cdots, a_{r-1}, f(\bar{a}))$. A diagram of an LFSR is given in Fig. 43.1.

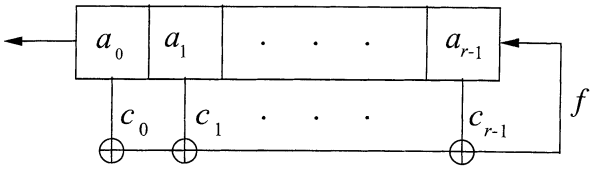

FIGURE 43.1 Linear feedback shift register.

In hardware the state change can be thought of as tapping the cells whose corresponding c_is equal 1 and adding the values modulo 2. Thus LFSRs are extremely fast, especially when implemented in hardware and when the number of tapped cells is small. They can be designed to generate sequences of large period—up to $2^r - 1$. A sequence of period $2^r - 1$ output by an LFSR of length r is called an **m-sequence.** These sequences have many of the desirable statistical properties mentioned in "Statistical Randomness." They are optimally balanced for odd period sequences. Every subsequence of length $t \leq r$ occurs 2^{r-t} times, except the all-zero subsequence which occurs $2^{r-t} - 1$ times. The shifted autocorrelations all equal -1. The distribution of subsequences of each length up to r is nearly uniform and the distribution on runs is nearly perfect.

There is a useful algebraic theory of LFSRs. To describe this, some algebraic background is needed. If $q = 2^r$, then there is a unique *finite field* with q elements, called $GF(q)$. An element α of $GF(q)$ is

called *primitive* if every nonzero element of $GF(q)$ is a power of α. (Compare to Chapter 38, Section 5.9). Primitive elements exist in every $GF(q)$. The minimal degree polynomial with coefficients in $GF(2) = \mathbf{Z}/2\mathbf{Z} = \{0, 1\}$ for which α is a root is called a *primitive polynomial.* We also need the *trace function,* defined by

$$Tr_1^r(x) = x + x^2 + x^4 + \cdots + x^{2^{r-1}} .$$

The trace function maps $GF(q)$ to $GF(2)$, is nonzero, and is $GF(2)$-linear, thinking of $GF(q)$ as a vector space over $GF(2)$. In fact, every such linear function is of the form $x \mapsto Tr_1^r(\gamma x)$ for some $\gamma \in GF(q)$. These notions generalize to a setting where the base field $GF(2)$ is replaced by an arbitrary finite field of arbitrary characteristic. This makes it possible to extend the following analysis of LFSR sequences to LFSRs whose entries lie in an arbitrary finite field.

We can associate to any eventually periodic sequence **a** the *generating function*

$$g(x) = \sum_{i=0}^{\infty} a_i x^i .$$

We can associate to any LFSR with feedback function $\sum_{i=0}^{r-1} c_i a_i$ the *connection polynomial*

$$q(x) = \sum_{i=1}^{r} c_{r-i} x^i - 1 .$$

These are defined over $GF(2)$. Then $g(x)$ is a rational function and, when represented as a quotient of two relatively prime polynomials, the denominator is the connection polynomial of the smallest LFSR that outputs **a**. An LFSR sequence is an m-sequence if and only if the connection polynomial is primitive. The period of **a** is the least n such that $g(x)$ divides $x^n - 1$. Also, it can be shown that if the connection polynomial of an LFSR is irreducible, then there are elements $\gamma, \alpha \in GF(2^r)$ such that

$$a_i = Tr_1^r\left(\gamma \alpha^i\right) .$$

The sequence **a** is an m-sequence if and only if α is primitive. It is these algebraic structures that make it possible to analyze many of the statistical properties of m-sequences mentioned above.

Despite their nice statistical properties m-sequences are cryptologically weak. This is due to the linearity of the feedback function and the associated algebraic structures.

If **a** is any sequence, then the size of the smallest LFSR that outputs **a** is called the **linear span** or **linear complexity** of **a**. We denote this quantity by $\lambda(\mathbf{a})$. There is an algorithm, due to Berlekamp and Massey [24] which, given $2\lambda(\mathbf{a})$ bits of a sequence, outputs a description of a minimal length LFSR that generates **a**. This algorithm is given in Fig. 43.2. At the kth stage the best rational representation of the generating function modulo x^k is found. Details of the proof that the algorithm achieves this and converges in $2\lambda(\mathbf{a})$ steps were given by Massey [24]. Furthermore, the Berlekamp–Massey algorithm can be made efficient by computing the product in step 11 from previous values in linear time. Thus if the algorithm examines T bits of a sequence, then it runs in time $\mathcal{O}(T^2)$. If the period of a sequence is exponentially larger than its linear span, then this time is quite small. This is the case for m-sequences. Thus LFSRs are unsuitable for generating sequences for stream ciphers. Moreover, sequences generated by other means must have large linear span or they will still be susceptible to the Berlekamp–Massey algorithm.

A major goal of research on stream ciphers has been to design efficient keystream generators whose output has large linear span. Despite the cryptographic weakness of LFSRs, their speed, simplicity, and ability to be analyzed make them important building blocks for stream ciphers. They are useful as well in other areas such as spread spectrum systems, radar systems, and Monte Carlo simulation. Many variations on LFSRs have been proposed that gain cryptographic strength by introducing some nonlinearity. Several of these are described in Section 43.3.

BERLEKAMP-MASSEY($\mathbf{a}$)

```
1   input a_i s until the first nonzero a_{k-1} is found
2   g ← a_{k-1} · x^{k-1}
3   p_{k-1} ← 0

5   m ← k − 1
6   p_k ← x^{k-1}
7   q_k ← x^{k-1} + 1
8   while there are more bits
9       do  input a new bit a_k
10          g ← g + a_k x^k
11          if g · q_k ≡ p_k ( mod x^{k+1})
12              then q_{k+1} ← q_k
13                   p_{k+1} ← p_k
14              else q_{k+1} ← q_k + x^{k−m} q_m
15                   p_{k+1} ← p_k + x^{k−m} p_m
16                   if deg(q_{k+1}) > deg(q_k)
17                       then m ← k
18          k = k + 1
19  return q_k, p_k
```

FIGURE 43.2 The Berlekamp–Massey algorithm.

It has long been known that a small change in a sequence can result in an enormous change in the linear span. For example, the all 0 sequence has linear span 0, but if we change every nth position to a 1, then the resulting sequence has linear span n (any register of length less than n that outputs this sequence must reach an all 0 state, and will output all 0s from then on, which is a contradiction). Suppose $\mathbf{a}$ is any sequence of period n and $\mathbf{b}$ is another sequence with the same period that differs from $\mathbf{a}$ in a small number k of bits per period. If a cryptanalyst is given a prefix $\bar{u} = a_0, \cdots, a_{m-1}$ of $\mathbf{a}$, she can run the Berlekamp–Massey algorithm for every m-tuple that differs from $\bar{u}$ in at most k positions. Among the resulting generators will be one that outputs $\mathbf{b}$, although it may be problematic deciding which generator to select. This led Ding, Xiao, and Shan [10] to define the **sphere complexity.** Let $O(\mathbf{a},k)$ be the set of sequences of period n that differ from $\mathbf{a}$ in at least 1 and at most k positions. Then the sphere complexity of $\mathbf{a}$ is defined as

$$\mathrm{SC}_k(\mathbf{a}) = \min_{\mathbf{b}\in O(\mathbf{a},k)} \lambda(\mathbf{b}) .$$

Although less important than the linear span, it is desirable that the sphere complexity of a sequence be large.

LFSRs can be generalized to feedback registers whose entries are elements of an arbitrary fixed finite field $GF(q)$. The coefficients a_i are arbitrary elements of $GF(q)$. Such a register outputs a sequence of

elements of $GF(q)$. Essentially everything we have said about LFSRs applies in this more general setting, although some slight modification is necessary in steps 14 and 15 of the Berlekemp–Massey algorithm.

43.3 State of the Art

The importance of cryptanalysis is threefold. First, it reveals weaknesses in existing systems so that users know what to avoid. Second, it provides a limited means of certification: users are more confident in a system that has withstood attack for a reasonable time. This is important in an area where formal proofs of security seem unlikely and systems often intentionally defy formal analysis. Third, the study of cryptanalysis often reveals general principles for the design of future cryptosystems. In addition to the Berlekamp–Massey algorithm there have been several general methods of cryptanalysis of stream ciphers. In the subsection on "Cryptanalysis" we discuss **correlation attacks** [12, 26, 36] and 2-adic rational approximation [20].

The ultimate goal of research on stream ciphers is to provide fast methods of securely transmitting data. Methods that have been proposed in recent years include feedback shift register based methods such as **nonlinear filter generators** [15]; **nonlinear combiners** [31]; **clock-controlled shift registers** [13]; shrinking generators; and cyclotomic generators [9]. There have also been several recent proposals of generators that are not based on shift registers, and are suitable for software implementations. These include RC4 and SEAL [29]. In the subsection on "Keystream Generation" we survey these approaches.

In contrast to public key cryptosystems, the theoretical foundations of stream ciphers are generally weak or only weakly connected to practice. In the subsection on "Universal Security" we discuss complexity theoretic models for stream cipher security [3, 39]; and models for security against broad generalizations of the Berlekamp–Massey algorithm [19].

Cryptanalysis

In this section we describe general methods of cryptanalyzing stream ciphers.

Correlation Attacks

Consider a situation in which one or more feedback registers are made to interact to produce an output sequence. Suppose a cryptanalyst knows the structure of the feedback registers and how they interact but not the start states. This is a typical arrangement when keystream generators are implemented in hardware. The goal of the cryptanalyst then is to determine the initial states of the registers from a known segment of key stream. If the generator is constructed so that the state is large enough, then an exhaustive search is infeasible. The idea behind a correlation attack is to find statistical correlations between keystream bits and state bits. These correlations can then be used to improve searches for the initial states. Typically, exhaustive search is performed on the start state of one of the underlying registers until the correlations match the prediction.

This general framework has been used to attack combination generators, nonlinear filter generators, and various clock controlled shift registers. These attacks are described in greater detail in the sections below on the specific generators.

2-Adic Rational Approximation

The method of 2-adic rational approximation is based on a class of feedback registers invented by Goresky and Klapper [20] that is analogous to LFSRs. These registers, called **feedback with carry shift registers** or FCSRs, are based on algebra over the integers and 2-adic numbers just as LFSRs are based on algebra over polynomials and power series. An FCSR of length r has an r-bit state vector $\bar{a} = (a_0, \cdots, a_{r-1})$ plus an integer memory m. The state is updated similarly to that of an LFSR, but the addition is performed as integers rather than modulo 2. The low bit is fed back to the register and the high

bits are retained in m as a carry to the next state change. More precisely, there is a linear feedback function

$$f(\bar{a}, m) = m + \sum_{i=0}^{r-1} c_i a_i \ ,$$

where each c_i is a bit. The state is updated by replacing $\bar{a}$ with

$$(a_1, \cdots, a_{r-1}, f\ (\bar{a}, m) \bmod 2)$$

and replacing m by

$$\lfloor f\ (\bar{a}, m)\ /2 \rfloor \ .$$

A diagram of an FCSR is given in Fig. 43.3.

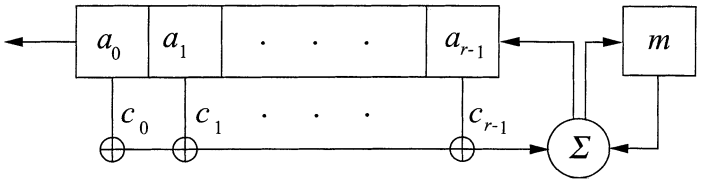

FIGURE 43.3 Feedback with carry shift register.

FCSRs are very simple and fast devices that can output sequences that are exponentially larger than the size of the register. There are many analogies between LFSRs and FCSRs. Associated with the output sequence **a** is the *2-adic number*

$$\alpha = \sum_{i=0}^{\infty} a_i 2^i \ .$$

The algebra of 2-adic numbers is like that of power series, but addition and multiplication are performed with carry to higher terms instead of modulo 2. Associated with the FCSR is the *connection number*

$$q = \sum_{i=1}^{r} c_{r-i} x^i - 1 \ .$$

An FCSR sequence is always eventually periodic. The associated 2-adic number α is rational, and q is the denominator of a rational representation of α. Thus the cryptanalytic problem of finding the smallest FCSR that outputs a given sequence is equivalent to the problem of finding the minimal rational representation for a 2-adic number. This problem was solved by de Weger's algorithm. An adaptive version appears in [20], where the notion of *2-adic span* (the minimal number of bits of storage used by an FCSR that outputs **a**) is defined. As with linear span, in order for a sequence to be cryptographically strong it must have large 2-adic span. It was further shown that sequences generated by summation combiners (see "Nonlinear Combiners") have relatively low 2-adic span. Various generalizations of FCSRs have been proposed by exploiting known generalizations of the algebra of 2-adic numbers.

Despite this cryptanalysis, maximal period FCSR sequences (ones for which 2 is a primitive root modulo the connection number) have many desirable statistical properties. Their periods are exponentially larger than the sizes of their generators, they are balanced, their arithmetic correlations vanish, and they are nearly de Bruijn sequences. Thus they are potential substitutes for m-sequences as building blocks for keystream generators.

Keystream Generation

In this section we survey various methods of generating sequences for stream ciphers. Much of the research in this area has concentrated on generating sequences with large linear span and immunity to correlation attacks.

Linear Congruential Generators

Linear congruential generators are often suggested as pseudorandom generators because they are simple, have large period, and are readily available on computer systems. However, they are highly linear and hence are cryptographically weak.

A linear congruential generator is determined by an integer modulus, m, and a pair of integers, u and v, with $0 < u < m$ and $0 \leq v < m$. A sequence of integers $a_0, a_1, a_2, \cdots$ is generated by choosing a_0 arbitrarily and computing

$$a_n = ua_{n-1} + v \bmod m \ .$$

If v is relatively prime to m and u has maximal order modulo m (that is, $u^i = 1 \bmod m$ only if $\phi(m)$ divides i, where ϕ is Euler's function), then this sequence has maximal period $\phi(m)$.

Several attacks on linear congruential generators have appeared in the literature. The one due to Boyar assumes that u, v, and m are unknown and the cryptanalyst does not know the $\log(\log(m))$ low order bits of each a_n [4]. Lagarias and Reeds have described an attack on a generalization of the linear congruential generator in which the linear function is replaced by an arbitrary polynomial.

Nonlinear Combiners

A nonlinear combiner takes the outputs from a set of k LFSRs and combines them with a nonlinear function $h : GF(2)^k \rightarrow GF(2)$. We denote by $\mathbf{a}^j$ the output from the jth LFSR. Then the output $\mathbf{b}$ of the nonlinear combiner is the sequence whose ith bit is $b_i = h(a_i^1, \cdots, a_i^k)$. A diagram of a nonlinear combiner with $k = 2$ is given in Fig. 43.4.

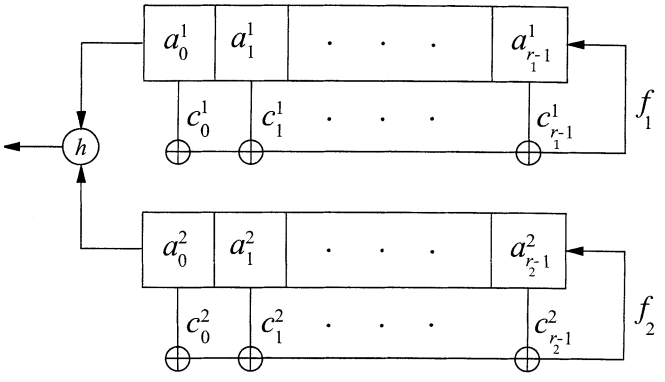

FIGURE 43.4 Nonlinear combiner.

The *Geffe generator* is a special case using three LFSRs. The output from the third register is used to select between the first two. That is, $h(a^1, a^2, a^3) = a^3a^1 \oplus (\neg a^3)a^2$. The period of the Geffe generator is $n_1n_2n_3$ and the linear span is

$$\lambda\left(\mathbf{a}^1\right)\lambda\left(\mathbf{a}^3\right) + \lambda\left(\mathbf{a}^2\right)\left(1 + \lambda\left(\mathbf{a}^3\right)\right) \ .$$

However, state information is leaked since

$$\text{Prob}\left(h\left(a^1, a^2, a^3\right) = a^1\right) = \text{Prob}\left(h\left(a^1, a^2, a^3\right) = a^2\right) = \frac{3}{4}\,.$$

Another special case is the *threshold generator.* This generator combines k LFSR sequences by outputting a 1 if and only if the majority of the outputs are 1. That is,

$$h\left(a^1, \cdots, a^k\right) = \begin{cases} 1 & \text{if } \sum_{i=1}^{k} a^i > \frac{k}{2} \\ 0 & \text{otherwise}\,. \end{cases}$$

In case $k = 3$ the period is $n_1 n_2 n_3$ and the linear span is

$$\lambda\left(\mathbf{a}^1\right)\lambda\left(\mathbf{a}^2\right) + \lambda\left(\mathbf{a}^2\right)\lambda\left(\mathbf{a}^3\right) + \lambda\left(\mathbf{a}^1\right)\lambda\left(\mathbf{a}^3\right)\,.$$

Once again, however, there is a positive correlation between the output sequence $\mathbf{b}$ and each sequence $\mathbf{a}^i$. Specifically, the mutual information $I(\mathbf{b}; \mathbf{a}^i)$ is 0.189 bits.

In the general case it is known that the period is bounded by

$$\rho(\mathbf{b}) \le \text{lcm}\left(\rho\left(\mathbf{a}^1\right), \cdots, \rho\left(\mathbf{a}^k\right)\right)$$

and the linear span is bounded by

$$\lambda(\mathbf{b}) \le h^*\left(\lambda\left(\mathbf{a}^1\right), \cdots, \lambda\left(\mathbf{a}^k\right)\right)\,,$$

where h^* is h thought of as a polynomial over the integers [32]. Further, Key [17] showed that these inequalities become equalities when the $\mathbf{a}^j$ are m-sequences with relatively prime periods. These results generalize to sequences over arbitrary finite fields.

Nonlinear combiners can be further generalized by allowing the combining function to retain a small amount of memory, say m bits. Such a combiner is specified by a pair of functions,

$$h : GF(2)^k \times GF(2)^m \to GF(2)$$

and

$$u : GF(2)^k \times GF(2)^m \to GF(2)^m\,.$$

Thus if the state of the memory is c, then the combiner outputs $b_i = h(a_i^1, \cdots, a_i^k, c)$ and updates the memory by $c = u(a_i^1, \cdots, a_i^k, c)$. Of particular interest is the *summation combiner* which adds its input sequence with carry, using the extra memory bits to save the carry. That is,

$$h\left(a^1, \cdots, a^k, c\right) = c + \sum_j a^j \bmod 2$$

and

$$u\left(a^1, \cdots, a^k, c\right) = \left\lfloor \left(c + \sum_j a^j\right)/2 \right\rfloor\,,$$

where we treat c as an integer. Rueppel [31] showed that if the input sequences to a summation combiner are m-sequences with relatively prime periods $\rho_1, \cdots, \rho_k$, then the output of the sequence has period $\prod_i \rho_i$ and linear span close to its period. Summation combiners are susceptible to a 2-adic rational approximation attack.

Combiner generators are vulnerable to correlation attacks. This was first observed by Siegenthaler. The cryptanalyst is assumed to know the combining function h and the individual LFSRs, but not the initial states of the LFSRs. This is equivalent to saying that the cryptanalyst knows the individual LFSR sequences but not the phase shifts that gave rise to the keystream. The idea of Siegenthaler's correlation attack is to pick one of the input sequences to h and compute the correlation of each phase shift with the known bits of the keystream until one is found that matches the predicted correlation. The time needed to determine the initial states of all the LFSRs is proportional to the sum of their periods times the number of known keystream bits. This is much smaller than the time needed to do an exhaustive search of all states, which is proportional to at least the products of the periods of the sequences. An attack such as this that attacks a piece of a generator at a time is sometimes called a *divide-and-conquer attack.*

To compute statistics it is assumed that each input to h is a sequence of independent uniformly distributed binary random variables. Let $\mathbf{b}$ be the output sequence and suppose $b_0, \cdots, b_{n-1}$ are known. For each j let p_j be the probability that the jth input to h equals the output. If p_j is close to $1/2$, then n must be enormous. On the other hand suppose p_j is far from $1/2$. For each phase shift τ the correlation

$$C_{\mathbf{a}^j,\mathbf{b}}(\tau) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=0}^{n-1}(-1)^{a_{i+\tau}^j}(-1)^{b_i}$$

is computed. For some T the phase shifts that give the T best correlations are chosen as candidates. (Best means closest to $2p_j - 1$, the *a priori* expected correlation.) If n and T are large enough, then the probability that the correct phase shift is in the candidate set is large. For example, suppose the length of the jth LFSR is 41, $p_j = 0.75$, and $n = 300$. Then the probability that the correct phase shift is among the best 1000 candidates is 0.98.

In order to build a combiner that resists this correlation attack, it is necessary that all the probabilities p_j be close to $1/2$. However, even if this is the case it may be possible to find a correlation between the output from h and a small subset of its inputs. In this case a similar divide-and-conquer attack can be used. The goal is then to find a combining function h that has no such correlations. This gives rise to the notion of **correlation immunity,** which was defined by Siegenthaler [34].

DEFINITION 43.1 A function $h(x_1, x_2, \cdots, x_k) : GF(2)^k \to GF(2)$ is *mth order correlation immune* if the random variable given by any m-tuple of x_js is statistically independent of $h(x_1, x_2, \cdots, x_k)$.

This condition is equivalent to the condition that, for every choice of binary vector $\bar{w} = (w_1, \cdots, w_k)$ with $||\bar{w}|| \leq m$, $h(x_1, x_2, \cdots, x_k)$ is statistically independent of the inner product $\bar{w} \cdot \bar{x}$. It can also be shown that h is mth order correlation immune if and only if $\hat{H}(\bar{w}) = 0$ whenever $1 \leq ||\bar{w}|| \leq m$ (where $\hat{H}(\bar{w})$ is the Walsh transform of h).

Siegenthaler showed that there is a trade-off between the order of correlation immunity and the attainable nonlinearity. The *nonlinear order* of h is the maximum number of variables in any monomial in the algebraic normal form of h. If h is mth-order correlation immune and $1 \leq m < k$, then its nonlinear order is at most $k - m$. This is lowered to $k - m - 1$ if h is balanced and $m \neq k - 1$, and this is tight. Since both measures cannot be large, memoriless nonlinear combiners are cryptographically weak.

Combiners with memory were invented in part to remedy this. For example, a combiner with output function

$$h(\bar{x}, \bar{y}) = \sum_{i=1}^{k} x_i + g(\bar{y}) \bmod 2$$

is $(n-1)$st-order immune for any nonzero g and any state change function u. Thus g and u can be chosen to satisfy any nonlinearity conditions. Meier and Staffelbach [26] observed that the correlation immunity of such combiners arises because the linear functions applied to input bits in computing the correlations

fail to take earlier bits into account. However, if at stage i one considers all bits

$$\left\{a_\ell^j : 0 \le \ell \le i \text{ and } 1 \le j \le k\right\} ,$$

then there must be correlations between the ith output bit b_i and linear functions of the form

$$\sum_{\ell=0}^{i}\sum_{j=1}^{k} w_{\ell,j} a_\ell^j .$$

For the summation combiner and for general combiners with a single bit of memory Meier and Staffelbach found explicit linear functions for which these correlations are large. This analysis was generalized to combiners with arbitrary amounts of memory by Golić [12], who showed that if the size of the memory is sufficiently large, then the correlations between inputs and outputs can be kept small.

Nonlinear Filter Generators

A nonlinear filter generator applies a nonlinear function h to the state of a linear feedback shift register to produce the output sequence **b**. Thus if the register has length r, then h is a function from $GF(2)^r$ to $GF(2)$. For speed and ease of implementation it is desirable that h have few terms when expressed as a polynomial. If n is the period of the underlying LFSR sequence, then it is possible to generate any sequence of period dividing n by a nonlinear filter generator. However, when the function h is expressed as a polynomial, it may have as many terms as the period of the sequence. Key [17] showed that if h has degree d then

$$\lambda(\mathbf{b}) \le \sum_{i=1}^{d} \binom{r}{i} .$$

This result was generalized by Chan, Goresky, and Klapper [6] to registers with nonlinear feedback functions. It follows from Key's result that h must have high degree. Lower bounds are the real need for cryptographic purposes but such results have been rare. Kumar and Scholtz [21] showed that if h is a bent function and 4 divides r, then

$$\lambda(\mathbf{b}) \ge 2^{r/4}\binom{r/2}{r/4} \sim 2\frac{2^{r/2}}{\sqrt{\pi r}} .$$

Weaker lower bounds for more general classes of filter generators have been shown by Bernasconi and Günther and Rueppel [31]. It is unknown how to construct filter generators with maximal linear span where h has few terms.

Chan and Games considered the following generalization. Let **a** be an m-sequence over a finite field $GF(q)$. Let $h : GF(q) \to GF(2)$. Let $b_i = h(a_i)$. The sequence **b** is called a *geometric sequence.* If q is even, then h can be represented algebraically and results of Herlestam [16] and Brynielsson can be used to show that if $h(x) = \sum_{i=0}^{q-1} c_i x^i$, then

$$\begin{aligned} \lambda(\mathbf{b}) &= \sum_{c_i \neq 0} \lambda(\mathbf{a})^{||i||} \\ &\le q^{\log_2(\lambda(\mathbf{a})+1)} . \end{aligned}$$

To be cryptographically strong, a register of this size would need a linear span close to $q^{\lambda(\mathbf{a})}$. Chan and Games showed that if q is odd, then $\lambda(\mathbf{b})$ can be made as large as $q^{\lambda(\mathbf{a})-1}$. Furthermore, geometric sequences have optimal autocorrelations (and in some cases low cross-correlations). However, Klapper later showed that if one considers these sequences as sequences over $GF(q)$ (that simply happen to have only two values), then the linear span is low and, by exploiting the imbalance of the sequences, the parameter q can be found with a probabilistic attack [18].

Filter generators are vulnerable to correlation attacks. This was first observed by Siegenthaler [35]. The easiest way to see this is to consider a filter generator whose underlying LFSR has length r as a nonlinear combiner with r input sequences. The LFSRs generating the input sequences are identical, but the initial state of the ith register is the second state of the $(i-1)$st register. Then the same correlation attack that was used on a nonlinear combiner can be used. In fact the attack is now faster since all the underlying registers have the same structure. It is only necessary to cycle through the set of initial states once looking for correlations.

Clock-Controlled Generators

A quite different way to introduce nonlinearity in a generator is to irregularly clock certain parts of the generator. A survey of these clock-controlled generators as of 1989 was given by Gollman and Chambers [13]. In a simple case, two LFSRs are used: L_1 and L_2 of lengths n_1 and n_2, respectively. We are also given a function

$$f : \{0, 1\}^{n_1} \to \mathbf{Z} .$$

At each step we clock L_1 once and extract $f(s_i)$ where $s_i = (s_{i,1}, \cdots, s_{i,n_1})$ is the ith state of L_1. Register L_2 then changes state (i.e., is clocked) $f(s_i)$ times and the bit produced by the last state change is taken as the ith output of the clock controlled generator (if $\mathbf{b}$ is the output from L_2, this is $c_i = b_{\sigma(i)}$, where $\sigma(i) = \Sigma_{i=0}^{i} f(s_i)$). The case when $f(s_i) = s_{i,1}$ is called the *stop-and-go generator* and is weak, since each change in the output reveals that a 1 has been generated by L_1. Also, there is a large correlation between consecutive output bits. The strength is improved by taking $f(s_i) = 1 + s_{i,1}$, giving rise to the *step-once-twice generator.*

For general clock-controlled generators, if ρ_i is the period of L_1 and T is the sum of the f values of the states of L_1 in one period, then the period of the output sequence $\mathbf{c}$ is

$$\rho(\mathbf{c}) = \rho_1 \rho_2 / \gcd(T, \rho_2) .$$

Assuming $\gcd(T, \rho_2) = 1$, the period is maximal. We make this assumption for the remainder of this discussion. The linear span of $\mathbf{c}$ is upper bounded by $\lambda(\mathbf{c}) \leq n_2 \rho_1$, hence is large but not maximal. If L_1 generates an m-sequence, then the stop-and-go generator achieves the upper bound. If L_1 and L_2 generate the same m-sequence, then both the stop-and-go and step-once-twice generators achieve the maximum linear span [1].

Several authors have described correlation attacks on clock controlled shift registers. For example, Golić showed that in some circumstances the feedback polynomial and the initial state of the clocked register can be determined [11].

A variation on the stop-and-go generator, called the *alternating step generator,* was proposed by Günther. Two stop-and-go generators are used, sharing the same control (L_1) register. The outputs are then added modulo 2. Let ρ_2 and ρ_2' be the periods of the L_2 registers, which have lengths n_2 and n_2'. Assume that the control register produces a de Bruijn sequence of period 2^m and the connection polynomials for the L_2 registers are irreducible. Then the output period is $2^m \rho_1 \rho_2$. The output linear span satisfies

$$\left(n_2 + n_2'\right) 2^{m-1} < \lambda(\mathbf{c}) \leq \left(n_2 + n_2'\right) 2^m .$$

Günther also gave conditions under which the distribution of subsequences and the autocorrelations are close to ideal. Unfortunately, the alternating step generator is vulnerable to a divide-and-conquer attack against the control register.

Clock-controlled shift registers can be extended by using a cascade of registers, each output sequence clocking the next register. The structure may be modified so that the output from stage $k-1$ both clocks stage i and is added to the output of stage k modulo 2. A diagram of a cascaded clock controlled shift register of height 3 is given in Fig. 43.5.

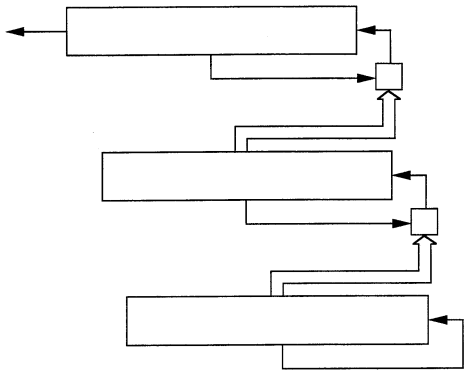

FIGURE 43.5 Cascaded clock controlled shift register of height = 3.

If 0,1 clocking is used (that is, a cascaded stop-and-go generator), each LFSR has maximal period and length n, and all LFSRs have distinct primitive connection polynomials, then the output period is $(2^n-1)^k$ and the linear span is $n(2^n-1)^{k-1}$. For arbitrary s, t clocking suppose the LFSRs have irreducible degree d connection polynomials and period p with $p^2 \not| (2^{p-1}-1)$. Then the output period is p^n and the output linear span is at least $d(p^n-1)/(p-1)$. The distribution of subsequences of any fixed length approaches the uniform distribution as k approaches infinity.

Correlation attacks may be used to recover state information about the last stage of a cascaded clock controlled shift register. Another attack based on iteratively reconstructing the states of the registers is possible in some circumstances [5]. The cryptanalyst is assumed to know the individual shift register sequences but not the correct phase shifts. She attempts to determine the phase shift of each stage in turn, starting with the last stage. In some cases if she guesses the phase of a given stage and reverses the register one step at a time, then the reconstructed output from the preceding stage eventually locks into the correct phase. This allows the reconstruction to be repeated at the preceding stage.

With a *self-clocking generator* a single LFSR is used to clock itself. The case when the clocking function satisfies $f(s_i) = d$ if $s_{i,1} = 0$ and $f(s_i) = k$ if $s_{i,1} = 1$ is called the $[d, k]$ self-decimation generator, to which we restrict our attention. We also assume the underlying LFSR has maximal period $2^n - 1$. The state graph of a $[d, k]$ self-decimation generator may not be purely cyclic. If $d \neq k$, then the (eventual) period is at most $(3/4)(2^n - 1)$. In case $\gcd(d, 2^n - 1) = 1$ and $2d \equiv k \bmod 2^n - 1$ or $2^{n-1}d \equiv k \bmod 2^n - 1$ the period is exactly $(2/3)(2^n - 1)$. The distribution of short subsequences is close to uniform. There is evidence that the linear span is at least 2^{n-1} but this has not been proved. The drawback to the $[d, k]$-self decimation generator is that each output bit reveals a state bit and reveals which state bit is revealed by the next output bit. One way of avoiding this is to use different state bits for output and clocking control.

The Shrinking Generator

A somewhat different type of clocking occurs in the *shrinking generator.* Again, we start with a pair of LFSRs, L_1 and L_2, with lengths n_1 and n_2 and output sequences **a** and **b**. At each stage, if $a_i = 1$, then b_i is output. Otherwise no bit is output. Thus the output **c** is a shrunken version of **b**: $c_j = b_{i_j}$ if i_j is the position of the jth 1 in **a**. If **a** and **b** are m-sequences and $\rho(\mathbf{a})$ and $\rho(\mathbf{b})$ are relatively prime, then **c** has period

$$\rho(\mathbf{c}) = \rho(\mathbf{b})2^{n_1-1} = \left(2^{n_2} - 1\right) 2^{n_1-1} .$$

The linear span of **c** satisfies

$$n_1 2^{n_2-2} < \lambda(\mathbf{c}) \leq n_1 2^{n_2-1} .$$

It can also be shown that the distribution on fixed length subsequences in **c** is close to uniform. One drawback is the irregularity of the output. A string of zeros in **a** leads to a delay in generating the next

bit. Buffering can be used to alleviate this problem. A variation called the *self shrinking generator,* where a single register clocks itself, has also been considered.

Cyclotomic Generator

Ding [9] proved a lower bound on the linear span of a sequence based only on its period. If n is an integer with prime factorization

$$n = \prod_{i=1}^{t} p_i^{e_i} ,$$

q is a prime power relatively prime to n, and $\mathbf{a}$ is a periodic sequence of period n over $GF(q)$, then

$$\lambda(\mathbf{a}) \geq \max \left\{ \text{ord}_{p_i}(q) : 1 \leq i \leq t \right\} .$$

The sphere complexity is similarly bounded. If $k < \min\{||\mathbf{a}||, n - ||\mathbf{a}||\}$, where $||\mathbf{a}||$ is the Hamming weight of a single period of $\mathbf{a}$, then

$$\text{SC}_k(\mathbf{a}) \geq \max \left\{ \text{ord}_{p_i}(q) : 1 \leq i \leq t \right\} .$$

In particular, if the period n is prime and q is a primitive element modulo n, then the linear span is at least $n - 1$, as is the sphere complexity for $k < \min\{||\mathbf{a}||, n - ||\mathbf{a}||\}$. When n is prime, various conditions guarantee that 2 is a primitive element modulo n. For example, (1) $n4t \pm 1$, t an odd prime; or (2) $n = t_1 t_2 \pm 1$, each t_i an odd prime and $2^{t_i} \not\equiv -1 \bmod n$.

Sequences satisfying the hypotheses of the above results can be produced by a class of generators called *cyclotomic generators* whose analysis is based on the theory of cyclotomic numbers. These generators use a base register that counts by ones modulo n. A function h is then applied to the value of the counter to produce an output bit. The simplest case is the cyclotomic generator of order $2k$, for which

$$h(i) = \left(i^{(n-1)/2k} \bmod n \right) \bmod 2 .$$

Here $(x \bmod n) \bmod 2$ means reduce x modulo n to a residue in the range 0 to $n - 1$, then take the parity. It can further be shown that the autocorrelations of these sequences are ideal. Several generalizations of this generator have also been considered by Ding [9].

RC4

RC4 is a byte-oriented stream cipher designed by Rivest for RSA Data Security, Inc. in 1987. It is intended for use in software. Its details were unpublished and proprietary until 1994, when they were anonymously leaked on the sci.crypt newsgroup. The state consists of two nonnegative integer variables x and y, each less than 256, and an array P of 256 bytes. P must contain a permutation of $\{0, 1, \cdots, 255\}$. A sequence of bytes is generated by the pseudocode in Fig. 43.6. All addition is modulo 256.

The key is an array of bytes, $K[0], \cdots, K[m - 1]$ for some m. This is used to initialize the state as follows: The variables x and y are set to 0 and the array P is set to $(0, 1, \cdots, 255)$. Then the RC4 algorithm in Fig. 43.6 is iterated 256 times, with line 3 replaced by

$$y \leftarrow y + P[x] + K[x \bmod m] ,$$

and with line 5 deleted. Finally, x and y are reset to 0. Very little is publicly known about the security of RC4. RSA Data Security, Inc. claims the algorithm is immune to linear and differential cryptanalysis, has no small cycles, and is highly nonlinear.

RC4(**a**)

```
1    while more bytes are needed
2        x ← x + 1
3        y ← y + P[x]
4        swap P[x] and P[y]
5        output P[P[x] + P[y]]
```

FIGURE 43.6 The RC4 stream cipher.

SEAL

Software-optimized encryption algorithm (SEAL) was proposed in 1993 by Rogaway and Coppersmith [29]. Since it is quite new, little is known about its cryptanalysis. SEAL is designed for use in software. It depends on a 32-bit architecture and uses eight 32-bit registers and about 3 kilobytes of cache. It is claimed to have a data rate ten to thirty times faster than DES, the most popular block cipher.

A basic design principle of SEAL is to generate a large table in a preprocessing stage. This stage is relatively slow but is intended to take place concurrently with the (generally slow) key exchange at the beginning of a session. In such a setting the preprocessing of SEAL incurs little extra cost. The table is generated by a complex mix of bit-wise ands, bit-wise ors, bit-wise exclusive-ors, bit-wise complements, concatenations, shifts, and additions modulo 2^{32}.

The input to SEAL is a 160 bit string a and a message size L. For each a, a function SEAL_a is determined from the set of positive integers to the set of infinite binary strings. Encryption is performed by computing the bit-wise exclusive or of the nth message and the first L bits of $\text{SEAL}_a(n)$. In practice only the first $128\lceil L/128\rceil$ bits of $\text{SEAL}_a(n)$ are generated. Again, the computation of $\text{SEAL}_a(n)$ is a complex mix of bit-wise ands, bit-wise ors, bit-wise exclusive-ors, bit-wise complements, concatenations, shifts, and additions modulo 2^{32}, plus table lookups using the tables generated in the preprocessing stage.

The assumed strength of SEAL depends on the fact that, if a is chosen uniformly at random, then $\text{SEAL}_a(n)$ is computationally indistinguishable from a random L-bit function of n.

Universal Security

In this section we consider the existence of universally secure generators from several theoretical viewpoints. We start with complexity theoretic considerations.

Blum–Micali Discrete Log Generator

Blum and Micali designed a generator whose security is based on the assumed hardness of the discrete log problem [3]. Suppose p is a prime number and g is a generator of $\mathbf{Z}_p^*$, the multiplicative group of integers modulo p. If $x \in \mathbf{Z}_p^*$, then the discrete logarithm of x with respect to g is the unique integer k such that $x = g^k \bmod p$. The discrete log problem is to find k given p, g, and x. This problem is widely believed to be computationally infeasible. If x is a quadratic residue modulo p, then its discrete log is of the form $2t$ with $0 \le t < (p-1)/2$. Its square roots are g^t and $g^{t+(p-1)/2}$. The latter is called the principle square root. The discrete log problem is polynomial time reducible to the problem of determining whether an element is a principle square root. Define the predicate

$$\psi_p(x) = \begin{cases} 1 & \text{if } x < (p-1)/2, \\ 0 & \text{otherwise}. \end{cases}$$

The state of a Blum–Micali generator is an element $x \in \mathbf{Z}_p^*$. At each stage the generator outputs $\psi(x)$ and changes state to $g^x \mod p$. It can be shown that if a certain assumption about the infeasibility of solving the discrete log problem with polynomial size circuits is true, then the Blum–Micali generator is perfect in the sense of the subsection "Unpredictability" in Section 43.2 when the initial state (seed) is chosen randomly.

Other Perfect Generators

The Blum–Micali generator is actually an example of a general construction that can be based on any one-way permutation f (in the case of the discrete log generator, $f(x) = g^x$) and binary predicate B on the domain of the predicate (in the case of the discrete log generator, $B(x) = \psi_p(x)$). There is a notion of an unpredictable predicate that guarantees that the resulting generator is perfect. The goal is to design a predicate whose unpredictability is equivalent to some problem that is infeasible. Such a predicate is called *hard core* for f. In reality we have no proof of infeasibility for the problems that arise this way, so belief in the security of such generators depends on belief in the infeasibility of the underlying problem (e.g., the discrete log problem).

One such construction is based on the infeasibility of inverting RSA ciphertexts. If $n = pq$ is a product of two primes and e is relatively prime to $(p-1)(q-1)$, then the domain is $\mathbf{Z}_n^*$. The permutation is $f(x) = x^e$ and the hard core predicate is the least significant bit. It can be shown that if RSA ciphertexts cannot be inverted in expected polynomial time, then the RSA generator is perfect.

Another such construction is based on the infeasibility of computing square roots modulo a product of two primes that are congruent to 3 modulo 4 [2]. This problem is known to be equivalent to factoring the modulus. Here the domain is the set of quadratic residues modulo an RSA modulus (i.e., a product of two large primes), the permutation is squaring, and the hard core predicate is the least significant bit. It can be shown that if it is impossible to compute modular square roots with polynomial size circuits on a polynomial fraction of the moduli n, correctly on all but a polynomial fraction of $\mathbf{Z}_n^*$, then the quadratic residue generator is perfect.

There have been several recent results that show that other bits (in addition to the least significant bit) are hard core, thus expanding the suite of perfect generators. For example, Näslund showed that any bit in a random linear function modulo a random prime is hard core for any one-way function.

Provable Security

Several attacks on stream ciphers synthesize a generator given a prefix of the keystream. The synthesized generator belongs to a specific class of generators $\mathcal{F}$. If enough bits are available, the attack should produce the smallest generator (in the sense of the size of the state space) in $\mathcal{F}$ that outputs the given sequence. The Berlekamp–Massey and the 2-adic rational approximation algorithms are examples of such attacks.

Klapper [19] studied the question of whether there exists a family of generators that resists all such attacks. For a family $\mathcal{F}$ and a sequence $\mathbf{a}$ the size of the smallest generator is denoted $\lambda_{\mathcal{F}}(\mathbf{a})$. Such an attack A is called *effective* if it runs in polynomial time and is successful whenever the number of bits available is at least a fixed polynomial in $\lambda_{\mathcal{F}}(\mathbf{a})$. The existence of an effective $\mathcal{F}$-synthesizing algorithm implies that $\lambda_{\mathcal{F}}(\mathbf{a})$ is a measure of security for stream ciphers, analogous to the linear span. By a diagonalization argument it can be shown that there exists a family of efficiently generated sequences S such that, for any effective algorithm synthesizing generators in a family $\mathcal{F}$, $\lambda_{\mathcal{F}}(\mathbf{a})$ grows superpolynomially in the log of the period of $\mathbf{a} \in S$. Various generalizations of this result are possible for weaker notions of security.

A quite different approach to provable security was taken by Maurer [25]. He considered stream ciphers based on the availability of a public global source of randomness. Maurer described such a *randomized stream cipher* that is perfectly secure with high probability. The proof of this result is based on Shannon's information theory. The sender and receiver need only share a short key, while the cryptanalyst must examine an infeasible number of random bits in order to attack the system. The drawback to this system is the difficulty in making a source of a large number of truly random bits publicly available.

43.4 Research Issues and Summary

In this article we provide a survey of techniques related to pseudorandom sequence generation and its role in cryptography. Stream ciphers, the resulting systems, are generally much faster than other cipher systems. Thus they are useful when high-speed secure communications is needed. Proving their security, however, is more difficult than that of many public key systems. Techniques for generating sequences that have cryptographically strong properties are presented, as well as techniques for cryptanalyzing sequences. A number of measures of randomness are also described.

A variety of sequence generators are presented. Many of these are based on modifications of linear feedback shift registers to eliminate vulnerability to Berlekamp–Massey type attacks. In most cases the best that can be said is that the generators resist certain known attacks and have various desirable randomness properties. In some cases the security of a generator is described in complexity theoretic (and in particular asymptotic) terms. Unfortunately such generators tend to be slow.

A few of the cryptanalytic techniques presented are general and can be tried on any stream cipher. Such techniques give rise to general measures of security. More often, cryptanalytic techniques are specific to generators or classes of generators. Nonetheless, they can sometimes be adapted to other classes of generators. Attempting the cryptanalysis of a generator is important for its certification as a secure system.

One focus of current research is the development of new techniques of keystream generation. There are no known provably secure efficient keystream generators, so their need persists. When each new technique of cryptanalysis is developed, new generators are needed that resist the new attack, as well as all old attacks. The difficulty faced by designers of keystream generators is that the presence of enough structure to prove that a generator resists known attacks and has other desirable properties often leads to the development of new cryptanalytic techniques to which the generator is vulnerable. The ideal would be to design a type of keystream generator that resists all computationally feasible cryptanalytic attacks, is efficient, and has an efficient description. This is a goal for security defined in various models.

Simultaneously, considerable research is focused on developing new cryptanalytic techniques. The challenge is to find exploitable structure in systems that are often designed to have little clear structure or to combine several types of apparently incompatible structure. The search for cryptanalytic tools may at first seem perverse and counter productive. However, when a system has weaknesses it is important that potential users be aware of this. These weaknesses may be known already to hostile cryptanalysts who are unlikely to advertise their knowledge.

43.5 Defining Terms

Autocorrelation: The number of positions where a periodic binary sequence agrees with a shift of itself minus the number of places where it disagrees.

Balance: The number of zeros minus the number of ones in a single period of a periodic binary sequence.

Clock-controlled generator: A keystream generator in which one LFSR is used to determine which output symbols of a second LFSR are used as the final output.

Correlation attack: A cryptanalytic attack on a keystream generator based on improving key search by exploiting correlations between output bits and initial state or seed bits.

Correlation immunity: A measure of resistance of a nonlinear combiner to correlation attacks.

Cryptographically strong pseudorandom bit generator (CSPRB): An efficient family of keystream generators such that it is infeasible to predict bits with probability significantly greater than one half.

Entropy: A formal measure of the uncertainty in a random variable.

Feedback with carry shift register (FCSR): A feedback register similar to an LFSR, but where the addition in the feedback function is performed with carry, the carry being retained for the next stage in extra memory.

Information theory: The mathematical study of the information content of random variables.

Keystream generator: A device or algorithm for generating a pseudorandom sequence.

Linear feedback shift register (LFSR): A device for generating infinite periodic sequences. The state updates by shifting its state vector one position and generating a new state symbol as a linear function of the old state vector. The output is the symbol shifted out of the register.

Linear span: Also called the linear complexity, the length of the shortest linear feedback shift register that outputs a given sequence.

m-Sequence: A maximal period linear feedback shift register sequence.

Next bit test: A family of circuits used to predict the next bit of a sequence given a prefix of the sequence.

Nonlinear filter generator: A linear feedback shift register modified so the output is computed as a nonlinear function of the state.

Nonlinear combiner: A keystream generator in which the outputs of several LFSRs are combined by a nonlinear function. The combining function may have a small amount of memory.

One-time pad: A stream cipher in which the key bits are chosen independently at random.

Pseudorandom sequence: An infinite periodic sequence that behaves like a truly random sequence with respect to various measures of randomness.

Stream cipher: A private key cryptosystem in which the key is added to the plaintext symbol by symbol modulo the size of the plaintext alphabet.

Strict avalanche condition (SAC): A nonlinearity condition. A function satisfies SAC if changing any single bit results in a function uncorrelated with f.

Further Information

Research on pseudorandom sequences and stream ciphers is extensively published in the *IEEE Transactions on Information Theory* and the *Journal of Cryptology.*

Many major results appear initially in the proceedings of the annual conferences Crypto, held in Santa Barbara, California, Eurocrypt, held in various countries in Europe, and Asiacrypt, held in various countries in Asia and Australia. The proceedings of these conferences appear in the Springer-Verlag *Lecture Notes in Computer Science* series. Crypto and Eurocrypt are held under the auspices of the IACR, the International Association for Cryptologic Research.

Many papers have also appeared at specialty workshops such as "Fast Software Encryption", whose proceedings also appear in the Springer-Verlag *Lecture Notes in Computer Science* series.

Information about the IACR and about many conferences on cryptography can be found at the IACR web-site, http://www.iacr.org/~iacr/.

The chapter by Rueppel in Simmon's *Contemporary Cryptography* [36] provides a more detailed summary of the state of the art as of 1990.

Menezes, van Oorschot, and Vanstone's *CRC Handbook of Applied Cryptograpy* [27] provides a thorough summary as of 1996.

A thorough treatment of the basic analysis of linear feedback shift registers can be found in Golomb's classic *Shift Register Sequences* [14].

Many aspects of shift registers, stream ciphers, and linear span are treated in Rueppel's *Analysis and Design of Stream Ciphers* [31].

Many of the more practical aspects of stream ciphers, as well as a thorough bibliography, can be found in Schneier's *Applied Cryptography* [33].

Good sources for the mathematical foundations of the study of pseudorandom sequences are Lidl and Niederreiter's *Finite Fields* [22] and McEliece's *Finite Fields for Computer Scientists and Engineers* [23].

Electronic Cash

Stefan Brands
Brands Technologies

44.1 Introduction

Soon you may find yourself e-mailing bytes representing your money to service providers across the ocean, using a smart card or a handheld computer to pay at your local grocery, and making backup copies to protect your money against hard-disk crashes. Now that technological advances in chip manufacturing have brought vast computing powers within everyone's reach, traditional cash is about to be replaced for an invention based on modern cryptography: electronic cash.

This chapter provides an overview of the state-of-the-art techniques for designing electronic cash systems, without going into great technical detail. We begin by quickly reviewing today's payment forms and analyzing their inherent shortcomings, to motivate the subsequent description of properties that are generally deemed desirable for an electronic equivalent of traditional money.

Traditional Cash Payments

Traditional cash is a bearer instrument that can be used spontaneously and instantaneously, to make payments from person to person without the involvement of a bank. It is the preferred method for low- and medium-value purchases, which make up the bulk of our everyday transactions. Cash payments also

offer privacy, because they are not normally traceable by a third party. Together these factors account for the wide acceptability of traditional cash.

Traditional cash also has several shortcomings. Creating cash that is hard to forge, transporting cash from one place to another, protecting cash transport and storage, and replacing worn out coins and bank notes all make traditional cash very costly to handle for banks. Bank notes are easily destroyed and can be forged using sophisticated color copier machines, coins are too heavy to carry around in bulk, and both are easily lost or stolen. Cash comes in fixed denominations and so typically many coins or bank notes need to change hands to pay a single amount. Because coins and bank notes reveal neither the payer's nor the payee's identity, cash is the preferred method of payment for money laundering, bribery, and extortion. Cash, moreover, can be passed on many times without the need for settlement by a bank, further conflicting with the desire of governmental organizations to trace criminal money. Another shortcoming of traditional cash, one that has become particularly urgent in recent years, is the inherent requirement for physical proximity of payer and payee; coins and bank notes cannot be used for payments over the phone or the Internet.

Payments by Instruction

Some of the problems of traditional cash have successfully been addressed over the past few decades with the introduction of checks, debit cards, and credit cards. Instead of value itself, the payer transfers to the payee an *instruction,* directing the payer's bank to transfer a specified amount. After reception of the transferred instruction from the payee's bank, the payer's bank moves the value from source to destination account, both of which are specified by the payment instruction. Because the actual value resides at all times within the banks, the risks of theft and loss are largely overcome. Checks moreover can be mailed by post, and credit cards can be used over the phone or even the Internet.

Payments by instruction also bring forth several problems of their own, mainly originating from the problem of ensuring their authenticity. Handwritten signatures are easily forged and magnetic stripes copied, PINs can be learned through fake point-of-sale terminals, and specified amounts can sometimes be modified by the payee. This can be addressed in part by upgrading to cryptographic authentication methods in combination with chip cards. Replacing magnetic stripe cards by chip cards with protected memory renders unauthorized card duplication almost infeasible, and fake terminal attacks can be overcome by using cards with a microprocessor that enable a PIN or a biometric to be entered into the card itself. The microprocessor can furthermore be used to compute message authentication codes or, in case it has sufficient processing power, digital signatures; these are much harder to forge than handwritten signatures, and moreover can be verified rapidly and with one hundred percent accuracy by processors in point-of-sale modules. The use of secret keys for cryptographic authentication also enables message encryption for protection against wire-tappers, and hence can protect against wire-tapping of credit card numbers sent across the Internet.

A problem that cannot be addressed by authentication techniques is the need for *on-line* verification of debit and credit card payments; for the former it is inherent, and in case of the latter it is needed (at least as a rule) to protect against overdrawing of accounts. On-line processing makes handling costs significantly higher than for traditional cash and is expensive for payees. A system that requires on-line payment verification moreover can suffer severely from a network breakdown or overload; this can lead to serious delays, and merchants may even have to refuse all payments for a while. Add to this the fact that payees typically need to satisfy stringent registration criteria (such as having a store front), and need to acquire expensive tamper-resistant modules, and it is easy to understand why the acceptability of credit and debit cards is much lower than of cash payments. Only guaranteed checks can be verified *off-line* and without special equipment, but these are not readily issued by banks, do not allow instantaneous payment, and are time-consuming to obtain, verify, process, and redeem.

Another inherent problem is that all payments are effortlessly *traceable* by the bank that performs the actual transfer of value, from source to destination account. This enables intrusive profiling of spending

behavior and, by inference drawing on mathematical techniques such as data mining, all manner of other personal information characteristics. This can lead to junk mail, unjustified or wrong assumptions about personal behavior and other characteristics, and outright discrimination. In the wrong hands, detailed information about spending and inferred habits is a valuable tool for victimizing people, be it by criminals to select their targets, or by political aggressors to track down or lock out opponents. Data protection laws can offer only limited protection against abuse of personal information, and cannot protect against the harmful consequences that may result from payment profiling errors.

Electronic Cash Properties

By combining the benefits of traditional cash with those of payments by instruction, while at the same time circumventing the shortcomings of each, a list of desirable properties for an electronic equivalent of traditional cash can be composed.

As with traditional cash, electronic cash should have high acceptability, should be cost-effective for low-value purchases, and should be suitable for payment from person to person. This means that payees should not need costly tamper-resistant modules provided by financial institutions, nor should they need to meet stringent registration criteria.

It should also be possible to verify payments off-line. Off-line payment capability is a prerequisite for platform independence and hence for cross-platform portability, a key feature of an open system. While for a platform such as the Internet, on-line verification need not become a bottleneck until a substantial number of users are active, for most other platforms on-line verification is not cost-effective and can lead to unacceptable delays. Systems requiring on-line payment verification go against the philosophy of cash payment, and cannot be considered true electronic cash.

As with payments by instruction, electronic cash should offer storage and transportation convenience, while protecting users against loss, theft, and accidental destruction. Physical proximity of payer and payee should not be needed, so that electronic cash payments can be made over the phone or the Internet. Furthermore, all manner of electronic cash handling should be dealt with electronically, to ensure cost-effectiveness, instantaneousness, and accuracy; this includes not only creating, issuing, spending, verifying, counting, transporting and revoking of electronic cash, but also fraud detecting and tracing.

The extent to which an electronic cash system offers privacy of payment may well be the decisive factor in its ultimate acceptance in an open consumer market. Three forms of privacy of payment can be distinguished. The first is known as *confidentiality,* and refers to the ability of account holders to hide transaction details from wire-tappers, and to hide information such as purchase descriptions from the bank. Payment confidentiality can be achieved fairly straightforwardly, by encrypting all sensitive data.

The second form of privacy is the ability to hide who is transacting with who, how many times, and so on. In case of Internet payments and the like, traffic analysis may easily reveal such information, regardless of whether messages are encrypted, unless special measures are taken. We do not consider techniques to hinder traffic analysis in this chapter, because they are platform dependent and not necessarily based on cryptography; for example, in the case of Internet payments one can use IP spoofing or anonymous remailers, and in other circumstances traffic analysis may be inherently difficult.

The third form of privacy is payment **untraceability.** Without the use of proper cryptographic design techniques, every electronic cash payment would cause a unique transaction identifier to end up in the computer files of the bank, and electronic cash would be no better in this respect than payments by instruction. Apart from off-line payment capability, it is the possibility to have payment untraceability that sets electronic cash apart from instruction-based payment forms.

In addition to the objective of untraceability of payments, any acceptable design for an electronic cash system should strike a balance between the perfect two-sided untraceability of traditional cash and the governmental desire to discourage criminal uses, such as money laundering, bribery, and extortion.

Achieving many or all of the properties listed above, without giving in on system security, may seem a daunting if not impossible task. However, as we will see in this chapter, with the right choice of

cryptographic techniques small miracles can be accomplished. We will successively examine payment authentication techniques, ways to represent electronic cash, techniques for electronic cash transfer, techniques to guarantee security even when tamper-resistance is compromised, security measures for account holders, and techniques to achieve payment privacy. This is followed by a detailed description of an example electronic cash system, designed on the basis of the considerations and insights of the preceding sections. At the end of this chapter a summary of the material presented is provided.

44.2 Preliminaries

Modeling Electronic Cash

The flow of electronic cash resembles that of traditional cash, but the minting need not necessarily take place by a central party. When electronic cash is backed by some commodity of generally trusted value, such as gold or traditional cash, different banks can be allowed to mint their own electronic cash. Electronic cash then merely serves as a sophisticated front for exchanging "real" money, and needs to be purchased from a minting bank, like any other good or service.

Each participant in an electronic cash system is represented by at least one computing device. When an account holder of some bank wants to withdraw some electronic cash minted by his bank, his computing device engages in an execution of a *withdrawal protocol* with a computing device of the bank. At the end of the protocol execution, the computing device of the account holder holds an amount of electronic cash, represented in either one of two forms discussed later. The bank has charged the account holder, by taking the equivalent amount of "traditional" money out of his bank account and moving it into a *float account*; the electronic cash is prepaid.

To spend electronic cash at a payee that accepts electronic cash issued by his own bank, the account holder interfaces his computing device to one of the payee, and the two computing devices perform an execution of a *payment protocol.* As a result, the representation of the electronic cash amount held by the account holder's device is adjusted, to reflect the new amount. Since the payment is off-line, the payee's computing device should correspondingly represent the received amount in some form. As we will see later on, the payee's representation of electronic cash need not necessarily be the same as that for the payer, and in fact it preferably is not.

Ultimately a party that holds electronic cash issued by the issuing bank needs to sell it back to that bank, to prevent losing money. At the very least, redemption is needed before electronic cash expires, but depending on system design it may also be needed because electronic cash received in a payment cannot be used for subsequent payments, or only up to a predetermined number of times. To this end the party interfaces his computing device to one of his own bank, and the two devices perform an execution of a *deposit protocol.* As a result, the account of the party depositing the electronic cash is credited by his bank with the equivalent amount of money. In case the crediting bank is the same as the issuing bank, it simply takes the money out of its float account. If, however, the crediting bank is the same as the issuing bank, it needs to settle with the issuing bank. Because the design of a suitable clearing infrastructure, no matter how important, is only remotely related to the cryptographic design of electronic cash systems, we do not discuss this further here.

For design purposes, an electronic cash system can conveniently be modeled as consisting of a single bank, one or more payers and one or more payees, each holding one or more computing devices. The core of a cryptographic design of an electronic cash system then consists of the protocols for withdrawal, payment and deposit. Depending on the functionality of the cash system, other cryptographic protocols may be needed.

The computing equipment of the bank can be viewed as a single device, so that one can speak of "the" computing device of the bank. Furthermore, a distinction can be made between *paying devices* and *receiving devices,* which is especially convenient when studying the security of value-transferring protocols.

Depending on system design, a device can be either a paying device or a receiving device, or both. For example, paying devices serve as receiving devices in the withdrawal protocol.

Regardless of the manner in which electronic cash held by a paying device is represented, it is clear that at least part of the device must be *tamper-resistant,* in order to prevent double-spending of electronic cash. Namely, if an attacker can determine the internal state of a paying device, then state freezing or copying enables the same electronic cash to be spent over and over again. This fraud can be detected, if at all, only once the forged cash is deposited to the bank.

Since tamper-resistant paying devices are typically smart cards, their microprocessors are preferably of low complexity and small size. Chip size increases with storage space, and the ability to rapidly perform public-key cryptographic multiplications requires a special cryptographic co-processor. Increased chip size and complexity contribute significantly to manufacturing cost and negatively affect chip reliability and durability. In "Guaranteeing Your Own Privacy" we will see how paying devices can be used in combination with other computing devices, such as a handheld device when paying in the local mall or a desktop computer when making Internet payments. Such an "interposed" computer of the account holder need not be tamper-resistant, can take over the greater part of the computational and storage burden of the paying device, and can offer many security and convenience advantages to its holder.

Authentication Techniques

Of utmost importance for the security of any electronic cash system is that forgery of electronic cash be infeasible, regardless of the form in which it is represented. This implies that receiving devices must be able to distinguish paying devices from attackers who try to pass for paying devices. To prove their authenticity, paying devices necessarily need to be equipped by the bank with a secret key. Correspondingly, receiving devices must be able to recognize whether they are communicating with a device holding a secret key installed by the bank. This requires a secure authentication mechanism.

An easy way for a receiving device to verify the authenticity of a paying device is to require the paying device to reveal its secret key. This, however, enables a wire-tapper to learn the secret key of the paying device, and to subsequently pass for it. More generally, a secure authentication protocol should resist a **replay attack.** This is an attack in which a wire-tapped *transcript* of an execution of an authentication protocol is reused by the attacker in order to pass for a paying device. **Static authentication,** in which the evidence provided to prove authenticity is always the same, does not offer adequate security.

Prevention of replay requires **dynamic authentication.** The key observation is that instead of revealing a secret key, it suffices to prove knowledge of the key, without revealing it. To achieve this seemingly contradictory task, the paying device must perform a computation that can be performed in a reasonable time span, if at all, only when it knows the secret key. The outcome of the computation must be verifiable by the receiving device, so that it can conclude that the outcome must have been generated by a paying device. To prevent a replay attack, the receiving device must ensure that a different computation is performed each time.

Protocols for dynamic authentication are commonly called *challenge–response protocols,* because the task that the receiving device wants to see performed can be regarded as a *challenge* to the paying device, and the result of the computation as the *response.* When designing a challenge–response protocol, care must be taken that wire-tappers cannot (feasibly) compute the secret key by analyzing transcripts of protocol executions, or by selecting challenges by themselves in some clever way.

Techniques for secure challenge–response authentication vary widely. An important distinction is between *conventional* dynamic authentication and dynamic authentication based on *public-key cryptography.* The following overview is focused especially on the applicability to electronic cash design.

Conventional Dynamic Authentication

In case the receiving device already knows the secret key of the paying device, it can verify a response by computing it by itself, and verifying for equality. The result of a computation that is based on a secret key and a message, and that can be verified only by using the same secret key, is called a MAC (message authentication code). Secure MACs are those that resist cryptanalysis even against active attackers, who can request and cryptanalyze arbitrarily many MACs for self-chosen messages. Secure MACs trivially enable the construction of secure challenge–response protocols: to this end the receiving device requests the paying device to compute a MAC for a challenge (and possibly such information as a device ID number). This is also known as symmetric authentication.

The challenge can be chosen either at random from a large domain, possibly by using a pseudo-random number generator, by concatenating a unique ID number of the receiving device to a sequence number (maintained by the receiving device and incremented upon each execution of the authentication protocol), or by using a sufficiently accurate estimate of the receiver's local time and date. In the case of random numbers an attacker who has learned MACs for many messages has negligible probability that a receiving device subsequently requests a MAC for a message seen earlier; in the case of sequence numbers and time/date estimates, challenges are guaranteed to differ with each protocol execution, but they can be anticipated and may conceivably be of greater value for a cryptanalytic attack.

Because receiving devices must know, or at least must be able to generate, the secret keys of the paying devices with which they need to be able to conduct transactions, receiving devices must be tamper-resistant as well. Therefore they must be issued by or on behalf of the bank, which takes care of installing the secret keys into all paying and receiving devices. When multiple banks each issue their own electronic cash, payees need different receiving devices for each bank. (In practice, this can take the form of different tamper-resistant chips plugged into a single standardized receiving module.)

The particular manner in which the secret keys are installed is of great importance to the system security. Three basic approaches are known.

The System-Wide Secret Key With this method, paying and receiving devices all hold the same random secret key, generated and installed by the bank. A major drawback is that an attacker needs merely be able to extract the secret key of any device, by compromising its tamper-resistance, in order to pass for any paying device.

Diversified Keys This method is similar to the preceding, with the difference that each paying device holds a unique secret key. Each receiving device must be able to recognize the secret keys of all paying devices. Since storing all the secret keys is inefficient, and adding new keys each time new paying devices are introduced is cumbersome, each receiving device stores a master key, generated at random and installed by the bank. The secret key of a paying device is computed as a function of the master key and a unique ID number of the paying device, and is called a **diversified key.** To ensure that the master key cannot be computed from a device secret key, the function must at least be one-way. In practice often a DES-based one-way function is used.

In case a secret key of a paying device has been extracted by an attacker, and used fraudulently, once the fraud is detected the compromised device can be traced and subsequently blacklisted. A weak point is that the master key is present in any receiving device, and extraction enables an attacker to pass for a paying device with an arbitrary ID number.

Certification of Diversified Keys A security improvement over the previous method can be achieved by *certification* of paying device ID numbers. To this end the bank stores into each paying device not only an ID number, but also its own digital signature on that ID number (and possibly also information such as an expiration date). In the payment protocol, the paying device transfers its ID number and the digital signature to the receiving device, which establishes the validity of the ID number by applying the public key of the bank to the digital signature. Message authentication then proceeds as with the preceding method.

The advantage over the diversified key method is that an attacker who knows the master key cannot pass for an arbitrary paying device, since he cannot forge signatures of the bank. Hence the attacker can pass only for a paying device for which he has learned the ID number and the digital signature, which conceivably makes it easier for the bank to trace the fraud.

Dynamic Authentication Based on Public-Key Cryptography

The vulnerability that is caused by the omnipresence of a master key can be removed by using *asymmetric* instead of symmetric authentication. As before, to prove its authenticity to a receiving device, a paying device computes a response based on its secret key and a challenge; but this time the receiving device verifies the result by applying the corresponding *public* key of the paying device.

As with the method of the system-wide secret key, it is not acceptable that all paying devices use the same secret key, and storing the public keys of paying devices into receiving devices is problematic for the same reasons as with the diversified key method. Instead, paying devices should provide their public keys to receiving devices during payment. Receiving devices must then be able to verify the validity of public keys, to which end the bank must certify the public keys of all paying devices. MAC certification voids the security benefits of public-key cryptographic authentication, because the bank's authentication key must be known to all receiving devices, so that only digital signatures are acceptable for certification. This also has the advantage that a single receiving device can be used to receive electronic cash issued by different banks.

Two basic public-key cryptographic techniques are known to design secure challenge–response protocols, *zero-knowledge authentication* and *digital signatures.* Zero-knowledge techniques can be used to design authentication protocols for which active attackers, who are allowed to cryptanalyze many protocol transcripts for self-chosen challenges, provably cannot learn any useful information beyond the public key.

In a secure digital signature scheme, it is infeasible for active attackers to subsequently forge a new (message, signature) pair. Hence a secure method of digital signing can be used effectively as a proof of knowledge of the secret key used for signing, without revealing "useful" information to attackers. A drawback is that the resistance against cryptanalytic attacks is harder to prove than for zero-knowledge authentication. On the other hand, a very important advantage of digital signatures over zero-knowledge authentication, as well as over conventional dynamic authentication, is that a digital signature constitutes an unforgeable transcript of a proof of knowledge of the secret key. It also demonstrates that any other information included in the challenge message, such as an amount, has been agreed to by the signer. A transcript of a protocol execution can therefore be used by a receiving device to demonstrate to the bank that a transaction has taken place; this does not require trust of the verifier in the tamper-resistance of the receiving device, and in fact receiving devices need not be tamper-resistant at all.

Many digital signature schemes, such as the RSA scheme in [35] and the Schnorr scheme in [36], are based on number-theoretic primitives. One-way functions built from block-ciphers (such as DES) can be processed two to four orders of magnitude more efficiently, and are of significant interest for electronic cash design because they allow implementation on paying devices with low-cost microprocessors. For this reason, we will now review several of these efficient schemes.

Lamport Signatures The first signature method we consider is the Lamport signature scheme [29]. The public key of a paying device is a set of $2k$ numbers, for an appropriate security parameter k, of the following form:

$$(f(s_{01}), f(s_{11})), (f(s_{02}), f(s_{12})), \ldots, (f(s_{0k}), f(s_{1k})), \tag{44.1}$$

and the secret key consists of the $2k$ preimages s_{ij}. The function $f(\cdot)$ is a one-way function that can be evaluated rapidly; an example is the function that assigns to a 55-bit input x the DES encryption of a fixed message, computed using the 56-bit key that is obtained from concatenating 0 to x. For storage efficiency,

the s_{ij} can be generated in a pseudo-random manner from a single secret, for example by applying a one-way function to i, j, and a randomly generated seed that is kept secret by the paying device.

To compute a Lamport signature on a message m of binary length k, the paying device sends to the receiving device a certificate of the bank on the public key. In addition, it releases, for each bit m_i of m, either $(s_{0i}, f(s_{1i}))$ or $(f(s_{0i}), s_{1i})$, depending on whether m_i is zero or one.

With this method, the binary length of a signature is $2k$ times the binary length of preimages of $f(\cdot)$, assuming inputs and outputs have the same length. In a practical implementation this typically exceeds storage requirements for, say, RSA signatures by an order of magnitude. As noted by Lamport, an alternative way to compute signatures is for the paying device to release a distinct subset of preimages for each message: this enables the signing of messages almost twice as long, using the same key set-up. Another method to achieve the same efficiency improvement is due to [32], in which it is proposed to expand all k-bit messages into codewords, by appending a count of the number of zero-bits; a message can then be signed securely by using a public key consisting of $k + \lceil \log_2 k \rceil$ instead of $2k$ ordered images of secret preimages.

Matrix-Based Signatures A further significant improvement in signature storage can be obtained by an improvement of Merkle [31]. In this improved method a secret key for a paying device consists of a matrix of r rows by $2c$ columns, which for explanatory purposes is best thought of as two matrices of r rows by c columns each, referred to as a "message" matrix and a "control" matrix, respectively. A key is generated by filling both matrices in a special way. To fill matrix j, for $j \in \{1, 2\}$, c random numbers, $s_{1j}, \ldots, s_{cj}$ are generated, and these are used to fill out the rth matrix row. The rest of the matrix is filled out row by row by applying the hash function $f(\cdot)$, as follows:

$$\begin{pmatrix} f^{r-1}(s_{1j}) & f^{r-1}(s_{2j}) & \ldots & f^{r-1}(s_{cj}) \\ \vdots & \vdots & \vdots & \vdots \\ f(s_{1j}) & f(s_{2j}) & \ldots & f(s_{cj}) \\ s_{1j} & s_{2j} & \ldots & s_{cj} \end{pmatrix} \tag{44.2}$$

The top rows of the two matrices are fed into a one-way hash function, referred to as a *compression* function, and the result is the public key for the paying device.

Using this key pair set-up, the paying device can sign any one of up to r^c messages. To sign a message of $\lfloor \log_2 r^c \rfloor$ bits, the message is first expanded into r-ary representation. Denoting the r-ary representation of m by $m_1 m_2 \cdots m_c$, the paying device releases $f^{r-1-m_i}(s_{i1})$ from the message matrix and $f^{m_i}(s_{i2})$ from the control matrix, for each $i \in \{1, \ldots, c\}$. As an example, consider $r = 4$ and $c = 3$. To sign the 6-bit message 010011, with 4-ary expansion 103, the paying device releases the numbers marked by the boxes:

$$\overbrace{\begin{pmatrix} f^3(s_{11}) & \boxed{f^3(s_{21})} & f^3(s_{31}) \\ \boxed{f^2(s_{11})} & f^2(s_{21}) & f^2(s_{31}) \\ f(s_{11}) & f(s_{21}) & f(s_{31}) \\ s_{11} & s_{21} & \boxed{s_{31}} \end{pmatrix}}^{\text{Message matrix}} \quad \overbrace{\begin{pmatrix} f^3(s_{12}) & f^3(s_{22}) & \boxed{f^3(s_{32})} \\ f^2(s_{12}) & f^2(s_{22}) & f^2(s_{32}) \\ \boxed{f(s_{12})} & f(s_{22}) & f(s_{32}) \\ s_{12} & \boxed{s_{22}} & s_{32} \end{pmatrix}}^{\text{Control matrix}} \tag{44.3}$$

To verify the signature, the receiving device computes the top row of each of the two matrices, by applying the appropriate number of one-way function applications to the matrix entries provided. By applying the compression function to the two computed top rows, it can then check whether the result matches the public key of the paying device.

It is important to note the need for the control matrix. If only the message matrix were used, then wire-tapping of a device signature for a message would enable signature forgery for any message that has digits in its r-ary expansion that all are no greater than those in the same position in the r-ary expansion of the first message. With the control matrix, in effect an additional "control" message has to be signed, for which each digit is equal to the additive inverse of the message. Releasing values higher up in the message

matrix thus requires releasing values moving downward in the control matrix, which requires the ability to invert $f(\cdot)$.

Storage of the secret key of the signer can be compressed using the same technique as for Lamport signatures. In particular, in practice the matrix rows may be generated from a short random seed in pseudo-random manner. A further improvement can be achieved by reducing the number of columns needed for the control matrix; instead of using one "control digit" per message digit, one can get away with logarithmically many control digits (and hence logarithmically many columns for the control matrix) by summing the digits of the message and signing the resulting number in a suitable expansion. Note that the dimensions of the message matrix and the control matrix need not be related; we assumed this merely for explanatory purposes.

The security of the Lamport and the matrix-based signature methods has recently been studied in detail in [23]. A further efficiency improvement can be found in [37], where it is observed that a matrix can be used for a larger message space, by defining a one-to-one relation between messages and subsets of entries in the matrix, such that no subset can be computed from any other and each subset contains exactly one entry in each column. This condition is fulfilled by taking entries according to a Latin square, or more generally by taking all subsets with entries such that the sum of the rows that the entries are in is a constant. A generalization of this technique to directed acyclic graphs is studied in [3].

Tree Authentication A serious drawback of both the Lamport and the matrix-based signature methods is that it is insecure for the bank to let paying devices sign more than once with respect to the same public key. As an extreme example, consider a wire-tapper who intercepts two signatures made by the same paying device, in either signature scheme, one for the message having all r-ary digits equal to zero and another having all r-ary digits equal to $r - 1$ (with $r = 2$ for the Lamport signature scheme); from then on he would be able to forge signatures of that paying device for any message. Signature schemes in which a public key may be used for signing only a single message are called *one-time* signature schemes.

An extension of one-time signatures, due to Merkle [32], enables paying devices to use a single certified public key for signing many messages, using a one-time signature for each. The method preserves much of the computational efficiency of the one-time signature scheme, and can be implemented in a standard 8-bit smart card microprocessor. To illustrate the technique, we use for concreteness the matrix-based one-time signature method as the basic building block, following Merkle; it will be clear that this technique can also be applied to any other one-time signature method. Viewing the message matrix and the control matrix as a single matrix, the idea is to take multiple matrix instances as leaves in a tree. Each node value in the level just above the leaves is computed by compressing the top rows of the child matrices. All the other node values in the tree are computed by compressing the child node values, and the value of the root node serves as the public key of the paying device.

To compute a digital signature on a message, the paying device uses a matrix in a leaf of the tree that has not been used before. In addition, the paying device must release the compression values of sufficiently many nodes, to enable the receiving device to compute the root value and thus to verify the public key. In case of a binary tree, the paying device to this end releases the compression result for the sibling leaf matrix and, for each of the internal nodes in the path from the leaf used to the root, the value of the sibling node. A binary tree of depth n enables the paying device to securely make 2^n signatures with respect to the same public key.

As with the one-time signature methods, the key storage space for the paying device can be reduced by generating the bottom rows of the leaf matrices all from a single secret. Only the seed and the certificate on the root value then need to be stored by the paying device. With respect to dynamic storage and computational efficiency for the paying device, one-time signatures are best used up from the leftmost to the rightmost leaf in order. As shown in [32], it is then possible to generate the additional node values for a new one-time signature in an efficient way from the additional node values of the previous one-time signature. According to later investigations, symmetric tree structures are not optimal in this respect; it is better to use a rake-shaped form.

44.3 Electronic Cash Techniques

We are now prepared for an explanation of the techniques for electronic cash design.

Representing Electronic Cash

The presentation thus far has been independent of how electronic cash is represented. Two fundamental ways exist for representing electronic cash in computing devices, whether paying or receiving devices. First is to indicate an amount of electronic cash by means of the value of a counter, maintained in a chip register. For example, 100 electronic dollars spendable up to cent granularity would be represented by a counter value of 10, 000. This representation is often referred to as **register-based cash.** Since money can be forged when counters can be bypassed or updated without bank authorization, the security of systems using this representation of electronic cash relies critically on tamper-resistance.

The other way to represent electronic cash is in the form of cryptographic tokens that are digitally signed by the bank. To each token at least a fixed denomination and currency are assigned, and possibly also attributes such as an expiration date and how many times it may be passed on. The tokens are called **electronic coins,** and must be unforgeable and verifiable solely by using the signature public key of the bank. In its simplest form, each coin is a different (message, signature) pair, from now on referred to as the *two-part form* for coins. The denomination and currency, and any other attributes, can be encoded into the message, or can be indicated by the particular key used by the bank to compute its digital signature. The security of electronic coins relies crucially on the secrecy of the bank's secret key for signing.

Each of the two methods for representing electronic cash has its own characteristic implications for security, functionality, and efficiency of a cash system. The register-based representation has the advantage over electronic coins that storage space is minimal. In contrast, for each electronic coin, storage space must be allocated. Coin verification moreover inherently requires the ability to verify digital signatures, which is more costly than verifying MACs. Furthermore, the complexity of communication and computation for coins increases with the number of coins needed to form an amount (although for some cryptographic embodiments, techniques are known to trade storage space against computational requirements). Another disadvantage is that when coins of appropriate denomination are not at hand, a payment requires change from the receiving device or a new withdrawal. In contrast, with register-based cash any amount less than the current register value (or a predetermined maximum) can be paid.

Cash held by paying and receiving devices can be either register-based or in the form of electronic coins, and within the same system any of the four possible combinations can make sense. Paying devices may even hold part of their value in the form of electronic coins, and the rest in the form of register-based cash (see "Discussion"). The implications of the various combinations will become clear in the rest of this section, and in particular in "Privacy of Payments" we will see that there are valid reasons for preferring coins over register-based cash.

Transferring Electronic Cash

To transfer electronic cash securely from a paying device to a receiving device, secure authentication by the paying device is required. The techniques for authentication detailed in "Authentication Techniques" can all be used in combination with either form of electronic cash representation, but significant differences exist in the manner in which this is accomplished. In any case, the internal cash balance (whether register-based cash or in the form of coins) of a paying device should be decreased before transferring the electronic cash; otherwise the transaction could be interrupted by the holder of the device between the sending of the electronic cash and the internal adjustment (and we do not want to depend on the receiving device to send an acknowledgment).

Transferring Register-Based Cash

When combining an authentication method with a register-based cash representation for paying devices, not only the paying device but also the amount that is transferred must be authenticated. The paying device must decrease its register value to reflect the amount that is transferred, and of course it must have been programmed by the bank to do so only when its current value represents an amount exceeding the payable amount.

In order to authenticate the amount, it can be encoded into the challenge. Because for security the varying part of the challenge must remain intact, the resulting challenge becomes longer. In case a correct response is returned, the receiving device is assured not only that the other device is a paying device, but also that the paying device has decreased its local balance by the specified amount (assuming that its tamper-resistance has not been broken, of course).

The receiving device can store the transferred cash either as register-based cash or in the form of an electronic coin. In the case of zero-knowledge authentication, or authentication by means of a MAC, only the former representation can be used, since the receiving device does not receive information that could only have been created by a paying device or by the bank. In the case of authentication by means of a digital signature computed by the paying device, the digital signature received can serve as an electronic coin, having a denomination specified by the challenge message that has been signed. Alternatively, the use of digital signatures only serves as a more efficient alternative to zero-knowledge authentication (less interaction) and to make an unforgeable transaction log for use by the bank, and the receiving device stores the amount received in the form of register-based cash; a system based on this approach has been proposed in [24].

In case the receiver stores the received amount in the form of a coin, either the coin may be passed on for a subsequent payment, or it can only be deposited. In the latter case one speaks of an **electronic check** payment, because the paying device fills out the amount at payment time and signs it in an unforgeable manner. A check that has not yet been filled out is called a blank check; it has no value when it is issued, and hence need not be prepaid. An important aspect of electronic check payment is that the bank does not need to trust in the tamper-resistance of receiving devices. For security, blank checks should have a maximum spending limit, assigned by the bank at the time of issuing.

Authentication of the paying device can also take place in an indirect manner, by using a *session key*. In the case of conventional authentication, to this end the paying device sends its ID number to the receiving device, which uses the master key to compute the diversified key of the paying device. The receiving device then sends a random challenge to the paying device, and both parties use the secret key of the paying device to compute a MAC for the challenge. However, rather than the paying device sending the MAC to the receiving device, as a response, both parties regard it as a session key. Further messages, such as for the transfer of an amount, are authenticated and/or encrypted using the session key. Since these tasks can be performed only if the session key is known, valid MACs and/or messages decrypting to meaningful messages convince the receiving device indirectly that the other device must be a paying device.

In the case of public-key cryptographic authentication, the two devices can send their certified public keys to one another, and develop a session key by means of Diffie–Hellman key exchange [21] or another method. The session key can be used to compute MACs for subsequent messages and/or to symmetrically encrypt messages. As with session keys derived from MACs, the ability to do any of the above demonstrates indirectly to the receiving device that the other device is a paying device. In contrast to session keys derived using conventional authentication, no master key needs to be held by devices outside the bank.

Alternatively, the following public-key cryptographic technique can be used to form a session key. The bank provides each tamper-resistant paying device with a unique secret key and a corresponding public key. The secret key is the trap-door of a trap-door one-way function $f(\cdot)$, specified by the public key of the device. To transfer cash to a receiving device, the paying device sends to the receiving device its public key and a certificate for it of the bank. The receiving device generates a random challenge x in the domain of $f(\cdot)$, and sends $f(x)$ to the paying device. The paying device uses its trap-door to uncover x,

and both devices use x, or a part of it, as the session key. Again, the actual transfer of the amount can be authenticated by means of a MAC or a digital signature. An advantage over the preceding method is that much faster cryptographic embodiments of this technique for forming session keys are known.

In case of conventional dynamic authentication it is sometimes preferable to reverse the roles of devices that hold a secret master key and devices that hold diversified secret keys. When receiving devices hold diversified keys and paying devices a master key, electronic cash transfer can take place based on the following observation: the ability of a paying device to compute a MAC using the secret key of the receiving device demonstrates to the receiving device that the device it is communicating with knows the master key, and hence that it must be a paying device. This is particularly useful in the withdrawal protocol, because it enables the bank to issue register-based electronic cash to paying devices without having to provide these with its master key.

Transferring Electronic Coins

To issue electronic coins to a paying device of an account holder, the bank computes digital signatures on distinct messages, sends these to the device (possibly encrypted to prevent wire-tapping) and debits the account of its holder by the total value of the coins. To make a payment, the paying device first determines whether coins of appropriate denominations are present. If the amount cannot be made up, either an excess amount must be formed and the receiving device must supply change, or first another withdrawal must be performed.

When coins are in the two-part form, the receiving device must be tamper-resistant and the coins must be encrypted before being transmitted, to protect against coin theft or copying. When using conventional authentication, a session key can be formed by the paying and the receiving device, which is then used by the paying device to encrypt the coins. Before sending out the coins, the paying device erases the coins from memory. The receiving device decrypts, verifies the coins using the public key of the bank, and stores them. Depending on the number of times the coins may be passed on, the receiving device can later on either deposit the coins or use (some of) them to make a payment. As we have seen, the presence of master-keys in devices outside the bank can be avoided by forming session keys using a public-key cryptographic method.

The need for receiving devices to be tamper-resistant can be avoided by defining a coin to be a triple consisting of a secret key, a corresponding public key, and a certificate of the bank on the public key. From now on this is referred to as a coin in the *three-part form.* The secret key of the coin belongs to a paying device, and at least part of it may not be known to anyone else than the device itself (and perhaps the bank). For each triple, the bank charges the account of the device holder for the value of the coin. To spend a coin, the paying device computes a digital signature on a challenge message of the receiving device (zero-knowledge authentication makes the approach pointless), using the secret key of the coin triple, and sends it to the receiving device, together with the public key and the certificate of the coin triple. The receiving device can verify the payment by using the public key of the bank. The received coin cannot be passed on, since the secret key of the coin has not been divulged by the paying device and in a subsequent payment another challenge will have to be signed. Consequently, the receiving device can only deposit the coin. By encoding into the challenge message a unique account identifier, uniquely associated by the bank with the account of the holder of the receiving device, it is effectively ensured that a wire-tapped coin cannot be deposited to another account. Note that this technique can also be applied to electronic checks.

Payments with electronic coins in the three-part form are very similar to electronic check payments. They differ in that for check payment a register-based cash representation is used and blank checks can be issued free of charge; the amount payable is encoded into the challenge message. In contrast, electronic coins are prepaid at withdrawal time, for their denomination value. Furthermore, each electronic coin is a new triple from the bank, while check payments can be made using a single triple (secret key, public key, certificate), installed by the bank in an initial stage. For greater efficiency, the bank can program paying devices such that they assist in spending coins in the three-part form a predetermined number of times

greater than one (a k-spendable coin at withdrawal time then must be prepaid for k times the coin value), but a limit is inevitable in order to determine the value for which the token must be prepaid.

When Tamper-Resistance is Compromised

Apart from stealing the secret key of the bank or discovering an algorithmic break or breakthrough (such as how to invert functions that are believed to be one-way), there are two ways in which an attacker may be able to forge electronic money. Thus far we have only touched on the possibility that tamper-resistance might be compromised, and investigated value transfer methods under the assumption that secret keys in tamper-resistant devices cannot be physically extracted by attackers. In reality, there is no such thing as tamper-proofness. Experience has shown that organized crime can hire expertise comparable to that in national laboratories, and even hackers nowadays have access to sophisticated tools. Moreover, care must be taken that device secrets cannot be extracted in much simpler ways than by direct read-out; see, for example, recent research results on cryptanalysis in the presence of induced hardware faults, initiated by [4]. When secrets can be extracted from paying or receiving devices, nothing distinguishes counterfeit from cash issued by the bank. What financial damages can this result in?

Tamper-resistance is best viewed as a matter of economics. Roughly speaking, a technology for tamper-resistance offers adequate security for the bank if the required cost for breaking tamper-resistance exceeds the fraudulent profit that can be made as a result. When estimating the expected fraudulent profit that can be made in an electronic cash system, one also needs to take into consideration the economics of large-scale cracking; to crack a single smart card, equipment and expertise running into hundreds of thousands of dollars may be needed, but this is largely a one-time investment. The damage that can be done ultimately depends on the measures incorporated into the system for preventing or discouraging forgery of electronic cash.

Fraud Detection

Of primary importance is the capability of the bank to *detect* whether unauthorized electronic cash is being introduced into the system. Unless special measures are incorporated, nothing prevents the bank from accurately keeping track of the electronic cash held at various moments in time by the paying and receiving devices of each of its account holders. To keep track of the flow of electronic cash between devices, transaction transcripts that reveal at least how much cash has been transferred must regularly be made available to the bank. If not, then the bypassing of registers of compromised paying devices, or the multiple spending of coins, cannot be detected in any other way than through the economic side-effect of hyper-inflation. With sufficiently detailed and regular transaction monitoring, the bank can at the very least detect whether more electronic cash is circulating than it has actually issued.

Electronic coins and checks in this respect have an important advantage over other methods: the transaction record is tied in with the received value, into the digitally signed message of the paying device, and hence received coins or checks cannot be deposited without automatically also revealing the corresponding transaction logs. There is also an important distinction between electronic coins and electronic checks. Instead of double-spending a check, an attacker can also make a profit by spending it for the maximum spending limit, while bypassing the register in the paying device. The bank can detect this only by keeping track of the balances of all paying devices. If such a "shadow" balance ever drops below zero, it is clear that forgery has taken place. With electronic coins, the only way for an attacker to make a fraudulent profit is by double-spending withdrawn coins, and so any forgery of electronic cash can alternatively be detected by the bank by maintaining a list of all deposited coins and checking at each deposit for double-spending. This distinction may not be relevant in case checks and coins are fully traceable, because in effect the same intrusive transaction logging takes place. However, it is crucial when privacy measures need to be incorporated, as we will see in "Privacy of Payments."

Fraud Tracing

In case a master key is present in devices outside the bank, an attack on the master key enables cash forgery that cannot be traced to a single device, at least not on the basis of transaction logs. With conventional authentication methods, the ability to extract the master key enables an attacker to perform the authentication for any paying device. When cash held by paying devices is in register-based form, the attacker can forge MACs for any legitimate amount, for any paying device.

In order to be able to *trace* devices that have been compromised, rather than merely those that have been passed for, the bank should not deploy system-wide secret keys. This calls for cash transfer based on public-key cryptographic authentication. When coins in the two-part form are transferred in encrypted form, an attacker needs to wire-tap and decrypt or to physically extract coins from the paying device or the receiving device, in order to double-spend coins. Even though in these cases the bank can determine which devices have been passed for thus far (to this end, transaction dumps should reveal the ID numbers of paying devices), it has no way of tracing the source of the fraud. Namely, when a coin in the two-part form has been double-spent, it is not clear whether the attack has been on the paying device or on any of the receiving devices in the chain of payments with that coin.

An important advantage of coins in the three-part form over coins in the two-part form is that a coin in the three-part form can be double-spent only by physically extracting the coin secret key from the paying device in which the coin is stored; short of a physical attack on the paying device, the secret key of a three-part coin never leaves the paying device. By keeping track of which paying device has stored which coin secret keys, any forgery of money, no matter how little, can always be traced by the bank to the compromised paying device.

Fraud Liability

When counterfeit can be traced to a specific device, it is not necessarily the case that its holder is a criminal. After all, the device might have been compromised by a thief. In order to be able to point the finger to the holder of the device on firm grounds, the bank must require all its account holders to comply with mechanisms for reporting loss, theft or hardware defects. It should also issue personalized paying devices, that may not be swapped. This can easily be achieved by issuing cards with an access control mechanism, such as a PIN or biometric verification; as will be discussed in "Preventing Loss," this is also desirable for account holders, in view of loss tolerance.

Furthermore, measures to ensure that thieves cannot operate stolen devices can be incorporated. In this respect, however, little added value comes from protecting tamper-resistant devices with PINs, passwords, or biometric access mechanisms, because it can be expected that a hardware attacker can bypass these as well. However, a special use of a secret access code can offer added security. To this end the secret key of a paying device is computed as a function of information held by the device and secret access information that is provided by its holder. Each time after having used the secret key to perform a transaction, the device erases it from memory together with the provided access information. This ensures that the secret key is never present for a long time in the memory of the computing device, and is never stored in nonvolatile memory. A randomly chosen eight-character password suffices to prevent a successful exhaustive search using currently available technology. In case a successful forgery due to the compromise of tamper-resistance is traced to a specific device, its holder is either a fraud or has been very sloppy with the secret access information.

To be able to noncontestably demonstrate that a forgery has been made using the keys held by a certain paying device, the trace information that becomes available to the bank in case of forgery should be such that not even the bank itself could have computed the trace information, had there been no forgery. For example, this evidence could be the secret key that the paying device uses to compute digital signatures at payment time (for checks or coins in the three-part form), or the bank's ability to show $k + 1$ signatures with respect to the same secret key of a device that has been programmed to compute only k signatures with the same key. To this end, paying devices must be able to choose their own secret keys, unknown to

the bank, which calls for at least some of the paying device's operations to be under the control of its holder. We will defer a discussion of how to achieve this to the section on "Guaranteeing Your Own Privacy," since this scenario is also very important to achieve privacy of payments.

Fraud Containment

When forgery of money can be traced to paying devices, the bank can blacklist the devices. To this end, it places the device ID numbers (or ranges thereof) in a list that is regularly distributed to all receiving devices, for example whenever these perform a deposit. Alternatively, the bank can blacklist (one-way hashes of) the secret or public keys used by the compromised devices for making payments. Furthermore, the ability to trace compromised paying devices may suffice to stop the fraudsters from continuing their fraud.

In case tracing of compromised devices is not possible, the bank can stop further fraud only by revoking its own keys. In case of conventional authentication this requires the distribution of a new master key, and in case of public-key cryptographic authentication a new public key for certification must be made available.

By refreshing master keys and certification keys on a regular basis, indicated by expiration dates, containment can be obtained even for frauds that are difficult to detect. For the same reason, it is desirable that tamper-resistant devices can make and/or receive payments only until a built-in expiration date.

Security for Account Holders

The major concern thus far has been security for the bank against forgery. For account holders, other security aspects are of importance. Firstly, the electronic cash held by a device should not disappear in any other way than by spending it at the approval of its legitimate holder. Secondly, it should not be possible for an attacker to redirect a payment to a party other than that intended by the legitimate holder of the device. Thirdly, whenever the behavior of an honest account holder is disputed, by the bank or another party, the account holder should be able to substantiate his innocence; this is also in the bank's interest, as discussed in "Fraud Liability."

Preventing Loss

In general, any lost electronic cash that cannot redeemed by the bank, for instance because proper recovery measures have not been incorporated, results in a profit for the bank. Once it becomes aware of the loss, the bank can take the value out of the float account.

There are various ways for an account holder to lose electronic cash. Firstly, the contents of his device may be garbled because of a device crash or a hardware fault, or his device may get lost or stolen; measures to protect against these events are referred to as loss-tolerance measures. Secondly, a payment transaction can be interrupted with the effect that the paying device has debited the payable amount while the other device has not received it; this must be protected against by fault-tolerance measures. Thirdly, another party may be able to withdraw from his account at the bank. Finally, in case of a receiving device that is not tamper-resistant, an attacker may have the device accept bogus money by modifying its software or by substituting its copy of the public key of the bank.

Loss-Tolerance Loss-tolerance is of concern for both paying and receiving devices, and requires that a destroyed, lost, or stolen amount of electronic cash can be recovered. Recovery from a lost or stolen device requires greater caution by the bank than recovery from a crash. Namely, in the case of a crashed device the bank can scrutinize the device to determine whether there is any chance of its holder having extracted the secret key (or having attempted to do so), while in the case of loss or theft the bank cannot *a priori* distinguish between a victimized account holder and one faking loss or theft. In view of this, tamper-resistant devices at the very least should have a suitable access control mechanism (PIN, password, or biometric), so that another party cannot spend (or deposit to their own account) the cash held by a lost

or stolen device without breaking its tamper-resistance. The bank should also require timely reporting of lost or stolen devices, so that device ID numbers, or withdrawn coins or blank checks, can be blacklisted.

The recovery itself can be done either by the victimized account holder himself or in cooperation with the bank. The former is possible only when the account-holder is able to regularly make backup copies of the contents of his device. In systems based on electronic coins in the three part-form or electronic checks, this measure can easily be applied for receiving devices, since these need not be tamper-resistant and received cash can be deposited only to the account specified in the digitally signed challenge message.

Cooperation with the bank is needed whenever a paying device crashes, or a receiving device that holds a secret key of the bank, because parties other than the bank cannot make backup copies of the secrets in these devices. In systems in which the bank can determine how much was present in the device before it crashed, for example by examining transaction logs and perhaps also information of the user about his most recent payments, the bank can issue new device and adjust its cash representation to reflect the value at the moment of the crash, or credit the account of the account holder for the lost value. A discussion of several loss-tolerance schemes for register-based cash can be found in [38].

In case a device is reported to have been lost or stolen, the bank should delay reimbursement, if necessary until the current version of electronic cash has expired, to make sure that cash can either be reimbursed through recovery or be spent by means of the normal paying protocol, but not both. Expiration dates can be built in by the bank changing its keys every now and then; this is desirable anyway, for the purpose of containment in the case of theft of the bank's own secret keys.

In "Discussion" we will see that loss-tolerance can be implemented even in case payments are untraceable.

Fault-Tolerance Fault-tolerance is mainly an implementation issue. To cope with transaction interruption, a device should at all times be prepared to resend the last message it sent out. For security, a device should as a rule resend only exactly the same message that it sent out previously (of course without modifying its internal cash representation a second time). When setting an interruption flag before sending out a message for the first time, upon reset the device can infer from the flag that it needs to do a re-transmittal. Once an acknowledgment is received (this can be implicit in the response message of the other device), or after a time-out, the device can clear its interruption flag. New actions are performed only once the flag has been cleared again. Transaction processing is a specialty in its own right, and the above is obviously an oversimplication to convey the general idea. A thorough account of transaction processing principles and methods can be found in [26].

Account Access Control In order to prevent withdrawal from account by an unauthorized party, the bank should grant account access only to parties that are properly authenticated. To this end, a MAC or a digital signature of the account holder must be required. In the former case, the secret key needed to gain access to an account is known also to the bank, and fraudulent parties (such as bank employees), may be able to gain access to the key. By digitally signing crucial parts of the withdrawal request, the requested amount, and date and time of the request (and perhaps also the most recent account balance), an account holder can always disavow an unauthorized withdrawal. Of course, withdrawal requests must also be protected against replay attacks; for this purpose each message should contain a fresh part (i.e., an account access sequence number, a random challenge, or a time/date estimate), that must be signed along with each request message.

Software Integrity An attacker who gains access to a receiving device must be prevented from modifying the software in order to have it accept bogus information. In case the receiving device is not tamper-resistant, the attacker may change, say, a function pointer, so that the software calls a verification routine that always accepts. Alternatively, an attacker can attempt to substitute the key used by the receiving device for verifying electronic cash payments (the master key or the public key of the bank). The attacker can even prevent the receiving device from being informed about the error at deposit time, by substituting

the error message of the bank by another, since he can also have the receiving device accept arbitrary strings for digital signatures or MACs of the bank. Protection against unauthorized access and computer viruses can be achieved by using measures such as password protection and secure operating system software.

Preventing Payment Redirection

A more subtle way in which an attacker might attempt to steal electronic cash is to redirect to its own receiving device a payment intended for another party, or to redirect it to the paying device of another party that the attacker intends to pay. This is known as a *man-in-the-middle attack*.

One way to prevent the wrong party from being paid is to explicitly direct an electronic cash payment to the (account of the) intended payee, by making a digital signature at payment time. To this end, three-part coins or blank checks can be used. When an ID number or a certified public key of the intended receiving device is known to the paying device, it can be included in the challenge message that is signed. Alternatively, a random number or a digital pseudonym can be used, as long as it is uniquely associated by the bank with the account of the payee; in this manner the payee can remain anonymous to the payer. As mentioned in "Transferring Electronic Coins," this measure also prevents an attacker from depositing wire-tapped electronic coins or checks to his own account.

For payment platforms in which the paying device and the receiving device need to be in physical proximity, a generally applicable technique known as *distance bounding* can be used to prevent a fraudulent receiving device from passing on a payment to another receiving device. The idea is for the receiving device and the paying device to mutually agree on the (random part of the) challenge message that is to be responded to by the paying device, by each sending a series of random bits to the other, one by one and interleaved, and concatenating the bits to form the challenge. By timing the delay, the receiving device can determine an upper bound on its distance to the other device. What makes this approach practical is that today's electronics can easily handle timings of a few nanoseconds, and light can travel only about 30 cm during one nsec. Even the timing between two consecutive periods of a 50 MgHz clock allows light to travel only three M and back. Details and variations of the above technique can be found in [12].

Nonrepudiation

Account holders should be able to disavow erroneous or false incrimination of fraudulent behavior. When parties with differing interests authenticate their messages using MACs or zero-knowledge proofs, the transcript of a communication cannot be used by another party to later on demonstrate that the communication took place, since zero-knowledge transcripts can be formed by anyone. Nonrepudiation requires the use of digital signatures, since these can only be computed by the party associated with the public key needed for verification (assuming proper protection of the secret key). When crucial parts of the withdrawal, payment and deposit protocols are digitally signed, all parties can disavow false claims. Of course, as in "Fraud Liability," this approach works only if each account holder can generate and control his own secret keys, which requires part of (the operations of) his device to be under his control; this is addressed further in "Guaranteeing Your Own Privacy."

Privacy of Payments

Confidentiality of transaction details is easily achieved by means of line encryption and not depositing details such as the purchase description, and the prevention of traffic analysis is a problem largely orthogonal to the design of an electronic cash system. We now turn to what might well be the most complex issue in the design of an electronic cash system: how can we incorporate untraceability of payments without encouraging criminal uses of electronic cash?

Relaxed Monitoring, Anonymous Accounts, and Anonymous Devices

Untraceability can to some extent be incorporated into an electronic cash system by the bank relaxing the requirements for transaction log dumping. When tamper-resistant receiving devices only dump transaction logs with aggregated transaction details, and leave out any information that can be correlated to paying devices or payers, payments cannot be traced. The bank still needs transaction logs to reveal payment amounts and, preferably, time and date of each transaction, in order to be able to detect counterfeit. A distinct problem with this measure is that the detection of counterfeit, originating from a successful hardware attack, is possible only when the aggregated amount of forgery exceeds the total amount in the bank's float account, which clearly is unacceptable for an open system. An improvement can be obtained by categorizing paying devices into several groups, and requiring aggregated transaction records to reveal these group IDs, but this causes a trade-off with payment untraceability. Further serious drawbacks of the approach are that fraud cannot be traced by electronic means only, blacklisting of devices is not possible, and payers have to trust receiving devices to not deposit individual transaction records (unless paying devices do not provide any trace information in the first place, which is the key to the approach in "Blinding"). Relaxed monitoring and security for the bank always need to be traded off with each other.

Another approach towards untraceability is anonymous bank accounts. Although the use of anonymous accounts protects the identity of payers, all the transactions conducted by the same account holder are linkable; a single identification of the account holder in any transaction enables the bank to trace all past and future transactions of the account holder. Increasing the degree to which payments are unlinkable to the payer by allowing users to swap their devices with other users conflicts with the desirability of a device access control mechanism (such as PIN verification). Not only can this approach hardly be said to offer privacy of payments, it also conflicts with the tracing capabilities of the bank in case of forgery. Anonymous accounts moreover are not allowed in most countries, because they interfere with the tax system.

A third straightforward approach is for the bank to issue tamper-resistant paying devices in such a manner that it does not know which account holder receives which device. Again, this approach cannot be said to offer privacy, because all payments made with the same tamper-resistant device are linkable. It is also difficult to run the device distribution process in a manner that randomly distributes the devices over sufficiently many account holders, and ultimately the provider has to be trusted to properly conduct the distribution. Furthermore, by withdrawing cash from a named account the identity of the holder of the device is revealed. Other drawbacks are that the tracing capabilities of the bank are seriously reduced, tracing cannot be conducted electronically on the basis of transaction logs, and it is difficult to assess to which extent the holder of the traced device is responsible for a fraud originating from that device.

Blinding

A much better way to ensure untraceability of payments is by application of special cryptographic techniques in the design of an electronic cash system. These can ensure that the information that the bank learns about its account holders and their devices is uncorrelated to the information that is revealed by devices when making payments.

In a basic cryptographic paradigm due to Chaum [15], a receiver can obtain from a signer a digital signature on a message, in such a manner that the message and the signature remain completely unknown to the signer. More specifically, in each execution of the protocol, the receiver can obtain with uniform probability a single pair (message, signature) from the set of all possible such pairs, and the signer has maximal uncertainty about the particular pair it has issued. The receiver is said to **blind** the execution of the protocol, and the protocol is called a blind signature issuing protocol.

Efficient blind signature issuing protocols are known for a variety of practical digital signature schemes. The most efficient such protocol known to date is for RSA signatures, and is due to Chaum [15]. It enables a receiver to obtain a pair $(m, m^{1/e} \bmod n)$, where n is an RSA modulus, e is an RSA encryption exponent

(co-prime to $\varphi(n)$) and m is a message satisfying an appropriate redundancy pattern (alternatively, m is a one-way hash of a message), as follows:

Step 1. The receiver picks at random a message m from the message space, and a random **blinding** factor r from $\mathbb{Z}_n^*$. The receiver then sends $m_0 := r^e m \bmod n$ to the signer;

Step 2. The signer sends $s_0 := m_0^{1/e} \bmod n$ to the receiver; and

Step 3. The receiver computes $s := r^{-1} s_0 \bmod n$.

It is easy to see that s is a digital signature of the signer on m, and that the condition for a blind signature issuing protocol is fulfilled.

The basic blinding technique can be used straightforwardly to design an untraceable electronic cash system, as follows. The bank issues electronic coins in the two-part form (message, signature), by means of a blind signature issuing protocol. To this end, the three steps above are performed in parallel, one execution for each requested coin, and the account holder in Step 1 specifies the desired number of coins and their denominations. The account holder also digitally signs its request message (and a fresh part, for replay prevention) to prove to be the holder of the account. For each denomination, the bank uses a different RSA exponent, and all RSA exponents are co-prime. To make a payment, the paying device selects coins of the appropriate denominations, encrypts them using an authenticated public key of the tamper-resistant receiving device, erases the coins and then transfers the encrypted payment message.

By following the blind signature issuing protocol, using properly generated random numbers, all payments are anonymous and unlinkable. In fact, even with infinite computing power the signer cannot trace payments, if only account holders use "genuinely random" blinding factors. For greater efficiency (and reconstructability), the blinding factors applied by an account holder may all be generated from a single secret key by using a pseudo-random number generator, but then untraceability is only computational. A particular danger of this is that many years from now it may be feasible to retroactively trace payments, by analyzing the archived deposit databases of the bank; the expected progression in sheer computing power and advances in algorithmics make this a realistic scenario. Surveillance and tracking capabilities are the primary tools of political oppressors to resist opposition, and changes in a political climate are not always predictable. For this reason it is preferable for any electronic cash design for national or global use to be independent of the particular manner in which blinding factors are generated.

By regarding the public key of a coin in the three-part form, (secret key, public key, certificate), as the message in a blind signature issuing protocol, it follows that a paying device can withdraw completely blinded coin triples by using the above blinding technique. Alternatively, blinded triples serve as blank checks, in combination with a register-based cash representation in the paying device. Note that the bank does not need to know the secret keys of the triples obtained by the paying device. As we have seen in "Fraud Liability" this is desirable for the bank, because it is then able to come up with an incontestable proof in case a k-spendable coin or blank check has been used at least $k + 1$ times. Of course, the bank must also prove that the coin or blank check has indeed been withdrawn by the account holder, and not been constructed by itself; this can be accomplished by showing the (digitally signed) request message that the account holder sent in Step 1 of the execution of the issuing protocol in which the coin or blank check was issued.

A general drawback of the basic blinding technique is that the bank can never *trace* forgery: even fraudulent payments are untraceable. For the same reason the bank cannot apply blacklisting to contain further fraud. Moreover, in case of checks substantial amounts of forged cash may be injected into the system without the bank even being able to detect this. As a consequence, the basic blinding technique is appropriate only to the design of electronic coin systems in which payments are deposited *on-line;* in case of a double-spending attempt, the bank can then simply tell the receiving device to not accept the payment. By having the paying device encrypt its coins for the bank, instead of for the payee's device, neither the paying nor the receiving device needs to be tamper-resistant. On the downside, one of the two major advantages of prepaid electronic cash over instruction-based payment forms, off-line payment

verification, has now been sacrificed completely in order to achieve the other, untraceability. We want to achieve *both* properties.

One-Show Blinding

In order to enable the bank to trace double-spent coins, without sacrificing the untraceability of coins that have been spent only once, the paradigm of **one-show blinding** has been introduced in [18]. This paradigm requires the construction of an issuing protocol and a payment protocol that securely act in concert, in the following manner. The payment protocol must be such that a signature of the paying device on one challenge message does not reveal any information that helps tracing, but any two different signatures, for the same coin, reveal trace information. This trace information must be encoded by the bank into each coin that is issued. To this end, coins are represented in the three-part form, (secret key, public key, certificate), and the issuing protocol must be such that the coin public key and the coin certificate can be fully blinded by the paying device, while the bank must make sure that the coin secret key contains an identifier (note that the tamper-resistance of the paying device may already have been defeated by an attacker before the issuing takes place), at least with substantial probability.

For the payment protocol, a one-time signature scheme can be used, with the property that the computation of two signatures with respect to the same coin public key enables the computation of the coin secret key, or at least of the identifier. To deposit the received coin, the receiving device transfers to the bank the coin public key, the coin certificate, the challenge and the signature of the paying device. The bank verifies the information by checking its own certificate, the signature, and the uniqueness and correct formation of the challenge message. Any double-spending of the same coin (for which the tamper-resistance of the paying device must be compromised) results in the deposit of a second signature with respect to the same coin public key, but on a different challenge message. From any two such different signatures the bank can compute the identifier, and hence trace the compromised paying device. Of course, this paradigm can also be used for electronic checks.

Two fundamentally different approaches are known for designing issuing protocols for the one-show blinding paradigm.

Cut-and-Choose Blinding The first approach can be inferred from Chaum et al. [18], and is commonly called **cut-and-choose blinding.** To retrieve a coin of the specified three-part form, the paying device and the bank engage in performing in parallel a great many executions of a basic blind signature issuing protocol, with the notable difference that the bank completes its part of the protocol only for one of the protocol runs, which it chooses at random. Moreover it does so only when the paying device can demonstrate for all the other protocol runs that it has properly encoded the required identifier into its messages (whence the name "cut-and-choose"); this is called *opening* of a blinded candidate.

To illustrate this process, consider using the blind RSA signature issuing protocol described in "Blinding" as the underlying blind signature issuing protocol. The paying device generates independently at random many "candidate" key pairs, (secret key, public key), such that each secret key contains the identifier in a prescribed manner. It blinds each of the public keys, in the same manner as one blinds messages in the basic blind RSA signature issuing protocol, and sends the resulting blinded public keys to the bank. The bank then requests the paying device to "open" all but one of the submitted blinded public keys, by revealing for each blinded public key the secret key and the blinding factor used in its construction. The bank verifies whether the opened candidates have been constructed properly and, if so, discards them and computes its RSA root of the remaining unopened candidate. Upon receiving the signed blinded candidate, the paying device removes the blinding factor, as in Step 3 of the blind RSA signature issuing protocol.

A very serious shortcoming of this straightforward implementation is that the probability of detecting a fraud increases only linearly in the number of protocol runs, and thus a huge amount of data must be exchanged in order to achieve a sufficiently low probability of successful deception. In the scheme actually proposed in [18], the security level is *exponentially* related to the number of protocol runs, an important improvement. Their construction, which is very specific and does not seem to allow for generalization, is

as follows. The pair (secret key, public key) of a coin triple is a key pair for making a Lamport signature (see "Dynamic Authentication based on Public-Key Cryptography"), but with a twist. Specifically, the public key is a set of k numbers, for an appropriate security parameter k, of the following form:

$$g\left(f\left(s_{01}\right), f\left(s_{11}\right)\right), \; g\left(f\left(s_{02}\right), f\left(s_{12}\right)\right), \ldots, g\left(f\left(s_{0k}\right), f\left(s_{1k}\right)\right) \; . \tag{44.4}$$

The functions $f(\cdot)$ and $g(\cdot)$ are collision-intractable, and the $2k$ secrets s_{ij} of the paying device are of the following form:

$$s_{0j} = \left(I \oplus a_j, b_j\right) \quad \text{and} \quad s_{1j} = \left(a_j, c_j\right), \quad \forall j \in \{1, \ldots, k\} \, , \tag{44.5}$$

for numbers (a_j, b_j, c_j) chosen at random by the paying device. The number I is an identifier, uniquely associated by the bank with the paying device. The certificate of the bank is an RSA signature on the public key. To retrieve a triple of the specified form, the paying device sends to the bank $2k$ blinded $g(f(s_{0j}), f(s_{1j}))$ terms, and opens only half of these, randomly selected by the bank. If the verification succeeds, the bank signs *the product* of the remaining k numbers. Upon removing the product of the k corresponding blinding factors, the paying device is left with one coin triple.

Of course, this time the paying device can slip in an erroneously formed $g(\cdot)$ term with probability $1/2$, and more generally n erroneously formed terms with probability close to $1/2^n$. To defeat successful spending of malformed coins, the payment protocol for a coin is designed as follows. The paying device sends the coin public key and the coin certificate to the receiving device, and in addition computes a Lamport signature on a k-bit challenge message, m. Denoting the binary expansion of m by $m_1 \cdots m_k$, the paying device releases for each bit m_i either $(s_{0i}, f(s_{1i}))$ or $(f(s_{0i}), s_{1i})$, depending on whether m_i is zero or one.

It is easy to see that one signature does not help the bank to trace the payment device, assuming that $f(\cdot)$ hides its first argument unconditionally. To guarantee that the probability of untraceable repeated spending is no greater than $1/2^n$, any two challenges must be guaranteed to differ in at least $2n$ bit positions (note that the possibility of payees cooperating with the payer must be taken into account). To this end, challenges can be expanded into code words with minimum distance $2n$. Double-spending the same coin (for which the tamper-resistance of the paying device must be compromised) results in the deposit of a second Lamport signature with respect to the same coin public key, but on a different challenge message. From any two such different signatures the bank can compute the identifier, I. Namely, for any two bit-positions where the two challenge messages differ, the bank knows both s_{0i} and s_{1i} and hence can compute a candidate identifier, by taking the exclusive-or of their first arguments; the majority candidate must then be the identifier sought for.

Note that the linear growth in the challenge length this time brings exponentially growing security, and that a guaranteed minimum distance of n may suffice to achieve the specified security level in case identifiers of account holders are random secrets and are never transmitted in the clear. Namely, in that case an attacker cannot encode valid identifiers of other account holders into his own coins, so that in case of double-spending with overwhelming probability only one of the computed candidate identifiers is valid.

Although ingenious, this improved realization of cut-and-choose blinding is still far from practical. For a practical implementation, k must be taken to be, say, 70, with 40 bits of each challenge containing a varying part, a receiving device ID and possibly an amount (in case of an electronic check), and the other 30 bits being the required hamming distance to get a sufficiently low probability of successful fraud without traceability. With practical choices for the numbers a_j, b_j, c_j and the blinding factors, the resulting signature size exceeds that for an RSA signature by about two orders of magnitude. Not only must all this information be transmitted, it must also be stored by the bank, for a duration at least as long as the validity of its certification key. Furthermore, the size of the data transmitted in the withdrawal of a single untraceable electronic coin or check is several hundred times the size of an RSA signature.

Restrictive Blinding The second approach to design issuing protocols for the one-show blinding paradigm is called **restrictive blinding.** It avoids the expensive cut-and-choose of the first approach, by inherently restricting the paying device in the manner in which it can blind the secret key for coin or check triples; the bank can then encode the identifier itself into the coin or check, by encoding it into the blinding-invariant part of the secret key.

In [9] a general technique is described to design efficient restrictive blind issuing protocols based on any so-called Fiat–Shamir type signature scheme (another protocol appears in [5], but its design does not follow a generally applicable technique). An important ingredient to this technique is the use of *secret-key certificates,* instead of public-key certificates, for coin or check triples. Although a secret-key certificate is not a digital signature of the bank on the public key of a triple, it offers the same functionality as a digital signature; see [8, 10] for details. The extra flexibility that comes from this can be exploited in the design of restrictive blind issuing protocols.

Following is an example of this technique, based on the Schnorr digital signature scheme [36] . The secret key of the bank is a k-tuple $(x_1, \ldots, x_k)$, where $k-1$ is the number of "identifiers" that the bank can encode independently into each triple that it issues; $k = 2$ suffices for electronic cash applications, as will be shown below. Its corresponding public key is

$$p,\ q,\ \mathcal{H}(\cdot),\ (g_0, g_1, \ldots, g_k)\ , \tag{44.6}$$

where q and p are primes such that q evenly divides $p-1$. The secret key $(x_1, \ldots, x_k)$ is chosen at random by the bank from $(\mathbb{Z}_q)^k$, g_0 is a random number of order q in $\mathbb{Z}_p^*$, and $\mathcal{H}(\cdot)$ is a collision-intractable hash function. (Alternatively, all computations can be performed on an elliptic curve of order q over a finite field; this allows working with much smaller numbers than needed in case of $\mathbb{Z}_p^*$, since the best known algorithms for discrete logarithms in such groups are exponential rather than subexponential.) The rest of the public key is generated deterministically:

$$g_i := g_0^{x_i} \bmod p \quad \forall i \in \{1, \ldots, k\}\ . \tag{44.7}$$

With the current state of computers and cryptographic knowledge, a 20-byte prime q and a 100-byte prime p should suffice for long-term security.

A certificate of the bank on a public key h of order q in $\mathbb{Z}_p^*$ for a paying device is a pair (r, c) such that

$$c = \mathcal{H}\left(h, g_0^c\, h^r \bmod p\right)\ . \tag{44.8}$$

Corresponding to the public key h of the paying device is a secret key $(y_1, \ldots, y_k)$ in $(\mathbb{Z}_q)^k$, such that

$$h = g_1^{y_1} \cdots g_k^{y_k} \bmod p\ . \tag{44.9}$$

The following issuing protocol enables the paying device to obtain a triple $(y_1, \ldots, y_k),\ h,\ (r, c)$ from the bank, in such a manner that the public key h and the certificate (r, c) are fully blinded, while the paying device cannot prevent the bank from encoding into the secret key $k-1$ numbers, $(I_2, \ldots, I_k)$, where $x_1 + \sum_{i=2}^{k} x_i I_i \neq 0 \bmod q$:

Step 1. The bank generates at random a number $w_0 \in \mathbb{Z}_q$, and sends $a_0 := g_0^{w_0} \bmod p$ to the paying device.

Step 2. The paying device generates at random three numbers $\alpha_1 \in \mathbb{Z}_q^*$, $\alpha_2, \alpha_3 \in \mathbb{Z}_q$, and computes

$$h := \left(g_1 g_2^{I_2} \cdots g_k^{I_k}\right)^{\alpha_1} \bmod p \tag{44.10}$$

and

$$c := \mathcal{H}\left(h, a_0 g_0^{\alpha_2} \left(g_1 g_2^{I_2} \cdots g_k^{I_k}\right)^{\alpha_3} \bmod p\right)\ . \tag{44.11}$$

The paying device then sends $c_0 := c - \alpha_2 \bmod q$ to the bank. Note that almost all of the workload can be precomputed, except for the modular multiplication by a_0 and the evaluation of $\mathcal{H}(\cdot)$.
Step 3. The bank sends $r_0 := (x_1 + x_2 I_2 + \cdots + x_k I_k)^{-1}(w_0 - c_0) \bmod q$ to the paying device.
Step 4. The paying device computes $r := \alpha_1^{-1}(r_0 + \alpha_3) \bmod q$.

It is not hard to show that if r_0 in Step 3 is such that

$$g_0^{c_0}\left(g_1 g_2^{I_2} \cdots g_k^{I_k}\right)^{r_0} = a_0 \bmod p\ , \tag{44.12}$$

which the paying device can verify if it so desires, then

- The pair (r, c) is a secret-key certificate of the bank on h;
- The pair $h,\ (r, c)$ is completely hidden from the "view" of the bank in the execution of the issuing protocol, regardless of the choice of $(I_2, \ldots, I_k)$; and
- The secret key $(y_1, \ldots, y_k)$ known by the paying device for h is such that $y_1^{-1} y_i = I_i \bmod q$, for all $i \in \{2, \ldots, k\}$. (Note that $\alpha_1 = 0 \bmod q$ results in an invalid public key.)

It can be proved, under a plausible assumption, that no conspiracy of attackers, each possibly with their own different tuple $(I_2, \ldots, I_k)$, can feasibly retrieve $l + 1$ different triples by performing l executions of the issuing protocol with the bank, for any $l \geq 0$, even if the executions can be arbitrarily interleaved. It can furthermore be proved that if the bank follows the protocol, then no conspiracy of up to $k - 1$ attackers can feasibly retrieve one triple (secret key, public key, certificate) from the bank for which the secret key does not contain any of the tuples $(I_2, \ldots, I_k)$ used by the bank in Step 3 of each of the protocol executions; if this were not the case, then it would be feasible to compute from scratch a pair $h, (r, c)$ such that $c = \mathcal{H}(h, g^c h^r \bmod p)$ without knowing $\log_g h \bmod q$, which is believed to be infeasible. It is believed that this result holds even for conspiracies of k or more attackers, although this conjecture has not been proved.

We now take $k = 2$, for simplicity, and show that the paying device can use the withdrawn triple to make a payment in accordance with the one-show blinding paradigm: two payments with the same triple enable the bank to compute I_2, while one payment does not reveal any information correlated to the execution of the protocol in which the triple was obtained. As before, the payment can be either an electronic check or an electronic coin payment. With h equal to $g_1^{y_1} g_2^{y_2} \bmod p$, the paying device can compute an Okamoto digital signature [33] on a challenge message m, as follows. It generates two random numbers s_1, s_2 from $\mathbb{Z}_q$, and computes $b := g_1^{s_1} g_2^{s_2} \bmod p$ and $d = \mathcal{H}(m, h, b)$. It then computes $r_1 := y_1 d + s_1 \bmod q$ and $r_2 := y_2 d + s_2 \bmod q$, and sends the signature (d, r_1, r_2) to the receiving device, together with the public key h and the certificate (r, c). The receiving device accepts the signature (r_1, r_2) if and only if the following holds:

$$d = \mathcal{H}\left(m, h, g_1^{r_1} g_2^{r_2} h^{-d} \bmod p\right)\ . \tag{44.13}$$

In addition, the receiving device must of course verify the certificate of the bank. At a later stage, the receiving device deposits the payment transcript. The bank verifies it in the same manner as described for the receiving device, and checks for double-depositing and double-spending.

It can be proved that the payment is unconditionally untraceable. Suppose now that the paying device is compromised by an attacker, and the attacker spends the same triple a second time, with respect to another challenge message, m^*, but using the same b. The signature for the new challenge message, m^*, is a triple (d^*, r_1^*, r_2^*) such that

$$d^* = \mathcal{H}\left(m^*, h, g_1^{r_1^*} g_2^{r_2^*} h^{-d^*} \bmod p\right)\ . \tag{44.14}$$

It follows from Eqs. (44.13) and (44.14), and the collision-intractability of $\mathcal{H}(\cdot)$, that

$$h = g_1^{\left(r_1 - r_1^*\right)/(d - d^*)} g_2^{\left(r_2 - r_2^*\right)/(d - d^*)} \bmod p\ . \tag{44.15}$$

Since $h = 1$ is not accepted by receiving devices (the bank will not redeem it, because it is not a generator), it follows that $\alpha_1 \neq 0 \bmod q$. But then

$$\left(r_2 - r_2^*\right) / \left(r_1 - r_1^*\right) = y_2/y_1 = \alpha_1 I_2/\alpha_1 = I_2 \bmod q \ . \tag{44.16}$$

To ensure that the attacker cannot use another b for the second spending of the same triple, b must be part of the triple. To this end, the bank requires in the payment protocol the use of a number b that has been hashed along by the paying device when computing c in Step 2 of the withdrawal protocol; this effectively turns the Okamoto signature scheme into a one-time signature scheme. Clearly, (r, c) must then satisfy $c = \mathcal{H}(h, b, g_0^c h^r \bmod p)$.

This technique can actually be used for a much more general paradigm than one-show blinding, because multiple identifiers can be encoded independently by the issuer. These identifiers may serve the role of credential values (attributes), about which all manner of properties can subsequently be demonstrated in the showing protocol. Specifically, returning to the general form $h = \prod_{i=1}^{k} g_i^{y_i} \bmod p$, Brands [11] shows how one can rapidly demonstrate that the numbers $y_1, \ldots, y_k$ satisfy a satisfiable formula from propositional logic, where the atomic propositions are linear relations modulo q, without revealing anything beyond the validity of the formula. This showing technique enables the paying device to rapidly demonstrate formulas such as

$$\text{“}\left[(5y_2 - 3y_3 = 5) \ \text{AND} \ (2y_3 + 3y_5 = 7)\right] \ \text{OR NOT} \ (y_2 + 4y_6 - 3y_8 = 5) \ .\text{”} \tag{44.17}$$

It can be ensured that if and only if the number of formulas (not necessarily the same) demonstrated with respect to the same h exceeds a predetermined threshold, then the bank can compute the secret key $(y_1, \ldots, y_k)$ of the triple. In the example electronic cash system described in Section 44.4, this general showing protocol technique is used as follows: by taking I_2 to be an identifier of the paying device, and letting I_3 denote a coin denomination specifier of the coin triple, the paying device at payment time can prove to the receiving device the denomination of the coin, without revealing anything about I_2. To this end, it proves the formula

$$\text{“NOT} \ (y_1 = 0) \ \text{AND} \ (y_3 = I_3 y_1) \ .\text{”} \tag{44.18}$$

If the coin is double-spent, I_2 can be computed and hence the coin can be traced to the compromised device.

Guaranteeing Your Own Privacy

The one-show blinding paradigm is not sufficient to design an untraceable electronic cash system. In fact, it is only half of the work. Namely, we have thus far assumed that paying devices are tamper-resistant and are issued by or on behalf of the bank; otherwise an attacker can easily forge money. However, if we do not entrust the bank with detailed information about the spending habits of its account holders, can we trust the bank to program paying devices so as to properly protect our privacy? This question is particularly relevant when one realizes that the idea of blinding fundamentally relies on the ability to produce random numbers that are unpredictable to the bank, and that today's smart cards can produce only pseudo-random numbers, on the basis of a random seed value. This seed value must be installed by the bank itself or at least under its supervision, because it must be guaranteed to be random and secret; but with the bank knowing all seed values, it can compute all the pseudo-random numbers that any paying device will ever compute, and thus the whole idea of blinding becomes pointless. Even if the bank were to tell us that it does not know the seed values, or that paying devices produce random numbers by postprocessing bits sampled from an internal source of “true” randomness (such as a noise diode), this cannot be publicly verified.

When transactions are conducted by directly interfacing a tamper-resistant paying device to a receiving device, it cannot be assessed whether the paying device secretly transfers additional information, such as a device ID, which would also make blinding pointless. A solution to this problem is to let all transfer of

information between the paying device and receiving devices flow through a computer that is *interposed* and trusted by the payer (a "user-controlled" computer). Its hardware and software may be purchased on the free market, and a knowledgeable user may even engage in manufacturing his own software and/or hardware. A desktop computer serves as a natural interposed computer when making Internet payments, and a handheld device is a natural candidate for paying at the local grocery store. When the paying device is in the form of a PC Card or a smart card, which must be inserted into a slot or a smart card reader, the user-controlled interposed computer can easily check that no data is transmitted in addition to that specified in the protocol description.

Usage of a user-controlled computer with a keyboard and display also offers another important advantage. Namely, the user can enter his password, PIN, or biometric using the computer's keyboard, and can read out the balance and payment information from the computer's display instead of having to rely on someone else's device. This makes fake terminal attacks impossible.

A further advantage is that the user-controlled computer can safeguard the user's secret keys, and can make, store (for the purpose of nonrepudiation), and verify all manner of digital signatures. It can also keep its own transaction logs, provide functions for cash-management, and so on. In addition, it may be able to take over part of the workload and/or storage burden of the tamper-resistant paying device, perhaps even to the extent that the tamper-resistant device does not need to perform any heavy number-theoretic operations.

However, without special measures the paying device may still be able to leak out covert information, by using a **subliminal channel** made available through the protocols used for communicating with the outside world (notably the protocols for withdrawal and payment). This leakage is called **outflow.** As a simple example, consider the paying device in the RSA-based one-show blinding system detailed in the section on "Blinding": in the secret values a_i, b_i, and c_i, some of which are revealed during payment, the paying device can easily encode an identifier and a great deal of other covert information, by using an encoding that only the receiving device, or perhaps only the bank, can recognize. Conversely, a receiving device may be able to transmit messages to the paying device through a subliminal channel, for example to instruct it to halt or to supply outflow in case its internal state adheres the supplied inflow information. This is called **inflow,** and can be achieved for instance by encoding the instruction into the random part of a challenge message.

In [16], and later in [20], a paradigm is proposed in which the interposed computer performs a much more active role than to merely check for the flow of additional information. Known as the "wallet-with-observer" paradigm, the idea is that proper cryptographic design of the withdrawal and the payment protocol may enable the interposed computer of the payer to ensure that the blinding factors used in the withdrawal protocol are unpredictable to the bank, and that no subliminal channels can exist.

To ensure that withdrawn coin triples are indeed uncorrelated to the view of bank, Chaum [16, 20] has the interposed computer develop any blinding factors and coin secret keys jointly with the paying device, in such a manner that they are randomized; randomized numbers cannot contain a subliminal channel.

In [17], an electronic cash system is described in which the interposed computer can prevent outflow and ensure correctness of the blinding process (a summary appears in [2]). Although this system suffers from several shortcomings, described shortly, we review it here for educational purposes and because it is the first (and, for a long time, the only) such system to have been proposed. Payments in the system are made using blank checks, as described in "Transferring Register-Based Cash." Blank checks are represented by triples (secret key, public key, certificate), which can be withdrawn from the bank by means of a basic blind signature issuing protocol. The (secret key, public key) pair of a triple is used to make a matrix-based signature, as described in "Dynamic Authentication based on Public-Key Cryptography," and the certificate is a blind RSA signature of the bank on the public key (as explained in "Blinding"). The following protocol steps take place:

Step 1. The tamper-resistant paying device and the user-controlled interposed computer together generate a mutually random number. The paying device ensures that the interposed computer does not learn it, while the interposed computer ensures that the check secret key, that will be derived from the random number by the paying device, cannot contain outflow. To this end, the paying device sends a commit on a (pseudo) random number, the interposed computer returns a random number, and the paying device combines the two numbers. The paying device does not (yet) open its commit to demonstrate its honest behavior in this process, because the interposed computer is not allowed to learn secret keys of check triples (this would enable multiple use of a blank check, without needing to break the tamper-resistance of the paying device).

Step 2. The paying device uses the mutually random number to compute the bottom row of a matrix, and to subsequently fill out all the entries in the matrix (as described in "Dynamic Authentication based on Public-Key Cryptography"). The paying device then computes the check public key by compressing the entries in the top row, and provides the public key to the interposed computer. Note that only the paying device knows the secret key (the entries in the matrix).

Step 3. The interposed computer now offers a blinded form of the public key to the bank, in order to obtain a blind RSA signature on it. The paying device may not develop the blinding factor itself, since in Step 6 the bank could then learn the check public key; on the other hand, the interposed computer may not determine the blinding factor itself, because that would enable it to have the bank sign any information, including public keys for which it knows the check secret key itself. Therefore, the interposed computer and the paying device develop the blinding factor in a mutually random manner, using the method of Step 1. The paying device afterwards opens its commit to show that it behaved properly.

Step 4. Although the interposed computer is assured that the blinding factor is really blind, it has no assurance that the paying device in Step 1 actually used its contribution in the formation of the check secret key. This is of importance because in the payment protocol (Step 7) the paying device will reveal matrix entries, and otherwise there could be a great deal of outflow. Hence at this point the interposed computer can request the paying device to open its commit of Step 1; the decision of whether to make the request or not is made by flipping a (not necessarily unbiased) coin. Because with the opening of the commit the interposed computer learns all the information needed to compute the matrix entry and thus the check secret key, the paying device in this case will not further assist the interposed computer, to prevent it from obtaining a blind RSA signature of the bank; instead, it halts the current protocol execution, and a new protocol execution must be started at Step 1.

Step 5. In case the interposed computer has not requested opening of the commit in Step 4, the protocol execution continues. Because the bank must make sure that it blindly signs only check public keys for which the interposed computer does not know the check secret key, the paying device computes a MAC for the blinded public key (using a secret key known also to the bank; this can be a diversified key) and provides it to the interposed computer. (Alternatively, it could compute a digital signature, but this requires greater computing power.)

Step 6. The interposed computer sends the blinded public key and the MAC to the bank, in the withdrawal protocol. The bank uses the secret key of the paying device to verify the MAC and, if it is correct, returns its RSA root of the blinded public key. The interposed computer removes the blinding factor and verifies the result, as described in "Blinding". The result of the actions up to this point is that the paying device and the interposed computer have together obtained a blank check triple, with the secret key being known only to the paying device.

Step 7. To make a payment with this blank check, the interposed computer passes the challenge message of the receiving device on to the paying device. The paying device reveals to the interposed computer the proper entries of the secret key, as described in "Dynamic Authentication based on Public-Key Cryptography". Upon verifying that these are correct (to prevent outflow), the interposed computing device passes them on to the receiving device.

This protocol has many shortcomings. A first shortcoming is that the paying device needs to perform a public-key cryptographic operation. Namely, in Step 5 it needs to authenticate the blinded public key, and hence must be able to compute the blinded public key or at least verify its correct formation. As shown in [1], probabilistic verification can be used to alleviate the task for the paying device. To this end, the paying device verifies a modularly reduced version of the blinding factor, using a secret prime modulus that has been installed by the bank during initialization of the paying device. This modulus can be chosen fairly small for a practical security level (typically eight bytes suffices), but its secrecy is of utmost importance and hence each paying device is preferably assigned a unique prime. The downside of this method is that it causes a lot of overhead communication and computation between the paying device and the interposed computer.

Another shortcoming is that the MAC of the paying device can contain outflow: any covert message (sufficiently short in comparison to the size of the MAC, for security) could be exclusive-ored into the MAC by the paying device, and extracted by the bank by removing the MAC. This particular problem can be overcome by a minor variation of Step 6, as described in [17]: instead of having the interposed computer pass on the MAC in Step 6, the bank computes it by itself and returns, say, the bit-wise exclusive-or of its RSA root and an expanded form of the MAC (for example, the expansion can be the symmetric encryption of the blinded public key, using the MAC as the encryption key). Only in case the interposed computer has received the MAC from the paying device can it remove the expanded MAC and extract the check certificate.

Yet another shortcoming is in the manner in which the interposed computer in Step 4 verifies that the secret key, and hence the signature at payment time, cannot contain outflow: verification takes place using a cut-and-choose strategy, much like with the cut-and-choose approach to one-show blinding. Hence the probability that cheating is detected increases only linearly with the average number of requests for commit opening.

Furthermore, the commit function in Step 1 could have a trapdoor, known to the paying device, in case of which it could always perform the opening in Step 5 correctly and still cause outflow. These problems can be overcome by the more drastic change of using a number-theoretic signature scheme to define the (secret key, public key) pair. In fact, this is the only difference of the protocols in [16, 20] (neither of which deals with the specific problem of electronic cash design) in comparison to the above protocol of Chaum [17]. As an example, consider using the Schnorr signature scheme: in Step 1, the paying device would select a random $x_1 \in \mathbb{Z}_q$ and send $h_1 := g^{x_1} \bmod p$ to the interposed computer; the interposed computer would return a random $x_2 \in \mathbb{Z}_q$, and the paying device would use $h := g^{x_1+x_2} \bmod p$ as the public key. The interposed computer could then check the correctness by verifying that $h = h_1 g^{x_2} \bmod p$, without needing to know the contribution x_1 of the paying device. Of course, the drawback of this approach is the much greater computational burden for the paying device; it now definitely needs to have a cryptographic co-processor in order to complete its computations in reasonable time.

Another problem that cannot be overcome is that the bank can retroactively trace all payments once the paying device is returned to the bank, if only the paying device stores the random numbers developed in Step 1 or, more efficiently, a few bytes of the random challenges received in Step 7; the bank can then match this information against the deposited information. More generally, the bank at issuing time cannot encode additional information, such as a check spending limit or (in case the triple would serve as a coin) a denomination, without the paying device needing to know it: such information can be encoded only by the choice of the encryption exponent and/or the RSA modulus used by the bank, and the paying device for the purpose of Step 5 needs to know both.

Still another problem is that the interposed computer in Step 7 cannot prevent the receiving device from encoding inflow into the fresh part of its challenge message, unless this is generated in a mutually agreed manner.

However, by far the most serious shortcoming and criticism of the above protocol is that withdrawn triples can be spent many times in an untraceable manner in case the paying device is compromised, because check triples are completely blinded. Incorporating the cut-and-choose blinding technique into

the above protocol would make the workload for withdrawing a check triple unacceptable: the paying device would have to assist in the construction of all blinded candidates, would have to authenticate all of them, and would have to assist in the opening of half of the candidates.

In [5, 6] techniques are introduced that are extensions of the restrictive blinding technique and the showing technique described in "One-Show Blinding." These techniques do not suffer from any of the above shortcomings. Specifically, they enable the paying device and the interposed computer to obtain a triple (secret key, public key, certificate), by performing a restrictive blind issuing protocol with the bank, in such a manner that

- The public key and the certificate can be blinded efficiently by the interposed computer, because it may determine the blinding factors by itself. In fact, the paying device need not take part in the withdrawal protocol at all, so that its holder can leave it in a safe place;
- The paying device assists in making a payment by providing a response to a challenge of the interposed computer. The only computational task that the paying device has to perform is to compute responses, and this can be done so rapidly that the paying device need merely have a simple 8-bit smart card microprocessor (in particular, payments can easily be made using several coins instead of a single check);
- Part of the secret key of each triple is a unique identifier of the paying device, and the paying device does not need to store dynamically any information from the triple: all it ever needs to do is increment sequence numbers and compute responses;
- Inflow and outflow in the withdrawal and in the payment protocol are actively prevented by the interposed computer, by blinding all communication between the paying device and the outside world on the flight (instead of using passive prevention by means of cut-and-choose verification). Moreover, this can be done at virtually no computational cost;
- Even in case the paying device stores all the challenges it receives during payments (this is all it can learn during the time it is held by the account holder), and is returned afterwards to the bank, the stored information cannot be used by the bank to retroactively trace payments by matching it against deposit information; the view of the paying device in the payment protocol is statistically uncorrelated to the view of the receiving device, at least for all receiving device views involving the same number of coins for each denomination. Moreover, by allowing the storage space allocated by the paying device to grow linearly in the number of coins that are withdrawn, it can even be ensured that the paying device cannot learn the denominations of the coins that are spent.

In Section 44.4 an example is described of a practical electronic cash system that is based on these techniques.

One-Sided vs. Two-Sided Untraceability

The one-show blinding and interposed-computer techniques suffice to offer payer untraceability. Even though payers are untraceable, accounts are all named and hence compliance with existing tax regulations is maintained. Since payees are known to the bank, payments are only *one-sided untraceable,* in the sense that payers can trace their own payments (with the help of the bank). Namely, coins and checks are deposited to named accounts, and can be recognized by their payers. Moreover, by disclosing the blinding factors used to withdraw their coins and checks, payers can provide incontestable proofs of payment. One-sided untraceability makes electronic cash unattractive for criminal uses: although a money launderer or a bribed user may readily accept criminal money at one particular moment, he may not be willing to trust the payer to not give evidence against him at a later stage, and victims of extortion have no reason to withhold evidence at all.

However, it is not sufficient for an electronic cash system to support one-sided untraceability. Indeed, one-sided untraceability can always be converted into *two-sided untraceability* (also called payee untrace-

ability), unless special measures are taken. Namely, an account holder can make a payment to a payee by withdrawing electronic coins or checks using blinded candidates that are provided by the payee; the account holder then merely acts as an intermediary between his account and the payee, providing one-time account access to the payee, and cannot learn what coin or check the payee ends up with. To this end, an extortioner may force the account holder to run modified software on his interposed computer, or a willing account holder may provide two-sided untraceability as a service for money laundering purposes. Because proximity of the payer and the payee is not required at any time the payee can remain anonymous throughout (for example, on the Internet all communication can be through spoofed IP addresses or anonymous remailers). In the case of fully blinded two-part coins, or three-part coins and checks, the payee can subsequently at his leisure deposit the coins or checks to his own account, by making a payment to himself; nobody, including the payer, can trace the payment.

To counter this strategy, electronic coins are best implemented in the three-part form, (secret key, public key, certificate), with the secret key containing a unique secret identifier known only to the paying device of the account holder. This is easily achieved by using the restrictive blinding technique. In that case the above strategy enables the other party to receive the public key and the certificate of a blinded coin or check, but not the required secret key. Nevertheless, it may still be possible to use this pair, by letting the paying device of the account holder cooperate also when spending the coin or check, using further active blinding to maintain payee untraceability. By designing the cash system so that the paying device responds only when provided with a challenge message that contains a payee (account) identifier, the untraceable payee cannot make a payment to himself without identifying his identifier to the paying device of the account holder (and hence to the interposed computer of the account holder, if present). Therefore, to maintain payee untraceability, the payee can use the electronic cash only to make a payment to another party, in return for goods or services, which makes the whole idea of conversion to two-sided untraceability pointless, because the account holder might as well have paid the other party directly; moreover, the third party may be of help in tracing.

Note that this measure to prevent two-sided untraceability conversion conflicts with measures to ensure that any information stored by the paying device cannot be used by the bank to retroactively trace payments upon return of the paying device; the (paying device of the) account holder learns the account identifier of the payee. More generally, if the views of the paying device and the payee are statistically uncorrelated, then two-sided untraceability conversion can always be accomplished. For a large-scale electronic cash implementation, it may hence be desirable to prevent only inflow and outflow, while ensuring that the views of the paying device and the receiving device are strongly correlated.

An attempt to circumvent this conflict might be to require the account holder at withdrawal time to demonstrate (in zero-knowledge or otherwise) that its blinding factors have been derived from a secret key, which corresponds to a registered public key of the account holder, according to a predetermined method. However, in the known blind and one-show blind signature issuing protocols this can be achieved only by using completely impractical general multiparty computations or inefficient cut-and-choose verification by the bank. Another serious problem, which moreover is inherent, is that privacy of payments can only be computational: with sufficient computing power the bank can compute the blinding factors by itself, for example by computing the secret key of the account holder.

44.4 An Example Electronic Cash System

In this section we describe an example electronic cash system, to illustrate many of the foregoing design principles and techniques. For the sake of brevity, the bank is denoted by $\mathcal{B}$, the account holder by $\mathcal{A}$, his (tamper-resistant) paying device by $\mathcal{P}$, his interposed computer by $\mathcal{C}$, and the receiving device by $\mathcal{R}$. Receiving devices need not be tamper-resistant. For the sake of clarity of the description, we do not incorporate fault-tolerance measures.

Bank Set-Up

$\mathcal{B}$ generates a secret key $(x_1,\ x_2,\ x_3)$ and a corresponding public key:

$$p,\ q,\ \mathcal{H}(\cdot),\ (g_0,\ g_1,\ g_2,\ g_3)\ . \tag{44.19}$$

This key pair will be used for the computation of coin certificates in the restrictive blind coin issuing protocol. As in the restrictive blind issuing protocol in "One-Show Blinding," p and q are primes such that q divedes $p-1$; $\mathcal{H}(\cdot)$ is a collision-intractable hash function; x_1, x_2, x_3 are three random numbers from $\mathbb{Z}_q$; g_0 is an element of order q in $\mathbb{Z}_p^*$; and, $g_1 = g_0^{x_1} \bmod p$, $g_2 = g_0^{x_2} \bmod p$ and $g_3 = g_0^{x_3} \bmod p$.

For concreteness, it is assumed that $\mathcal{B}$ issues electronic coins of denomination $2^{\texttt{index}}$, for $\texttt{index} \in \{0, \ldots, l\}$, for some limit l and measured in some appropriate unit (for example, dollar cents); alternatively, any other mapping from the set of valid index numbers to the set of valid denominations may be used.

Opening an Account

When $\mathcal{A}$ opens an account, $\mathcal{B}$ provides $\mathcal{A}$ with a tamper-resistant paying device $\mathcal{P}$. $\mathcal{P}$ holds a randomly chosen secret key $I \in \mathbb{Z}_q$, installed by $\mathcal{B}$ and serving as an identifier of $\mathcal{P}$; $\mathcal{B}$ will be able to trace double-spending to the compromised paying device by computing I. The corresponding public key $h := g_2^I \bmod p$ is made available to $\mathcal{C}$.

$\mathcal{P}$ uses a pseudo-random number generator, PRGN$\mathcal{P}$, that takes as inputs triples of the form

$$\text{(seed, index value, sequence number)}\ . \tag{44.20}$$

The seed is a random secret of $\mathcal{P}$, known also to $\mathcal{B}$; for efficiency, we take it to be the same as I. The design of PRGN$\mathcal{P}$ is such that a simple 8-bit smart card micro-processor can evaluate it within a few hundredths of a second; one can build it, for example, from a one-way hash function with pseudo-random properties, such as SHA.

For each coin denomination, $\mathcal{P}$ keeps track of a sequence number, seqnum$\mathcal{P}$(index), which it increments each time when it assists in spending a coin of that denomination. The pseudo-random number output by PRGN$\mathcal{P}$, on input (I, index, seqnum$\mathcal{P}$(index)), is $\mathcal{P}$'s contribution to the secret key of the coin of that denomination and sequence number; $\mathcal{B}$ encodes it into the coin at withdrawal time (note that $\mathcal{B}$ can compute the pseudo-random numbers of $\mathcal{P}$), and it is needed again to spend the coin.

$\mathcal{C}$ for each coin denomination keeps track of its own sequence number, seqnum$\mathcal{C}$(index). It increments this number upon each coin withdrawal. $\mathcal{C}$ also keeps track of a copy of each seqnum$\mathcal{P}$(index), and in any case can always request the current values from $\mathcal{P}$, to stay in synch with $\mathcal{P}$.

Initially, seqnum$\mathcal{P}$(index) and seqnum$\mathcal{C}$ (index) are set to zero, for each coin denomination. At any moment in time, if $\mathcal{C}$ has properly performed the withdrawal protocol, $\mathcal{C}$ and $\mathcal{P}$ together hold seqnum$\mathcal{C}$(index) - seqnum$\mathcal{P}$ (index) coins of denomination $2^{\texttt{index}}$. In practice, one can use four bytes of storage space for each sequence number, three of which serve to store the actual number and one containing an error-correcting code.

$\mathcal{C}$ also generates its own key pair for message signing purposes, and $\mathcal{B}$ registers $\mathcal{C}$'s message public key with the account.

Coin Withdrawal Protocol

To withdraw an electronic coin with denomination $2^{\texttt{index}}$, $\mathcal{C}$ and $\mathcal{B}$ perform the following withdrawal protocol:

Step 1. $\mathcal{C}$ sends to $\mathcal{B}$ a digitally signed withdrawal request, specifying the account of $\mathcal{A}$, index and seqnum$\mathcal{C}$(index). To prevent replay of withdrawal requests, the withdrawal request also contains, say, an account access counter.

Step 2. If the signature on the withdrawal request is correct, $\mathcal{B}$ generates two random numbers, $w_0, v \in \mathbb{Z}_q$. The number v is computed in a pseudo-random manner, as follows:

$$v := \mathrm{PRGN}\mathcal{P}(I,\ \mathtt{index},\ \mathtt{seqnum}\mathcal{C}(\mathtt{index}))\ . \tag{44.21}$$

$\mathcal{B}$ then computes

$$a_0 := g_0^{w_0} \bmod p \quad \text{and} \quad u := g_2^{v} \bmod p\ , \tag{44.22}$$

and sends (a_0, u) to $\mathcal{C}$.

Step 3. $\mathcal{C}$ generates a random number $\alpha_1 \in \mathbb{Z}_q^*$ and five random numbers $\alpha_2, \alpha_3, \alpha_4, \alpha_5, \alpha_6 \in \mathbb{Z}_q$. $\mathcal{C}$ then computes

$$h' := (g_1\, h\, g_3^{\mathtt{index}})^{\alpha_1} \bmod p\ , \tag{44.23}$$

$$c := \mathcal{H}(h',\ u\,(h')^{\alpha_4}\, g_2^{\alpha_5}\, h^{\alpha_6} \bmod p,\ a_0\, g_0^{\alpha_2}\, (g_1\, h\, g_3^{\mathtt{index}})^{\alpha_3} \bmod p) \tag{44.24}$$

and

$$c_0 := c - \alpha_2 \bmod q\ . \tag{44.25}$$

$\mathcal{C}$ then sends c_0 to $\mathcal{B}$. (Note that $\mathcal{C}$ can perform the bulk of the workload in a precomputation phase, before connecting to $\mathcal{B}$; virtually the only on-line computations are the multiplications by a_0 and u.)

Step 4. $\mathcal{B}$ computes

$$r_0 := (x_1 + x_2\, I + x_3\, \mathtt{index})^{-1}\ (w_0 - c_0) \bmod q\ , \tag{44.26}$$

charges the account of $\mathcal{A}$ by $2^{\mathtt{index}}$ units, and sends r_0 to $\mathcal{C}$. $\mathcal{B}$ also increases the account access counter for $\mathcal{A}$ by one.

Step 5. $\mathcal{C}$ computes

$$r := \alpha_1^{-1}\ (r_0 + \alpha_3) \bmod q\ . \tag{44.27}$$

$\mathcal{C}$ stores $(\alpha_1, \alpha_4, \alpha_5, \alpha_6)$ and (r, c) onto its "coin stack" of denomination $2^{\mathtt{index}}$ (note that these are all "small" numbers), indexed by $\mathtt{seqnum}\mathcal{C}(\mathtt{index})$, and increments $\mathtt{seqnum}\mathcal{C}(\mathtt{index})$ and its account access counter both by one.

In case $\mathcal{A}$ wants to withdraw many coins, not necessarily having the same denomination, the request in Step 1 should specify all coins requested; Steps 2 through 5, which must be performed once for each coin, can be performed in parallel for all coins. The withdrawal protocol thus consists of four message transmissions, independent of the number of coins requested.

For authentication and nonrepudiation, the messages sent in Steps 2 through 4 should also be digitally signed by the sender. The digital signature of $\mathcal{C}$ on its message in Step 3 (and details of the preceding messages) can serve to $\mathcal{B}$ as a proof that $\mathcal{C}$ has requested the withdrawal of the specified amount, and authorizes $\mathcal{B}$ to debit $\mathcal{A}$'s account. By requiring $\mathcal{B}$ to be able to resend its response(s) in Step 4 whenever requested to do so, at least until a time-out or until $\mathcal{C}$ requests withdrawal of a new set of coins (this proves that $\mathcal{C}$ has successfully completed the previous withdrawal session), it is ensured that $\mathcal{B}$ obtains $\mathcal{C}$'s debit authorization if and only if $\mathcal{C}$ is able to obtain the requested coins (possibly with the help of a judge).

In Step 5, $\mathcal{C}$ may wish to verify that

$$g_0^{c_0}\ \left(g_1\, h\, g_3^{\mathtt{index}}\right)^{r_0} = a_0 \bmod p\ . \tag{44.28}$$

For efficiency, this verification can normally be omitted. In particular, if r_0 is incorrect then $\mathcal{C}$ will notice this because $\mathcal{R}$ will not accept when the coin is spent; $\mathcal{C}$ can then use the digital signature of $\mathcal{B}$ on its message in Step 5, to demonstrate that r_0 has been formed incorrectly by $\mathcal{B}$. This requires $\mathcal{C}$ to store the digital signature of $\mathcal{B}$ on its message in Step 4 (and details of the preceding messages) at least until the withdrawn coins have been spent.

Furthermore, all messages may be encrypted, for confidentiality. This can be done using symmetric encryption, using a mutually known random session key; $\mathcal{C}$ can generate the session key in Step 1, and send it along with the withdrawal request in encrypted form (using a special encryption public key of $\mathcal{B}$). For efficiency, the RSA signature scheme may be used for message signing, the RSA encryption scheme for session key encryption, and triple-DES for message encryption.

Coin Payment Protocol

If $\texttt{seqnum}\mathcal{C}(\texttt{index})$ exceeds $\texttt{seqnum}\mathcal{P}(\texttt{index})$ then $\mathcal{C}$ and $\mathcal{P}$ together hold $\texttt{seqnum}\mathcal{C}(\texttt{index})$ - $\texttt{seqnum}\mathcal{P}(\texttt{index})$ coins of denomination $2^{\texttt{index}}$. To transfer a coin to $\mathcal{R}$, $\mathcal{C}$ and $\mathcal{R}$ perform the following payment protocol (with $\mathcal{P}$ necessarily assisting $\mathcal{C}$):

Step 1. A challenge message m is determined by $\mathcal{C}$ and $\mathcal{R}$, by concatenating an account identifier of $\mathcal{R}$, the number $\texttt{index}$, and a fresh part (such as a random number of $\mathcal{R}$, or a sufficiently accurate time/date estimate by $\mathcal{C}$ that is approved by $\mathcal{R}$). $\mathcal{C}$ retrieves $(\alpha_1, \alpha_4, \alpha_5, \alpha_6)$ and (r, c), indexed by $\texttt{seqnum}\mathcal{P}(\texttt{index})$ in its coin stack for coins of denomination $2^{\texttt{index}}$. $\mathcal{C}$ then recomputes h' from α_1 (of course, $\mathcal{C}$ could alternatively have stored h' in its coin stack at withdrawal time), and computes

$$d := \mathcal{H}(m,\ h',\ (r, c)) \quad \text{and} \quad e := d + \alpha_6 \bmod q\ . \tag{44.29}$$

$\mathcal{C}$ then sends e to $\mathcal{P}$, together with $\texttt{index}$, to indicate the denomination of the coin it wants to spend.
Step 2. $\mathcal{P}$ computes

$$y := I\, e + \text{PRGN}\mathcal{P}(I,\ \texttt{index},\ \texttt{seqnum}\mathcal{P}(\texttt{index})) \bmod q\ , \tag{44.30}$$

increments $\texttt{seqnum}\mathcal{P}(\texttt{index})$ by one, and sends y to $\mathcal{C}$.
Step 3. $\mathcal{C}$ computes

$$r_1 := y + \alpha_5 \bmod q, \quad \text{and} \quad r_2 := -\alpha_1^{-1} d + \alpha_4 \bmod q \tag{44.31}$$

and sends

$$h',\ (r, c),\ (d, r_1, r_2) \tag{44.32}$$

to $\mathcal{R}$ (and possibly also missing details of m).
Step 4. For the challenge message m approved or decided on by $\mathcal{R}$, $\mathcal{R}$ verifies that

$$c \ = \ \mathcal{H}\left(h',\ g_1^d\, g_2^{r_1}\, g_3^{d\,\texttt{index}}\, (h')^{r_2} \bmod p,\ g_0^c\, (h')^r \bmod p\right) \tag{44.33}$$

and

$$d \ = \ \mathcal{H}(m,\ h',\ (r, c))\ . \tag{44.34}$$

If the verification holds, $\mathcal{R}$ accepts the coin payment.

In Step 3, $\mathcal{C}$ may wish to verify that

$$g_2^y\, h^{-e} = u \bmod p\ . \tag{44.35}$$

For efficiency this can normally be omitted. Even if the verification is never performed, if y is incorrect then $\mathcal{R}$ will not accept the payment, while at most one bit of outflow can result (namely, whether the coin is correct or not).

In a typical scenario, this payment protocol is performed simultaneously for multiple coins of suitable denominations, in order to make up the exact amount payable. For increased efficiency, a single m and a

single d can be used for all coins. To this end, m must specify `index` for each of the coins (alternatively, and more compactly, the payable amount may be specified), and to compute d the hash function $\mathcal{H}(\cdot)$ must take as inputs m and, for each coin, $(h',\ (r, c))$ of that coin.

In Step 4, $\mathcal{R}$ can send a digitally signed receipt to $\mathcal{C}$. For confidentiality, $\mathcal{C}$ and $\mathcal{R}$ may use session key encryption. To this end, $\mathcal{C}$ can generate a random session key in Step 3, publicly encrypt it using a (certified) public key of $\mathcal{R}$, symmetrically encrypt the payment message using the session key, and send both encryptions over to $\mathcal{R}$.

Coin Deposit Protocol

To deposit the received coin at a convenient moment later on, $\mathcal{R}$ performs the following deposit protocol with $\mathcal{B}$:

Step 1. $\mathcal{R}$ sends to $\mathcal{B}$ the payment transcript:

$$h',\ (r, c),\ (d, r_1, r_2)\ ,\ m\ . \tag{44.36}$$

Step 2. $\mathcal{B}$ verifies that the purportedly fresh part of the challenge message m has not been used before by $\mathcal{R}$ (note that for this reason the use of an accurate time and date indication is preferred, since $\mathcal{B}$ then merely needs to store the most recent time and date indication of $\mathcal{R}$); this excludes double-depositing by $\mathcal{R}$. If this is the case, $\mathcal{B}$ verifies the payment transcript in the same way as specified for $\mathcal{R}$ in Step 4 of the payment protocol, reading `index` from m. If the verification holds, $\mathcal{B}$ credits the account that is indicated by the account identifier in m by $2^{\texttt{index}}$ units.

Of course, $\mathcal{R}$ can deposit multiple payment transcripts at once, and should preferably sign its deposit request in Step 1. Likewise, $\mathcal{B}$ in Step 2 should return a digitally signed statement, to inform $\mathcal{R}$ of which payment transcripts have been accepted. To hide who is depositing how much, both parties can encrypt their messages using a session key suggested by $\mathcal{R}$, which $\mathcal{R}$ sends to $\mathcal{B}$ in public-key encrypted form.

Forgery Detecting and Tracing

At a suitable moment, which might be at the time of deposit by $\mathcal{R}$ but could also be later on, $\mathcal{B}$ checks for double-spending. To this end, $\mathcal{B}$ verifies whether $\mathcal{H}(h')$ already appears in a "forgery-detect" database. If this is the case, $\mathcal{B}$ subsequently traces the physically compromised paying device, by retrieving from a "forgery-trace" database the "old" pair (d^*, r_1^*) (indexed by the hash of h' that is already in the forgery-detect database) and computing

$$\left(d - d^*\right)^{-1} \left(r_1 - r_1^*\right) \bmod q\ ; \tag{44.37}$$

this number is equal to I. In addition, $\mathcal{B}$ can blacklist $\mathcal{H}(h')$.

On the other hand, if the coin has not been double-spent, $\mathcal{B}$ stores $\mathcal{H}(h')$ in the forgery-detect database and the pair (d, r_1) in the forgery-trace database, indexed by $\mathcal{H}(h')$. The forgery-detect database can be maintained on computer hard-disks, while the forgery-trace database can be stored on tape or WORM disks.

Discussion

There are several noteworthy aspects in the design of this example cash system. Firstly, the withdrawal protocol is the restrictive blind issuing protocol discussed in "One-Show Blinding." Secondly, the interposed computer computes the blinding factors by itself, and in fact the tamper-resistant paying device

does not take part in the withdrawal protocol. When assisting in a coin payment, the paying device performs a simple computation that can be performed rapidly by a simple smart card processor. Furthermore, it does not store any part of the withdrawn coins; it merely increments coin sequence numbers that occupy preallocated storage space, which can be well below 100 bytes in a practical implementation. Hence the desired low complexity for paying devices is achieved. Thirdly, the receiving device need not be tamper-resistant, and payment transcripts can be deposited only to the account of the payee indicated in the challenge message. Finally, the active blinding by the interposed computer in the payment protocol ensures unconditional protection against inflow and outflow.

Moreover, it can be proved that even if $\mathcal{P}$ stores the challenges e received in all executions of the payment protocol performed by $\mathcal{C}$, and $\mathcal{B}$ analyzes all information stored by $\mathcal{P}$ upon its return, the payments of $\mathcal{C}$ still cannot be traced, regardless of the strategy followed by $\mathcal{B}$, $\mathcal{P}$ and all receiving devices, and regardless of their computing power. Of course, this untraceability holds only amongst all payments made with the same number of coins and of the same denominations, because $\mathcal{P}$ does learn the coin denominations involved in a payment. This can be improved on, by using a single list of sequence number instead of one for each denomination, but then the amount of data that must be stored by the paying device grows linearly instead of logarithmically with the number of coins that have been withdrawn. Namely, at withdrawal time it cannot be predicted in which order coin denominations will be addressed at payment time, and in the worst case the paying device must hop almost randomly through the list of sequence numbers to select coins of the appropriate denomination, keeping track of all the sequence numbers used thus far.

In order to keep the size of the forgery-detect and forgery-trace databases manageable, $\mathcal{B}$ should regularly change its own secret key for certifying coins. Once coins have expired for deposit, $\mathcal{B}$ can erase the databases or archive them. The use of coin expiration dates also helps to contain the financial damage that can be done by an attacker who gets hold of $\mathcal{B}$'s secret certification key. In fact, for this purpose it is highly desirable that $\mathcal{B}$ can at any instant declare the current coin version invalid, and start issuing coins using a new certification key. To make this work smoothly in practice, coin versions should be given a separate expiration dates for at least the withdrawal and the deposit protocols.

In view of the possibility of a crash, loss or theft of $\mathcal{C}$ and/or $\mathcal{P}$, $\mathcal{C}$ should generate backup copies of all its coins. $\mathcal{C}$ can make a backup each time when it withdraws new coins, and any coins that have been spent since the last backup can be removed or overwritten. Specifically, for each withdrawn coin that has not yet been spent, a backup entry is kept of the form

$$\texttt{index},\ \alpha_1,\ b, (r, c)\ . \tag{44.38}$$

Here, b denotes $u\,(h')^{\alpha_4}\,g_2^{\alpha_5}\,h^{\alpha_6} \bmod p$; this number is computed by $\mathcal{C}$ in Step 3 of the withdrawal protocol, for inclusion in the hash function. (To reduce storage space, $\mathcal{H}(b)$ can be stored instead of b itself; the definition of the coin certificate, (r, c), must then be modified correspondingly.) In case $\mathcal{A}$ wants to recover, $\mathcal{C}$ reads the backup entries, and sends them to $\mathcal{B}$. Of course, in case $\mathcal{C}$ was involved in the crash, loss or theft, this requires $\mathcal{A}$ to first obtain a new $\mathcal{C}$ and/or to reinstall $\mathcal{C}$'s software. For each coin, the provided entry information is sufficient for $\mathcal{B}$ to reconstruct h' and to check (r, c), and in particular to verify that the information indeed specifies a coin it had issued to $\mathcal{A}$. $\mathcal{B}$ reimburses $\mathcal{A}$ for all the coins that have not been spent, to which end it matches h' against the forgery-detect database. In case the paying device has been reported lost or stolen, $\mathcal{B}$ should not unconditionally reimburse $\mathcal{A}$ until the expiry date for payment or deposit of the current coin version, to prevent abuse of the recovery procedure for the purpose of double-spending. Note that the recovery method is independent of the manner in which blinding factors are computed, and of whether or not the account holder has a paying device at his disposal at the time of recovery (issuing a new one requires a physically secure channel, while $\mathcal{A}$ may want to suspend his account). Moreover, the backup information cannot be used by a thief to spend the coins, since part of the secret key of each coin triple is not stored. Finally, $\mathcal{B}$ can incontestably prove to $\mathcal{A}$ that a coin offered for recovery appears already in its deposit database by showing the signature (d, r_1, r_2), which it could not have made by itself. To this end it also needs to store r_2 at deposit time.

For cross-platform portability, the same paying device can be used in combination with different user-controlled computer devices. Of course, this requires a mechanism for the various user-controlled computers to exchange coin information, since coins withdrawn using one computer may need to be spent using another.

In line with our earlier discussions, a minor variation allows the protocols to be used for electronic checks, which can be spent for any amount up to a predetermined maximum. A special value of `index` can be used to denote checks (alternatively, several extra values are defined, each specifying a different maximum spending limit). The only required change to the protocols is that the challenge message m in the payment protocol must now specify in addition the amount for which the check is filled out, and d must be computed by $\mathcal{P}$ itself in Step 2; correspondingly, there is no use for α_6 anymore, and $\mathcal{C}$ in Step 1 of the payment protocol must provide $\mathcal{P}$ with m, h' and (r, c), instead of with e. (Alternatively, $\mathcal{C}$ provides m and a hash of $(h', (r, c))$ to $\mathcal{P}$, and $\mathcal{P}$ computes d by hashing these two numbers. This approach is especially convenient when using a single m and d for multiple coins, because $\mathcal{P}$ can then be given m and a hash of all $(h', (r, c))$, and these two numbers then form the input to $\mathcal{H}(\cdot)$ for computing d; of course, the verification by $\mathcal{R}$ and $\mathcal{B}$ must be modified correspondingly. Furthermore, parts of m may be hashed, perhaps even with a random salt, to prevent $\mathcal{P}$ from learning or recognizing them.) Before sending out y in Step 2, $\mathcal{P}$ must decrement its register value by the amount for which the check is filled out. Note that now an additional protocol is needed, for withdrawing electronic cash; what we called the withdrawal protocol for coins is now the issuing protocols for blank checks. This can easily be constructed using the conventional authentication techniques described in "Authentication Techniques."

The check variation has the drawback that $\mathcal{B}$ can retroactively trace all payments of $\mathcal{C}$ once $\mathcal{P}$ is returned to $\mathcal{B}$, if only $\mathcal{P}$ stores for each execution of the payment protocol m or a relevant part of it. On the other hand, having $\mathcal{P}$ compute d by itself has the advantage for law enforcement that one-sided untraceability cannot be converted into two-sided untraceability, as discussed in "One-Sided Versus Two-Sided Untraceability." This adjustment can also be applied to the described coin protocols.

A more serious drawback of the check variation, which as we have seen is unavoidable, is that by physically extracting the secret key I of $\mathcal{P}$, an attacker can introduce counterfeit without detection by the bank. The following trade-off is believed to be of practical interest: the bank issues coins as well as checks (in both cases preventing conversion to two-sided untraceability), and paying devices use checks only to pay fractional amounts that would otherwise require too many coins. The bank specifies a low spending limit for checks, and monitors the number of checks withdrawn by each of its account holders in order to limit excessive check withdrawal. This ensures that an attacker cannot make a significant profit without being exposed.

44.5 Summary and Research Issues

As we have seen in this chapter, techniques for designing electronic cash systems vary widely and range from elementary to complex. Assuming that it is infeasible for attackers to compromise tamper-resistance, register-based electronic cash is preferable over electronic coins for reason of efficiency. We have seen that payment authentication must take place on the basis of dynamic authentication, in the form of challenge-response protocols, to prevent replay attacks. Authentication can be performed using symmetric cryptography, whereby MACs are communicated, or by using public-key cryptography. The former approach is (in general) much more efficient than the latter, but the presence of system-wide secrets in receiving devices is inherent to this approach, and hence tamper-proofness of receiving devices is critical. In the latter approach, it is not of concern to the bank whether receiving devices are tamper-resistant, if only electronic cash is issued in the form of coins or checks in the three-part form. This can be accomplished in one of the following two ways: either paying devices withdraw electronic coins, or they hold register-based cash and digitally sign the payable amount using a blank check. When tamper-resistance can be relied upon, achieving security against forgery is mainly a matter of designing cash transfer protocols that resist cryptanalysis by wire-tappers.

We have also seen that an important aspect of system design is to ensure security for the bank, under the assumption that secrets in tamper-resistant devices can be extracted and registers bypassed. It is here that crucial design decisions must be made. When electronic cash is represented in the form of register-based cash, a forgery can be detected by the bank only by monitoring how much cash ought to be present in each paying device at various moments in time. This requires receiving devices to deposit transaction transcripts that reveal at least a paying device ID and the transferred amount. In case receiving devices are tamper-proof, the bank can trust receiving devices for performing truthful depositing of transaction logs. In case receiving devices are not tamper-resistant, or at least their tamper-resistance is not relied on, truthful depositing of transaction details can be ensured only by issuing electronic cash in the three-part form (coins or blank checks).

Because such monitoring is in conflict with privacy of payments, we have also discussed techniques for incorporating untraceability of payments. The straightforward approaches of relaxed monitoring, anonymous accounts, and anonymously issued paying devices were all seen to offer only a very weak form of privacy (all payments are linkable, and trust in the bank or receiving devices is required), and moreover inevitably cause a trade-off with security for the bank. Much better are cryptographic techniques based on the paradigm of blinding. When electronic coins or check triples are withdrawn by means of a basic blind signature protocol, all information can be blinded by the withdrawing party, and forgery can at best be detected by the bank (untraceability is perfect even for attackers who manage to forge electronic cash). An important improvement is one-show blinding, for which two techniques exist: cut-and-choose blinding and restrictive blinding. The former is very expensive, and for practical purposes only the latter is acceptable.

The one-show blinding paradigm is only half of the work that is needed to design an untraceable electronic cash system, because paying devices that are tamper-resistant cannot be guaranteed to compute random blinding factors, or to otherwise follow the protocols; and in case paying devices are not tamper-resistant but user-controlled, there is no prior restraint of double-spending. As we have seen, the other half of the work can be accomplished by having the account holder interpose a computer of his own between his paying device and any outside devices, to ensure that the paying device cannot leak information that helps the bank to trace his payments. The cash system should then be designed such that the interposed computer can prevent inflow and outflow by blinding on the flight all communication between the paying device and the outside world, and during withdrawal can compute the blinding factors either by itself or randomize them.

By ensuring that paying devices are provided with the challenge information that needs to be signed at payment time, one-sided untraceability cannot be converted into two-sided untraceability, thus making electronic cash unattractive for criminal uses such as money laundering, bribery, and extortion. If this property is not deemed relevant, it can even be ensured that paying devices cannot learn information that enables the bank to trace payments when analyzing their contents upon return. Finally, we have seen a detailed example of a practical electronic cash system, based on the discussed principles and techniques.

An important area for further research is to rigorously prove the cryptographic security of practical electronic cash systems, by proving all manner of attacks as hard as breaking well-understood cryptographic primitives. For a start in this direction, see [7].

44.6 Defining Terms

Blinding: A paradigm according to which a receiver in an execution of a protocol obtains digitally signed information that remains hidden from the issuer. Also refers to the cryptographic actions by a party interposed between two other parties in a cryptographic protocol, to destroy subliminal channels.

Cut-and-choose blinding: A technique for designing an issuing protocol for the one-show blinding paradigm. A great many basic blind issuing protocols are performed in parallel, and the signer

completes the blind signature issuing protocol only for some of these, after having verified for the rest that the blinded candidates contain an identifier.

Diversified key: A secret key that is computed by hashing at least a master secret key and an identifier, using a one-way hash function.

Dynamic authentication: A method for a device to prove its authenticity, in such a manner that replay attacks have negligible or zero probability of success.

Electronic check: A method for transferring electronic cash. A blank check is a triple (secret key, public key, certificate), issued by the bank to a paying device that holds cash in register-based form. At payment time the check is filled out by the paying device for any amount up to a predetermined maximum amount, by signing the amount and subtracting it from its internal cash balance. Blank checks are not prepaid, because they do not carry value.

Electronic coin: A method for representing electronic cash. A coin is a prepaid public-key cryptographic token, digitally signed by the bank, to which a fixed value and currency are assigned at issuing time. Coins can be either in the two-part form, (message, signature), or in the three-part form, (secret key, public key, certificate).

Inflow: Covert information that is communicated by an outside device to a paying device, through a subliminal channel in a system protocol.

One-show blinding: A cryptographic paradigm, requiring the design of a signature issuing protocol and a corresponding signature showing protocol, such that showing an obtained signature once is untraceable, while showing it twice allows a built-in identifier to be computed.

Outflow: Covert information that is communicated by a paying device to an outside device, through a subliminal channel in a system protocol.

Register-based cash: A method for representing electronic cash. The amount of cash held by a tamper-resistant device is indicated by the value of a counter, maintained in a register in a chip.

Replay attack: An attack whereby information revealed by a party when proving its authenticity is reused to pass a subsequent authenticity test.

Restrictive blinding: A technique for designing an issuing protocol for the one-show blinding paradigm. The issuer can issue a triple (secret key, public key, certificate) in such a manner that the receiver can blind the public key and the certificate, but not a nontrivial blinding-invariant part of the secret key; in this part one or more identifiers can be encoded.

Static authentication: A method whereby one device proves its authenticity to another by always revealing the same predetermined secret, such as a password or an identifier. Not secure against replay attacks.

Subliminal channel: A channel present in a cryptographic protocol, by means of which a party can secretly communicate information to another party, in a manner unrecognizable by interposed parties.

Untraceability: In an untraceable electronic cash system, payments cannot be traced to the payer by examining information revealed through system protocols, and payments by the same payer are unlinkable. Untraceable cash systems can be designed using cryptographic blinding techniques.

Further Information

Literature

Public literature on the design of electronic cash systems is scarce and dispersed. Since 1995 several books have been published about electronic commerce, but these are all nontechnical and focus on credit-card systems. The main source for articles on the cryptographic design of electronic cash systems are the annual Eurocrypt and Crypto conferences. Interesting technical information may also be found in proceedings of smart-card conferences, and by entering relevant keywords into a search engine for the World Wide Web. Patents are another useful source of information on techniques related to electronic cash systems.

In this chapter we have not discussed all manner of functionality extensions and variations that have been proposed for untraceable electronic cash. To name a few, off-line transferability for coins in the three-part form is discussed in [19]; a technique for tick payments for blank checks is introduced in [34]; escrow functionality for electronic coin systems is introduced in [13], and improved by [14]; and divisibility of electronic coins is addressed, among others, by [22]. An account of legal aspects of untraceable electronic cash can be found in [25], and a compact overview of cryptographic techniques for untraceable cash in [30]. The February issue of [27] is devoted entirely to technological aspects of electronic money.

Electronic Cash Today

Most prepaid electronic purse initiatives are based on symmetric authentication and encryption. Many of these are modeled after the Proton system, a nonanonymous register-based cash system developed by Banksys, the association of Belgium banks. One of first electronic purse projects of significance has been a Danish initiative allied to Visa International, called Danmønt. Other national purse scheme initiatives are underway in the Netherlands (Chipknip, by Interpay), Switzerland (Telekurs bank consortium) and Portugal (Multibanco Electronic Purse). A related technology called Visa Cash has been developed by Visa International, and has been piloted at the 1996 Summer Olympics.

International standardization efforts for electronic purse schemes are the CEN Intersector Electronic Purse and the EMV 3.0 specifications.

Another development is the Mondex prepaid system of Mondex International Limited, which enables repeated off-line transferability of value from person to person. All devices are tamper-resistant, and offer a keyboard and display. The version currently in operation uses conventional cryptographic authentication. In September 1995, a Fair Trading Act complaint was filed against Mondex for falsely advertising their system as anonymous, and the claim was upheld after a nine-month investigation by the Fair Trading Office; see [28] and the references provided therein.

Citibank is developing a cash system called the Electronic Monetary System (EMS), with functionality similar to that of Mondex. In particular, cash can repeatedly be transferred from person to person, without the involvement of central party, and all devices (Money Modules) are tamper-resistant and have a keypad and a display. Instead of using a register-based cash representation, cash appears to be stored and transferred in the form of two-part coins. Each note carries a complete electronic audit trail, and (invisibly to the user) electronic notes are submitted to the bank for validation and control whenever a withdrawal or deposit is made. Security is based on the ability of the bank to trace all transactions to devices.

CAFE is a European Commission sponsored project, involving thirteen leading European parties from academic research and industries, that has tested an off-line electronic cash system in the commission headquarters in Brussels. The CAFE system is based on the one-show blinding paradigm and the wallet-with-observer paradigm, and more specifically on the public-key cryptographic techniques of Brands [5, 6] for withdrawing, paying, and depositing. Transactions are conducted using a tamper-resistant smart card inserted into a handheld computer with a keyboard and display, and limited off-line transferability is offered.

Four financial institutions (the Mark Twain bank, the Merita bank, the Deutsche bank and the Advance bank) and the Sweden Post offer (or are about to) a system for untraceable electronic cash payments over the Internet. This system is a software-only on-line payment system based on Chaum's basic blind RSA signatures, developed by Amsterdam-based DigiCash. Because two-sided untraceability is not prevented, this system is open to criminal uses such as extortion, bribery and money laundering.

Recently, CyberCash has launched a payment system called CyberCoin, also for on-line payments over the Internet. This system has been designed to have functionality similar to the DigiCash system, but lacks provisions for anonymity. According to public statements from CyberCash, value resides at all times within the bank and the system actually is an instruction-based system.

Parallel Computation: Models and Complexity Issues[1]

Raymond Greenlaw
Armstrong Atlantic State University

H. James Hoover
University of Alberta

45.1 Introduction

The theory of **parallel computation** is concerned with the development and analysis of parallel computing models, the techniques for solving and classifying problems on such models, and the implications of this work.

Despite technology that continually improves the performance of individual processors, humans are adept at inventing problems for which a single processor is simply too slow. Only by using many processors in parallel is there any hope of quickly solving such problems. In principle, having more processors working on a problem means it can be solved much faster. Ideally, we expect a speedup of the following form:

$$(\text{Parallel Time}) = \frac{(\text{Sequential Time})}{(\text{Number of Processors})}$$

In practice, parallel algorithms seldom attain ideal *speedup*,[2] are more complex to design, and are more difficult to implement than single-processor algorithms. The designer of a parallel algorithm must grapple with these fundamental issues:

1. What parallel resources are available,
2. What kind of speedup is desired,
3. What machine architecture should be used,
4. How the problem may be decomposed to exploit parallelism, and
5. Whether the problem is even amenable to a parallel attack?

The dilemma of parallel computation is that at some point every problem begins to resist speedup. The reality is that as one adds processors one must devote (disproportionately) more resources to interprocessor communication, and one must deal with more problems caused by processors waiting for others to finish. Furthermore, some problems appear to be so resistant to speedup via parallelism that they have earned the name *inherently sequential.*

Pragmatic versus Asymptotic Parallelism

The practice of parallel computation can be loosely divided into the pragmatic and the asymptotic.

The goal of *pragmatic parallel computation* is simply to speed up the computation as much as possible using whatever parallel techniques and equipment are available. For example, doing arithmetic on 32 bits in parallel, overlapping independent I/O operations on a storage subsystem, fetching instructions and precomputing branch conditions, or using 4 processors interconnected on a common bus to share workload are all pragmatic uses of parallelism. Pragmatic parallelism is tricky, very problem-specific, and highly effective at obtaining the modest factor of 3 or 4 speedup that can suddenly make a problem reasonable to solve. This article is not directly concerned with pragmatic parallel computation as defined above; the models and techniques we explain in this article are.

Asymptotic parallel computation, in contrast to pragmatic, is more concerned with the architecture for general parallel computation; parallel algorithms for solving broadly applicable, fundamental problems; and the ultimate limitations of parallel computation. For example, are shared memory multiprocessors more powerful than mesh-connected parallel machines? Given an unlimited number of processors, just how fast can one do n-bit arithmetic? Or, can every polynomial time sequential problem be solved in polylogarithmic time on a parallel machine? Asymptotic parallel computation does provide tools for the pragmatic person too, for example, the algorithm designer with many processors available can make use of the results from this field.

The field of asymptotic parallel computation can be subdivided into the following main areas:

1. Models: comparing and evaluating different parallel machine architectures.

[2]The speedup is simply the ratio (Sequential Time/Parallel Time). In general, the speedup is less than the number of processors.

2. Algorithm design: using a particular architecture to solve a specific problem.
3. Computational complexity: classifying problems according to their intrinsic difficulty of solution.

Many books are devoted to the design of parallel algorithms, for example [17, 23, 38]. The focus of this article is on models of parallel computation and complexity.

When discussing parallel computation it is common to adopt the following informal definitions:

- A problem is **feasible** if it can be solved by a parallel algorithm with worst-case time and processor complexity $n^{O(1)}$.
- A problem is **feasible highly parallel** if it can be solved by an algorithm with worst-case time complexity $(\log n)^{O(1)}$ and processor complexity $n^{O(1)}$.
- A problem is **inherently sequential** if it is feasible but has no feasible highly parallel algorithm for its solution.

Chapter Overview

Section 45.2—two fundamental models of parallel computation, the parallel random access machines and uniform Boolean circuit families.

Section 45.3—the fundamental parallel complexity classes P and NC.

Section 45.4—other important parallel models and mutual simulations.

Section 45.5—P-completeness, the theory of inherently sequential problems.

Section 45.6—various examples of P-**complete** problems.

Section 45.7—research issues and summary.

Section 45.8—defining terms.

45.2 Two Fundamental Models of Parallel Computation

Introduction

An important part of parallel computation involves the description, classification, and comparison of abstract models of parallel machines.

One of the prerequisites to studying a problem is specifying the resources that we are concerned about consuming, and the abstract machine model on which we want to compute our solutions. For practicing programmers, these two items are usually dictated by the real machines at their disposal. For example, having only a small number of processors, each with a very large memory, is a much different situation from having tens of thousands of processors each with limited memory. In the first situation we wish to minimize the number of processors required by our solution, and will choose a model that ignores memory consumption. In the second situation, where minimizing local memory may be more important, we choose a model that provides many processors (although not extravagantly many) and in which all basic operations are assumed to take the same amount of time to execute. The single biggest issue to be faced from the standpoint of developing a parallel algorithm is the *granularity* of the parallel operations. Should the problem be broken up into very small units of computations, which can be done in parallel but then may incur costly communication overhead, or should the problem be divided into relatively large chunks that can be done in parallel but where each chunk is processed sequentially?

The opposite ends of our granularity spectrum are captured by the two main models of parallel computation: *parallel random access machines* and *uniform Boolean circuit families.* For high-level, coarse-

granularity situations the preferred model is the PRAM, while for more detailed questions of implementability and small resource bounds, the finer granularity uniform Boolean circuit model is used.

Although there are many differences between parallel models, for feasible, highly parallel computations, most models are equivalent to within a polynomial in both time and hardware resources, simultaneously. By this we mean that if the size-n instances of some problem can be solved in time $T(n) = (\log n)^{O(1)}$ and processors $P(n) = n^{O(1)}$ on a machine from model M_1, then there exists a machine from model M_2 that can solve the size n instances of the problem in time $T(n)^{O(1)}$ and $P(n)^{O(1)}$ processors. Thus, if a problem is feasibly highly parallel on one model, it is so on all other equivalent models. (See Section 45.4 for more details.) This says that the class of problems solvable by feasibly highly parallel computations is robust and insensitive to minor variations in the underlying computational model.

Parallel Random Access Machines

One of the natural ways of modeling parallel computation is the generalization of the single processor into a *shared memory multiprocessor,* as illustrated in Fig. 45.1. This machine consists of many powerful independent machines (usually viewed as being of the same type) that share a large common memory which is used for computation and communication. The parallel machines envisioned in such a model contain very large numbers of processors, on the order of millions. Such enormous machines do not yet exist, but machines with 64,000 processors can be built now, and economics rather than technology is the main factor that limits their size.

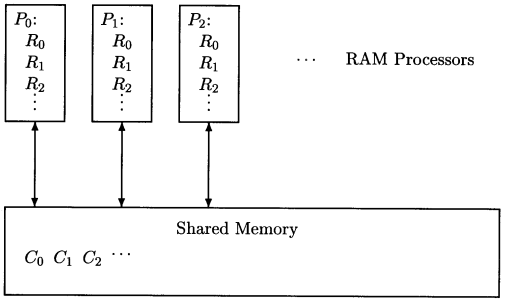

FIGURE 45.1 The Parallel Random Access Machine (PRAM). A PRAM consists of a large number of processors connected to a common memory. Each processor is quite powerful by itself, and operates independently of the others. Processors communicate by passing information through the shared memory. Arbitration may be required when more than one processor attempts to access a given memory cell.

The formal model of the shared memory multiprocessor is called a *parallel random access machine* (PRAM), and was introduced independently in [15] and [18, 19]. The PRAM model consists of a collection of random access machine (RAM) processors that run in parallel and communicate via a common memory. The basic PRAM model consists of an unbounded collection of numbered RAM processors $P_0, P_1, P_2, \ldots$ and an unbounded collection of shared memory cells $C_0, C_1, C_2, \ldots$ (see Fig. 45.1). Inputs and outputs to the PRAM computation are placed in shared memory to allow concurrent access. Each instruction is executed in unit time, synchronized over all active processors.

Each RAM processor P_i has its own local memory, knows its own index i, and has instructions for direct and indirect read/write access to the shared memory. Local memory is unbounded, and consists of memory cells $R_0, R_1, R_2, \ldots$, with each cell capable of holding an integer of unbounded size. The usual complexity measures for each individual processor's RAM computation are *time,* in the form of the number of instructions executed, and *space,* in the form of the number of memory cells accessed.

A typical PRAM instruction set, with addressing modes, is given in Table 45.1. In this simple machine, local memory cell R_0 serves as an accumulator so that at most one read and one write to shared memory occurs for each instruction. The multiply and divide instructions take only a constant operand in order to prevent the rapid generation and testing of very large numbers. These restrictions also prevent the consumption of an exponential amount of space in polynomial time.

TABLE 45.1 Sample PRAM Instruction Set

Instruction	Description
$\alpha \leftarrow \beta$	move data to cell with address α from cell with address β Address — Description R_i — local cell R_i R_{R_i} — local cell with address given by contents of R_i C_i — shared cell C_i C_{R_i} — shared cell with address given by contents of R_i
IDENT	load the processor number into R_0
CONST c	load the constant c into R_0
ADD α	add contents of α to R_0
SUB α	subtract contents of α from R_0
MULT c	multiply contents of R_0 by constant c
DIV c	divide contents of R_0 by constant c and truncate
GOTO i	branch to instruction i
IFZERO i	branch to instruction i if contents of R_0 is 0
HALT	stop execution of this processor

Two important technical issues must be dealt with by the model. The first is the manner in which a finite number of the processors from the potentially infinite pool are activated for a computation. A common way is for processor P_0 to have a special activation register that specifies the maximum index of an active processor. Any nonhalted processor with an index smaller than the value in the register can execute its program. Initially only processor P_0 is active, and all others are suspended waiting to execute their first instruction. P_0 then computes the number of processors required for the computation and loads this value into the special register. Computation proceeds until P_0 halts, at which point all active processors halt. The SIMDAG model is an example of a PRAM using such a convention [19]. Another common approach is to have active processors explicitly activate new ones via FORK instructions [15].

The second technical issue concerns the way in which simultaneous access to shared memory is arbitrated. In all models, it is assumed that the basic instruction cycle separates shared memory read operations from write operations. Each PRAM instruction is executed in a cycle with three phases. First the read operation (if any) from shared memory is performed, then the computation associated with the instruction (if any) is done, and finally the write operation (if any) to shared memory is performed. This eliminates read/write conflicts to shared memory, but does not eliminate all access conflicts. This is dealt with in a number of ways as described in Table 45.2 (see [48] and [14] for more details). All of these variants of the PRAM are deterministic, except for the ARBITRARY CRCW-PRAM, for which it is possible that repeated executions on identical inputs result in different outputs.

Any given PRAM computation will use some specific time and hardware resources. The complexity measure corresponding to *time* is simply the time taken by the longest running processor. The measure corresponding to *hardware* is the maximum number of active processors during the computation.

TABLE 45.2 How Different PRAM Models Resolve Access Conflicts

CRCW	Concurrent-Read Concurrent-Write
	Allows simultaneous reads and writes to the same memory cell with a mechanism for arbitrating simultaneous writes to the same cell:
	PRIORITY — only the write by the lowest numbered contending processor succeeds.
	COMMON — the write succeeds only if all processors are writing the same value.
	ARBITRARY — any one of the writes succeeds.
CREW	Concurrent-Read Exclusive-Write
	Allows simultaneous reads of the same memory cell, but only one processor may attempt to write to a cell.
CROW	Concurrent-Read Owner-Write
	A common restriction of the CREW-PRAM that preassigns an owner to each common memory cell. Simultaneous reads of the same memory cell are allowed, but only the owner can write to the cell, thus ensuring exclusive-write access.
EREW	Exclusive-Read Exclusive-Write
	Requires that no two processors simultaneously access any given memory cell.

Our standard PRAM model will be the CREW-PRAM with a processor activation register in processor P_0. This means that processor P_0 is guaranteed to have run for the duration of the computation, and the largest value in the activation register is an upper bound on the number of processors used. We also need to specify how the inputs are provided to a PRAM computation, how the outputs are extracted, and how the cost of the computation is accounted:

DEFINITION 45.1 Let M be a PRAM. The **input/output conventions** for M are as follows. An input $x \in \{0, 1\}^n$ is presented to M by placing the integer n in shared memory cell C_0, and the bits $x_1, \ldots, x_n$ of x in shared memory cells $C_1, \ldots, C_n$. M displays its output $y \in \{0, 1\}^m$ similarly: integer m in shared memory cell C_0, and the bits $y_1, \ldots, y_m$ of y in shared memory cells $C_1, \ldots, C_m$.

M computes in **parallel time** $T(n)$ **and processors** $P(n)$ if and only if for every input $x \in \{0, 1\}^n$, machine M halts within at most $T(n)$ time steps, activates at most $P(n)$ processors, and presents some output $y \in \{0, 1\}^*$.

M computes in **sequential time** $T(n)$ if and only if it computes in parallel time $T(n)$ using 1 processor.

With these conventions in place, and having decided on one version of the PRAM model to be used for all computations, we can talk about a function being computed in parallel time $T(n)$ and processors $P(n)$.

DEFINITION 45.2 Let f be a function from $\{0, 1\}^*$ to $\{0, 1\}^*$. The function f is **computable in parallel time** $T(n)$ **and processors** $P(n)$ if and only if there is a PRAM M that on input x outputs $f(x)$ in time $T(n)$ and processors $P(n)$.

Note that no explicit accounting is made of the local or shared memory used by the computation. Since the PRAM is prevented from generating large numbers, that is, for $T \geq \log n$ no number may exceed $O(T)$ bits in T steps, a computation of time T with P processors cannot store more than $O(PT^2)$ bits of information. Hence, for our purposes P and T together adequately characterize the memory requirement of the computation, and there is no need to parameterize it separately.

All of the various PRAM models are polynomially equivalent with respect to feasible, highly parallel computations, and so any one is suitable for defining the complexity classes P and NC that we present in Section 45.3. The final important point to note about the PRAM model is that it is generally not difficult to see (in principle) how to translate an informally described parallel algorithm into a PRAM algorithm.

Uniform Boolean Circuit Families

Boolean circuits are designed to capture very fine-grained parallel computation at the resolution of a single bit—they are a formal model of the combinational logic circuit. Circuits are basic technology, consisting of very simple logical gates connected by "bit-carrying wires". They have no memory and no notion of state. Circuits avoid almost all issues of machine organization and instruction repertoire. Their computational components correspond directly with devices that we can actually fabricate, although the circuit model is still an idealization of real electronic devices. The circuit model ignores a host of important practical considerations such as circuit area, volume, pin limitations, power dissipation, packaging, and signal propagation delay. Such issues are addressed more accurately by more complex VLSI models (see [34]). But for much of the study of parallel computation, the Boolean circuit model provides a good compromise between simplicity and realism.

Each circuit is an acyclic directed graph in which the edges carry unidirectional logical signals and the vertices compute elementary Boolean logical functions. Formally we denote the logical functions by the sets $B_k = \{f \mid f : \{0,1\}^k \rightarrow \{0,1\}\}$, that is, each B_k is the set of all k-ary Boolean functions. We refer informally to such functions by strings "1", "0", "$\neg$", "$\wedge$", "$\vee$", "NOT", "AND", "OR", and so on. The entire graph computes a Boolean function from the inputs to the outputs in a natural way.

DEFINITION 45.3 A **Boolean circuit** α is a labeled finite oriented directed acyclic graph. Each vertex v has a type $\tau(v) \in \{I\} \cup B_0 \cup B_1 \cup B_2$. A vertex v with $\tau(v) = I$ has indegree 0 and is called an **input**. The inputs of α are given by a tuple $\langle x_1, \ldots, x_n \rangle$ of distinct vertices. A vertex v with outdegree 0 is called an **output**. The outputs of α are given by a tuple $\langle y_1, \ldots, y_m \rangle$ of distinct vertices. A vertex v with $\tau(v) \in B_i$ must have indegree i and is called a **gate**.

Note that fanin is less than or equal to two but fanout is unrestricted. Inputs and gates can also be outputs. See Fig. 45.2 for an example.

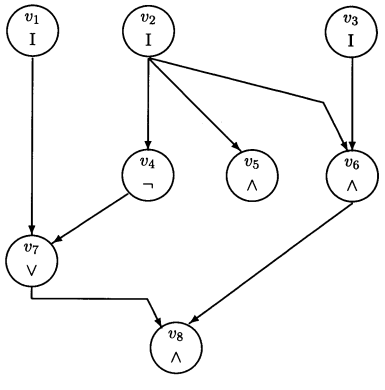

FIGURE 45.2 A Sample Boolean Circuit. A Boolean circuit with inputs $\langle v_1, v_2, v_3 \rangle$ and outputs $\langle v_5, v_8 \rangle$. It has size 8, depth 3, and width 2. Input v_2 has fanout 3. Gate v_4 has fanin 1 and fanout 1.

DEFINITION 45.4 A Boolean circuit α with inputs $\langle x_1, \ldots, x_n \rangle$ and outputs $\langle y_1, \ldots, y_m \rangle$ **computes a function** $f : \{0,1\}^n \rightarrow \{0,1\}^m$ in the following way: input x_i is assigned a value $\nu(x_i)$ from $\{0,1\}$ representing the ith bit of the argument to the function. Every other vertex v is assigned the unique value $\nu(v) \in \{0,1\}$ obtained by applying $\tau(v)$ to the value(s) of the vertices incoming to v. The value of the function is the tuple $\langle \nu(y_1), \ldots, \nu(y_m) \rangle$ in which output y_j contributes the jth bit of the output.

The most common resource measures of interest for a circuit are its *size* and *depth.*

DEFINITION 45.5 The **size** of α, denoted size(α), is the number of vertices in α. The **depth** of α, denoted depth(α), is the length of the longest path in α from an input to an output.

A less common measure is *width,* which intuitively corresponds to the maximum number of gate values, not counting inputs, that need to be preserved when the circuit is evaluated level-by-level.

DEFINITION 45.6 The **width** of α, denoted width(α), is

$$\max_{0<i<\text{depth}(\alpha)} \left| \left\{ v \ : \ \begin{array}{l} 0 < d(v) \leq i \text{ and} \\ \text{there is an edge from vertex } v \text{ to a vertex } w, d(w) > i \end{array} \right\} \right|$$

where d(w), the depth of w, is the length of the longest path from any input to vertex w.

Each circuit α is described by a binary string denoted by $\overline{\alpha}$. This description can be thought of as a blueprint for that circuit, or alternatively as a parallel program executed by a universal circuit simulator. In any case, although we speak of circuits, we actually generate and manipulate circuit descriptions (exactly as we manipulate programs and not Turing machines). One common description is the *standard encoding,* the precise details of which are not important to this chapter (see [39]). The main point is that circuit descriptions are simple objects to generate and manipulate.

An individual circuit with n inputs and m outputs is a finite object computing a function from binary strings of length n to binary strings of length m. In contrast to a PRAM computation in which one algorithm handles all possible lengths of inputs, different circuits are required for different length inputs. The collection of different circuits for the various input lengths is called a *circuit family.*

The simplest kind of circuit family is used for computing some function f whose output length m is a function, possibly constant, only of the length of the input. That is, the length of $f(x)$ on n-bit inputs x is some function $m(n)$. In this case we can represent the function $f : \{0,1\}^* \rightarrow \{0,1\}^*$ by an infinite sequence of circuits, $\{\alpha_n\}$, where circuit α_n computes f restricted to inputs of length n. Such a sequence is called a *Boolean circuit family.*

DEFINITION 45.7 A **Boolean circuit family** $\{\alpha_n\}$ is a collection of circuits, each α_n computing a function $f^n : \{0,1\}^n \rightarrow \{0,1\}^{m(n)}$. The **function computed by** $\{\alpha_n\}$, denoted f_α, is the function $f_\alpha : \{0,1\}^* \rightarrow \{0,1\}^*$, defined by $f_\alpha(x) \equiv f^{|x|}(x)$.

Functions where the output length varies with the value of x as well as its length can be handled by special encodings (similar to the output convention used for PRAMs). The case where the length of the output is always 1 is particularly important for defining formal languages.

DEFINITION 45.8 Let $\{\alpha_n\}$ be a Boolean circuit family that computes the function $f_\alpha : \{0,1\}^* \rightarrow \{0,1\}$. The **language decided by** $\{\alpha_n\}$, denoted by L_α, is the set $L_\alpha = \{x \in \{0,1\}^* \mid f_\alpha(x) = 1\}$.

Defining an infinite collection of circuits with no computational constraints gives *nonuniform* circuit families. Nonuniform circuit families are unexpectedly powerful in that they can "compute" noncomputable functions. These circuit families are widely used as objects of lower bound proofs, where their power merely serves to strengthen the significance of the lower bounds. However, they are a somewhat unsatisfactory model in which to consider upper bounds. In particular, there may be no effective way, given n, to obtain a description of the n-th circuit α_n.

The *uniform* approach gives an explicit algorithm for constructing the elements of the circuit family. Each circuit family is defined by a program in some computational model that takes n as input and then outputs the encoding $\overline{\alpha_n}$ of the nth member. In doing so, an infinite object, the family, is effectively described by a finite object, the program. The question then becomes, how much computational power is permitted in producing the description $\overline{\alpha_n}$?

Borodin, arguing that the circuit constructor should have no more computational power than the object it constructs, introduced the notion of *uniformity* [1]. One such example of a weak constructor is a Turing machine that is limited to only $O(\log n)$ work space on inputs of length n. Such machines have limited computing power but can still describe a wide class of useful circuit families.

DEFINITION 45.9 A family $\{\alpha_n\}$ of Boolean circuits is **logarithmic space uniform** if the transformation $1^n \rightarrow \bar{\alpha_n}$ can be computed in $O(\log(\text{size}(\alpha_n)))$ space on a deterministic Turing machine.

Note how the complexity of producing the description of α_n is expressed in terms of the size of the resulting circuit. Logarithmic space uniformity is sometimes called *Borodin–Cook uniformity,* and was first mentioned in [5]. This notion of uniformity has the desirable property that the description $\overline{\alpha_n}$ can be produced in polynomial time sequentially, or in polylogarithmic time in parallel with a polynomial number of processors. Thus, the circuit constructor is reasonable from both sequential and parallel perspectives.

Equivalence of PRAMs and Uniform Boolean Circuit Families

We have remarked that many parallel models are equivalent with respect to feasible highly parallel algorithms. That is, if a problem has a feasible highly parallel solution on one model, then it also has one on any equivalent model. Originally the notion of feasible and highly parallel came from the observation that certain problems had polylogarithmic time and polynomial processor solutions on many different models. This ability to support feasibly highly parallel algorithms has now become the defining characteristic of all "reasonable" parallel models. In order for any new parallel model to be considered reasonable, it must be able to relatively efficiently simulate some existing reasonable model and vice versa. (See the remarks in Section 45.7 about more realistic parallel models.)

In this sense, PRAMs and uniform Boolean circuits are both reasonable parallel models, and can simulate each other in a way that maintains feasible highly parallel computations. This result, as other simulation results, is quite technical, and sensitive to the precise details of each model involved. The basic ideas are relatively simple, and easily worked to completion by those with a penchant for detail (see [21] for more details). To simulate a circuit operating on input x of length n, the PRAM first uses the uniformity condition to compute the description of the circuit from the family that handles the inputs of length n. Then it initializes the inputs and does a gate-by-gate simulation of the circuit, evaluating in parallel all the gates at the same level. The simulation of a PRAM by a circuit is a bit more complex. The circuit for inputs of length n has to account for the worst case time and processor consumption of the PRAM, and the product of these two gives the size of the circuit. The circuit is then organized as a sequence of layers, each layer of which simulates one time step of each processor of the PRAM.

THEOREM 45.1 *A function f from $\{0,1\}^*$ to $\{0,1\}^*$ can be computed by a logarithmic space uniform Boolean circuit family $\{\alpha_n\}$ with depth$(\alpha_n) = (\log n)^{O(1)}$ and size$(\alpha_n) = n^{O(1)}$ if and only if f can be computed by a CREW-PRAM M on inputs of length n in time $T(n) = (\log n)^{O(1)}$ and processors $P(n) = n^{O(1)}$.*

Similar simulation results among the various models of parallel computation (see Section 45.4) allow us to observe that if a problem is inherently sequential on one reasonable parallel model, then it is inherently sequential on all other reasonable models.

45.3 Fundamental Parallel Complexity Classes

Introduction

The most important complexity classes in parallel computation are P, NC, and the class of P-complete problems. The problems in P are considered to be easy to solve on a single processor; they are *tractable* or *feasible.* Such problems may still take unacceptable amounts of sequential time to solve and so are ideal candidates for parallel computation. NC consists of those problems in P that can be solved very fast in parallel. The P-complete problems appear to be outside of NC. The classes NC and P are defined formally in the next section, and the P-complete problems, which require more technical background, are defined formally in Section "Completeness."

Nick's Class (NC) and Polynomial Time (P)

Because of their simplicity, language recognition and decision problems are the standard mechanisms for defining the computational classes of complexity theory. We refer the reader to Chapters 27, 28, and 29 for background and more in-depth discussion. The following definitions aid in defining the classes[3] NC and P.

DEFINITION 45.10 Let L be a language over $\{0, 1\}^*$. The **characteristic function** of L is the function f_L defined on all $x \in \{0, 1\}^*$ such that $f_L(x) = 1$ if $x \in L$, and $f_L(x) = 0$ if $x \notin L$.

DEFINITION 45.11 A language $L \subseteq \{0, 1\}^*$ is **decidable in sequential time** $T(n)$ if and only if the characteristic function of L can be computed in sequential time $T(n)$.

DEFINITION 45.12 A language $L \subseteq \{0, 1\}^*$ is **decidable in parallel time** $T(n)$ **with** $P(n)$ **processors** if and only if the characteristic function of L is computable in parallel time $T(n)$ and processors $P(n)$.

A single sequential processor running in polynomial time can easily simulate a polynomial number of processors running in polynomial time, and conversely. This means we can ignore sequential computation and restrict our attention to PRAMs, as per the following lemma.

LEMMA 45.1 A language L is decidable in sequential time $n^{O(1)}$ if and only if L is decidable in parallel time $n^{O(1)}$ with $n^{O(1)}$ processors.

We can now define the class of feasible highly parallel problems, NC, and the class of polynomial time sequential problems, P.

DEFINITION 45.13 The class NC is the set of all languages L that are decidable in parallel time $(\log n)^{O(1)}$ and processors $n^{O(1)}$.

DEFINITION 45.14 The class P is the set of all languages L that are decidable in parallel time $n^{O(1)}$ and processors $n^{O(1)}$.

[3] NC was named after Nick Pippenger.

Many complexity classes have functional analogs, typically denoted by prefixing the class with the letter F. For example, FNC denotes "function NC" — the class of functions computable in the resource bounds of the class NC. Similarly, FP denotes "function P." We assume the reader has an intuition for what these classes are.

From Lemma 45.1, we know that $NC \subseteq P$. The important open question for parallel computation is whether this inclusion is proper.

A Basic Example—Parallel Sums

Many problems in P have truly dramatic speed improvements when solved in parallel. Here we consider a simple but important problem, **parallel sums,** defined as follows:

Given: Natural numbers $a_1, a_2, \ldots, a_n$, and t.

Problem: Is $t = a_1 + a_2 + \cdots + a_n$?

We can solve this problem *sequentially* by adding numbers together two at a time. Such a procedure requires $n - 1$ additions to compute the total, and the total can be checked against t to solve the problem. Parallel sums is an example of a problem that is *sequentially feasible.* Now consider solving parallel sums using a number of processors operating in parallel.

With *limited parallelism,* which means using a fixed number of processors, we can never achieve more than a *constant factor* of improvement over the best-known sequential time. For example, with two processors we can never be more than twice as fast as with one. But suppose that processors were so plentiful and inexpensive that we could consider using thousands or more in parallel. This introduces a qualitative change in the way we approach parallel computation. What kind of speedup could be achieve if we had essentially an unlimited number of processors?

With *polynomially bounded parallelism,* we have the potential to achieve more than a constant factor speedup. For example, suppose that we use $P(n) = n/2$ processors to solve an instance of parallel sums consisting of n numbers and a value t. That is, we have one processor for each pair of numbers. The computation can then be organized as a binary tree in which we add as many pairs of numbers as possible in each time step. The time to compute the addition of n numbers is the height of the tree, so the computation can be done in $O(\log n)$ elapsed time using $n/2$ processors assuming a unit cost for addition.

We must emphasize the importance of this example. Using only a relatively small number of processors (about half the size of the problem instance), we have achieved an *exponential*[4] improvement in the solution of parallel sums by going from $O(n)$ sequential time to $O(\log n)$ parallel time. Problems that exhibit this kind of improvement are exactly those that belong to the class NC.

Does *NC* Equal *P*?

Many of the problems in P have highly parallel solutions similar to parallel sums, and one wonders if perhaps every problem in P can be solved fast on a parallel machine.

> *Does every problem with a feasible sequential solution also have a feasible highly parallel solution? That is, does NC equal P?*

Unfortunately, it seems that some problems in P do not lie in NC, and one of the main tasks of complexity theory is to identify these suspected *inherently sequential problems.* The theory of P-completeness described in Section 45.5 provides evidence suggesting NC and P are indeed different classes.

[4] By exponential we mean going from a polynomial function to a polylogarithmic function. Therefore, an improvement from n^3 to $(\log n)^2$ is considered an exponential improvement.

45.4 Parallel Models and Simulation Results

Introduction

Parallel models of computation vary widely in *modes of communication, instruction sets,* and in what constitutes a *processor.* There is no clearly superior architecture for a general purpose parallel computer, and the same is true for the theoretical models of parallel computation. Thus there is room for inventing new architectures and computational features. These *new* models are evaluated by two basic methods: assessing how well they speed up existing sequential computation classes, and how well they do in mutual simulations with existing parallel models. The comparison with existing parallel models also provides information about how easy the model is to use and how close the model is to a real machine. The ultimate aim of this exercise is to identify the key attributes that must be present in any reasonable parallel model.

In this section we introduce a number of synchronous parallel models and some simulation results. A parallel machine is **synchronous** if all processors must complete the execution of their current instruction before any processor begins execution of its next instruction. Brief descriptions, providing only a taste of the models, are given in "The Fixed Structure Models" and "The Modifiable Structure Models". Many of the important technical issues concerning the models can be extrapolated from the PRAM and Boolean circuit models given in "Parallel Random Access Machines" and "Uniform Boolean Circuit Families." The meanings of the names of complexity classes used in this section are easily inferred, and are mostly historical. For example, UAG-TIME stands for uniform aggregate time and ATIME, SPACE represents alternating Turing machines with simultaneous time and space bounds.

The simulation results that relate two seemingly different parallel models M_1 and M_2 follow a basic pattern. If any problem Π can be solved on a machine of type M_1 using T_{M_1} time and P_{M_1} processors, can Π be solved on an M_2 machine in some related bounds? For example, using $f_T(T_{M_1})$ time and $f_P(P_{M_1})$ processors, where f_T and f_P are two well-behaved functions relating M_1's resources of time and processors respectively, to M_2's. What about vice versa? Do time and processor bounds for problem Π on model M_2 imply time and processor bounds on M_1?

The simulation results that relate a parallel model and a sequential model have a different purpose. Here the focus is on how parallel resources relate to sequential resources. This provides an understanding of what kinds of sequential problems can be automatically parallelized. A useful framework for this was proposed by [6]; we follow his discussion and build upon it in the next section.

Cook's Classification Scheme for Parallel Models

The various parallel models, which are defined in the following sections, are grouped into two classes: the *fixed structure* models and the *modifiable structure* models. "The fixed structure models correspond to sequential machines with a fixed storage structure such as Turing machine tape". They consist of *alternating Turing machines, bounded fanin uniform Boolean circuit families, conglomerates, k-PRAMs,* and *uniform aggregates.* This class represents parallel models whose interconnection pattern is fixed throughout a computation.

"The *modifiable structure* models, correspond to the modifiable sequential Storage Modification Machines [41] and RAMs." They consist of *hardware modification machines, MRAMs* (standard RAMs with a multiplication instruction [22]), *PRAMs, SIMDAGs, unbounded fanin uniform Boolean circuit families,* and *vector machines.* This class represents parallel machines whose communication links are allowed to vary during a computation.

The above mentioned parallel machines can be grouped according to their *time* resource usage as related to *sequential space* on a Turing machine. For a fixed structure model X, the following relationship typically holds:

$$\text{X-TIME}(S(n)) \subseteq \text{DSPACE}(S(n)) \subseteq \text{NSPACE}(S(n)) \subseteq \text{X-TIME}(S(n)^2) \tag{45.1}$$

whereas a modifiable structure model Y usually satisfies

$$\text{Y-TIME}(S(n)) \subseteq \text{DSPACE}(S(n)^2) \subseteq \text{Y-TIME}(S(n)^2) \tag{45.2}$$

For more on DSPACE (deterministic Turing machine space) and NSPACE (nondeterministic Turing machine space) see Chapter 27. Equation[5] (45.2) is not known to be true for some of the models in the modifiable class. For example, it is not known how to simulate $S(n)$ space bounded Turing machines by vector machines or MRAMs running in time $S(n)$. The SIMDAG can simulate NSPACE($S(n)$) in linear time.

The Fixed Structure Models

Uniform Families of Bounded Fanin Boolean Circuits

As presented in Section "Uniform Boolean Circuit Families" the resources of interest for circuits are depth, size, and width. Circuit depth is a useful measure of parallel time because a lower bound on the running time for a problem Π using the circuit model can be applied to parallel machines that are implemented using circuit technology, or to parallel models that are equivalent to circuits with respect to the time resource. The fixed structure of circuits as opposed to the programmable nature of some other parallel models facilitates the proof of lower bounds as noted by [43].

A shortcoming of the circuit model is that it does not provide a very good measure of hardware. The size of the circuit provides an upper bound on the hardware size but intuitively this is a poor bound because a circuit is not allowed to reuse any of its gates. Width seems to provide a reasonable measure of hardware size for synchronous circuits (see Theorem 45.4). Uniform circuit depth corresponds to sequential space in the following way:

THEOREM 45.2 *[1] For* $T(n) \geq \log n$ $UDEPTH(T(n)) \subseteq DSPACE(T(n)) \subseteq NSPACE(T(n)) \subseteq UDEPTH(T(n)^2)$.

The time bound $T(n)$ has to be computable within the same resource constraints established by the uniformity conditions of the model. This is in practice only a technical annoyance, and so from now on unless otherwise stated we assume that $T(n) \geq \log n$, and that it is constructible in $O(\log n)$ space.

Uniform Aggregates

Aggregates, defined in [11], are circuits with feedback that have a special input convention that does not count the hardware required to hold the input. The feedback allows gates to be reused during a computation and thus reflects more accurately the amount of hardware required to solve problems. The resources of interest for an aggregate are *hardware* and *time*. Aggregates, like circuits, work for only one fixed input length per aggregate, and thus they require the same notions of family and uniformity as for circuits. The unusual input convention for aggregates allows a computation to use less than linear hardware. Aggregates like circuits provide a reasonable measure of parallel time. In fact, the following theorem shows that they provide the same measure of time as circuits. (All of these are results from [11] and [12]).

[5] As is customary, we refer to the relations in (1) and (2) as Eqs. (1) and (2), respectively, even though they are not mathematical equations but only LaTeX equations.

THEOREM 45.3 *UAG-TIME*$(T(n)) = UDEPTH(T(n))$.

As a corollary to Theorems 45.2 and 45.3, we get the following result.

COROLLARY 45.1 UAG-TIME$(T(n)) \subseteq$ DSPACE$(T(n)) \subseteq$ NSPACE$(T(n)) \subseteq$ UAG-TIME$(T(n)^2)$.

Theorem 45.2 and Corollary 45.1 provide evidence for the Parallel Computation Thesis that is discussed further in its own section. The following result relates uniform synchronous circuit width to uniform aggregate hardware. A circuit is **synchronous** if all inputs to a gate v come from gates at depth $(d(v) - 1)$ (see Definition 45.5).

THEOREM 45.4 *DSPACE*$(S(n)) = UAG\text{-}HARDWARE(S(n)) = USWIDTH(S(n))$.

Width represents the maximum number of gates that have to be active at any one time during a level-by-level evaluation of a circuit, and thus gives a reasonable measure for hardware size.

Conglomerates

A conglomerate is defined as a collection of interconnected finite state machines M_0, M_1, M_2, ... [18]. Each M_i is deterministic and has $r \geq 1$ inputs and 1 output. The conglomerate is unlike a circuit in that it may have loops, and unlike an aggregate in that its input convention implies hardware size $\Omega(n)$. A uniformity requirement on the connection function of conglomerates similar to what one does for circuits and aggregates is imposed. On a given input of size n, the first n machines each contain one bit of the input. All machines begin in a designated initial state. The computation halts if M_0 enters a special final state.

THEOREM 45.5 *[19] If C is a conglomerate whose connection function f can be computed in space n on a Turing machine then CONG-TIME*$(T(n)) \subseteq DSPACE(T(n)) \subseteq NSPACE(T(n)) \subseteq CONG\text{-}TIME(T(n)^2)$.

Time is the only resource that has been formally studied for the conglomerate. The obvious definition of hardware for a conglomerate is the number of finite state machines that are "used" during a computation. For values of hardware size $\Omega(n)$, conglomerates provide the same measure of hardware that aggregates do.

k-PRAMs

The k-PRAM [40] does not have any global memory structure. Instead a processor is allowed to communicate with another processor through a *call* by passing parameters or via a *return* through the *channel registers.* A processor is also allowed the following instruction: if "child processor" returned then label_1 else label_2. This provides an additional way to communicate because the return time can affect the parent's computation. Communication between processors in a k-PRAM is much more restricted than in PRAM models whose processors share a global memory. The constant k indicates the branching factor out of a processor. The inability of a processor to communicate with an unbounded number of processors is the motivation for placing the model in the fixed structure class. Theorem 45.6 shows that time on this nondeterministic model is polynomially related to sequential space, although this result is not as tight as for some of the other parallel models.

THEOREM 45.6 *[40] If* $T(n) \geq n$ *is k-PRAM-countable then NSPACE*$(T(n)) \subseteq k\text{-}NPRAM\text{-}TIME(T(n)^2)$. *If* $T(n) \geq n$ *is RAM-constructible then k-NPRAM-TIME*$(T(n)) \subseteq NSPACE(T(n)^3)$.

Alternating Turing Machines

An alternating Turing machine [2] is a generalization of a nondeterministic Turing machine to have universal acceptance states as well as existential acceptance states. (See Chapter 27.) ATM resources are *time, space,* and *alternation,* where **alternation** counts the maximum number of changes between existential and universal acceptance states, in an accepting subtree of an ATM computation.

ATMs are particularly suited for problems that can be modeled as two person games. One drawback of the ATM as a parallel model is that there does not seem to be a resource measure for the ATM that corresponds to hardware [6].

The result stated below demonstrates the close relationship between ATMs and uniform families of bounded fanin Boolean circuits.

THEOREM 45.7 *[39] If S and T are computable in deterministic time $O(T(n))$ then ATIME, SPACE$(T(n), S(n))$ = UDEPTH, SIZE$(T(n), 2^{O(S(n))})$.*

The next theorem of Ruzzo and Tompa, (see [43] for a proof) shows that ATMs with alternation considered as a resource are a good model of unbounded fanin, parallel computation (see Section "SIMDAGs and CRCW-PRAMs").

THEOREM 45.8 *If $T(n)$ and $S(n)$ are suitable functions then ATM-ALT, SPACE$(T(n), S(n))$ = CRCW-PRAM-TIME, PROC$(T(n), 2^{O(S(n))})$.*

The Modifiable Structure Models

SIMDAGs and CRCW-PRAMs

The SIMDAG was formally defined in [18]. SIMDAG is an acronym for *S*ingle *I*nstruction Stream, *M*ultiple *Da*ta Stream, *G*lobal Memory. The model is now more commonly known as the CRCW-PRAM. Goldschlager proposed a fair cost per instruction version of the SIMDAG, called the *charged* SIMDAG. The charged SIMDAG satisfies Eq. (45.1), whereas the following theorem holds for the SIMDAG.

THEOREM 45.9 *[18] If $T(n) \geq \log n$ is SIMDAG-countable then NSPACE$(T(n)) \subseteq$ SIMDAG-TIME$(T(n)) \subseteq$ DSPACE$(T(n)^2)$.*

Uniform Families of Unbounded Fanin Boolean Circuits

Lower bounds for unbounded fanin Boolean circuits were proved in [16]. The following theorem by Stockmeyer and Vishkin relates CRCW-PRAMs to uniform families of unbounded fanin Boolean circuits in such a way that these lower bounds also hold for the CRCW-PRAM.

THEOREM 45.10 *[43] There is a constant c and a function $q(P, T, n)$ bounded above by a polynomial in P, T, and n such that the following holds. Let M be a CRCW-PRAM with processor bound $P(n)$ that operates in time $T(n)$. There is a constant d_M and, for each n, a circuit C_n of size $d_M q(P(n), T(n), n)$ and depth $cT(n)$ such that C_n realizes the input-output behavior of M on inputs of size n.*

Combining Theorem 45.10 with results from [16], we get the following corollary.

COROLLARY 45.2 [43] A CRCW-PRAM with a polynomially bounded number of processors that operates in constant time cannot compute parity, multiply integers, find the transitive closure of a graph, determine whether a graph has a perfect matching, or sort integers.

This corollary illustrates why Theorem 45.10 is a useful step toward unifying the modifiable parallel models. It allows the lower bounds already known for one model to be transferred over to another. It is possible to simulate unbounded fanin Boolean circuits via PRAMs [43]. See Section "Equivalence of PRAMs and Uniform Boolean Circuit Families" for the bounded fanin case of this simulation.

Hardware Modification Machines

The hardware modification machine (HMM) (see [10, 11, 12]) was defined to measure hardware more effectively. A hardware modification machine is made up of a finite collection of finite state machines. The machines are connected together in the same manner as in the conglomerate, the main difference being that the connections may be changed locally *during* a computation. A single HMM works for all input lengths so there is no need to define uniformity. The resources of interest for HMMs are *time* and *hardware*. The input convention for the HMM is such that we can consider hardware values that are sublinear. The following theorem shows that the HMM satisfies Eq. (45.2).

THEOREM 45.11 *[11, 12]* $DSPACE(T(n)) \subseteq HMM\text{-}TIME(T(n)) \subseteq DSPACE(T(n)^2)$.

This theorem illustrates that despite the HMM's processors being allowed only a bounded number of connections at any step during the computation, the HMM can still simulate DSPACE linearly. The following theorem shows the relationship between DSPACE and HMM hardware.

THEOREM 45.12 *[11, 12]* $HMM\text{-}HARDWARE(H(n)) \subseteq DSPACE(H(n)(\log n + \log H(n)))$.

Other interesting results for *parallel pointer machines* are given in [32].

Parallel Computation Thesis

The **Parallel Computation Thesis** is that time-bounded parallel machines are polynomially related to space-bounded sequential machines [18]. That is, for any function $T(n)$,

$$\text{PARALLEL-TIME}(T(n)^{O(1)}) = \text{SEQUENTIAL-SPACE}(T(n)^{O(1)}) \; . \tag{45.3}$$

The Parallel Computation Thesis, by constructively relating sequential space to parallel time, provides an automatic mechanism for obtaining a fast parallel algorithm from a highly space efficient sequential algorithm.

Any model satisfying Eqs. (45.1) or (45.2) gives support to the Parallel Computation Thesis. For example, Theorem 45.2, Corollary 45.1, Theorem 45.5, and Theorem 45.11 are results of the form described in Eq. (45.1) for uniform bounded fanin circuits, uniform aggregates, conglomerates, and HMMs, respectively. The next few results provide additional evidence supporting the Parallel Computation Thesis for vector machines, CREW-PRAMs, and ATMs.

THEOREM 45.13 *[36] If* $T(n)$ *is VM-countable and* $T(n) \geq \log n$ *then* $NSPACE(T(n)) \subseteq VM\text{-}TIME(T(n)^2)$. *If* $T(n)$ *is RAM-constructible and* $T(n) \geq \log n$ *then* $VM\text{-}TIME(T(n)) \subseteq DSPACE(T(n)^2)$.

THEOREM 45.14 *[15]* $CREW\text{-}PRAM\text{-}TIME(T(n)) \subseteq DSPACE(T(n)^2) \subseteq CREW\text{-}PRAM\text{-}TIME(T(n)^2)$.

THEOREM 45.15 *[2]* $ATIME(T(n)) \subseteq DSPACE(T(n)) \subseteq NSPACE(T(n)) \subseteq ATIME(T(n)^2)$.

The proofs of the simulation of sequential space by parallel time are similar to, and motivated by, Savitch's Theorem (see Chapter 27). The general structure of such proofs is as follows:

1. Let M be an $S(n)$ space bounded Turing machine (deterministic or nondeterministic) with initial configuration C_0 and unique final configuration C_f.
2. Observe that M has at most $2^{O(S(n))}$ possible configurations.
3. Construct the state transition matrix or transition graph for M.
4. Compute the transitive closure by repeated squaring of the transition matrix or perform path doubling in the transition graph.
5. Accept if and only if the entry at position C_0C_f is 1 in the transition matrix, or if and only if there is a path from C_0 to C_f in the transition graph.

For the other direction, of simulating parallel time by sequential space, the basic technique is to perform a depth-first search on the instructions executed by the machine being simulated. This is done using a recursive procedure. The recursive procedure's initial call often has the form VERIFY(q, x, t), where q is a final condition, x is the input, and t is the time bound. The procedure VERIFY checks to see that the *final* state or *accept* instruction is reached on input x in time t. The recursion depth is the same as the running time, say $T(n)$, of the machine being simulated. In situations where the recursion requires only constant space at each level, the whole simulation is performed using linear space. If the recursion needs space $T(n)$ in each call to store parameters and return values, then the simulation takes quadratic space.

45.5 *P*-Completeness Theory

The following is a basic presentation of P-completeness theory. For an in-depth study, see [21].

Reducibility

The theory of P-completeness is useful for categorizing problems that are potentially inherently sequential; it parallels the theory of NP-completeness. One of the key ideas required in the development of the theory is the ability to relate one problem to another, via the notion of *reducibility* (see Chapter 28 for more on this subject). Here we focus on one of the most basic forms.

DEFINITION 45.15 A language L is NC **many-one reducible** or NC **reducible** to L', written $L \leq_m^{NC} L'$, if and only if there is a function f in FNC such that $x \in L$ if and only if $f(x) \in L'$.

Since NC reducibility is transitive, we can use a series of individual reductions to achieve a more complicated reduction.

LEMMA 45.2 NC reducibility is transitive. That is, whenever $L \leq_m^{NC} L'$ and $L' \leq_m^{NC} L''$, then $L \leq_m^{NC} L''$.

In many reductions from a language L to a language L', the exact complexity of L' is unknown. Although this gives us no absolute information about the computational complexity of L, it still provides useful information about the relative difficulties of the two languages. In particular, assuming the reduction is not too powerful, it implies that L is no more difficult to decide than L'. It is important to note that if the reduction is allowed too much power, it will mask the complexity of L'. The following shows that NC reducibility has the appropriate level of power, since it preserves membership in NC.

LEMMA 45.3 If $L' \in NC$ and $L \leq_m^{NC} L'$ then $L \in NC$.

A less powerful notion called AC^0 reducibility is discussed at length in Chapter 28.

Completeness

The idea of P-completeness is to identify those problems in P that are the "hardest".

DEFINITION 45.16 A language L is P-**hard under** NC **reducibility** if and only if $L' \leq_m^{NC} L$ for every $L' \in P$. A language L is P-**complete under** NC **reducibility** if and only if $L \in P$ and L is P-hard.

THEOREM 45.16 *If any P-complete language is in NC then NC equals P.*

Theorem 45.16 tells us that the fundamental question of whether NC equals P has the same answer as the question of whether any P-complete problem is in NC. Much evidence has accumulated showing that it is unlikely that NC equals P, and so the P-complete problems are likely to be inherently sequential. Thus, when trying to design a highly parallel algorithm, one should avoid solving P-complete problems. That is, do not make use of a subroutine call to solve a P-complete problem since this will create a parallel bottleneck.

Proof Methodology for *P*-Completeness

The steps required to show that a language L is P-complete are as follows:

1. Demonstrate that L is in P
   (a) provide an algorithm A for L
   (b) prove algorithm A is correct
   (c) prove algorithm A runs in polynomial time
2. Prove that L is P-hard
   (a) for all $L' \in P$, prove that $L' \leq_m^{NC} L$ (this is usually done by providing a function f reducing a known P-complete problem to L)
   (b) prove f is a valid reduction
   (c) prove f is in FNC

In the next section we examine the most fundamental P-complete problems. These are the problems that, by application of Lemma 45.2, are most frequently used to demonstrate a new problem is P-complete.

45.6 Examples of *P*-Complete Problems

Our goal in this section is to acquaint the reader with a number of P-complete problems. The full proofs of P-completeness may be found in [21].

Generic Machine Simulation

The canonical device for performing sequential computations is the Turing machine, with its single processor and serial access to memory. Of course, the usual machines that we call sequential are not

nearly so primitive, but fundamentally they all suffer from the same bottleneck created by having just one processor. So to say that a problem is inherently sequential is to say that solving it on a parallel machine is not substantially better than solving it on a Turing machine. What could be more sequential than the problem of simulating a Turing machine computation? If we could just discover how to simulate efficiently, in parallel, every Turing machine that uses polynomial time, then every feasible sequential computation could be translated automatically into a highly parallel form. Thus, we are interested in the following problem.

DEFINITION 45.17 Generic Machine Simulation Problem (GMSP)
Given: A string x, a description $\overline{M}$ of a Turing machine M, and an integer t coded in unary. The input is coded as $x\#\overline{M}\#^t$, where # is a delimiter character not otherwise present in the string and $\#^t$ is the unary encoding of t.
Problem: Does M accept x within t steps?

Intuitively at least, it is easy to see that this problem is solvable in polynomial time sequentially—just interpret M's program step-by-step on input x until either M accepts or t steps have been simulated, whichever comes first. Such a step-by-step simulation of an arbitrary Turing machine by a fixed one is the essence of the fundamental result that universal Turing machines exist. Given a reasonable encoding $\overline{M}$ of M, the simulation of it by the universal machine will take time polynomial in t and the lengths of x and $\overline{M}$, which in turn is polynomial in the length of the universal machine's input. (This is why we insist that t be encoded in unary.)

It is easy to NC reduce an arbitrary language L in P to the generic machine simulation problem. Let M_L be a Turing machine recognizing L in polynomial time and let $r(n) = n^{O(1)}$ be an easy-to-compute upper bound on that running time. To accomplish the reduction, given a string x, simply generate the string $f(x) = x\#\overline{M_L}\#^{r(|x|)}$. Then $f(x)$ will be a "yes" instance of the generic machine simulation problem if and only if x is in L. This transformation is easily performed in NC (see [21] for details).

THEOREM 45.17 *The generic machine simulation problem is P-complete.*

GMSP is in fact a bit too generic to be very useful for proving other problems are P-complete. A problem that is better suited for this is described in the next section.

The Circuit Value Problem and Variants

The fundamental P-complete problem is the **circuit value problem**, defined as follows:

DEFINITION 45.18 Circuit Value Problem (CVP)
Given: An encoding $\overline{\alpha}$ of a Boolean circuit α, inputs $x_1, \ldots, x_n$, and a designated output y.
Problem: Is output y of α TRUE on input $x_1, \ldots x_n$?

THEOREM 45.18 *[31] The Circuit Value Problem is P-complete.*

The circuit value problem plays the same role in P-completeness theory that *satisfiability* (SAT) [3] does in NP-completeness theory. Like SAT, CVP is the fundamental P-complete problem in the sense that it is most frequently used to show that other problems are P-complete. Also like SAT, CVP has many restricted variants that are P-complete and can often simplify the construction of reductions. Table 45.3 summarizes these variants of CVP.

TABLE 45.3 Other P-Complete Variants of the Circuit Value Problem

Topologically Ordered CVP	A **topological ordering** is a vertex numbering so that the source vertex of each edge is less than the sink vertex. All CVP variants here remain P-complete even if we require that the vertices be presented in topological order in the circuit encoding (and thus the evaluation order is provided in the CVP instance).
NORCVP	CVP is restricted to contain only NOR gates. Reductions are often simpler when only one gate type needs to be simulated.
Monotone CVP (MCVP)	CVP restricted to **monotone** gates, that is, AND's and OR's. Useful in the situation where negations are hard to simulate.
Alternating, Monotone CVP (AMCVP)	A special case of MVCP. A monotone circuit is **alternating** if on any path from an input to an output the gates alternate between OR and AND. For AMCVP, inputs must connect only to OR gates, and outputs must be OR gates. Reductions often replace individual gates by certain small "gadgets." The alternating property reduces the number and kinds of interactions between gadgets that must be considered.
Fanin 2, Fanout 2 AMCVP (AM2CVP)	A restriction of AMCVP, where all gates are restricted to have fanin and fanout two, with the obvious exception of inputs and outputs. Having a fixed fanout often simplifies reductions.
Synchronous AM2CVP (SAM2CVP)	Restriction of AM2CVP to synchronous circuits (defined in "Uniform Aggregates"). All output vertices are required to be on the highest level of the circuit, so that it can be partitioned into layers, with all edges going from one layer to the next higher one, and all outputs on the last layer. Note that in a circuit that is both alternating and synchronous, all gates on any given level must be of the same type. The fanin two and fanout two restrictions further imply that every level contains exactly the same number of vertices. This structural regularity simplifies some reductions.

There are two key ideas in the proof of Theorem 45.18. The first is that for any circuit there is a simple sequential algorithm that given any input to the circuit evaluates individual gates of the circuit in a fixed order, evaluating each exactly once, and arriving at the circuit's designated output value in polynomial time. Thus CVP is in P.

The second key idea (see Chapter 27 for full details) is used to show that CVP is P-complete. Every language $L \in P$ has an associated Turing machine that decides membership of a length n string x in L in time $T(n)$, polynomial in n. Any polynomially time-bounded Turing machine computation can only use a polynomial amount of tape, and this means that the state of the tape at any instant can be simulated by a constant depth polynomially sized circuit "slice". On an input of length n, the Turing machine runs for at most $T(n)$ steps, and so at most $T(n)$ tape simulation slices are required. Thus there is a circuit family associated with L such that the nth circuit of the family decides membership of all strings of length n. This reduces the question of $x \in L$ to whether a specific polynomially sized circuit with input x outputs the value 1, and therefore shows that CVP is P-hard.

Additional *P*-Complete Problems

There are hundreds of P-complete problems (see [21]), from many areas of computer science: circuit complexity, graph theory, graph searching, combinatorial optimization and flow, local optimality, logic, formal languages, algebra, geometry, real analysis, games, and miscellaneous topics. Here are three of the more interesting P-complete problems. This first problem is from graph theory and was proved P-complete in [7].

DEFINITION 45.19 Lexicographically First Maximal Independent Set (LFMIS)

Given: An undirected graph $G = (V, E)$ with an ordering on the vertices and a designated vertex v.

Problem: Is vertex v in the lexicographically first maximal independent set of G?

Below we prove LFMIS is P-complete.

THEOREM 45.19 *[7] The Lexicographically First Maximal Independent Set Problem is P-complete.*

PROOF Membership in P follows from the standard greedy algorithm: vertices are processed in numerical order and added to the independent set if they do not have an edge to any vertex already in the independent set.

Completeness follows by reducing the NOR circuit value problem (NORCVP) to LFMIS using the construction given in [21]. Without loss of generality, we assume the instance α of NORCVP has its gates numbered (starting from 1) in topological order with inputs numbered first and outputs last. Suppose y is the designated output gate in the instance of NORCVP. We construct from α an instance of LFMIS, namely an undirected graph G. The graph G will be exactly the same as the graph underlying the circuit α, except that we add a new vertex, numbered 0, that is adjacent to all 0-inputs of α. It is easy to verify by induction that a vertex i in G is included in the lexicographically first maximal independent set if and only if either i equals 0 (the new vertex), or gate i in α has value TRUE. A choice of v equal to y completes the reduction.

The proof that the reduction can be performed in NC amounts to showing that the required edges from the new vertex 0 to the 0-inputs can be produced easily. The remainder of the circuit connections are easy to output directly.

The next problem is from graph searching and was proved P-complete in [37].

DEFINITION 45.20 Lexicographically First Depth-first Search Ordering

Given: An undirected graph $G = (V, E)$ with fixed ordered adjacency lists, and two designated vertices u and v.

Problem: Is vertex u visited before vertex v in the depth-first search of G induced by the order of the adjacency lists?

The final problem is from formal languages and was proved P-complete in [26].

DEFINITION 45.21 Context-Free Grammar Membership

Given: A context-free grammar $G = (N, T, P, S)$ and a string $x \in T^*$.

Problem: Is $x \in L(G)$?

It is likely that all these problems are inherently sequential. However, each of the problems has a related variant that is feasibly highly parallel. For example, each of these are in NC: finding *some* maximal independent set, finding the lexicographically first depth-first numbering for directed *acyclic* graphs, and context-free grammar membership for ϵ-free (ϵ denotes the empty string) grammars. References to these algorithms can be found in [21]. In practice, when the problem you want to solve is P-complete, there is often a closely related variant that is feasible and highly parallel. Whether this variant is useful to you is of course another matter.

Open Problems

There are a few simple problems for which it is unknown whether the problem is in NC or is P-complete. We give some of these here. The original references for these, and other, problems may be found in [21].

DEFINITION 45.22 Integer Greatest Common Divisor (IntegerGCD)
Given: Two n-bit positive integers a and b.
Problem: Compute the greatest common divisor of a and b.

DEFINITION 45.23 Lexicographically First Maximal Matching (LFMM)
Given: An undirected graph $G = (V, E)$ with an ordering on its edges and distinguished edge $e \in E$.
Problem: Is e in the lexicographically first maximal matching of G? A matching is **maximal** if it cannot be extended.

DEFINITION 45.24 Directed or Undirected Depth-First Search (DFS)
Given: A graph $G = (V, E)$ and a vertex s.
Problem: Construct a depth-first search numbering of G starting from vertex s.

DEFINITION 45.25 Maximum Matching (MM)
Given: An undirected graph $G = (V, E)$.
Problem: Find a maximum matching of G. A **matching** is a subset of edges $E' \subseteq E$ such that no two edges in E' share a common endpoint. A matching is **maximum** if no matching of larger cardinality exists.

DEFINITION 45.26 Subtree Isomorphism (STI)
Given: Two unrooted trees $T = (V, E)$ and $T' = (V', E')$.
Problem: Is T *isomorphic* to a subtree of T'?

It is notable that LFMM is *CC-complete* (circuits composed of comparators), and that DFS, MM, and STI have randomized feasible highly parallel algorithms (i.e., they are in RNC, which is the class random NC).

45.7 Research Issues and Summary

Many issues in parallel computation remain unresolved. The big question of asymptotic complexity theory is whether every feasible sequential problem has a feasible highly parallel solution, that is, does NC equal P? Although we have strong evidence[6] suggesting there are fundamental limits to the speedup attainable through parallel computation, this evidence does not constitute proof. It seems that deciding this question will require a major breakthrough in complexity theory. Another important complexity question is whether randomization helps in highly parallel computation. It is clear that NC is a subset of RNC (the randomized version of NC), but not known if the two classes are equal. Finally, there are many problems that have feasible highly parallel algorithms but whose algorithms are not **optimal**. That is, their **work** (time-processor product) is more than a constant factor greater than the running time of the best

[6] We have never explicitly stated the evidence in this chapter due to its technical nature. Chapter 5 of [21] goes into the evidence in detail.

known sequential algorithm. Attempting to improve the time or processor bounds for such problems is one way of understanding the relationship between sequential and parallel computation.

From the standpoint of algorithm design, the most important issue is finding a parallel model that is more realistic. That is, a model that reflects the kinds of parallel machines that will actually be built in the foreseeable future, and on which algorithms will be implemented. The works [8, 9, 44, 45], are some first steps in this direction. The main assumption of these models is that all parallel machines will essentially consist of a moderate number (thousands not millions) of highly powerful individual processors each with substantial memory, and interconnected by a high (but not infinite) capacity network.

Each model is parameterized so that any given instance of these kinds of parallel machines can be modeled so as to account for the architectural features which dominate the design of a parallel algorithm for that machine. The parameters include the number of processors, the communication bandwidth on the interconnection network, the *latency* or *delay* in transmitting over the network, granularity, and the overhead of initiating communication over the network.

The presence of these parameters forces the designer of the parallel algorithm not only to account for the computational aspects of the problem (deciding what is to be done and by what processor), but also to consider the communication aspects of the problem (where should data be placed and how should accesses be scheduled). By putting equal emphasis on computation and communication, such models more accurately capture reality, while avoiding architectural details like the kind of interconnection network. The task is now to develop parallel algorithms that can be used for as wide a range of parameter values as possible, and thus be robust over a much broader class of real machines.

45.8 Defining Terms

Circuit Value Problem: [31]
Given: An encoding $\overline{\alpha}$ of a Boolean circuit α, inputs $x_1, \ldots, x_n$, and a designated output y.
Problem: Is output y of α TRUE on input $x_1, \ldots x_n$?

NC**:** The set of all languages L that are decidable in parallel time $(\log n)^{O(1)}$ and processors $n^{O(1)}$.

NC **many-one reducibility:** A language L is NC **many-one reducible** or NC **reducible** to L', written $L \leq_m^{NC} L'$, if there is a function f in FNC such that $x \in L$ if and only if $f(x) \in L'$.

P**:** The set of all languages L that are decidable in sequential time $n^{O(1)}$.

Parallel computation thesis: Sequential space is polynomially related to parallel time.

Path Systems: [4]
Given: A path system $P = (X, R, S, T)$, where $S \subseteq X$, $T \subseteq X$, and $R \subseteq X \times X \times X$.
Problem: Is there an admissible vertex in S? A vertex x is **admissible** if and only if $x \in T$, or there exists admissible $y, z \in X$ such that $(x, y, z) \in R$.

P**-complete:** A language L is P**-hard under** NC **reducibility** if $L' \leq_m^{NC} L$ for every $L' \in P$. A language L is P**-complete under** NC **reducibility** if $L \in P$ and L is P-hard.

Acknowledgments

A warm thanks to Mike Atallah for inviting us to work with him on this exciting project. A special thanks to Larry Ruzzo for many enlightening discussions about the material in this chapter. Thanks to the anonymous referees for carefully reading the chapter and providing us with many helpful suggestions. This chapter was written while Ray was on sabbatical at the Universitat Politècnica de Catalunya in Barcelona. The department's hospitality is greatly appreciated.

Further Information

Much of our material is adapted from *Limits to Parallel Computation* [21], and many more details can be found there. The relationships among various parallel models can be found in the excellent surveys [6, 14, 27]. Additional papers surveying other aspects of parallel models and parallel computing include [24, 29, 42, 46, 48].

The book *Efficient Parallel Algorithms* [17] has a brief discussion of parallel models of computation followed by substantial material on parallel algorithms. The text *An Introduction to Parallel Algorithms* [23] devotes a chapter to discussing parallel models and then extensively delves into parallel algorithms. The text *Introduction to Parallel Algorithms and Architectures: Arrays, Trees, Hypercubes* [33] contains a detailed discussion of many different types of parallel models and algorithms. The collection *Synthesis of Parallel Algorithms* [38], contains about twenty chapters organized around parallel algorithms for particular types of problems, together with an introductory chapter on P-completeness [20], and one surveying PRAM models [14]. The chapter "Parallel Algorithms for Shared-Memory Machines" by [27] in the *Handbook of Theoretical Computer Science* [47] describes a variety of highly parallel algorithms. In the same handbook, the chapter "A Catalog of Complexity Classes" [25] is a thorough overview of basic complexity theory and of the current state of knowledge about most complexity classes. It is an excellent reference for establishing the context of each class and its established relationships to others. The papers [28, 29, 30] provide extensive bibliographies of papers about parallel algorithms and parallel algorithm development for combinatorial optimization problems.

Algorithmic Techniques for Networks of Processors

Russ Miller
State University of New York at Buffalo

Quentin F. Stout
University of Michigan

46.1 Introduction

This chapter is concerned with designing algorithms for machines constructed from multiple processors. In particular, we discuss algorithms for machines in which the processors are connected to each other by some simple, systematic, interconnection pattern. For example, consider a chess board, where each square represents a processor (for example, a processor similar to one in a home computer) and every generic processor is connected to its 4 neighboring processors (those to the north, south, east, and west). This is an example of a *mesh computer,* a network of processors that is important for both theoretical and practical reasons.

The focus of this chapter is on algorithmic techniques. Initially, we define some basic terminology that is used to discuss parallel algorithms and parallel architectures. Following this introductory material, we define a variety of **interconnection networks,** including the mesh (chess board), which are used to allow processors to communicate with each other. We also define an abstract parallel model of computation, the *PRAM,* where processors communicate with memory instead of with each other. We then discuss several parallel programming paradigms, including the use of high-level data movement operations, **divide-and-conquer, pipelining,** and **master–slave.** Finally, we discuss the problem of mapping the structure of an inherently parallel problem onto a target parallel architecture. This mapping problem can arise in a variety

of ways, and with a wide range of problem structures. In some cases, finding a good mapping is quite straightforward, but in other cases it is a computationally intractable NP-complete problem.

46.2 Terminology

In order to initiate our investigation, we first define some basic terminology that will be used throughout the remainder of this chapter.

Shared Memory vs. Distributed Memory

In a **shared memory** machine, there is a single global image of memory that is available to all processors in the machine, typically through a common bus or switching network (see Fig. 46.1). This model is similar to a blackboard, where any processor can read or write to any part of the board (memory), and where all communication is performed through messages placed on the board.

Each processor in a **distributed memory** machine has access only to its private (local) memory (see Fig. 46.1). In this model, processors communicate by sending messages to each other, with the messages being sent through some form of interconnection network. This model is similar to a school in which each professor occupies a unique classroom equipped with a blackboard. For professor W to access information maintained on the board of professor X, W sends a message to X requesting the information, and X sends a message back with the information. In this classroom scenario, messages might be transmitted by students running through the halls. In such message-passing systems, the overhead and delay can be significantly reduced if it can be arranged so that X sends the information to W without a request being sent. This is particularly useful if it can be arranged so that the data from X arrives before W needs to use it, for then W will not be delayed waiting for the data. This analogy represents an important aspect of developing efficient programs for distributed memory machines, especially general-purpose machines in which communication can take place concurrently with calculation so that the communication time is effectively hidden.

For small shared memory systems, it may be that the network is such that each processor can access all memory cells in the same amount of time. For example, many symmetric multiprocessor (SMP) systems have this property. However, since memory takes space, systems with a large number of processors are typically constructed as modules (i.e., a processor/memory pair) that are connected to each other via an interconnection network. Thus, while memory may be logically shared in such a model, in terms of performance each processor acts as if it is distributed, with some memory being "close" (fast access) to the processor and some memory being "far" (slow access) from the processor. Notice the similarity to distributed memory machines, where there is a significant difference in speed between a processor accessing its own memory versus a processor accessing the memory of a distant processor. Such shared memory machines are called NUMA (nonuniform memory access) machines, and often the most efficient programs for NUMA machines are developed by using algorithms efficient for distributed memory architectures, rather than using ones optimized for uniform access shared memory architectures.

The efficient use of an interconnection network in a parallel computer is often an important consideration in developing and tuning parallel programs. For example, in either shared or distributed memory machines, communication will be delayed if a packet of information must pass through many communication links. Similarly, communication will be delayed by contention if many packets need to pass through the same link. As an example of contention at a link, in a distributed memory machine configured as a binary tree of processors, suppose that all leaf processors on one side of the machine need to exchange values with all leaf processors on the other side of the machine. Then a bottleneck occurs at the root since the passage of information proceeds in a sequential manner through the links in and out of the root.

Both shared and distributed memory systems can also suffer from contention at the destinations. In a distributed memory system, too many processors may simultaneously send messages to the same processor,

which causes a processing bottleneck. In a shared memory system, there may be memory contention, where too many processors try to simultaneously read or write from the same location.

Another common feature of both shared and distributed memory systems is that the programmer has to be sure that computations are properly synchronized, i.e., that they occur in the correct order. This tends to be easier in distributed memory systems, where each processor controls the access to its data, and the messages used to communicate data also have the side-effect of communicating the status of the sending processor. For example, suppose processor W is calculating a value, which will then be sent to processor R. If the program is constructed so that R does not proceed until the message from W arrives, then it is guaranteed of using the correct value in the calculations. In a shared memory system, the programmer needs to be more careful. For example, in the same scenario, W may write the new value to a memory location that R reads. However, if R reads before W has written, then it may proceed using the wrong value. This is known as a *race condition,* where the correctness of the calculation depends on the order of the operations. To avoid this, various locking or signaling protocols need to be enforced so that R does not read the location until after W has written to it. Race conditions are a common source of programming errors, and are often difficult to locate because they disappear when a deterministic, serial debugging approach is used.

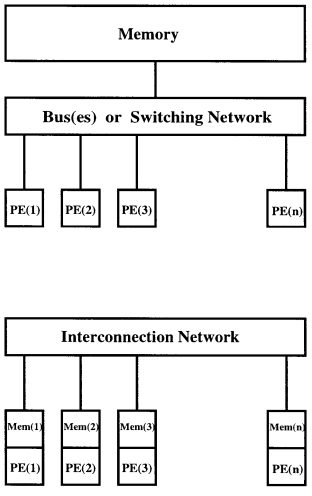

FIGURE 46.1 Shared memory (top) and distributed memory (bottom) machines. (*PE* is used represent a processing element and *Mem* is used to represent memory.)

Flynn's Taxonomy

In 1966, Michael Flynn classified computer architectures with respect to the *instruction stream,* that is, the sequence of operations performed by the computer, and the *data stream,* that is, the sequence of items operated on by the instructions [4]. While extensions and modifications to Flynn's taxonomy have appeared, Flynn's original taxonomy [5] is still widely used. Flynn characterized an architecture as belonging to one of the following four classes.

- Single-Instruction Stream, Single-Data Stream (SISD)
- Single-Instruction Stream, Multiple-Data Stream (SIMD)
- Multiple-Instruction Stream, Single-Data Stream (MISD)

- Multiple-Instruction Stream, Multiple Data Stream (MIMD)

Standard serial computers fall into the *single-instruction stream, single data stream (SISD)* category, in which one instruction is executed per unit time. This is the so-called von Neumann model of computing, in which the stream of instructions and the stream of data can be viewed as being tightly coupled, so that one instruction is executed per unit time to produce one useful result. Modern "serial" computers include various forms of modest parallelism in their execution of instructions, but most of this is hidden from the programmer and only appears in the form of faster execution of a sequential program.

A *single-instruction stream, multiple-data stream (SIMD)* machine typically consists of multiple processors, a control unit (controller), and an interconnection network, as shown in Fig. 46.2. The control unit

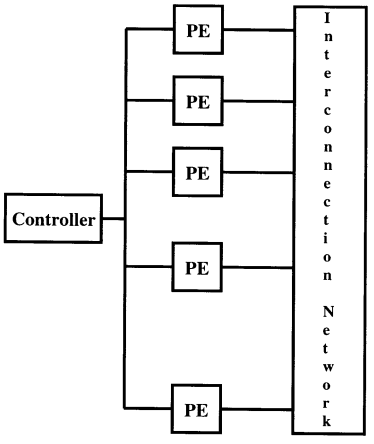

FIGURE 46.2 A SIMD machine. (*PE* is used to represent a processing element.)

stores the program and broadcasts the instructions to all processors simultaneously. Active processors execute the instruction on the contents of their own local memory. Through the use of a *mask*, processors may be in either an active or inactive state at any time during the execution of the program. Masks can be dynamically determined, based on local data or the processor's coordinates. Note that one side-effect of having a centralized controller is that the system is synchronous, so that no processor can execute a second instruction until all processors are finished with the first instruction. This is quite useful in algorithm design, as it eliminates many race conditions and makes it easier to reason about the status of processors and data.

Multiple-instruction stream, single-data stream (MISD) machines consist of two or more processors that perform separate instructions on the same data. This model is rarely implemented.

A *multiple-instruction stream, multiple-data stream (MIMD)* machine typically consists of multiple processors and an interconnection network. In contrast to the single-instruction stream model, the multiple-instruction stream model allows each of the processors to store and execute its own program, providing multiple instruction streams. Each processor fetches its own data on which to operate. (Thus, there are multiple data streams, as in the SIMD model.) Often, all processors are executing the same program, but may be in different portions of the program at any given instant. This is the *single-program multiple-data (SPMD)* style of programming, which is an important mode of programming because it is rarely feasible to have a large number of different programs for different processors. The SPMD style, like the SIMD architectures, also makes it somewhat simpler to reason about the status of data structures and processors.

MIMD machines have emerged as the most commonly used general-purpose parallel computers, and are available in a variety of configurations. Both shared and distributed memory machines are available,

as are mixed architectures where small numbers of processors are grouped together as a shared memory symmetric multiprocessor, and these SMPs are linked together in a distributed memory fashion.

Granularity

When discussing parallel architectures, the term *granularity* is often used to refer to the relative number and complexity of the processors. A *fine-grained machine* typically consists of a relatively large number of small, simple processors (in terms of local memory and computational power), while a *coarse-grained machine* typically consists of relatively few processors, each of which is large and powerful. Fine-grained machines typically fall into the SIMD category, where all processors operate in lockstep fashion (i.e., synchronously) on the contents of their own small, local, memory. Coarse-grained machines typically fall into the shared memory MIMD category, where processors operate asynchronously on the large, shared memory. Medium-grained machines are typically built from commodity microprocessors, and are found in both distributed and shared memory models, almost always in MIMD designs.

For a variety of reasons, medium-grained machines currently dominate the parallel computer marketplace in terms of number of installations. Because they utilize commodity processors and have the ability to efficiently perform as general-purpose (parallel) machines, medium-grained machines tend to have cost/performance advantages over systems utilizing special-purpose processors. In addition, they can also exploit much of the software written for their component processors. Fine-grained machines are difficult to use as general-purpose computers because it is often difficult to determine how to efficiently distribute the work to such simple processors. However, fine-grained machines can be quite effective in tasks such as image processing or pattern matching.

By analogy, one can also use the granularity terminology to describe data and algorithms. For example, a database is a coarse-grained view of data, while considering the individual records in the database is a fine-grained view of the same data.

46.3 Interconnection Networks

In this section, we discuss interconnection networks that are used for communication among processors in a distributed memory machine. First, we define some terminology. The *degree of processor* P is the number of other processors that P is directly connected to via bidirectional communication links. The *degree of the network* is the maximum degree of any processor in the network. The *distance* between two processors is the number of communication links on a shortest path between the processors. The *communication diameter* of the network is the maximum, over all pairs of processors, of the distance between the processors. The *bisection bandwidth* of the network corresponds to the minimum number of communication links that need to be removed (or cut) in order to partition the network into two pieces, each with the same number of processors. Goals for interconnection networks include minimizing the degree of the processors (to minimize the cost of building a processor), minimizing the communication diameter (to minimize the communication time for any single message), and maximizing the bisection bandwidth (to minimize contention when many messages are being sent concurrently). Unfortunately, these design goals are in conflict. Other important design goals include simplicity (to reduce the design costs for the hardware and software) and scalability (so that similar machines, with a range of sizes, can be produced).

Before defining some network models (i.e., distributed memory machines characterized by their interconnection networks), we briefly discuss the **parallel random access machine (PRAM),** which is an idealized parallel model of computation, with a unit-time communication diameter. The PRAM is a shared memory machine that consists of a set of identical processors, where all processors have unit-time access to any memory location. The appeal of a PRAM is that one can ignore issues of communication when designing algorithms, focusing instead on obtaining the maximum parallelism possible in order to mini-

mize the running time necessary to solve a given problem. The PRAM model typically assumes a SIMD strategy, so that operations are performed synchronously. If multiple processors try to simultaneously read or write from the same memory location, then a memory conflict occurs. There are several variations of the PRAM model targeted at handling these conflicts, ranging from the Exclusive Read Exclusive Write (EREW) model, which prohibits all such conflicts, to Concurrent Read Concurrent Write (CRCW) models, which have various ways of resolving the effects of simultaneous writes. One popular intermediate model is the concurrent read exclusive write (CREW) PRAM, in which there may be concurrent reads to a memory location, but not concurrent writes. For example, a classroom is usually conducted in a CREW manner. In the classroom, even if several students are writing simultaneously on the blackboard, they are doing so in different locations, and hence there are no write conflicts.

The PRAM does not use a regular interconnection scheme for communication and the unit-time memory access requirement is not scalable (i.e., it is not realistic for a large number of processors and memory). However, in creating parallel programs, it is sometimes useful to describe a PRAM algorithm and then either perform a stepwise simulation of every PRAM operation on the target machine, or perform a higher-level simulation by using **global operations.** In such settings, it is often useful to design the algorithm for a powerful CRCW PRAM model, since often the CRCW PRAM can solve a problem faster or more naturally than an EREW PRAM. Since one is not trying to construct an actual PRAM, objections to the difficulty of implementing CRCW are not relevant; rather, having a simpler and/or faster algorithm is the dominant consideration.

In the remainder of this section, several specific interconnection networks are defined. See Fig. 46.3 for illustrations of these. The networks defined in this section are among the most commonly utilized networks. However, additional networks have appeared in both the literature and in real machines, and variations of the basic networks described here are numerous.

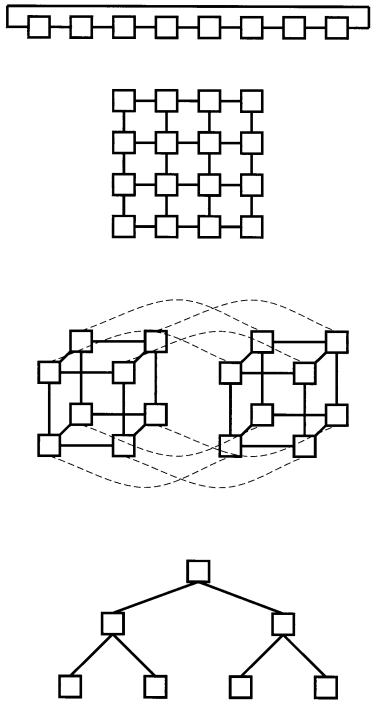

FIGURE 46.3 Sample interconnection networks (from top to bottom): ring, mesh, hypercube, and tree.

46.4 Ring

In a *ring* network, the n processors are connected in a circular fashion so that processor P_i is directly connected to processors P_{i-1} and P_{i+1} (the indices are computed modulo n, so that processors P_0 and P_{n-1} are connected). While the degree of the network is only 2, the communication diameter is $\lfloor n/2 \rfloor$, which is quite high. The bisection bandwidth is only 2, which is quite low.

Meshes and Tori

The n processors of a *two-dimensional square mesh* network are configured so that an interior processor $P_{i,j}$ is connected to its four neighbors, processors $P_{i-1,j}$, $P_{i+1,j}$, $P_{i,j-1}$, and $P_{i,j+1}$. The four corner processors are each connected to their two neighbors, while the remaining processors that are on the edge of the mesh are each connected to three neighbors. So, by increasing the degree of the network to 4, as compared to the degree 2 of the ring, the communication diameter of the network is reduced to $2(\sqrt{n}-1)$, and the bisection bandwidth is increased to $\sqrt{n}$. The diameter is further reduced, to $2\lfloor \sqrt{n}/2 \rfloor$, and the bisection bandwidth is increased, to $2\sqrt{n}$, in a *two-dimensional torus,* which has all the connections of the two-dimensional mesh plus connections between the first and last processors in each row and column. Meshes and tori of higher dimensions can be constructed, where the degree of a d-dimensional mesh or torus is $2d$, and, when n is a perfect dth power, the diameter is either $d(n^{1/d}-1)$ or $d\lfloor n^{1/d}/2 \rfloor$, respectively, and the bisection bandwidth is either $n^{(d-1)/d}$ or $2n^{(d-1)/d}$, respectively. Notice that the ring is a one-dimensional torus.

For a two-dimensional mesh, and similarly for higher-dimensional meshes, the mesh can be rectangular, instead of square. This allows a great deal of flexibility in selecting the size of the mesh, and the same flexibility is available for tori as well.

Hypercube

A *hypercube* with n processors, where n is an integral power of 2, has the processors indexed by the integers $\{0, \ldots, n-1\}$. Viewing each integer in this range as a $(\log_2 n)$-bit string, two processors are directly connected if and only if their indices differ by exactly one bit. Some advantages of a hypercube are that the communication diameter is only $\log_2 n$ and the bisection bandwidth is $n/2$. A disadvantage of the hypercube is that the number of communication links needed by each processor grows as $\log_2 n$, unlike the fixed degree for processors in ring and mesh networks. This makes it difficult to manufacture reasonably generic hypercube processors that could scale to extremely large machines, though in practice this is not a concern because the cost of an extremely large machine would be prohibitive.

Tree

A *complete binary tree* of height k, $k \geq 0$ an integer, has $n = 2^{k+1} - 1$ processors. The root node is at level 0 and the 2^k leaves are at level k. Each processor at level $1, \ldots, k-1$ has two children and one parent, the root processor does not have a parent processor, and the leaves at level k do not have children processors. Notice that the degree of the network is 3 and that the communication diameter is $2k = 2\lfloor \log_2 n \rfloor$. One severe disadvantage of a tree is that when extensive communication occurs, all messages traveling from one side of the tree to the other must pass through the root, causing a bottleneck. This is because the bisection bandwidth is only 1. Fat trees, introduced by Leiserson [9], alleviate this problem by increasing the bandwidth of the communication links near the root. This increase can come from changing the nature of the links, or, more easily, by using parallel communication links. Other generalizations of binary trees include complete t-ary trees of height k, where each processor at level $0, \ldots, k-1$ has t children. There are $(t^{k+1}-1)/(t-1)$ processors, the maximum degree is $t+1$, and the diameter is $2k = 2\lfloor \log_t n \rfloor$.

46.5 Designing Algorithms

Viewed from the highest level, many parallel algorithms are purely sequential, with the same overall structure as an algorithm designed for a more standard "serial" computer. That is, there may be an input and initialization phase, then a computational phase, and then an output and termination phase. The differences, however, are manifested within each phase. For example, during the computational phase, an efficient parallel algorithm may be inherently different from its efficient sequential counterpart.

For each of the phases of a parallel computation, it is often useful to think of operating on an entire structure simultaneously. This is a SIMD-style approach, but the operations may be quite complex. For example, one may want to update all entries in a matrix, tree, or database, and view this as a single (complex) operation. For a fine-grained machine, this might be implemented by having a single (or few) data item per processor, and then using a purely parallel algorithm for the operation. For example, suppose an $n \times n$ array A is stored on an $n \times n$ two-dimensional torus, so that $A(i, j)$ is stored on processor $P_{i,j}$. Suppose one wants to replace each value $A(i, j)$ with the average of itself and the four neighbors $A(i-1, j)$, $A(i+1, j)$, $A(i, j-1)$ and $A(i, j+1)$, where the indices are computed modulo n (i.e., "neighbors" is in the torus sense). This average filtering can be accomplished by just shifting the array right, left, up, and down by one position in the torus, and having each processor average the four values received along with its initial value.

For a medium- or coarse-grained machine, operating on entire structures is most likely to be implemented by blending serial and parallel approaches. On such an architecture, each processor uses an efficient serial algorithm applied to the portion of the data in its processor, and communicates with other processors in order to exchange critical data. For example, suppose the $n \times n$ array of the previous paragraph is stored in a $p \times p$ torus, where p evenly divides n, so that $A(i, j)$ is stored in processor $P_{\lfloor ip/n \rfloor, \lfloor jp/n \rfloor}$. Then, in order to do the same average filtering on A, each processor $P_{k,l}$ still needs to communicate with its torus neighbors $P_{k\pm1,l}$, $P_{k,l\pm1}$, but now sends them either the leftmost or rightmost column of data, or the topmost or bottommost row. Once a processor receives its boundary set of data from its neighboring processors, it can then proceed serially through its subsquare of data and produce the desired results. To maximize efficiency, this can be performed by having each processor send the data needed by its neighbors, then perform the filtering on the part of the array that it contains that does not depend on data from the neighbors, and then finally perform the filtering on the elements that depend on the data from neighbors. Unfortunately, while this maximizes the possible overlap between communication and calculation, it also complicates the program because the order of computations within a processor needs to be rearranged.

Global Operations

To manipulate entire structures in one step, it is useful to have a collection of operations that perform such manipulations. These *global operations* may be very problem-dependent, but certain ones have been found to be widely useful. For example, the average filtering example above made use of shift operations to move an array around. *Broadcast* is another common global operation, used to send data from one processor to all other processors. Extensions of the broadcast operation include simultaneously performing a broadcast within every (predetermined and distinct) subset of processors. For example, suppose matrix A has been partitioned into submatrices allocated to different processors, and one needs to broadcast the first row of A so that if a processor contains any elements of column i then it obtains the value of $A(1, i)$. In this situation, the more general form of a subset-based broadcast can be used.

Besides operating within subsets of processors, many global operations are defined in terms of a commutative, associative, semigroup operator $\otimes$. Examples of such semigroup operators include `minimum`, `maximum`, `or`, `and`, `sum`, and `product`. For example, suppose there is a set of values $V(i)$, $1 \le i \le n$, and

the goal is to obtain the maximum of these values. Then $\otimes$ would represent maximum, and the operation of applying $\otimes$ to all n values is called *reduction.* If the value of the reduction is broadcast to all processors, then it is sometimes known as *report.* A more general form of the reduction operation involves labeled data items, i.e., each data item is embedded in a record that also contains a label, where at the end of the reduction operation the result of applying $\otimes$ to all values with the same label will be recorded in the record.

Global operations provide a useful way to describe major actions in parallel programs. Further, since several of these operations are widely useful, they are often made available in highly optimized implementations. The language APL provided a model for several of these operations, and some parallel versions of APL have appeared. Languages such as C* [15] and FORTRAN 90 [3] also provide for some forms of global operations, as do message-passing systems such as MPI [14]. Reduction operations are so important that most parallelizing compilers detect them automatically, even if they have no explicit support for other global operations.

Besides broadcast, reduction, and shift, other important global operations include the following.

Sort: Let $X = \{x_0, x_1, \ldots, x_{n-1}\}$ be an ordered set such that $x_i < x_{i+1}$, for all $0 \leq i < n-1$. (That is, X is a subset of a linearly ordered data type.) Given that the n elements of X are arbitrarily distributed among a set of p processors, the sort operation will (re)arrange the members of X so that they are ordered with respect to the processors. That is, after sorting, elements $x_0, \ldots, x_{\lfloor n/p \rfloor}$ will be in the first processor, elements $x_{\lfloor n/p \rfloor + 1}, \ldots, x_{\lfloor 2n/p \rfloor}$ will be in the second processor, and so forth. Note that this assumes an ordering on the processors, as well as on the elements.

Merge: Suppose that sets D_1 and D_2 are subsets of some linearly ordered data type, and D_1 and D_2 are each distributed in an ordered fashion among disjoint sets of processors $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively. Then the merge operation combines D_1 and D_2 to yield a single sorted set stored in ordered fashion in the entire set of processors $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2$.

Associative Read/Write: These operations start with a set of *master* records indexed by unique keys. In the associative read, each processor specifies a key and ends up with the data in the master record indexed by that key, if such a record exists, or else a flag indicating that there is no such record. In the associative write, each processor specifies a key and a value, and each master record is updated by applying $\otimes$ to all values sent to it. (Master records are generated for all keys written.)

These operations are extensions of the CRCW PRAM operations. They model a PRAM with associative memory and a powerful combining operation for concurrent writes. On most distributed memory machines, the time to perform these more powerful operations is within a multiplicative constant of the time needed to simulate the usual concurrent read and concurrent write, and the use of the more powerful operations can result in significant algorithmic simplifications and speedups.

Compression: Compression moves data into a region of the machine where optimal interprocessor communication is possible. For example, compressing k items in a fine-grained two-dimensional mesh will move them to a $\sqrt{k} \times \sqrt{k}$ subsquare.

Parallel Prefix (Scan): Given a set of values a_i, $1 \leq i \leq n$, the *parallel prefix* computation determines $p_i = a_1 \otimes a_2 \otimes \cdots \otimes a_i$, for all i. This operation is available in APL, where it is called *scan.* Note that the hardware feature known as "fetch-and-op" implements a variant of parallel prefix, where "op" is $\otimes$ and the ordering of the processors is not required to be deterministic.

All-to-All Broadcast: Given data $D(i)$ in processor i, every processor receives a copy of $D(i)$, for all i.

All-to-All Personalized Communication: Every processor P_i has a data item $D(i, j)$ that is sent to processor P_j, for all $i \neq j$.

Example: Maximal Point Problem

As an example of the use of global operations, consider the following problem from computational geometry. Let S be a finite set of planar (i.e., two-dimensional) points. A point $p = (p_x, p_y)$ in S is a *maximal point* of S if $p_x > q_x$ or $p_y > q_y$, for every point $(q_x, q_y) \neq p$ in S. The *maximal point problem* is to determine all maximal points of S. See Fig. 46.4. The following parallel algorithm for the maximal point problem was apparently first noted by Atallah and Goodrich [2].

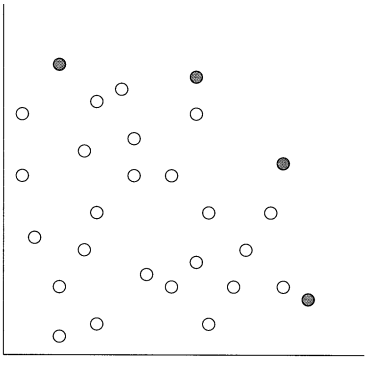

FIGURE 46.4 The maximal points of the set are shaded.

1. Sort the n planar points in reverse order by x-coordinate, with ties broken by reverse order by y-coordinate. Let (i_x, i_y) denote the coordinates of the ith point after the sort is complete. Therefore, after sorting, the points will be ordered so that if $i < j$ then either $i_x > j_x$ or $i_x = j_x$ and $i_y > j_y$.
2. Use parallel prefix on the i_y values, where the operation $\otimes$ is taken to be maximum. The resulting values $\{L_i\}$ are such that L_i is the largest y-coordinate of any point with index less than i.
3. The point (i_x, i_y) is an extreme point if and only if $i_y > L_i$.

The running time $T(n)$ of this algorithm is given by

$$T(n) = Sort(n) + Prefix(n) + O(1) , \tag{46.1}$$

where $Sort(n)$ is the time to sort n items and $Prefix(n)$ is the time to perform parallel prefix. On all parallel architectures known to the authors, $Prefix(n) = O(Sort(n))$, and hence on such machines the time of the algorithm is $\Theta(Sort(n))$. It is worth noting that for the sequential model, it has been shown [7] that the problem of determining maximal points is as hard as sorting.

Divide-and-Conquer

Divide-and-conquer is a powerful algorithmic paradigm that exploits the repeated subdivision of problems and data into smaller, similar problems. It is quite useful in parallel computation because the logical subdivisions into subproblems can correspond to physical decomposition among processors, where eventually the problem is broken into subproblems that are each contained within a single processor. These small subproblems are typically solved by an efficient sequential algorithm within each processor.

As an example, consider the problem of labeling the figures of a black/white image, where the interpretation is that of black objects on a white background. Two black pixels are defined to be *adjacent* if they are vertical or horizontal neighbors, and *connected* if there is a path of adjacent black pixels between them.

A *figure* (i.e., *connected component*) is defined to be a maximally connected set of black pixels in the image. The figures of an image are said to be *labeled* if every black pixel in the image has a label, with two black pixels having the same label if and only if they are in the same figure.

We utilize a generic parallel divide-and-conquer solution for this problem, given, for example, in [11]. Suppose that the $n \times n$ image has been divided into p subimages, as square as possible, and distributed one subimage per processor. Each processor labels the subimage it contains, using whatever serial algorithm is best and using labels that are unique to the processor (so that no two different figures can accidentally get the same label). For example, often the label used is a concatenation of the row and column coordinates of one of the pixels in the figure. Notice that so as long as the global row and column coordinates are used, the labels will be unique. After this step, the only figures that could have an incorrect global label are those that lie in two or more subimages, and any such figures must have a pixel on the border of each subimage it is in (see Fig. 46.5). To resolve these labels, a record is prepared for each black pixel on the border of a subimage, where the record contains information about the pixel's position in the image, and its current label. There are far fewer such records than there are pixels in the original image, yet they contain all of the information needed to determine the proper global labels for figures crossing subimages. The problem of reconciling the local labels may itself be solved via divide-and-conquer, repeatedly merging results from adjacent regions, or may be solved via other approaches. Once these labels have been resolved, information is sent back to the processors generating the records, informing them of the proper final label.

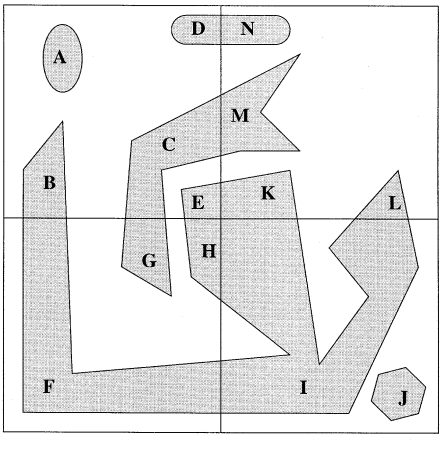

FIGURE 46.5 Divide-and-conquer for labeling figures. The 14 labels shown were generated after each quadrant performed its own local labeling algorithm. While the labels are unique, they need to be resolved globally. Notice that once the labels are resolved (not shown), the image will have only 5 unique labels, one corresponding to each of the 5 figures.

One useful feature of many of the networks described in the section on Interconnection Networks is that they can be divided into similar subnetworks, in a manner that matches the divide-and-conquer paradigm. For example, if the component labeling algorithm just described were performed on a mesh computer, then each subregion of the image would correspond to a subsquare of the mesh. As another example, consider an implementation of quicksort on a hypercube. Suppose a pivot is chosen and that the data is partitioned into items smaller than the pivot and items larger than the pivot. Further, suppose that the hypercube is logically partitioned into two subcubes, where all of the small items are moved into one subcube and all of the large items are moved into the other subcube. Now, the quicksort routine

may proceed recursively within each subcube. Because the recursive divide-and-conquer occurs within subcubes, all of the communication will occur within the subcubes and not cause contention with the other subcube.

Master–Slave

One algorithmic paradigm based on real-world organization paradigms is the master–slave (sometimes referred to as manager–worker) paradigm. In this approach, one processor acts as the master, directing all of the other slave processors. For example, many branch-and-bound approaches to optimization problems keep track of the best solution found so far, as well as a list of subproblems that need to be explored. In a master–slave implementation, the master maintains both of these items and is responsible for parceling out the subproblems to the slaves. The slaves are responsible for processing the subproblems and reporting the result to the master (which will determine if it is the current best solution), reporting new subproblems that need to be explored to the master, and notifying the master when it is free to work on a new subproblem. There are many variations on this theme, but the basic idea is that one processor is responsible for overall coordination, and the other processors are responsible for solving assigned subproblems. Note that this is a variant of the SPMD style of programming, in that there are two programs needed, rather than just one.

Pipelining and Systolic Algorithms

Another common parallel algorithmic technique is based on models that resemble an assembly line. A large problem, such as analyzing a number of images, may be broken into a sequence of steps that must be performed on each image (e.g., filtering, labeling, scene analysis). If one had three processors, and if each step takes about the same amount of time, one could start the first image on the first processor that does the filtering. Then the first image is passed on to the next processor for labeling, while the first processor starts filtering the second image. In the third time step, the initial image is at the third processor for scene analysis, the second image is at the second processor for labeling, and the third image is at the first processor for filtering. This form of processing is called *pipelining,* and it maps naturally to a parallel computer configured as a linear array (i.e., a one-dimensional mesh or, equivalently, a ring without the wraparound connection).

This simple scenario can be extended in many ways. For example, as in a real assembly line, the processors need not all be identical, and may be optimized for their task. Also, if some task takes longer to perform than others, then more than one processor can be assigned to it. Finally, the flow may not be a simple line. For example, an automobile assembly process may have one line working on the chassis, while a different line is working on the engine, and eventually these two lines are merged. Such generalized pipelining is called *systolic processing.* For example, some matrix and image-processing operations can be performed in a two-dimensional systolic manner (see [16]).

46.6 Mappings

Often, a problem has a natural structure to be exploited for parallelism, and this needs to be mapped onto a target machine. Several examples follow.

- The average filtering problem, discussed in the section on Designing Algorithms, has a natural array structure that can easily be mapped onto a mesh computer. If, however, one had the same problem, but a tree computer, then the mapping might be much more complicated.
- Some artificial intelligence paradigms exploit a blackboard-like communication mechanism that naturally maps onto a shared memory machine. However, a blackboard-like approach is more difficult to map onto a distributed-memory machine.

- Finite-element decompositions have a natural structure whereby calculations at each grid point depend only on values at adjacent points. A finite-element approach is frequently used to model automobiles, airplanes, and rocket exhaust, to name a few. However, the irregular (and perhaps dynamic) structure of such decompositions might need to be mapped onto a target parallel architecture that bears little resemblance to the finite-element grid.
- A more traditional example consists of porting a parallel algorithm designed for one parallel architecture onto another parallel architecture.

In all of these examples, one starts with a source structure that needs to be mapped onto a target machine. The goal is to map the source structure onto the target architecture so that calculation and communication steps on the source structure can be efficiently performed by the target architecture. Usually, the most critical aspect is to map the calculations of the source structure onto the processors of the target machine, so that each processor performs the same amount of calculations. For example, if the source is an array, and each position of the array represents calculations that need to be performed, then one tries to map the array onto the machine so that all processors contain the same number of entries. If the source model is a shared-memory paradigm with agents reading from a blackboard, then one would map the agents to processors, trying to balance the computational work.

Besides trying to balance the computational load, one must also try to minimize the time spent on communication. The approaches used for these mappings depend on the source structure and target architecture, and some of the more widely used approaches are discussed in the following subsections.

Simulating Shared Memory

If the source structure is a shared memory model, and the target architecture is a distributed memory machine, then besides mapping the calculations of the source onto the processors of the target, one must also map the shared memory of the source onto the distributed memory of the target.

To map the memory onto the target machine, suppose that there are memory locations $0 \ldots n-1$ in the source structure, and p processors in the target. Typically one would map locations $0 \ldots \lfloor n/p - 1 \rfloor$ to processor 0 of the target machine, locations $\lfloor n/p \rfloor \ldots \lfloor 2n/p - 1 \rfloor$ to processor 1, and so forth. Such a simple mapping balances the amount of memory being simulated by each target processor, and makes it easy to determine where data is located. For example, if a target processor needs to read from shared memory location i, it sends a message to target processor $\lfloor ip/n \rfloor$ asking for the contents of simulated shared memory location i.

Unfortunately, some shared memory algorithms utilize certain memory locations far more often than others, which can cause bottlenecks in terms of getting data in and out of processors holding the popular locations. If popular memory locations form contiguous blocks, then this congestion can be alleviated by stripping (mapping memory location i to processor $i \bmod p$) or other mappings. Replication (having copies of frequently read locations in more than one processor) or adaptive mapping (dynamically moving simulated memory locations from heavily loaded processors to lightly loaded ones) are occasionally employed to relieve congestion, but such techniques are more complicated and involve additional overhead.

Simulating Distributed Memory

It is often useful to view distributed memory machines as graphs. Processors in the machine are represented by vertices of the graph, and communication links in the machine are represented by edges in the graph. Similarly, it is often convenient to view the structure of a problem as a graph, where vertices represent work that needs to be performed, and edges represent values that need to be communicated in order to perform the desired work. For example, in a finite-element decomposition, the vertices of a decomposition might represent calculations that need to be performed, while the edges correspond to flow of data. That is, in

a typical finite-element problem, if there is an edge from vertex p to vertex q, then the value of q at time t depends on the values of q and p at time $t-1$. (Most finite-element decompositions are symmetric, so that p at time t would also depend on q at time $t-1$.) Questions about mapping the structure of a problem onto a target architecture can then be answered by considering various operations on the related graphs.

The best situation is when the graph representing the structure of a problem is a subgraph of the graph representing the target architecture. For example, if the structure of a problem was represented as a connected string of p vertices and the target architecture was a ring of p processors, then the mapping of the problem onto the architecture would be straightforward and efficient. In graph terms, this is described through the notion of embedding. An *embedding* of an undirected graph $G = (V, E)$ (i.e., G has vertex set V and edges E) into an undirected graph $G' = (V', E')$ is a mapping ϕ of V into V' such that

- every pair of distinct vertices $u, v \in V$, map to distinct vertices $\phi(u), \phi(v) \in V'$, and
- for every edge $\{u, v\} \in E$, $\{\phi(u), \phi(v)\}$ is an edge in E'.

Let G represent the graph corresponding to the structure of a problem (i.e., the *source structure*) and let G' represent the graph corresponding to the target architecture. Notice that if there is an embedding of G into G', then values that need to be communicated may be transmitted by a single communication step in the target architecture represented by G'. The fact that embeddings map distinct vertices of G to distinct vertices of G' ensures that a single calculation step for the problem can be simulated in a single calculation step of the target architecture.

One reason that hypercube computers were quite popular is that many graphs can be embedded into the hypercube (graph). An embedding of the one-dimensional ring of size 2^d into a d-dimensional hypercube is called a *d-dimensional Gray code*. In other words, if $\{0, 1\}^d$ denotes the set of all d-bit binary strings, then the d-dimensional Gray code G_d is a 1-1 map of $0 \ldots 2^d - 1$ onto $\{0, 1\}^d$, such that $G_d(j)$ and $G_d((j+1) \bmod 2^d)$ differ by a single bit, for $0 \le j \le 2^d - 1$. The most common Gray codes, called *reflected binary* Gray codes, are recursively defined as follows: $\mathcal{G}_d$ is a 1–1 mapping from $\{0, 1, \ldots, 2^d - 1\}$ onto $\{0, 1\}^d$, given by $\mathcal{G}_1(0) = 0$, $\mathcal{G}_1(1) = 1$, and for $d \ge 2$,

$$\mathcal{G}_d(x) = \begin{cases} 0\mathcal{G}_{d-1}(x) & 0 \le x \le 2^{d-1} - 1 \\ 1\mathcal{G}_{d-1}\left(2^d - 1 - x\right) & 2^{d-1} \le x \le 2^d - 1 \,. \end{cases} \tag{46.2}$$

Alternatively, the same Gray code can be defined in a nonrecursive fashion as $\mathcal{G}_d(x) = x \oplus \lfloor x/2 \rfloor$, where x and $\lfloor x/2 \rfloor$ are interpreted as d-bit strings. Further, the inverse of the reflected binary Gray code can be determined by

$$\mathcal{G}_d^{-1}\left(y_0 \ldots y_{d-1}\right) = x_0 \ldots x_{d-1} \,, \tag{46.3}$$

where $x_{d-1} = y_{d-1}$, and $x_i = y_{d-1} \oplus \cdots \oplus y_i$ for $0 \le i < d-1$.

Meshes can also be embedded into hypercubes. Let M be a d-dimensional mesh of size $m_1 \times m_2 \times \cdots \times m_d$, and let $r = \Sigma_{i=1}^{d} \lceil \log_2 m_i \rceil$. Then M can be embedded into the hypercube of size 2^r. To see this, let $r_i = \lceil \log_2 m_i \rceil$, for $1 \le i \le d$. Let ϕ be the mapping of mesh node $(a_1, \ldots, a_d)$ to the hypercube node which has as its label the concatenation $G_{r_1}(a_1) \cdot \ldots \cdot G_{r_d}(a_d)$, where G_{r_i} denotes any r_i-bit Gray code. Then ϕ is an embedding. Wrapped dimensions can be handled using reflected Gray codes rather than arbitrary ones. (A mesh M is *wrapped* in dimension j if, in addition to the normal mesh adjacencies, vertices with indices of the form $(a_1, \ldots, a_{j-1}, 0, a_{j+1}, \ldots, a_d)$ and $(a_1, \ldots, a_{j-1}, m_j - 1, a_{j+1}, \ldots, a_d)$ are adjacent. A torus is a mesh wrapped in all dimensions.) If dimension j is wrapped and m_j is an integral power of 2, then the mapping ϕ suffices. If dimension j is wrapped and m_j is even, but not an integral power of 2, then to ensure that the first and last nodes in dimension j are mapped to adjacent hypercube nodes, use ϕ, but replace $G_{r_j}(a_j)$ with

$$\begin{cases} \mathcal{G}_{r_j}\left(a_j\right) & \text{if } 0 \le a_j \le m_j/2 - 1 \\ \mathcal{G}_{r_j}\left(a_j + 2^{r_j} - m_j\right) & \text{if } m_j/2 \le a_j \le m_j - 1 \,, \end{cases} \tag{46.4}$$

where $\mathcal{G}_{r_j}$ is the r_j-bit reflected binary Gray code. This construction ensures that $\mathcal{G}_{r_j}(m_j/2 - 1)$ and $\mathcal{G}_{r_j}(2^{r_j} - m_j/2)$ differ by exactly one bit (the highest-order one), which in turns ensures that the mapping takes mesh nodes neighboring in dimension j to hypercube neighbors.

Any tree T can be embedded into a $(|T| - 1)$-dimensional hypercube, where $|T|$ denotes the number of vertices in T, but this result is of little use since the target hypercube is exponentially larger than the source tree. Often one can map the tree into a more reasonably sized hypercube, but it is a difficult problem to determine the minimum dimension needed, and there are numerous papers on the subject.

In general, however, one cannot embed the source structure into the target architecture. For example, a complete binary tree of height 2, which contains 7 processors, cannot be embedded into a ring of any size. Therefore, one must consider weaker mappings, which allow for the possibility that the target machine has fewer processors than the source and does not contain the communication links of the source. A *weak embedding* of a directed source graph $G = (V, E)$ into a directed target graph $G' = (V', E')$ consists of

- a map ϕ_v of V into V', and
- a map ϕ_e of E onto *paths* in G', such that if $(u, v) \in E$ then $\phi_e((u, v))$ is a path from $\phi_v(u)$ to $\phi_v(v)$.

(Note that if G is undirected, each edge becomes two directed edges that may be mapped to different paths in G'. Most machines that are based on meshes, tori, or hypercubes have the property that a message from processor P to processor Q may not necessarily follow the same path as a message sent from processor Q to processor P, if P and Q are not adjacent.) The map ϕ_v shows how computations are mapped from the source onto the target, and the map ϕ_e shows the communication paths that will be used in the target.

There are several measures that are often used to describe the quality of a weak embedding (ϕ_v, ϕ_e) of G into G', including the following.

Processor Load: The maximum, over all vertices $v' \in V'$, of the number of vertices in V mapped onto v' by ϕ_v. Note that if all vertices of the source structure represent the same amount of computation, then the processor load is the maximum computational load by any processor in the target machine. The goal is to make the processor load as close as possible to $|V|/|V'|$. If vertices do not all represent the same amount of work, then one should use labeled vertices, where the label represents the amount of work, and try to minimize the maximum, over all vertices $v' \in V'$, of the sum of the labels of the vertices mapped onto v'.

Link Load (Link Congestion): The maximum, over all edges $(u', v') \in E'$, of the number of edges $(u, v) \in E$ such that (u', v') is part of the path $\phi_e((u, v))$. If all edges of the source structure represent the same amount of communication, then the link load represents the maximum amount of communication contending for a single communication link in the target architecture. As for processor load, if edges do not represent the same amount of communication, then weights should be balanced instead.

Dilation: The maximum, over all edges $(u, v) \in E$, of the path length of $\phi_e((u, v))$. The dilation represents the longest delay that would be needed to simulate a single communication step along an edge in the source, if that was the only communication being performed.

Expansion: The ratio of the number of vertices of G' divided by the number of vertices of G. As was noted in the example of trees embedding into hypercubes, large expansion is impractical. In practice, usually the real target machine has far fewer processors than the idealized source structure, so expansion is not a concern.

In some machines, dilation is an important measure of communication delay, but in most modern general-purpose machines it is far less important because each message has a relatively large start-up time that may be a few orders of magnitude larger than the time per link traversed. Link contention may still be a problem in such machines, but some solve this by increasing the bandwidth on links that would have heavy contention. For example, as noted earlier, *fat-trees* [9] add bandwidth near the root to avoid the

bottlenecks inherent in a tree architecture. This increases the bisection bandwidth, which reduces the link contention for communication that poorly matches the basic tree structure.

For machines with very large message start-up times, often the number of messages needed becomes a dominant communication issue. In such a machine, one may merely try to balance calculation load and minimize the number of messages each processor needs to send, ignoring other communication effects. The number of messages that a processor needs to send can be easily determined by noting that processors p and q communicate if there are adjacent vertices u and v in the source structure such that ϕ_v maps u to p and v to q.

For many graphs that cannot be embedded into a hypercube, there are nonetheless useful weak embeddings. For example, keeping the expansion as close to 1 as is possible (given the restriction that a hypercube has a power of 2 processors), one can map the complete binary tree onto the hypercube with unit link congestion, dilation two, and unit processor contention [8].

In general, however, finding an optimal weak embedding for a given source and target is an NP-complete problem. This problem, sometimes known as the *mapping problem,* is often solved by various heuristics. This is particularly true when the source structure is given by a finite-element decomposition or other approximation schemes for real entities, for in such cases the sources are often quite large and irregular. Fortunately, the fact that such sources often have an underlying geometric basis makes it easier to find fairly good mappings rather quickly.

For example, suppose the source structure is an irregular grid representing the surface of a three-dimensional airplane, and the target machine is a two-dimensional mesh. One might first project the airplane onto the x-y plane, ignoring the z-coordinates. Then one might locate a median x-coordinate, call it $\bar{x}$, where half of the plane's vertices lie to the left of $\bar{x}$ and half to the right. The vertices may then be mapped so that those that lie to the left of $\bar{x}$ are mapped onto the left half of the target machine, and those vertices that lie to the right of $\bar{x}$ are mapped to the right half of the target. In the left half of the target, one might locate the median y-coordinate, denoted $\bar{y}$, of the points mapped to that half, and map the points above $\bar{y}$ to the top-left quadrant of the target, and map points below $\bar{y}$ to the bottom-left. On the right half a similar operation would be performed for the points mapped to that side. Continuing in this recursive, divide-and-conquer manner, eventually the target machine would have been subdivided down into single processors, at which point the mapping would have been determined. This mapping is fairly straightforward, balances the processor load, and roughly keeps points adjacent in the grid near to each other in the target machine, and hence it does a reasonable approximation of minimizing communication time.

Note that if message start-up time is very high, then this probably would not minimize the number of messages sent by each processor, and in such a situation it may be better to partition the plane by cutting along only, say, the x-axis at each step. Each processor would end up with a cross-sectional slab, with all of the source vertices in given range of x-coordinates. If grid edges are not longer than the width of such a slab, then each processor would have to send messages to only two processors, namely the processor with the slab to the left and the processor with the slab to the right.

Other complications can arise because the nodes or edges of such sources may not all represent the same amount of computation or calculation, respectively, in which case weighted mappings are appropriate. A variety of programs are available that perform such mappings, and over time the quality of the mapping achieved, and the time to achieve it, has significantly improved. For irregular source structures, such packages are generally superior to what one would achieve without considerable effort.

A more serious complication is that the natural source structure may be dynamic, adding nodes or edges over time. In such situations one often needs to dynamically adjust the mapping to keep the computational load balanced and keep communication minimal. This introduces additional overhead, which one must weigh against the costs of not adjusting the imbalance. Often the dynamical remappings are made incrementally, moving only a little of the data to correct the worst imbalances. Deciding how often to check for imbalance, and how much to move, typically depends quite heavily on the problem being solved.

46.7 Research Issues and Summary

The development of parallel algorithms and efficient parallel programs lags significantly behind that of standard serial computers. This is perhaps due to the fact that only recently have parallel computers become commercially available. Therefore, parallel computing is in a rapidly growing phase, with important research and development still needed in almost all areas. Extensive theoretical and practical work continues in discovering parallel programming paradigms, in developing a wide range of efficient parallel algorithms, in developing ways to describe and manage parallelism, in developing techniques to automatically detect parallelism, and in developing libraries of parallel routines.

Another factor that has hindered parallel algorithm development is the fact that there are many different parallel computing models. As noted earlier, architectural differences can significantly affect the efficiency of an algorithm, and hence parallel algorithms have traditionally been tied to specific parallel models. One advance is that various hardware and software approaches are being developed to help hide some of the architectural differences. Thus, one may have, say, a distributed memory machine, but have a software system that allows the programmer to view it as a shared memory machine. While it is true that a programmer will usually only be able to achieve the highest performance by directly optimizing the code for a target machine, in many cases acceptable performance can be achieved without tying the code to excessive details of an architecture. This, then, allows code to be ported to a variety of machines, which encourages code development. In the past, extensive code revision was needed every time the code was ported to a new parallel machine, and this strongly discouraged many users who did not want to plan for an unending parade of changes.

Another factor that has limited parallel algorithm development is that most computer scientists were not trained in parallel computing. As the field matures, more courses will incorporate parallel computing and the situation will improve. However, many thousands of small shared-memory systems have already been purchased, often to be used as departmental or corporate compute servers. Unfortunately, do to the dearth of parallel programmers, many of these systems are used only to run concurrent serial programs, or to run turnkey parallel programs (such as databases). There is a serious need for professionals who are able to utilize the full power of these parallel machines, since there are a great many problems which are beyond the power of single processors.

46.8 Defining Terms

Distributed memory: Each processor only has access to only its own private (local) memory, and communicates with other processors via messages.

Divide-and-conquer: A programming paradigm whereby large problems are solved by decomposing them into smaller, yet similar, problems.

Global operations: Parallel operations that affect system-wide data structures.

Interconnection network: The communication system that links together all of the processors and memory of a parallel machine.

Master–slave: A parallel programming paradigm whereby a problem is broken into a collection of smaller problems, with a master processor keeping track of the subproblems and assigning them to the slave processors.

Parallel random access machine (PRAM): A theoretical shared-memory model, where typically the processors all execute the same instruction synchronously, and access to any memory location occurs in unit time.

Pipelining: A parallel programming paradigm that abstracts the notion of an assembly line. A task is broken into a sequence of fixed subtasks corresponding to the stations of an assembly line. A series of similar tasks is solved by starting one task through the subtask sequence, then starting

the next task through as soon as the previous task has finished its first subtask. At any point in time, several tasks are in various stages of completion.

Shared memory: All processors have the same global image of (and access to) all of the memory.

Single program multiple data (SPMD): The dominant style of parallel programming, where all of the processors utilize the same program, though each has its own data.

Further Information

A good introduction to parallel computing at the undergraduate level is *Parallel Computing: Theory and Practice* by Michael J. Quinn. This book provides a nice introduction to parallel computing, including parallel algorithms, parallel architectures, and parallel programming languages. *Parallel Algorithms for Regular Architectures: Meshes and Pyramids* by Russ Miller and Quentin F. Stout focuses on fundamental algorithms and paradigms for fine-grained machines. It advocates an approach of designing algorithms in terms of fundamental data movement operations, including sorting, concurrent read, and concurrent write. Such an approach allows one to port algorithms in an efficient manner between architectures. *Introduction to Parallel Algorithms and Architectures: Arrays, Trees, Hypercubes* is a comprehensive book by F. Thomson Leighton that also focuses on fine-grained algorithms for several traditional interconnection networks. Finally, for the reader interested in algorithms for the PRAM, *An Introduction to Parallel*

Algorithms by J. JáJá covers fundamental algorithms in geometry, graph theory, and string matching. It also includes a chapter on randomized algorithms.

There are several professional societies that sponsor conferences, publish books, and publish journals in the area of parallel algorithms. These include the Association for Computing Machinery (ACM), which can be found at http://www.acm.org, The Institute for Electrical and Electronics Engineers, Inc. (IEEE), which can be found at http://www.ieee.org, and the Society for Industrial and Applied Mathematics (SIAM), which can be found at http://www.siam.org.

Since parallel computing has become so pervasive, most computer science journals cover work concerned with parallel and distributed systems. For example, one would expect a journal on programming languages to publish articles on languages for shared-memory machines, distributed memory machines, networks of workstations, and so forth. For several journals, however, the primary focus is on parallel algorithms. These journals include the *Journal for Parallel and Distributed Computing,* published by Academic Press (http://www.apnet.com), the *IEEE Transactions on Parallel and Distributed Systems* (http://computer.org/pubs/tpds), and for results that can be expressed in a condensed form, *Parallel Processing Letters,* published by World Scientific. Finally, several comprehensive journals should be mentioned that publish a fair number of articles on parallel algorithms. These include the *IEEE Transactions on Computers, Journal of the ACM,* and *SIAM Journal on Computing.*

Unfortunately, due to very long delays from submission to publication, most results that appear in journals (with the exception of *Parallel Processing Letters*) are actually quite old. (A delay of 3–5 years from submission to publication is not uncommon.) Recent results appear in a timely fashion in conferences, most of which are either peer reviewed or panel reviewed. The first conference devoted primarily to parallel computing is the International Conference on Parallel Processing (ICPP), which had its inaugural conference in 1972. Many landmark papers have been presented at ICPP, especially during the 1970s and 1980s. Proceedings from this conference have been published in recent years by the IEEE Computer Society and CRC. In recent years, the International Parallel Processing Symposium (IPPS) (http://www.ippsxx.org) has emerged as the premier conference devoted to parallel computing. IPPS is quite comprehensive in that in addition to the conference, it offers a wide variety of workshops and tutorials. Another conference that has matured nicely in recent years is the ACM Symposium on Parallel and Distributed Processing (SPDP). It is interesting to note that both IPPS and SPDP initially started as regional conferences. In fact, in 1998, IPPS and SPDP will hold a combined conference. A conference that focuses on very theoretical, primarily PRAM-based, algorithms is the ACM Symposium on Parallel Algorithms and Architectures (SPAA). This conference is an offshoot of the premier theoretical conferences in computer science, ACM Symposium on Theory of Computing (STOC) and IEEE Symposium on Foundations of Computer Science (FOCS). A conference that focuses on very large parallel systems is SC 'XY (http://www.supercomp.org), where XY represents the last two digits of the year. This conferences includes the presentation of the Gordon Bell Prize for best parallelization. Awards are given in various categories, such as highest sustained performance and best price/performance.

Finally, a variety of sites exist that can be used to effectively navigate the web, including the IEEE Technical Committee on Parallel Processing (IEEETCPP), which can be found at http://www.cs.buffalo.edu/tcpp. This site contains links to conferences, journals, people in the field, bibliographies on parallel processing, on-line course material, books, and so forth. Another nice site (http://www.computer.org/parascope) is currently maintained by David A. Bader (University of New Mexico) with support from the IEEE. Finally, several newsgroups cater to parallel computing, including comp.parallel and comp.arch.

47.1 Introduction

The subject of this chapter is the design and analysis of parallel algorithms. Most of today's algorithms are sequential, that is, they specify a sequence of steps in which each step consists of a single operation. These algorithms are well suited to today's computers, which basically perform operations in a sequential fashion. Although the speed at which sequential computers operate has been improving at an exponential rate for many years, the improvement is now coming at greater and greater cost. As a consequence, researchers have sought more cost-effective improvements by building "parallel" computers—computers that perform multiple operations in a single step. In order to solve a problem efficiently on a parallel computer, it is usually necessary to design an algorithm that specifies multiple operations on each step, i.e., a parallel algorithm.

As an example, consider the problem of computing the sum of a sequence A of n numbers. The standard algorithm computes the sum by making a single pass through the sequence, keeping a running sum of

the numbers seen so far. It is not difficult however, to devise an algorithm for computing the sum that performs many operations in parallel. For example, suppose that, in parallel, each element of A with an even index is paired and summed with the next element of A, which has an odd index, i.e., $A[0]$ is paired with $A[1]$, $A[2]$ with $A[3]$, and so on. The result is a new sequence of $\lceil n/2 \rceil$ numbers that sum to the same value as the sum that we wish to compute. This pairing and summing step can be repeated until, after $\lceil \log_2 n \rceil$ steps, a sequence consisting of a single value is produced, and this value is equal to the final sum.

The parallelism in an algorithm can yield improved performance on many different kinds of computers. For example, on a parallel computer, the operations in a parallel algorithm can be performed simultaneously by different processors. Furthermore, even on a single-processor computer the parallelism in an algorithm can be exploited by using multiple functional units, pipelined functional units, or pipelined memory systems. Thus, it is important to make a distinction between the parallelism in an algorithm and the ability of any particular computer to perform multiple operations in parallel. Of course, in order for a parallel algorithm to run efficiently on any type of computer, the algorithm must contain at least as much parallelism as the computer, for otherwise resources would be left idle. Unfortunately, the converse does not always hold: some parallel computers cannot efficiently execute all algorithms, even if the algorithms contain a great deal of parallelism. Experience has shown that it is more difficult to build a general-purpose parallel computer than a general-purpose sequential computer.

The remainder of this chapter consists of nine sections. We begin in Section 47.2 with a discussion of how to model parallel computers. Next, in Section 47.3 we cover some general techniques that have proven useful in the design of parallel algorithms. Sections 47.4 through Section 47.8 present algorithms for solving problems from different domains. We conclude in Section 47.9 with a discussion of current research topics, a collection of defining terms, and finally sources for further information.

Throughout this chapter, we assume that the reader has some familiarity with sequential algorithms and asymptotic notation and analysis.

47.2 Modeling Parallel Computations

The designer of a sequential algorithm typically formulates the algorithm using an abstract model of computation called the *random-access machine* (RAM) model [2, Chapter 1]. In this model, the machine consists of a single processor connected to a memory system. Each basic CPU operation, including arithmetic operations, logical operations, and memory accesses, requires one time step. The designer's goal is to develop an algorithm with modest time and memory requirements. The random-access machine model allows the algorithm designer to ignore many of the details of the computer on which the algorithm will ultimately be executed, but captures enough detail that the designer can predict with reasonable accuracy how the algorithm will perform.

Modeling parallel computations is more complicated than modeling sequential computations because in practice parallel computers tend to vary more in organization than do sequential computers. As a consequence, a large portion of the research on parallel algorithms has gone into the question of modeling, and many debates have raged over what the "right" model is, or about how practical various models are. Although there has been no consensus on the right model, this research has yielded a better understanding of the relationship between the models. Any discussion of parallel algorithms requires some understanding of the various models and the relationships among them.

In this chapter we divide parallel models into two classes: **multiprocessor models** and **work-depth models.** In the remainder of this section we discuss these two classes and how they are related.

Multiprocessor Models

A *multiprocessor model* is a generalization of the sequential RAM model in which there is more than one processor. Multiprocessor models can be classified into three basic types: local memory machine models, modular memory machine models, and parallel random-access machine (PRAM) models. Figure 47.1 illustrates the structure of these machine models. A local memory machine model consists of a set of n processors each with its own local memory. These processors are attached to a common communication network. A modular memory machine model consists of m memory modules and n processors all attached to a common network. An n-processor PRAM model consists of a set of n processors all connected to a common shared memory [32, 37, 38, 77].

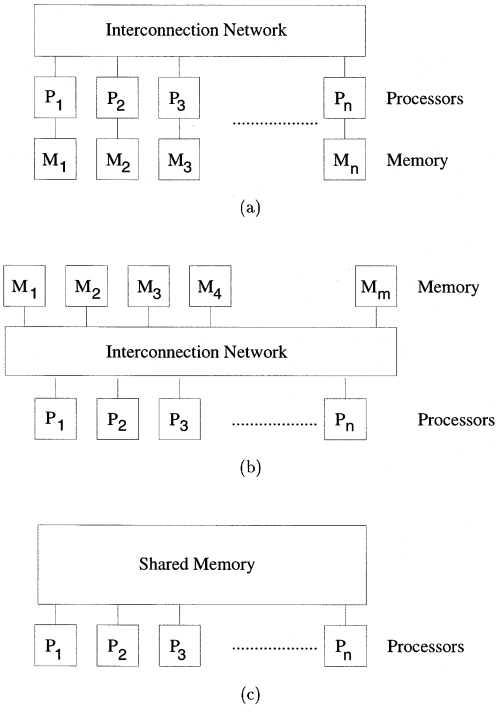

FIGURE 47.1 The three types of multiprocessor machine models. (a) A local memory machine model. (b) A modular memory machine model. (c) A parallel random-access machine (PRAM) model.

The three types of multiprocessors differ in the way that memory can be accessed. In a local memory machine model, each processor can access its own local memory directly, but can access the memory in another processor only by sending a memory request through the network. As in the RAM model, all local operations, including local memory accesses, take unit time. The time taken to access the memory in another processor, however, will depend on both the capabilities of the communication network and the pattern of memory accesses made by other processors, since these other accesses could congest the network. In a modular memory machine model, a processor accesses the memory in a memory module by sending a memory request through the network. Typically the processors and memory modules are arranged so that the time for any processor to access any memory module is roughly uniform. As in a local memory machine model, the exact amount of time depends on the communication network and the memory access pattern. In a **PRAM model,** a processor can access any word of memory in a single step. Furthermore, these accesses can occur in parallel, i.e., in a single step, every processor can access the shared memory.

The PRAM models are controversial because no real machine lives up to its ideal of unit-time access to shared memory. It is worth noting, however, that the ultimate purpose of an abstract model is not to directly model a real machine, but to help the algorithm designer produce efficient algorithms. Thus, if an algorithm designed for a PRAM model (or any other model) can be translated to an algorithm that runs efficiently on a real computer, then the model has succeeded. In "Emulations Among Models" we show how an algorithm designed for one parallel machine model can be translated so that it executes efficiently on another model.

The three types of multiprocessor models that we have defined are broad and allow for many variations. The local memory machine models and modular memory machine models may differ according to their network topologies. Furthermore, in all three types of models, there may be differences in the operations that the processors and networks are allowed to perform. In the remainder of this section we discuss some of the possibilities.

Network Topology

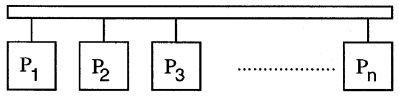
A network is a collection of switches connected by communication channels. A processor or memory module has one or more communication ports that are connected to these switches by communication channels. The pattern of interconnection of the switches is called the network topology. The topology of a network has a large influence on the performance and also on the cost and difficulty of constructing the network. Figure 47.2 illustrates several different topologies.

The simplest network topology is a bus. This network can be used in both local memory machine models and modular memory machine models. In either case, all processors and memory modules are typically connected to a single bus. In each step, at most one piece of data can be written onto the bus. This data might be a request from a processor to read or write a memory value, or it might be the response from the processor or memory module that holds the value. In practice, the advantage of using a bus is that it is simple to build and, because all processors and memory modules can observe the traffic on the bus, it is relatively easy to develop protocols that allow processors to cache memory values locally. The disadvantage of using a bus is that the processors have to take turns accessing the bus. Hence, as more processors are added to a bus, the average time to perform a memory access grows proportionately.

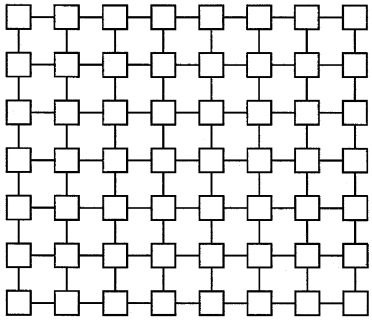
A two-dimensional *mesh* is a network that can be laid out in a rectangular fashion. Each switch in a mesh has a distinct label (x, y) where $0 \leq x \leq X - 1$ and $0 \leq y \leq Y - 1$. The values X and Y determine the length of the sides of the mesh. The number of switches in a mesh is thus $X \cdot Y$. Every switch, except those on the sides of the mesh, is connected to four neighbors: one to the north, one to the south, one to the east, and one to the west. Thus, a switch labeled (x, y), where $0 < x < X - 1$ and $0 < y < Y - 1$, is connected to switches $(x, y + 1)$, $(x, y - 1)$, $(x + 1, y)$, and $(x - 1, y)$. This network typically appears in a local memory machine model, i.e., a processor along with its local memory is connected to each switch, and remote memory accesses are made by routing messages through the mesh. Figure 47.2(b) shows an example of an 8×8 mesh.

Several variations on meshes are also popular, including three-dimensional meshes, toruses, and hypercubes. A *torus* is a mesh in which the switches on the sides have connections to the switches on the opposite sides. Thus, every switch (x, y) is connected to four other switches: $(x, y + 1 \bmod Y)$, $(x, y - 1 \bmod Y)$, $(x + 1 \bmod X, y)$, and $(x - 1 \bmod X, y)$. A hypercube is a network with 2^n switches in which each switch has a distinct n-bit label. Two switches are connected by a communication channel in a hypercube if and only if the labels of the switches differ in precisely one bit position. A hypercube with 16 switches is shown in Fig. 47.2(c).

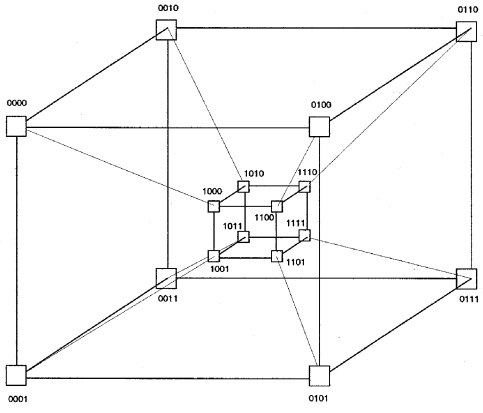
A *multistage network* is used to connect one set of switches called the *input switches* to another set called the *output switches* through a sequence of stages of switches. Such networks were originally designed for telephone networks [15]. The stages of a multistage network are numbered 1 through L, where L is the depth of the network. The switches on stage 1 are the input switches, and those on stage L are the output switches. In most multistage networks, it is possible to send a message from any input switch to any output



(a) Bus



(b) 2-dimensional Mesh



(c) Hypercube

FIGURE 47.2 Bus, mesh, and hypercube network topologies.

switch along a path that traverses the stages of the network in order from 1 to L. Multistage networks are frequently used in modular memory computers; typically processors are attached to input switches, and memory modules are attached to output switches. A processor accesses a word of memory by injecting a memory access request message into the network. This message then travels through the network to the appropriate memory module. If the request is to read a word of memory, then the memory module sends the data back through then network to the requesting processor. There are many different multistage network topologies. Figure 47.3(a), for example, shows a depth-2 network that connects 4 processors to 16 memory modules. Each switch in this network has two channels at the bottom and four channels at the top. The ratio of processors to memory modules in this example is chosen to reflect the fact that, in practice, a processor is capable of generating memory access requests faster than a memory module is capable of servicing them.

A *fat-tree* is a network structured like a tree [56]. Each edge of the tree, however, may represent many communication channels, and each node may represent many network switches (hence the name "fat"). Figure 47.3(b) shows a fat-tree with the overall structure of a binary tree. Typically the capacities of the edges near the root of the tree are much larger than the capacities near the leaves. For example, in this tree the two edges incident on the root represent 8 channels each, while the edges incident on the leaves

represent only 1 channel each. A natural way to construct a local memory machine model is to connect a processor along with its local memory to each leaf of the fat-tree. In this scheme, a message from one processor to another first travels up the tree to the least common-ancestor of the two processors, and then down the tree.

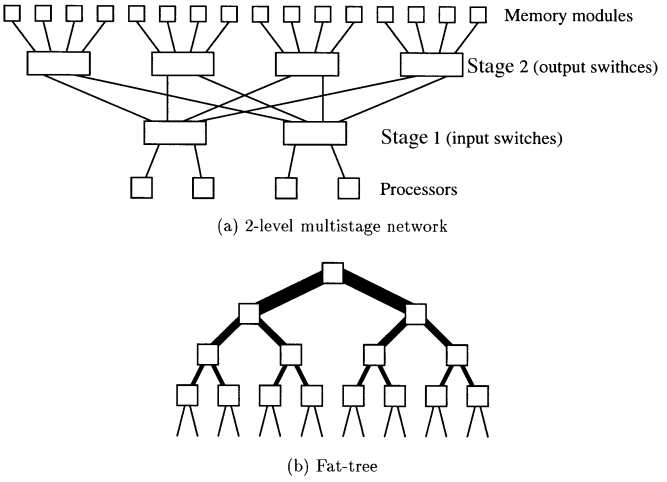


FIGURE 47.3 Multistage and fat-tree network topologies.

Many algorithms have been designed to run efficiently on particular network topologies such as the mesh or the hypercube. For extensive treatment such algorithms, see [55, 67, 73, 80]. Although this approach can lead to very fine-tuned algorithms, it has some disadvantages. First, algorithms designed for one network may not perform well on other networks. Hence, in order to solve a problem on a new machine, it may be necessary to design a new algorithm from scratch. Second, algorithms that take advantage of a particular network tend to be more complicated than algorithms designed for more abstract models like the PRAM models, because they must incorporate some of the details of the network. Nevertheless, there are some operations that are performed so frequently by a parallel machine that it makes sense to design a fine-tuned network-specific algorithm. For example, the algorithm that routes messages or memory access requests through the network should exploit the network topology. Other examples include algorithms for broadcasting a message from one processor to many other processors, for collecting the results computed in many processors in a single processor, and for synchronizing processors.

An alternative to modeling the topology of a network is to summarize its routing capabilities in terms of two parameters, its latency and bandwidth. The latency, L, of a network is the time it takes for a message to traverse the network. In actual networks this will depend on the topology of the network, which particular ports the message is passing between, and the congestion of messages in the network. The latency is often modeled by considering the worst-case time assuming that the network is not heavily congested. The bandwidth at each port of the network is the rate at which a processor can inject data into the network. In actual networks this will depend on the topology of the network, the bandwidths of the network's individual communication channels and, again, the congestion of messages in the network. The bandwidth often can be usefully modeled as the maximum rate at which processors can inject messages into the network without causing it to become heavily congested, assuming a uniform distribution of message destinations. In this case, the bandwidth can be expressed as the minimum *gap* g between successive injections of messages into the network.

Three models that characterize a network in terms of its latency and bandwidth are the Postal model [14], the Bulk-Synchronous Parallel (BSP) model [85], and the LogP model [29]. In the Postal model, a network

is described by a single parameter L, its latency. The Bulk-Synchronous Parallel model adds a second parameter g, the minimum ratio of computation steps to communication steps, i.e., the gap. The LogP model includes both of these parameters, and adds a third parameter o, the overhead, or wasted time, incurred by a processor upon sending or receiving a message.

Primitive Operations

A machine model must also specify the types of operations that the processors and network are permitted to perform. We assume that all processors are allowed to perform the same local instructions as the single processor in the standard sequential RAM model. In addition, processors may have special instructions for issuing nonlocal memory requests, for sending messages to other processors, and for executing various global operations, such as synchronization. There may also be restrictions on when processors can simultaneously issue instructions involving nonlocal operations. For example a model might not allow two processors to write to the same memory location at the same time. These restrictions might make it impossible to execute an algorithm on a particular model, or make the cost of executing the algorithm prohibitively expensive. It is therefore important to understand what instructions are supported before one can design or analyze a parallel algorithm. In this section we consider three classes of instructions that perform nonlocal operations: (1) instructions that perform concurrent accesses to the same shared memory location, (2) instructions for synchronization, and (3) instructions that perform global operations on data.

When multiple processors simultaneously make a request to read or write to the same resource—such as a processor, memory module, or memory location—there are several possible outcomes. Some machine models simply forbid such operations, declaring that it is an error if two or more processes try to access a resource simultaneously. In this case we say that the model allows only *exclusive* access to the resource. For example, a PRAM model might only allow exclusive read or write access to each memory location. A PRAM model of this type is called an exclusive-read exclusive-write (**EREW**) PRAM model. Other machine models may allow unlimited access to a shared resource. In this case we say that the model allows *concurrent* access to the resource. For example, a concurrent-read concurrent-write (**CRCW**) PRAM model allows both concurrent read and write access to memory locations, and a CREW PRAM model allows concurrent reads but only exclusive writes. When making a concurrent write to a resource such as a memory location there are many ways to resolve the conflict. The possibilities include choosing an arbitrary value from those written (arbitrary concurrent write), choosing the value from the processor with lowest index (priority concurrent write), and taking the *logical or* of the values written. A final choice is to allow for *queued* access. In this case concurrent access is permitted but the time for a step is proportional to the maximum number of accesses to any resource. A queue-read queue-write (QRQW) PRAM model allows for such accesses [36].

In addition to reads and writes to nonlocal memory or other processors, there are other important primitives that a model might supply. One class of such primitives support synchronization. There are a variety of different types of synchronization operations and the costs of these operations vary from model to model. In a PRAM model, for example, it is assumed that all processors operate in lock step, which provides implicit synchronization. In a local-memory machine model the cost of synchronization may be a function of the particular network topology. A related operation, broadcast, allows one processor to send a common message to all of the other processors. Some machine models supply more powerful primitives that combine arithmetic operations with communication. Such operations include the prefix and **multiprefix** operations, which are defined in Sections "Scans" and "Multiprefix and Fetch-and-Add."

Work-Depth Models

Because there are so many different ways to organize parallel computers, and hence to model them, it is difficult to select one multiprocessor model that is appropriate for all machines. The alternative to focusing

on the machine is to focus on the algorithm. In this section we present a class of models called work-depth models. In a *work-depth* model, the cost of an algorithm is determined by examining the total number of operations that it performs, and the dependencies among those operations. An algorithm's *work* W is the total number of operations that it performs; its *depth* D is the longest chain of dependencies among its operations. We call the ratio $\mathcal{P} = W/D$ the *parallelism* of the algorithm.

The **work-depth models** are more abstract than the multiprocessor models. As we shall see however, algorithms that are efficient in work-depth models can often be translated to algorithms that are efficient in the multiprocessor models, and from there to real parallel computers. The advantage of using a work-depth model is that there are no machine-dependent details to complicate the design and analysis of algorithms. Here we consider three classes of work-depth models: circuit models, vector machine models, and language-based models. We will be using a language-based model in this chapter, so we will return to these models in Section "Model Used in this Chapter." The most abstract work-depth model is the *circuit model.* A circuit consists of nodes and directed arcs. A node represents a basic operation, such as adding two values. Each input value for an operation arrives at the corresponding node via an incoming arc. The result of the operation is then carried out of the node via one or more outgoing arcs. These outgoing arcs may provide inputs to other nodes. The number of incoming arcs to a node is referred to as the *fan-in* of the node and the number of outgoing arcs is referred to as the *fan-out.* There are two special classes of arcs. A set of *input arcs* provide input values to the circuit as a whole. These arcs do not originate at nodes. The *output arcs* return the final output values produced by the circuit. These arcs do not terminate at nodes. By definition, a circuit is not permitted to contain a directed cycle. In this model, an algorithm is modeled as a family of directed acyclic circuits. There is a circuit for each possible size of the input.

Figure 47.4 shows a circuit for adding 16 numbers. In this figure all arcs are directed toward the bottom. The input arcs are at the top of the figure. Each + node adds the two values that arrive on its two incoming arcs, and places the result on its outgoing arc. The sum of all of the inputs to the circuit is returned on the single output arc at the bottom.

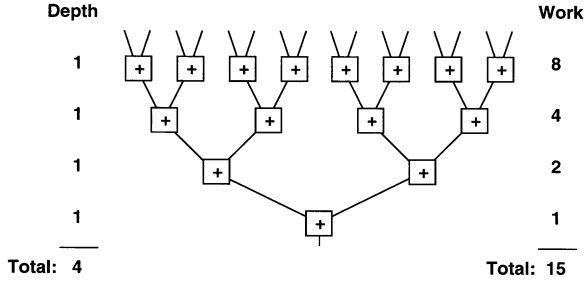

FIGURE 47.4 Summing 16 numbers on a tree. The total depth (longest chain of dependencies) is 4 and the total work (number of operations) is 15.

The **work** and **depth** of a circuit are measured as follows. The work is the total number of nodes. The work in Fig. 47.4, for example, is 15. (The work is also called the *size* of the circuit.) The depth is the number of nodes on the longest directed path from an input arc and an output arc. In Fig. 47.4, the depth is 4. For a family of circuits, the work and depth are typically parameterized in terms of the number of inputs. For example, the circuit in Fig. 47.4 can be easily generalized to add n input values for any n that is a power of two. The work and depth for this family of circuits is $W(n) = n - 1$ and $D(n) = \log_2 n$.

Circuit models have been used for many years to study various theoretical aspects of parallelism, for example to prove that certain problems are difficult to solve in parallel. See [48] for an overview.

In a *vector model* an algorithm is expressed as a sequence of steps, each of which performs an operation on a vector (i.e., sequence) of input values, and produces a vector result [19, 69]. The work of each step is

equal to the length of its input (or output) vector. The work of an algorithm is the sum of the work of its steps. The depth of an algorithm is the number of vector steps.

In a *language* model, a work-depth cost is associated with each programming language construct [20, 22]. For example, the work for calling two functions in parallel is equal to the sum of the work of the two calls. The depth, in this case, is equal to the maximum of the depth of the two calls.

Assigning Costs to Algorithms

In the work-depth models, the cost of an algorithm is determined by its work and by its depth. The notions of work and depth can also be defined for the multiprocessor models. The work W performed by an algorithm is equal to the number of processors multiplied by the time required for the algorithm to complete execution. The depth D is equal to the total time required to execute the algorithm.

The depth of an algorithm is important, because there are some applications for which the time to perform a computation is crucial. For example, the results of a weather forecasting program are useful only if the program completes execution before the weather does!

Generally, however, the most important measure of the cost of an algorithm is the work. This can be argued as follows. The cost of a computer is roughly proportional to the number of processors in the computer. The cost for purchasing time on a computer is proportional to the cost of the computer multiplied by the amount of time used. The total cost of performing a computation, therefore, is roughly proportional to the number of processors in the computer multiplied by the amount of time, i.e., the work.

In many instances, the cost of running a computation on a parallel computer may be slightly larger than the cost of running the same computation on a sequential computer. If the time to completion is sufficiently improved, however, this extra cost can often be justified. As we shall see, however, there is often a tradeoff between time-to-completion and total work performed. To quantify when parallel algorithms are efficient in terms of cost, we say that a parallel algorithm is **work-efficient** if asymptotically (as the problem size grows) it requires at most a constant factor more work than the best sequential algorithm known.

Emulations Among Models

Although it may appear that a different algorithm must be designed for each of the many parallel models, there are often automatic and efficient techniques for translating algorithms designed for one model into algorithms designed for another. These translations are **work-preserving** in the sense that the work performed by both algorithms is the same, to within a constant factor. For example, the following theorem, known as Brent's Theorem [24], shows that an algorithm designed for the circuit model can be translated in a work-preserving fashion to a PRAM model algorithm.

THEOREM 47.1 *[Brent's Theorem] Any algorithm that can be expressed as a circuit of size (i.e., work) W and depth D and with constant fan-in nodes in the circuit model can be executed in $O(W/P + D)$ steps in the CREW PRAM model.*

PROOF The basic idea is to have the PRAM emulate the computation specified by the circuit in a level-by-level fashion. The level of a node is defined as follows. A node is on level 1 if all of its inputs are also inputs to the circuit. Inductively, the level of any other node is one greater than the maximum of the level of the nodes that provide its inputs. Let l_i denote the number of nodes on level i. Then, by assigning $\lceil l_i/P \rceil$ operations to each of the P processors in the PRAM, the operations for level i can be performed in $O(\lceil l_i/P \rceil)$ steps. Concurrent reads might be required since many operations on one level might read

the same result from a previous level. Summing the time over all D levels, we have

$$\begin{aligned} T_{PRAM}(W, D, P) &= O\left(\sum_{i=1}^{D} \left\lceil \frac{l_i}{P} \right\rceil\right) \\ &= O\left(\sum_{i=1}^{D} \left(\frac{l_i}{P} + 1\right)\right) \\ &= O\left(\frac{1}{P}\left(\sum_{i=1}^{D} l_i\right) + D\right) \\ &= O\left(W/P + D\right) . \end{aligned}$$

The last step is derived by observing that $W = \sum_{i=1}^{D} l_i$, i.e., that the work is equal to the total number of nodes on all of the levels of the circuit.

The total work performed by the PRAM, i.e., the processor-time product, is $O(W + PD)$. This emulation is work-preserving to within a constant factor when the parallelism ($\mathcal{P} = W/D$) is at least as large as the number of processors P, for in this case the work is $O(W)$. The requirement that the parallelism exceed the number of processors is typical of work-preserving emulations.

Brent's Theorem shows that an algorithm designed for one of the work-depth models can be translated in a work-preserving fashion to a multiprocessor model. Another important class of work-preserving translations are those that translate between different multiprocessor models. The translation we consider here is the work-preserving translation of algorithms written for the PRAM model to algorithms for a modular memory machine model that incorporates the feature of network topology. In particular we consider a *butterfly machine* [55, Chapter 3.6] model in which P processors are attached through a butterfly network of depth $\log P$ to P memory banks. We assume that, in constant time, a processor can hash a virtual memory address to a physical memory bank and an address within that bank using a sufficiently powerful hash function. This scheme was first proposed by Karlin and Upfal [47] for the EREW PRAM model. Ranade [72] later presented a more general approach that allowed the butterfly to efficiently emulate CRCW algorithms.

THEOREM 47.2 *Any algorithm that takes time T on a P-processor PRAM model can be translated into an algorithm that takes time $O(T(P/P' + \log P'))$, with high probability, on a P'-processor butterfly machine model.*

Sketch of proof: Each of the P' processors in the butterfly emulates a set of P/P' PRAM processors. The butterfly emulates the PRAM in a step-by-step fashion. First, each butterfly processor emulates one step of each of its P/P' PRAM processors. Some of the PRAM processors may wish to perform memory accesses. For each memory access, the butterfly processor hashes the memory address to a physical memory bank and an address within the bank, and then routes a message through the network to that bank. These messages are pipelined so that a butterfly processor can have multiple outstanding requests. Ranade proved that if each processor in the P-processor butterfly sends at most P/P' messages, and if the destinations of the messages are determined by a sufficiently powerful random hash function, then the network can deliver all of the messages, along with responses, in $O(P/P' + \log P')$ time. The $\log P'$ term accounts for the latency of the network, and for the fact that there will be some congestion at memory banks, even if each processor sends only a single message.

This theorem implies that the emulation is work preserving when $P \geq P' \log P'$, i.e., when the number of processors employed by the PRAM algorithm exceeds the number of processors in the butterfly by a factor of at least $\log P'$. When translating algorithms from one multiprocessor model (e.g., the PRAM

model), which we call the *guest model,* to another multiprocessor model (e.g., the butterfly machine model), which we call the *host model,* it is not uncommon to require that the number of guest processors exceed the number of host processors by a factor proportional to the latency of the host. Indeed, the latency of the host can often be hidden by giving it a larger guest to emulate. If the bandwidth of the host is smaller than the bandwidth of a comparably sized guest, however, it is usually much more difficult for the host to perform a work-preserving emulation of the guest.

For more information on PRAM emulations, the reader is referred to [43, 86]

Model Used in This Chapter

Because there are so many work-preserving translations between different parallel models of computation, we have the luxury of choosing the model that we feel most clearly illustrates the basic ideas behind the algorithms, a work-depth language model. Here we define the model that we use in this chapter in terms of a set of language constructs and a set of rules for assigning costs to the constructs. The description here is somewhat informal, but should suffice for the purpose of this chapter. The language and costs can be properly formalized using a profiling semantics [22].

Most of the syntax that we use should be familiar to readers who have programmed in Algol-like languages, such as Pascal and C. The constructs for expressing parallelism, however, may be unfamiliar. We will be using two parallel constructs—a parallel *apply-to-each* construct and a *parallel-do* construct—and a small set of parallel primitives on sequences (one-dimensional arrays). Our language constructs, syntax and cost rules are loosely based on the NESL language [20].

The *apply-to-each* construct is used to apply an expression over a sequence of values in parallel. It uses a set like notation. For example, the expression

$$\{a * a : a \in [3, -4, -9, 5]\}$$

squares each element of the sequence $[3, -4, -9, 5]$ returning the sequence $[9, 16, 81, 25]$. This can be read: "in parallel, for each a in the sequence $[3, -4, -9, 5]$, square a." The apply-to-each construct also provides the ability to subselect elements of a sequence based on a filter. For example

$$\{a * a : a \in [3, -4, -9, 5] | a > 0\}$$

can be read: "in parallel, for each a in the sequence $[3, -4, -9, 5]$ such that a is greater than 0, square a." It returns the sequence $[9, 25]$. The elements that remain maintain the relative order from the original sequence.

The *parallel-do* construct is used to evaluate multiple statements in parallel. It is expressed by listing the set of statements after the keywords **in parallel do**. For example, the following fragment of code calls FUNCTION1 on (X) and assigns the result to A and in parallel calls FUNCTION2 on (Y) and assigns the result to B.

in parallel do
  $A :=$ FUNCTION1(X)
  $B :=$ FUNCTION2(Y)

The parallel-do completes when all of the parallel subcalls complete.

Work and depth are assigned to our language constructs as follows. The work and depth of a scalar primitive operation is one. For example, the work and depth for evaluating an expression such as $3 + 4$ is one. The work for applying a function to every element in a sequence is equal to the sum of the work for each of the individual applications of the function. For example, the work for evaluating the expression

$$\{a * a : a \in [0..n)\},$$

which creates an n-element sequence consisting of the squares of 0 through $n-1$, is n. The depth for applying a function to every element in a sequence is equal to the maximum of the depths of the individual applications of the function. Hence, the depth of the previous example is one. The work for a parallel-do construct is equal to the sum of the work for each of its statements. The depth is equal to the maximum depth of its statements. In all other cases, the work and depth for a sequence of operations are equal to the sums of the work and depth for the individual operations.

In addition to the parallelism supplied by apply-to-each, we use four built-in functions on sequences, *distribute,* ++ (append), *flatten,* and ← (write,) each of which can be implemented in parallel. The function *distribute* creates a sequence of identical elements. For example, the expression

$$distribute(3, 5)$$

creates the sequence

$$[3, 3, 3, 3, 3] .$$

The ++ function appends two sequences. For example $[2, 1]++[5, 0, 3]$ create the sequence $[2, 1, 5, 0, 3]$. The *flatten* function converts a nested sequence (a sequence in which each element is itself a sequence) into a flat sequence. For example,

$$flatten([[3, 5], [3, 2], [1, 5], [4, 6]])$$

creates the sequence

$$[3, 5, 3, 2, 1, 5, 4, 6] .$$

The ← function is used to write multiple elements into a sequence in parallel. It takes two arguments. The first argument is the sequence to modify and the second is a sequence of integer-value pairs that specify what to modify. For each pair (i, v) the value v is inserted into position i of the destination sequence. For example

$$[0, 0, 0, 0, 0, 0, 0, 0] \leftarrow [(4, -2), (2, 5), (5, 9)]$$

inserts the -2, 5 and 9 into the sequence at locations 4, 2 and 5, respectively, returning

$$[0, 0, 5, 0, -2, 9, 0, 0] .$$

As in the PRAM model, the issue of concurrent writes arises if an index is repeated. Rather than choosing a single policy for resolving concurrent writes, we will explain the policy used for the individual algorithms. All of these functions have depth one and work n, where n is the size of the sequence(s) involved. In the case of ←, the work is proportional to the length of the sequence of integer-value pairs, not the modified sequence, which might be much longer. In the case of ++, the work is proportional to the length of the second sequence.

We will use a few shorthand notations for specifying sequences. The expression $[-2..1]$ specifies the same sequence as the expression $[-2, -1, 0, 1]$. Changing the left or right bracket surrounding a sequence to a parenthesis omits the first or last elements, e.g., $[-2..1)$ denotes the sequence $[-2, -1, 0]$. The notation $A[i..j]$ denotes the subsequence consisting of elements $A[i]$ through $A[j]$. Similarly, $A[i, j)$ denotes the subsequence $A[i]$ through $A[j-1]$. We will assume that sequence indices are zero based, i.e., $A[0]$ extracts the first element of the sequence A.

Throughout this chapter our algorithms make use of random numbers. These numbers are generated using the functions *rand_bit(),* which returns a random bit, and *rand_int(h),* which returns a random integer in the range $[0, h-1]$.

47.3 Parallel Algorithmic Techniques

As in sequential algorithm design, in parallel algorithm design there are many general techniques that can be used across a variety of problem areas. Some of these are variants of standard sequential techniques, while others are new to parallel algorithms. In this section we introduce some of these techniques, including parallel divide-and-conquer, randomization, and parallel pointer manipulation. We will make use of these techniques in later sections.

Divide-and-Conquer

A divide-and-conquer algorithm first splits the problem to be solved into subproblems that are easier to solve than the original problem, and then solves the subproblems, often recursively. Typically the subproblems can be solved independently. Finally, the algorithm merges the solutions to the subproblems to construct a solution to the original problem.

The divide-and-conquer paradigm improves program modularity, and often leads to simple and efficient algorithms. It has therefore proven to be a powerful tool for sequential algorithm designers. Divide-and-conquer plays an even more prominent role in parallel algorithm design. Because the subproblems created in the first step are typically independent, they can be solved in parallel. Often the subproblems are solved recursively and thus the next divide step yields even more subproblems to be solved in parallel. As a consequence, even divide-and-conquer algorithms that were designed for sequential machines typically have some inherent parallelism. Note however, that in order for divide-and-conquer to yield a highly parallel algorithm, it is often necessary to parallelize the divide step and the merge step. It is also common in parallel algorithms to divide the original problem into as many subproblems as possible, so that they can all be solved in parallel.

As an example of parallel divide-and-conquer, consider the sequential mergesort algorithm. Mergesort takes a set of n keys as input and returns the keys in sorted order. It works by splitting the keys into two sets of $n/2$ keys, recursively sorting each set, and then merging the two sorted sequences of $n/2$ keys into a sorted sequence of n keys. To analyze the sequential running time of mergesort we note that two sorted sequences of $n/2$ keys can be merged in $O(n)$ time. Hence the running time can be specified by the recurrence

$$T(n) = \begin{cases} 2T(n/2) + O(n) & n > 1 \\ O(1) & n = 1 \end{cases} \tag{47.1}$$

which has the solution $T(n) = O(n \log n)$. Although not designed as a parallel algorithm, mergesort has some inherent parallelism since the two recursive calls are independent, thus allowing them to be made in parallel. The parallel calls can be expressed as

ALGORITHM: MERGESORT(A)
1 **if** ($|A| = 1$) **then return** A
2 **else**
3 **in parallel do**
4 $L :=$ MERGESORT($A[0..|A|/2)$)
5 $R :=$ MERGESORT($A[|A|/2..|A|)$)
6 **return** MERGE(L, R)

Recall that in our work-depth model we can analyze the depth of an algorithm that makes parallel calls by taking the maximum depth of the two calls, and the work by taking the sum of the work of the two calls. We assume that the merging remains sequential so that the work and depth to merge two sorted sequences of $n/2$ keys is $O(n)$. Thus for mergesort the work and depth are given by the recurrences

$$W(n) = 2W(n/2) + O(n) \tag{47.2}$$

$$D(n) = \max(D(n/2), D(n/2)) + O(n) \quad (47.3)$$
$$= D(n/2) + O(n) \quad (47.4)$$

As expected, the solution for the work is $W(n) = O(n \log n)$, i.e., the same as the time for the sequential algorithm. For the depth, however, the solution is $D(n) = O(n)$, which is smaller than the work. Recall that we defined the parallelism of an algorithm as the ratio of the work to the depth. Hence, the parallelism of this algorithm is $O(\log n)$ (not very much). The problem here is that the merge step remains sequential, and is the bottleneck.

As mentioned earlier, the parallelism in a divide-and-conquer algorithm can often be enhanced by parallelizing the divide step and/or the merge step. Using a parallel merge [52], two sorted sequences of $n/2$ keys can be merged with work $O(n)$ and depth $O(\log \log n)$. Using this merge algorithm, the recurrence for the depth of mergesort becomes

$$D(n) = D(n/2) + O(\log \log n) \quad (47.5)$$

which has solution $D(n) = O(\log n \log \log n)$. Using a technique called **pipelined divide-and-conquer** the depth of mergesort can be further reduced to $O(\log n)$ [26]. The idea is to start the merge at the top level before the recursive calls complete.

Divide-and-conquer has proven to be one of the most powerful techniques for solving problems in parallel. In this chapter, we will use it to solve problems from computational geometry, for sorting, and for performing fast Fourier transforms. Other applications range from solving linear systems, to factoring large numbers, to performing n-body simulations.

Randomization

Random numbers are used in parallel algorithms to ensure that processors can make local decisions that, with high probability, add up to good global decisions. Here we consider three uses of randomness.

Sampling One use of randomness is to select a representative sample from a set of elements. Often, a problem can be solved by selecting a sample, solving the problem on that sample, and then using the solution for the sample to guide the solution for the original set. For example, suppose we want to sort a collection of integer keys. This can be accomplished by partitioning the keys into buckets and then sorting within each bucket. For this to work well, the buckets must represent nonoverlapping intervals of integer values, and each bucket must contain approximately the same number of keys. **Random sampling** is used to determine the boundaries of the intervals. First each processor selects a random sample of its keys. Next all of the selected keys are sorted together. Finally these keys are used as the boundaries. Such random sampling is also used in many parallel computational geometry, graph, and string matching algorithms.

Symmetry Breaking Another use of randomness is in **symmetry breaking.** For example, consider the problem of selecting a large independent set of vertices in a graph in parallel. (A set of vertices is *independent* if no two are neighbors.) Imagine that each vertex must decide, in parallel with all other vertices, whether to join the set or not. Hence, if one vertex chooses to join the set, then all of its neighbors must choose not to join the set. The choice is difficult to make simultaneously for each vertex if the local structure at each vertex is the same, for example if each vertex has the same number of neighbors. As it turns out, the impasse can be resolved by using randomness to break the symmetry between the vertices [58].

Load Balancing A third use of randomness is load balancing. One way to quickly partition a large number of data items into a collection of approximately evenly sized subsets is to randomly assign each element to a subset. This technique works best when the average size of a subset is at least logarithmic in the size of the original set.

Parallel Pointer Techniques

Many of the traditional sequential techniques for manipulating lists, trees, and graphs do not translate easily into parallel techniques. For example, techniques such as traversing the elements of a linked list, visiting the nodes of a tree in postorder, or performing a depth-first traversal of a graph appear to be inherently sequential. Fortunately these techniques can often be replaced by parallel techniques with roughly the same power.

Pointer Jumping One of the oldest parallel pointer techniques is **pointer jumping** [88]. This technique can be applied to either lists or trees. In each pointer jumping step, each node in parallel replaces its pointer with that of its successor (or parent). For example, one way to label each node of an n-node list (or tree) with the label of the last node (or root) is to use pointer jumping. After at most $\lceil \log n \rceil$ steps, every node points to the same node, the end of the list (or root of the tree). This is described in more detail in Section "Pointer Jumping."

Euler Tour Technique An Euler tour of a directed graph is a path through the graph in which every edge is traversed exactly once. In an undirected graph each edge is typically replaced by two oppositely directed edges. The Euler tour of an undirected tree follows the perimeter of the tree visiting each edge twice, once on the way down and once on the way up. By keeping a linked structure that represents the Euler tour of a tree it is possible to compute many functions on the tree, such as the size of each subtree [83]. This technique uses linear work, and parallel depth that is independent of the depth of the tree. The Euler tour technique can often be used to replace a standard traversal of a tree, such as a depth-first traversal.

Graph Contraction **Graph contraction** is an operation in which a graph is reduced in size while maintaining some of its original structure. Typically, after performing a graph contraction operation, the problem is solved recursively on the contracted graph. The solution to the problem on the contracted graph is then used to form the final solution. For example, one way to partition a graph into its connected components is to first contract the graph by merging some of the vertices with neighboring vertices, then find the connected components of the contracted graph, and finally undo the contraction operation. Many problems can be solved by contracting trees [64, 65], in which case the technique is called **tree contraction.** More examples of graph contraction can be found in Section 47.5.

Ear Decomposition An ear decomposition of a graph is a partition of its edges into an ordered collection of paths. The first path is a cycle, and the others are called ears. The end-points of each ear are anchored on previous paths. Once an ear decomposition of a graph is found, it is not difficult to determine if two edges lie on a common cycle. This information can be used in algorithms for determining biconnectivity, triconnectivity, 4-connectivity, and planarity [60, 63]. An ear decomposition can be found in parallel using linear work and logarithmic depth, independent of the structure of the graph. Hence, this technique can be used to replace the standard sequential technique for solving these problems, depth-first search.

Other Techniques

Many other techniques have proven to be useful in the design of parallel algorithms. Finding small graph separators is useful for partitioning data among processors to reduce communication [75, Chapter 14]. Hashing is useful for load balancing and mapping addresses to memory [47, 87]. Iterative techniques are useful as a replacement for direct methods for solving linear systems [18].

47.4 Basic Operations on Sequences, Lists, and Trees

We begin our presentation of parallel algorithms with a collection of algorithms for performing basic operations on sequences, lists, and trees. These operations will be used as subroutines in the algorithms that follow in later sections.

Sums

As explained near the beginning of this chapter, there is a simple recursive algorithm for computing the sum of the elements in an array.

ALGORITHM: SUM(A)
1 **if** $|A| = 1$ **then return** $A[0]$
2 **else return** SUM($\{A[2i] + A[2i+1] : i \in [0..|A|/2)\}$)

The work and depth for this algorithm are given by the recurrences

$$W(n) = W(n/2) + O(n) \tag{47.6}$$
$$D(n) = D(n/2) + O(1) \tag{47.7}$$

which have solutions $W(n) = O(n)$ and $D(n) = O(\log n)$. This algorithm can also be expressed without recursion (using a **while** loop), but the recursive version foreshadows the recursive algorithm for the **scan** function.

As written, the algorithm only works on sequences that have lengths equal to powers of 2. Removing this restriction is not difficult by checking if the sequence is of odd length and separately adding the last element in if it is. This algorithm can also easily be modified to compute the "sum" using any other binary associative operator in place of $+$. For example the use of max would return the maximum value in the sequence.

Scans

The *plus-scan* operation (also called all-prefix-sums) takes a sequence of values and returns a sequence of equal length for which each element is the sum of all previous elements in the original sequence. For example, executing a plus-scan on the sequence [3, 5, 3, 1, 6] returns [0, 3, 8, 11, 12]. An algorithm for performing the scan operation [81] is shown below.

ALGORITHM: SCAN(A)
1 **if** $|A| = 1$ **then return** $[0]$
2 **else**
3 $S = \text{SCAN}(\{A[2i] + A[2i+1] : i \in [0..|A|/2)\})$
4 $R = \{\textbf{if } (i \bmod 2) = 0 \textbf{ then } S[i/2] \textbf{ else } S[(i-1)/2] + A[i-1] : i \in [0..|A|)\}$
5 **return** R

The algorithm works by element-wise adding the even indexed elements of A to the odd indexed elements of A, and then recursively solving the problem on the resulting sequence (Line 3). The result S of the recursive call gives the plus-scan values for the even positions in the output sequence R. The value for each of the odd positions in R is simply the value for the preceding even position in R plus the value of the preceding position from A.

The asymptotic work and depth costs of this algorithm are the same as for the SUM operation, $W(n) = O(n)$ and $D(n) = O(\log n)$. Also, as with the SUM operation, any binary associative operator can be used in place of the $+$. In fact the algorithm described can be used more generally to solve various recurrences, such as the first-order linear recurrences $x_i = (x_{i-1} \otimes a_i) \oplus b_i$, $0 \leq i \leq n$, where $\otimes$ and $\oplus$ are both binary associative operators [51].

Scans have proven so useful in the design of parallel algorithms that some parallel machines provide support for scan operations in hardware.

Multiprefix and Fetch-and-Add

The *multiprefix* operation is a generalization of the scan operation in which multiple independent scans are performed. The input to the multiprefix operation is a sequence A of n pairs (k, a), where k specifies a key and a specifies an integer data value. For each key value, the multiprefix operation performs an independent scan. The output is a sequence B of n integers containing the results of each of the scans such that if $A[i] = (k, a)$ then

$$B[i] = sum(\{b : (t, b) \in A[0..i) \mid t = k\})$$

In other words, each position receives the sum of all previous elements that have the same key. As an example,

$$\text{MULTIPREFIX}([(1, 5), (0, 2), (0, 3), (1, 4), (0, 1), (2, 2)])$$

returns the sequence

$$[0, 0, 2, 5, 5, 0]$$

The *fetch-and-add* operation is a weaker version of the multiprefix operation, in which the order of the input elements for each scan is not necessarily the same as the order in the input sequence A. In this chapter we do not present an algorithm for the multiprefix operation, but it can be solved by a function that requires work $O(n)$ and depth $O(\log n)$ using concurrent writes [61].

Pointer Jumping

Pointer jumping is a technique that can be applied to both linked lists and trees [88]. The basic pointer jumping operation is simple. Each node i replaces its pointer $P[i]$ with the pointer of the node that it points to, $P[P[i]]$. By repeating this operation, it is possible to compute, for each node in a list or tree, a pointer to the end of the list or root of the tree. Given a set P of pointers that represent a tree (i.e., pointers from children to parents), the following code will generate a pointer from each node to the root of the tree. We assume that the root points to itself.

ALGORITHM: POINT_TO_ROOT(P)
1 **for** j **from** 1 **to** $\lceil \log |P| \rceil$
2 $\quad P := \{P[P[i]] : i \in [0..|P|)\}$

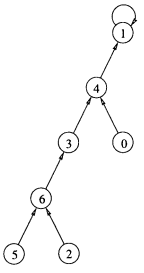
The idea behind this algorithm is that in each loop iteration the distance spanned by each pointer, with respect to the original tree, will double, until it points to the root. Since a tree constructed from $n = |P|$ pointers has depth at most $n - 1$, after $\lceil \log n \rceil$ iterations each pointer will point to the root. Because each iteration has constant depth and performs $\Theta(n)$ work, the algorithm has depth $\Theta(\log n)$ and work $\Theta(n \log n)$.

Figure 47.5 illustrates algorithm POINT_TO_ROOT applied to a tree consisting of seven nodes.

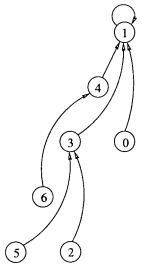
List Ranking

The problem of computing the distance from each node to the end of a linked list is called *list ranking*. Function POINT_TO_ROOT can be easily modified to compute these distances, as shown below.

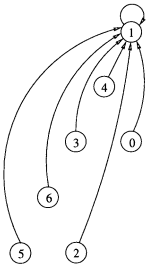
ALGORITHM: LIST_RANK(P)
1 $V = \{$**if** $P[i] = i$ **then** 0 **else** $1 : i \in [0..|P|)\}$
2 **for** j **from** 1 **to** $\lceil \log |P| \rceil$
3 $\quad V := \{V[i] + V[P[i]] : i \in [0..|P|)\}$
4 $\quad P := \{P[P[i]] : i \in [0..|P|)\}$
5 **return** V



(a) The input tree $P = [4, 1, 6, 4, 1, 6, 3]$.



(b) The tree $P = [1, 1, 3, 1, 1, 3, 4]$ after one iteration of the algorithm.



(c) The final tree $P = [1, 1, 1, 1, 1, 1, 1]$.

FIGURE 47.5 The effect of two iterations of algorithm POINT_TO_ROOT.

In this function, $V[i]$ can be thought of as the distance spanned by pointer $P[i]$ with respect to the original list. Line 1 initializes V by setting $V[i]$ to 0 if i is the last node (i.e., points to itself), and 1 otherwise. In each iteration, Line 3 calculates the new length of $P[i]$. The function has depth $\Theta(\log n)$ and work $\Theta(n \log n)$.

It is worth noting that there are simple sequential algorithms that perform the same tasks as both functions POINT_TO_ROOT and LIST_RANK using only $O(n)$ work. For example, the list ranking problem can be solved by making two passes through the list. The goal of the first pass is simply to count the number of elements in the list. The elements can then be numbered with their positions from the end of the list in a second pass. Thus, neither function POINT_TO_ROOT nor LIST_RANK are work-efficient, since both require $\Theta(n \log n)$ work in the worst case. There are, however, several work-efficient parallel solutions to both of these problems.

The following parallel algorithm uses the technique of random sampling to construct a pointer from each node to the end of a list of n nodes in a work-efficient fashion [74]. The algorithm is easily generalized to solve the list-ranking problem.

1. Pick m list nodes at random and call them the *start* nodes.
2. From each start node u, follow the list until reaching the next start node v. Call the list nodes between u and v the *sublist* of u.

3. Form a shorter list consisting only of the start nodes and the final node on the list by making each start node point to the next start node on the list.
4. Using pointer jumping on the shorter list, for each start node create a pointer to the last node in the list.
5. For each start node u, distribute the pointer to the end of the list to all of the nodes in the sublist of u.

The key to analyzing the work and depth of this algorithm is to bound the length of the longest sublist. Using elementary probability theory, it is not difficult to prove that the expected length of the longest sublist is at most $O((n \log m)/m)$. The work and depth for each step of the algorithm are thus computed as follows.

1. $W(n, m) = O(m)$ and $D(n, m) = O(1)$
2. $W(n, m) = O(n)$ and $D(n, m) = O((n \log m)/m)$
3. $W(n, m) = O(m)$ and $D(n, m) = O(1)$
4. $W(n, m) = O(m \log m)$ and $D(n, m) = O(\log m)$
5. $W(n, m) = O(n)$ and $D(n, m) = O((n \log m)/m)$

Thus, the work for the entire algorithm is $W(m, n) = O(n + m \log m)$, and the depth is $O((n \log m)/m)$. If we set $m = n/\log n$, these reduce to $W(n) = O(n)$ and $D(n) = O(\log^2 n)$.

Using a technique called *contraction,* it is possible to design a list ranking algorithm that runs in $O(n)$ work and $O(\log n)$ depth [8, 9]. This technique can also be applied to trees [64, 65].

Removing Duplicates

This section presents several algorithms for removing the duplicate items that appear in a sequence. Thus, the input to each algorithm is a sequence, and the output is a new sequence containing exactly one copy of every item that appears in the input sequence. It is assumed that the order of the items in the output sequence does not matter. Such an algorithm is useful when a sequence is used to represent an unordered set of items. Two sets can be merged, for example, by first appending their corresponding sequences, and then removing the duplicate items.

Approach 1: Using an Array of Flags

If the items are all nonnegative integers drawn from a small range, we can use a technique similar to bucket sort to remove the duplicates. We begin by creating an array equal in size to the range, and initializing all of its elements to 0. Next, using concurrent writes we set a flag in the array for each number that appears in the input list. Finally, we extract those numbers with flags that have been set. This algorithm is expressed as follows.

ALGORITHM: REM_DUPLICATES(V)
1 RANGE := 1+ MAX(V)
2 FLAGS := *distribute* (0,RANGE) $\leftarrow$ $\{(i, 1) : i \in V\}$
3 **return** $\{j : j \in [0..\text{RANGE})|$ FLAGS$[j] = 1\}$

This algorithm has depth $O(1)$ and performs work $O(|V| + \text{MAX}(V))$. Its obvious disadvantage is that it explodes when given a large range of numbers, both in memory and in work.

Approach 2: Hashing

A more general approach is to use a hash table. The algorithm has the following outline. The algorithm first creates a hash table that contains a prime number of entries, where the prime is approximately

twice as large as the number of items in the set V. A prime size is best, because it makes designing a good hash function easier. The size must also be large enough that the chance of collisions in the hash table is not too great. Let m denote the size of the hash table. Next, the algorithm computes a hash value $hash(V[j], m)$ for each item $V[j] \in V$, and attempts to write the index j into the hash table entry $hash(V[j], m)$. For example, Fig. 47.6 describes a particular hash function applied to the sequence [69, 23, 91, 18, 42, 23, 18]. We assume that if multiple values are simultaneously written into the same memory location, one of the values will be correctly written (the arbitrary concurrent write model). An item $V[j]$ is called a *winner* if the index j is successfully written into the hash table. In our example, the winners are $V[0]$, $V[1]$, $V[2]$, and $V[3]$, i.e., 69, 23, 91, and 18. The winners are added to the duplicate-free sequence that is being constructed, and then set aside. Among the losers, we must distinguish between two types of items, those that were defeated by an item with the same value, and those that were defeated by an item with a different value. In our example, $V[5]$ and $V[6]$ (23 and 18) were defeated by items with the same value, and $V[4]$ (42) was defeated by an item with a different value. Items of the first type are set aside because they are duplicates. Items of the second type are retained, and the algorithm repeats the entire process on them using a different hash function. In general, it may take several iterations before all of the items have been set aside, and in each iteration the algorithm must use a different hash function.

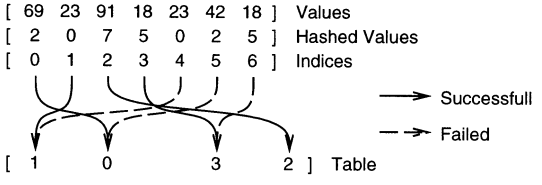


FIGURE 47.6 Each key attempts to write its index into a hash table entry.

The code for removing duplicates using hashing is shown below.

ALGORITHM: REMOVE_DUPLICATES(V)

```
1  m := NEXT_PRIME(2 * |V|)
2  TABLE := distribute(−1, m)
3  i := 0
4  RESULT := {}
5  while |V| > 0
6     TABLE := TABLE ← {(hash(V[j], m, i), j) : j ∈ [0..|V|)}
7     WINNERS := {V[j] : j ∈ [0..|V|) | TABLE[hash(V[j], m, i)] = j}
8     RESULT := RESULT ++ WINNERS
9     TABLE := TABLE ← {(hash(k, m, i), k) : k ∈ WINNERS}
10    V := {k ∈ V | TABLE[hash(k, m, i)] ≠ k}
11    i := i + 1
12 return RESULT
```

The first four lines of function REMOVE_DUPLICATES initialize several variables. Line 1 finds the first prime number larger than $2 * |V|$ using the built-in function NEXT_PRIME. Line 2 creates the hash table, and initializes its entries with an arbitrary value (-1). Line 3 initializes i, a variable that simply counts iterations of the **while** loop. Line 4 initializes the sequence RESULT to be empty. Ultimately, RESULT will contain a single copy of each distinct item from the sequence V.

The bulk of the work in function REMOVE_DUPLICATES is performed by the **while** loop. While there are items remaining to be processed, the code performs the following steps. In Line 6, each item $V[j]$

attempts to write its index j into the table entry given by the hash function $hash(V[j], m, i)$. Note that the hash function takes the iteration i as an argument, so that a different hash function is used in each iteration. Concurrent writes are used so that if several items attempt to write to the same entry, precisely one will win. Line 7 determines which items successfully wrote indices in Line 6, and stores the values of these items in an array called WINNERS. The winners are added to the RESULT in Line 8. The purpose of Lines 9 and 10 is to remove all of the items that are either winners or duplicates of winners. These lines reuse the hash table. In Line 9, each winner writes its value, rather than its index, into the hash table. In this step there are no concurrent writes. Finally, in Line 10, an item is retained only if it is not a winner, and the item that defeated it has a different value.

It is not difficult to prove that, provided that the hash values $hash(V[j], m, i)$ are random and sufficiently independent, both between iterations and within an iteration, each iteration reduces the number of items remaining by some constant fraction until the number of items remaining is small. As a consequence, $D(n) = O(\log n)$ and $W(n) = O(n)$.

The remove-duplicates algorithm is frequently used for set operations. For instance, given the code for REMOVE_DUPLICATES, it is easy to write the code for the set union operation.

47.5 Graphs

Graph problems are often difficult to parallelize since many standard sequential graph techniques, such as depth-first or priority-first search, do not parallelize well. For some problems, such as minimum-spanning tree and biconnected components, new techniques have been developed to generate efficient parallel algorithms. For other problems, such as single-source shortest paths, there are no known efficient parallel algorithms, at least not for the general case.

We have already outlined some of the parallel graph techniques in Section 47.3. In this section we describe algorithms for breadth-first search, for finding connected components, and for finding minimum spanning trees. These algorithms use some of the general techniques. In particular, randomization and graph contraction will play an important role in the algorithms. In this chapter we limit ourselves to algorithms on sparse undirected graphs. We suggest the following sources for further information on parallel graph algorithms [75, Chapters 2-8], [45, Chapter 5], [35, Chapter 2].

Graphs and Graph Representations

A *graph* $G = (V, E)$ consists of a set of *vertices* V and a set of *edges* E in which each edge connects two vertices. In a *directed graph* each edge is directed from one vertex to another, while in an *undirected graph* each edge is symmetric, i.e., goes in both directions. A *weighted graph* is a graph in which each edge $e \in E$ has a weight $w(e)$ associated with it. In this chapter we use the convention that $n = |V|$ and $m = |E|$. Qualitatively, a graph is considered sparse if m is much less than n^2 and dense otherwise. The *diameter* of a graph, denoted $D(G)$, is the maximum, over all pairs of vertices (u, v), of the minimum number of edges that must be traversed to get from u to v.

There are three standard representations of graphs used in sequential algorithms: edge lists, adjacency lists, and adjacency matrices. An *edge list* consists of a list of edges, each of which is a pair of vertices. The list directly represents the set E. An *adjacency list* is an array of lists. Each array element corresponds to one vertex and contains a linked list of pointers to the neighboring vertices, i.e., the linked list for a vertex v contains pointers to the vertices $\{u|(v, u) \in E\}$). An *adjacency matrix* is an $n \times n$ array A such that A_{ij} is 1 if $(i, j) \in E$ and 0 otherwise. The adjacency matrix representation is typically used only when the graph is dense since it requires $\Theta(n^2)$ space, as opposed to $\Theta(n + m)$ space for the other two representations. Each of these representations can be used to represent either directed or undirected graphs.

For parallel algorithms we use similar representations for graphs. The main change we make is to replace the linked lists with arrays. In particular the edge-list is represented as an array of edges and the

adjacency-list is represented as an array of arrays. Using arrays instead of lists makes it easier to process the graph in parallel. In particular, they make it easy to grab a set of elements in parallel, rather than having to follow a list. Figure 47.7 shows an example of our representations for an undirected graph. Note that for the edge-list representation of the undirected graph each edge appears twice, once in each direction (this property is important for some of the algorithms described in this chapter[1]). To represent a directed graph we simply only store the edge once in the desired direction. In the text we will refer to the left element of an edge pair as the *source vertex* and the right element as the *destination vertex*.

(c)

FIGURE 47.7 Representations of an undirected graph. (a) A graph G with 5 vertices and 5 edges. (b) An edge-list representation of G. (c) The adjacency-list representation of G. Values between square brackets are elements of an array, and values between parentheses are elements of a pair.

In designing algorithms, it is sometimes more efficient to use an edge list and sometimes more efficient to use an adjacency list. It is therefore important to be able to convert between the two representations. To convert from an adjacency list to an edge list (representation (c) to representation (b) in Fig. 47.7) is straightforward. The following code will do it with linear work and constant depth:

$$flatten(\{\{(i, j) : j \in G[i]\} : i \in [0..|G|\})$$

where G is the graph in the adjacency list representation. For each vertex i this code pairs up i with each of i's neighbors. The *flatten* is used since the nested apply-to-each will return a sequence of sequences that needs to be flattened into a single sequence.

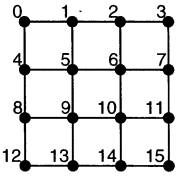
To convert from an edge list to an adjacency list is somewhat more involved, but still requires only linear work. The basic idea is to sort the edges based on the source vertex. This places edges from a particular vertex in consecutive positions in the resulting array. This array can then be partitioned into blocks based on the source vertices. It turns out that since the sorting is on integers in the range $[0..|V|)$, a radix sort can be used (see Section "Radix Sort"), which requires linear work. The depth of the radix sort depends on the depth of the multiprefix operation (see Section "Multiprefix and Fetch-and-Add").

Breadth First Search

The first algorithm we consider is parallel breadth-first search (BFS). BFS can be used to solve problems such as determining if a graph is connected or generating a spanning tree of a graph. Parallel BFS is similar to the sequential version, which starts with a source vertex s and visits levels of the graph one after the other using a queue to keep track of vertices that have not yet been visited. The main difference is that each level is going to be visited in parallel and no queue is required. As with the sequential algorithm each vertex will only be visited once and each edge at most twice, once in each direction. The work is therefore

[1] If space is of serious concern, the algorithms can be easily modified to work with edges stored in just one direction.

linear in the size of the graph, $O(n+m)$. For a graph with diameter D, the number of levels visited by the algorithm will be at least $D/2$ and at most D, depending on where the search is initiated. We will show that each level can be visited in constant depth, assuming a concurrent-write model, so that the total depth of parallel BFS is $O(D)$.



(a)

Step	Frontier
0	[0]

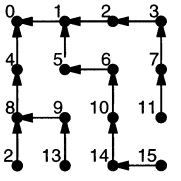
(b)



(c)

FIGURE 47.8 Example of parallel breadth-first search. (a) A graph G. (b) The frontier at each step of the BFS of G with $s = 0$. (c) A BFS tree.

The main idea of parallel BFS is to maintain a set of frontier vertices that represent the current level being visited, and to produce a new frontier on each step. The set of frontier vertices is initialized with the singleton s (the source vertex). A new frontier is generated by collecting all of the neighbors of the current frontier vertices in parallel and removing any that have already been visited. This is not sufficient on its own, however, since multiple vertices might collect the same unvisited vertex. For example, consider the graph in Fig. 47.8. On step 2 vertices 5 and 8 will both collect vertex 9. The vertex will therefore appear twice in the new frontier. If the duplicate vertices are not removed the algorithm can generate an exponential number of vertices in the frontier. This problem does not occur in the sequential BFS because vertices are visited one at a time. The parallel version therefore requires an extra step to remove duplicates.

The following function performs a parallel BFS. It takes as input a source vertex s and a graph G represented as an adjacency-array, and returns as its result a breadth-first-search tree of G. In a BFS tree each vertex visited at level i points to one of its neighbors visited at level $i-1$ (see Fig. 47.8(c)). The source s is the root of the tree.

ALGORITHM: BFS(s, G)

```
1  FRONT := [s]
2  TREE := distribute(−1, |G|)
3  TREE[s] := s
4  while (|FRONT| ≠ 0)
5     E := flatten({{(u, v) : u ∈ G[v]} : v ∈ FRONT})
6     E' := {(u, v) ∈ E | TREE[u] = −1}
7     TREE := TREE ← E'
8     FRONT := {u : (u, v) ∈ E' | v = TREE[u]}
9  return TREE
```

In this code FRONT is the set of frontier vertices, and TREE is the current BFS tree, represented as an array of indices (pointers). The pointers (indices) in TREE are all initialized to -1, except for the source s which is initialized to point to itself. Each vertex in TREE is set to point to its parent in the BFS tree when it is visited. The algorithm assumes the arbitrary concurrent write model.

We now consider each iteration of the algorithm. The iterations terminate when there are no more vertices in the frontier (Line 4). The new frontier is generated by first collecting into an edge-array the set of edges from current frontier vertices to the neighbors of these vertices (Line 5). An edge from v to u is kept as the pair (u, v) (this is backwards from the standard edge representation and is used below to write from v to u). Next, the algorithm subselects the edges that lead to unvisited vertices (Line 6). Now for each remaining edge (u, v) the algorithm writes the source index v into the BFS tree entry for the destination vertex u (Line 7). In the case that more than one edge has the same destination, one of the source indices will be written arbitrarily—this is the only place that the algorithm uses a concurrent write. These indices become the parent pointers for the BFS tree, and are also used to remove duplicates for the next frontier set. In particular, the algorithm checks whether each edge succeeded in writing its source by reading back from the destination. If an edge reads the value it wrote, its destination is included in the new frontier (Line 8). Since only one edge that points to a given destination vertex will read back the same value, no duplicates will appear in the new frontier.

The algorithm requires only constant depth per iteration of the while loop. Since each vertex and its associated edges are visited only once, the total work is $O(m + n)$. An interesting aspect of this parallel BFS is that it can generate BFS trees that cannot be generated by a sequential BFS, even allowing for any order of visiting neighbors in sequential BFS. We leave the generation of an example as an exercise. We note, however, that if the algorithm used a priority concurrent write (see Section "Model Used in this Chapter") on Line 7, then it would generate the same tree as a sequential BFS.

Connected Components

We now consider the problem of labeling the connected components of an undirected graph. The problem is to label all the vertices in a graph G such that two vertices u and v have the same label if and only if there is a path between the two vertices. Sequentially the connected components of a graph can easily be labeled using either depth-first or breadth-first search. We have seen how to perform a breadth-first search, but the technique requires depth proportional to the diameter of a graph. This is fine for graphs with small diameter, but does not work well in the general case. Unfortunately, in terms of work, even the most efficient polylogarithmic-depth parallel algorithms for depth-first search and breadth-first search are very inefficient. Hence, the efficient algorithms for solving the connected components problem use different techniques.

The two algorithms we consider are based on *graph contraction*. Graph contraction works by contracting the vertices of a connected subgraph into a single vertex. The techniques we use allow the algorithms to make many such contractions in parallel across the graph. The algorithms therefore proceed in a sequence of steps, each of which contracts a set of subgraphs, and forms a smaller graph in which each subgraph has been converted into a vertex. If each such step of the algorithm contracts the size of the graph by a constant fraction, then each component will contract down to a single vertex in $O(\log n)$ steps. By running the contraction in reverse, the algorithms can label all the vertices in the components. The two algorithms we consider differ in how they select subgraphs for contraction. The first uses randomization and the second is deterministic. Neither algorithm is work efficient because they require $O((n + m) \log n)$ work for worst-case graphs, but we briefly discuss how they can be made work efficient in Section "Improved Versions of Connected Components." Both algorithms require the concurrent write model.

Random Mate Graph Contraction

The random mate technique for graph contraction is based on forming a set of star subgraphs and contracting the stars. A *star* is a tree of depth one—it consists of a root and an arbitrary number of children. The random mate algorithm finds a set of nonoverlapping stars in a graph, and then contracts each star into a single vertex by merging each child into its parent. The technique used to form the stars uses randomization. For each vertex the algorithm flips a coin to decide if that vertex is a parent or a

child. We assume the coin is unbiased so that every vertex has a 50% probability of being a parent. Now for each child vertex the algorithm selects a neighboring parent vertex and makes that parent the child's root. If the child has no neighboring parent, it has no root. The parents are now the roots of a set of stars, each with zero or more children. The children either belong to one of these stars or are left on their own (if they had no neighboring parents). The algorithm now contracts these stars. When contracting, the algorithm updates any edge that points to a child of a star to point to the root. Figure 47.9 illustrates a full contraction step. This contraction step is repeated until all components are of size 1.

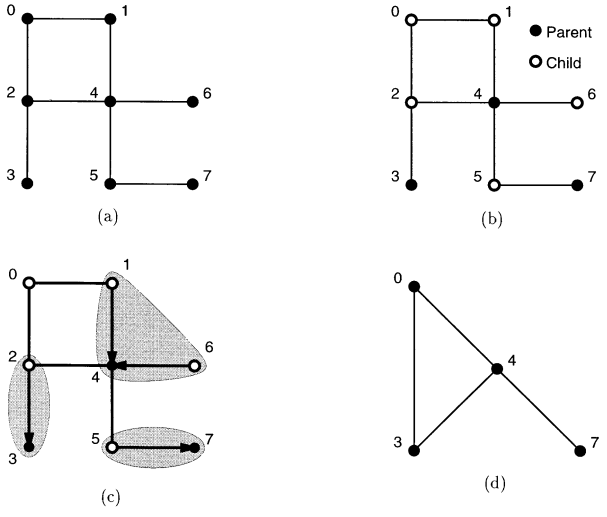


FIGURE 47.9 Example of one step of random mate graph contraction. (a) The original graph G. (b) G after selecting the parents randomly. (c) The stars formed after each child is assigned a neighboring parent as its root (each star is shaded). (d) The graph after contracting each star and relabeling the edges to point to the roots. Children with no neighboring parent remain in the graph.

To analyze the number of contraction steps required to complete we need to know how many vertices the algorithm removes on each contraction step. First we note that a contraction step is only going to remove children, and only if they have a neighboring parent. The probability that a vertex will be deleted is therefore the probability that a vertex is a child multiplied by the probability that at least one of its neighbors is a parent. The probability that it is a child is 1/2 and the probability that at least one neighbor is a parent is at least 1/2 (every vertex that is not fully contracted has one or more neighbors). The algorithm is therefore expected to remove at least 1/4 of the remaining vertices at each step, and since this is a constant fraction, it is expected to complete in $O(\log n)$ steps. The full probabilistic analysis is somewhat involved since it is possible to have a streak of bad flips, but it is not too hard to show that the algorithm is very unlikely to require more than $O(\log n)$ contraction steps.

The following algorithm uses random mate contraction for labeling the connected components of a graph. The algorithm works by contracting until each component is a single vertex and then re-expanding so that it can label all vertices in that component with the same label. The input to the algorithm is a graph G in the edge-list representation (note that this is a different representation than used in BFS), along with the labels of the vertices. The labels of the vertices are initialized to be unique indices in the range $0..|V|-1$. The output of the algorithm is a label for each vertex such that two vertices will have the same label if and only if they belong to the same component. In fact, the label of each vertex will be the original label of one of the vertices in the component.

ALGORITHM: CC_RANDOM_MATE(LABELS, E)

```
1  if (|E| = 0) then return LABELS
2  else
3     CHILD := {rand_bit() : v ∈ [1..n]}
4     HOOKS := {(u, v) ∈ E | CHILD[u] and ∧¬ CHILD[v]}
5     LABELS := LABELS ← HOOKS
6     E' := {(LABELS[u], LABELS[v]) : (u, v) ∈ E | LABELS[u] ≠ LABELS[v]}
7     LABELS' := CC_RANDOM_MATE(LABELS, E')
8     LABELS' := LABELS' ← {(u, LABELS' [v]) : (u, v) ∈ HOOKS}
9     return LABELS'
```

The algorithm works recursively by (a) executing one random-mate contraction step, (b) recursively applying itself to the contracted graph, and (c) reexpanding the graph by passing the labels from each root of a contracted star [from step (a)] to its children. The graph is therefore contracted while going down the recursion and expanded while coming back up. The termination condition is that there are no remaining edges (Line 1). To form stars for the contraction step the algorithm flips a coin for each vertex (Line 3) and subselects all edges HOOKS that go from a child to a parent (Line 4). We call these edges *hook edges* and they represent a superset of the star edges (each child can have multiple hook edges, but only one root in a star). For each hook edge the algorithm writes the parent's label into the child's label (Line 5). If a child has multiple neighboring parents, then one of the parent's labels is written arbitrarily—we assume an arbitrary concurrent write. At this point each child is labeled with one of its neighboring parents, if it has one. The algorithm now updates each edge by reading the labels from its two endpoints and using these as its new endpoints (Line 6). In the same step, the algorithm removes any edges that are within the same star. This gives a new sequence of edges E'. The algorithm has now completed the contraction step, and calls itself recursively on the contracted graph (Line 7). The LABELS$'$ returned by the recursive call are passed on to the children of the stars, effectively expanding the graph (Line 8). The same hooks that were used for contraction can be used for this update.

Two things should be noted about this algorithm. First, the algorithm flips coins on all of the vertices on each step even though many have already been contracted (there are no more edges that point to them). It turns out that this will not affect our worst-case asymptotic work or depth bounds, but it is not difficult to flip coins only on active vertices by keeping track of them—just keep an array of the labels of the active vertices. Second, if there are cycles in the graph, then the algorithm will create redundant edges in the contracted subgraphs. Again, keeping these edges is not a problem for the correctness or cost bounds, but they could be removed using hashing as discussed in "Removing Duplicates."

To analyze the full work and depth of the algorithm we note that each step only requires constant depth and $O(n+m)$ work. Since the number of steps is $O(\log n)$ with high probability, as mentioned earlier, the total depth is $O(\log n)$ and the work is $O((n+m)\log n)$, both with high probability. One might expect that the work would be linear since the algorithm reduces the number of vertices on each step by a constant fraction. We have no guarantee, however, that the number of edges is also going to contract geometrically, and in fact for certain graphs they will not. In "Improved Versions of Connected Components" we discuss how to improve the algorithm so that it is work-efficient.

Deterministic Graph Contraction

Our second algorithm for graph contraction is deterministic [41]. It is based on forming a set of disjoint subgraphs, each of which is tree, and then using the POINT_TO_ROOT routine ("Pointer Jumping") to contract each subgraph to a single vertex. To generate the trees, the algorithm hooks each vertex into a neighbor with a smaller label (by *hooking* a into b we mean generating a directed edge from a to b). Vertices with no smaller-labeled neighbors are left unhooked. The result of the hooking is a set of disjoint trees since hooking only from larger to smaller guarantees there are no cycles, and every node

is hooked into at most one parent. Figure 47.10 shows an example of a set of trees created by hooking. Since a vertex can have more than one neighbor with a smaller label, a given graph can have many different hookings. For example, in Fig. 47.10 vertex 2 could have hooked into vertex 1, rather than vertex 0.

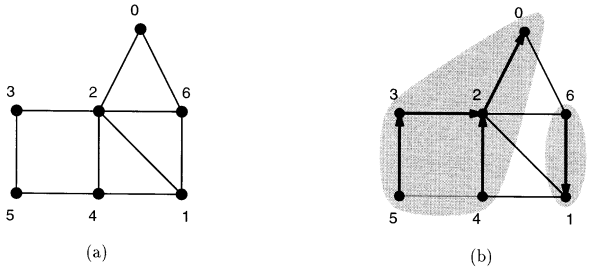

FIGURE 47.10 Tree-based graph contraction. (a) A graph G. (b) The hook edges induced by hooking larger to smaller vertices and the subgraphs induced by the trees.

The following algorithm performs the tree-based graph contraction. We assume that the labels are initialized to the indices of the vertices.

ALGORITHM: CC_TREE_CONTRACT (LABELS, E)
1 **if** ($|E| = 0$)
2 **then return** LABELS
3 **else**
4 HOOKS := $\{(u, v) \in E \mid u > v\}$
5 LABELS := LABELS $\leftarrow$ HOOKS
6 LABELS := POINT_TO_ROOT(LABELS)
7 E' := {(LABELS[u],LABELS[v]) : $(u, v) \in E \mid$ LABELS[u] $\neq$ LABELS[v]}
8 **return** CC_TREE_CONTRACT(LABELS, E')

The structure of the algorithm is similar to the random-mate graph contraction algorithm. The main differences are how the hooks are selected (Line 4), the pointer jumping step to contract the trees (Line 6), and the fact that no relabeling is required when returning from the recursive call. The hooking step simply selects edges that point from larger numbered vertices to smaller numbered vertices. This is called a *conditional hook*. The pointer jumping step uses the algorithm in Section "Pointer Jumping." This labels every vertex in the tree with the root of the tree. The edge relabeling is the same as in the random-mate algorithm. The reason the contraction algorithm does not need to relabel the vertices after the recursive call is that the pointer jumping step will do the relabeling.

Although the basic algorithm we have described so far works well in practice, in the worst case it can take $n - 1$ steps. Consider the graph in Fig. 47.11(a). After hooking and contracting only one vertex has been removed. This could be repeated up to $n - 1$ times. This worst-case behavior can be avoided by trying to hook in both directions (from larger to smaller and from smaller to larger) and picking the hooking that hooks more vertices. We make use of the following lemma.

LEMMA 47.1 Let $G = (V, E)$ be an undirected graph in which each vertex has at least one neighbor. Then either $|\{u \mid (u, v) \in E, u < v\}| \geq |V|/2$ or $|\{u \mid (u, v) \in E, u > v\}| > |V|/2$.

PROOF Every vertex must either have a neighbor with a lesser index or a neighbor with a greater index.

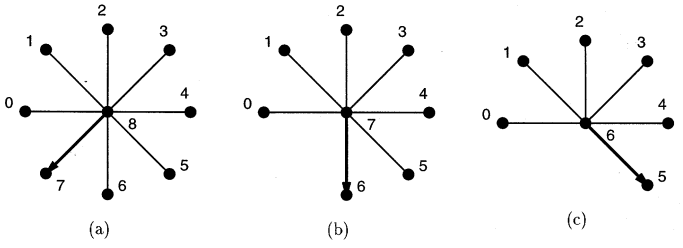

FIGURE 47.11 A worst-case graph. (a) A star graph G with the maximum index at the root of the star. (b) G after one step of contraction. (c) G after two steps of contraction.

This means that if we consider the set of vertices with a lesser neighbor and the set of vertices with a greater neighbor, then one of those sets must consist of at least one half the vertices.

This lemma will guarantee that if we try hooking in both directions and pick the better one we will remove at least 1/2 of the vertices on each step, so that the number of steps is bounded by $\lceil \log_2 n \rceil$.

We now consider the total cost of the algorithm. The hooking and relabeling of edges on each step takes $O(m)$ work and constant depth. The tree contraction using pointer jumping on each step requires $O(n \log n)$ work and $O(\log n)$ depth, in the worst case. Since there are $O(\log n)$ steps, in the worst case, the total work is $O((m + n \log n) \log n)$ and depth $O(\log^2 n)$. However, if we keep track of the active vertices (the roots) and only pointer jump on active vertices, then the work is reduced to $O((m+n) \log n)$, since the number of vertices decreases geometrically in each step. This requires that the algorithm expands the graph on the way back up the recursion as done for the random-mate algorithm. The total work with this modification is the same work as the randomized technique, although the depth has increased.

Improved Versions of Connected Components

There are many improvements to the two basic connected component algorithms we described. Here we mention some of them.

The deterministic algorithm can be improved to run in $O(\log n)$ depth with the same work bounds [13, 79]. The basic idea is to interleave the hooking steps with the **shortcutting** steps. The one tricky aspect is that we must always hook in the same direction (e.g., from smaller to larger), so as not to create cycles. Our previous technique to solve the star-graph problem therefore does not work. Instead each vertex checks if it belongs to any tree after hooking. If it does not then it can hook to any neighbor, even if it has a larger index. This is called an *unconditional hook.*

The randomized algorithm can be improved to run in optimal work, $O(n + m)$ [33]. The basic idea is to not use all of the edges for hooking on each step, and instead use a sample of the edges. This technique, first applied to parallel algorithms, has since been used to improve some sequential algorithms, such as deriving the first linear-work algorithm for finding a minimum spanning tree [46].

Another improvement is to use the EREW model instead of requiring concurrent reads and writes [42]. However this comes at the cost of greatly complicating the algorithm. The basic idea is to keep circular linked lists of the neighbors of each vertex, and then to splice these lists when merging vertices.

Extensions to Spanning Trees and Minimum Spanning Trees

The connected-component algorithms can be extended to finding a spanning tree of a graph or minimum spanning tree of a weighted graph. In both cases we assume the graphs are undirected.

A *spanning tree* of a connected graph $G = (V, E)$ is a connected graph $T = (V, E')$ such that $E' \subseteq E$ and $|E'| = |V| - 1$. Because of the bound on the number of edges, the graph T cannot have any cycles and therefore forms a tree. Any given graph can have many different spanning trees.

It is not hard to extend the connected-component algorithms to return the spanning tree. In particular, whenever components are hooked together the algorithm can keep track of which edges were used for hooking. Since each edge will hook together two components that are not connected yet, and only one edge will succeed in hooking the components, the collection of these edges across all steps will form a spanning tree (they will connect all vertices and have no cycles). To determine which edges were used for contraction, each edge checks if it successfully hooked after the attempted hook.

A *minimum spanning tree* of a connected weighted graph $G = (V, E)$ with weights $w(e)$ for $e \in E$ is a spanning tree $T = (V, E')$ of G such that

$$w(T) = \sum_{e \in E'} w(e) \tag{47.8}$$

is minimized. The connected-component algorithms can also be extended to find a minimum spanning tree. Here we will briefly consider an extension of the random-mate technique. Let us assume, without loss of generality, that all of the edge weights are distinct. If this is not the case, then lexicographical information can be added to the edges weights to break ties. It is well known that if the edge weights are distinct, then there is a unique minimum spanning tree. Furthermore, given any $W \subset V$, the minimum weight edge from W to $V - W$ must be in the minimum spanning tree. As a consequence, the minimum edge incident on a vertex will be in the minimum spanning tree. This will be true even after we contract subgraphs into vertices, since each subgraph is a subset of V.

For the minimum-spanning-tree algorithm, we modify the random mate technique so that each child u instead of picking an arbitrary parent to hook into, finds the incident edge (u, v) with minimum weight and hooks into v if it is a parent. If v is not a parent, then the child u does nothing (it is left as an orphan). Figure 47.12 illustrates the algorithm. As with the spanning-tree algorithm, we keep track of the hook

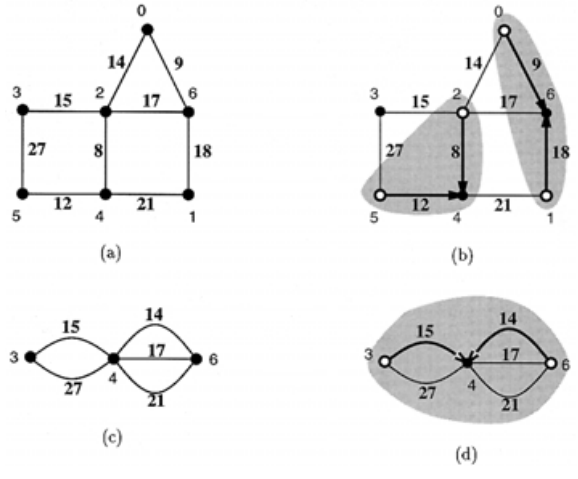

FIGURE 47.12 Example of the minimum-spanning-tree algorithm. (a) The original weighted graph G. (b) Each child (light) hooks across its minimum weighted edge to a parent (dark), if the edge is incident on a parent. (c) The graph after one step of contraction. (d) The second step in which children hook across minimum weighted edges to parents.

edges and add them to a set E'. This new rule will still remove $1/4$ of the vertices on each step on average since a vertex has $1/2$ probability of being a child, and there is $1/2$ probability that the vertex at the other end of the minimum edge is a parent. The one complication in this minimum spanning-tree algorithm is finding for each child the incident edge with minimum weight. Since we are keeping an edge list, this is not

trivial to compute. If the algorithm used an adjacency list, then it would be easy, but since the algorithm needs to update the endpoints of the edges, it is not easy to maintain the adjacency list. One way to solve this problem is to use a priority concurrent write. In such a write, if multiple values are written to the same location, the one coming from the leftmost position will be written. With such a scheme the minimum edge can be found by presorting the edges by weight so the lowest weighted edge will always win when executing a concurrent write. Assuming a priority write, this minimum-spanning-tree algorithm has the same work and depth as the random-mate connected-components algorithm.

There is also a linear-work logarithmic-depth randomized algorithm for finding a minimum-spanning tree [27], but it is somewhat more complicated than the linear-work algorithms for finding connected components.

47.6 Sorting

Sorting is a problem that admits a variety of parallel solutions. In this section we limit our discussion to two parallel sorting algorithms, QuickSort and radix sort. Both of these algorithms are easy to program, and both work well in practice. Many more sorting algorithms can be found in the literature. The interested reader is referred to [3, 45, 55] for more complete coverage.

QuickSort

We begin our discussion of sorting with a parallel version of QuickSort. This algorithm is one of the simplest to code.

ALGORITHM: QUICKSORT(A)
1 **if** $|A| = 1$ **then return** A
2 $i := rand\_int(|A|)$
3 $p := A[i]$
4 **in parallel do**
5 $L := \text{QUICKSORT}(\{a : a \in A \mid a < p\})$
6 $E := \{a : a \in A \mid a = p\}$
7 $G := \text{QUICKSORT}(\{a : a \in A \mid a > p\})$
8 **return** $L + + E + + G$

We can make an optimistic estimate of the work and depth of this algorithm by assuming that each time a partition element p is selected, it divides the set A so that neither L nor H has more than half of the elements. In this case, the work and depth are given by the recurrences

$$W(n) = 2W(n/2) + O(n) \tag{47.9}$$

$$D(n) = D(n/2) + 1 \tag{47.10}$$

which have solutions $W(n) = O(n \log n)$ and $D(n) = O(\log n)$. A more sophisticated analysis [50] shows that the expected work and depth are indeed $W(n) = O(n \log n)$ and $D(n) = O(\log n)$, independent of the values in the input sequence A.

In practice, the performance of parallel QuickSort can be improved by selecting more than one partition element. In particular, on a machine with P processors, choosing $P - 1$ partition elements divides the keys into P sets, each of which can be sorted by a different processor using a fast sequential sorting algorithm. Since the algorithm does not finish until the last processor finishes, it is important to assign approximately the same number of keys to each processor. Simply choosing $p - 1$ partition elements at random is unlikely to yield a good partition. The partition can be improved, however, by choosing a larger number,

sp, of candidate partition elements at random, sorting the candidates (perhaps using some other sorting algorithm), and then choosing the candidates with ranks $s, 2s, \ldots, (p-1)s$ to be the partition elements. The ratio s of candidates to partition elements is called the *oversampling ratio*. As s increases, the quality of the partition increases, but so does the time to sort the sp candidates. Hence there is an optimum value of s, typically larger than one, that minimizes the total time. The sorting algorithm that selects partition elements in this fashion is called *sample sort* [23, 76, 89].

Radix Sort

Our next sorting algorithm is radix sort, an algorithm that performs well in practice. Unlike QuickSort, radix sort is not a *comparison sort*, meaning that it does not compare keys directly in order to determine the relative ordering of keys. Instead, it relies on the representation of keys as b-bit integers.

The basic radix sort algorithm (whether serial or parallel) examines the keys to be sorted one "digit" position at a time, starting with the least significant digit in each key. Of fundamental importance is that this intermediate sort on digits be *stable*: the output ordering must preserve the input order of any two keys with identical digit values in the position being examined.

The most common implementation of the intermediate sort is as a counting sort. A counting sort first counts to determine the *rank* of each key—its position in the output order—and then permutes the keys by moving each key to the location indicated by its rank. The following algorithm performs radix sort assuming one-bit digits.

ALGORITHM: RADIX_SORT(A, b)

```
1  for i from 0 to b − 1
2      FLAGS := {(a >> i) mod 2 : a ∈ A}
3      NOTFLAGS := {1 − b : b ∈ B}
4      R0 := SCAN(NOTFLAGS)
5      s0 := SUM(NOTFLAGS)
6      R1 := SCAN(FLAGS)
7      R := {if FLAGS[j] = 0 then R0[j] else R1[j] + s0 : j ∈ [0..|A|)}
8      A := A ← {(R[j], A[j]) : j ∈ [0..|A|)}
9  return A
```

For keys with b bits, the algorithm consists of b sequential iterations of a **for** loop, each iteration sorting according to one of the bits. Lines 2 and 3 compute the value and inverse value of the bit in the current position for each key. The notation $a >> i$ denotes the operation of shifting a to the right by i bit positions. Line 4 computes the rank of each key that has bit value 0. Computing the ranks of the keys with bit value 1 is a little more complicated, since these keys follow the keys with bit value 0. Line 5 computes the number of keys with bit value 0, which serves as the rank of the first key that has bit value 1. Line 6 computes the relative order of the keys with bit value 1. Line 7 merges the ranks of the even keys with those of the odd keys. Finally, Line 8 permutes the keys according to rank.

The work and depth of RADIX_SORT are computed as follows. There are b iterations of the **for** loop. In each iteration, the depths of Lines 2, 3, 7, 8, and 9 are constant, and the depths of Lines 4, 5, and 6 are $O(\log n)$. Hence the depth of the algorithm is $O(b \log n)$. The work performed by each of Lines 2 through 9 is $O(n)$. Hence, the work of the algorithm is $O(bn)$.

The radix sort algorithm can be generalized so that each b-bit key is viewed as b/r blocks of r bits each, rather than as b individual bits. In the generalized algorithm, there are b/r iterations of the **for** loop, each of which invokes the SCAN function 2^r times. When r is large, a multiprefix operation can be used for generating the ranks instead of executing a SCAN for each possible value [23]. In this case, and assuming the multiprefix operation runs in linear work, it is not hard to show that as long as $b = O(\log n)$ (and

$r = \log n$, so that there are only $O(1)$ iterations), the total work for the radix sort is $O(n)$, and the depth is the same order as the depth of the multiprefix operation.

Floating-point numbers can also be sorted using radix sort. With a few simple bit manipulations, floating-point keys can be converted to integer keys with the same ordering and key size. For example, IEEE double-precision floating-point numbers can be sorted by first inverting the mantissa and exponent bits if the sign bit is 1, and then inverting the sign bit. The keys are then sorted as if they were integers.

47.7 Computational Geometry

Problems in computational geometry involve calculating properties of sets of objects in k-dimensional space. Some standard problems include finding the minimum distance between any two points in a set of points (closest-pair), finding the smallest convex region that encloses a set of points (convex-hull), and finding line or polygon intersections. Efficient parallel algorithms have been developed for most standard problems in computational geometry. Many of the sequential algorithms are based on divide-and-conquer and lead in a relatively straightforward manner to efficient parallel algorithms. Some others are based on a technique called plane sweeping, which does not parallelize well, but for which an analogous parallel technique, the *plane sweep tree* has been developed [1, 10]. In this section we describe parallel algorithms for two problems in two dimensions—closest pair and convex hull. For convex hull we describe two algorithms. These algorithms are good examples of how sequential algorithms can be parallelized in a straightforward manner.

We suggest the following sources for further information on parallel algorithms for computational geometry: [6, 39], [45, Chapter 6], and [75, Chapters 9 and 11],

Closest Pair

The *closest-pair problem* takes a set of points in k dimensions and returns the two points that are closest to each other. The distance is usually defined as Euclidean distance. Here we describe a closest-pair algorithm for two-dimensional space, also called the planar closest-pair problem. The algorithm is a parallel version of a standard sequential algorithm [16, 17], and for n points, it requires the same work as the sequential versions, $O(n \log n)$, and has depth $O(\log^2 n)$. The work is optimal.

The algorithm uses divide-and-conquer based on splitting the points along lines parallel to the y axis, and is expressed as follows.

ALGORITHM: CLOSEST_PAIR(P)
1 **if** ($|P| < 2$) **then return** (P, ∞)
2 $x_m := \text{MEDIAN}(\{x : (x, y) \in P\})$
3 $L := \{(x, y) \in P \mid x < x_m\}$
4 $R := \{(x, y) \in P \mid x \geq x_m\}$
5 **in parallel do**
6 $(L', \delta_L) := \text{CLOSEST\_PAIR}(L)$
7 $(R', \delta_R) := \text{CLOSEST\_PAIR}(R)$
8 $P' := \text{MERGE\_BY\_Y}(L', R')$
9 $\delta_P := \text{BOUNDARY\_MERGE}(P', \delta_L, \delta_R, x_m)$
10 **return** (P', δ_P)

This function takes a set of points P in the plane and returns both the original points sorted along the y axis, and the distance between the closest two points. The sorted points are needed to help merge the results from recursive calls, and can be thrown away at the end. It would not be difficult to modify the routine to return the closest pair of points in addition to the distance between them. The function

works by dividing the points in half based on the median x value, recursively solving the problem on each half and then merging the results. The MERGE_BY_Y function merges L' and R' along the y axis and can use a standard parallel merge routine. The interesting aspect of the code is the BOUNDARY_MERGE routine, which works on the principle described by Bentley and Shamos [16, 17], and can be computed with $O(\log n)$ depth and $O(n)$ work. We first review the principle and then show how it can be performed in parallel.

The inputs to BOUNDARY_MERGE are the original points P sorted along the y axis, the closest distance within L and R, and the median point x_m. The closest distance in P must be either the distance δ_L, the distance δ_R, or a distance between a point in L and a point in R. For this distance to be less than δ_L or δ_R, the two points must lie within $\delta = \min(\delta_L, \delta_R)$ of the line $x = x_m$. Thus, the two vertical lines at $x_l = x_m - \delta$ and $x_r = x_m + \delta$ define the borders of a region M in which the points must lie (see Fig. 47.13). If we could find the closest distance in M, call it δ_M, then the closest overall distance would be $\delta_P = \min(\delta_L, \delta_R, \delta_M)$.

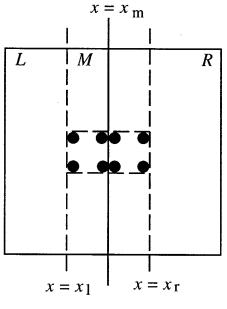

FIGURE 47.13 Merging two rectangles to determine the closest pair. Only eight points can fit in the $2\delta \times \delta$ dashed rectangle.

To find δ_M we take advantage of the fact that not many points can be packed close together within M since all points within L or R must be separated by at least δ. Figure 47.13 shows the tightest possible packing of points in a $2\delta \times \delta$ rectangle within M. This packing implies that if the points in M are sorted along the y axis, each point can determine the minimum distance to another point in M by looking at a fixed number of neighbors in the sorted order, at most 7 in each direction. To see this consider one of the points along the top of the $2\delta \times \delta$ rectangle. To determine if there are any points below it that are closer than δ we need only to consider the points within the rectangle (points below the rectangle must be further than δ away). As the figure illustrates, there can be at most 7 other points within the rectangle. Given this property, the following function performs the border merge.

ALGORITHM: BOUNDARY_MERGE$(P, \delta_L, \delta_R, x_m)$

```
1  δ := min(δ_L, δ_R)
2  M := {(x, y) ∈ P | (x ≥ x_m − δ) ∧ (x ≤ x_m + δ)}
3  δ_M := min({min({distance(M[i], M[i + j]) : j ∈ [1..7]})
4              : i ∈ [0..|P| − 7)}
5  return min(δ, δ_M)
```

For each point in M this function considers the seven points following it in the sorted order and determines the distance to each of these points. It then takes the minimum over all distances. Since the distance relationship is symmetric, there is no need to consider points appearing before a point in the sorted order.

The work of BOUNDARY_MERGE is $O(n)$ and the depth is dominated by the taking the minimum, which has $O(\log n)$ depth.[2] The work of the merge and median steps in CLOSEST_PAIR are also $O(n)$, and the depth of both are bounded by $O(\log n)$. The total work and depth of the algorithm can therefore be expressed by the recurrences

$$W(n) = 2W(n/2) + O(n) \quad (47.11)$$

$$D(n) = D(n/2) + O(\log n) \quad (47.12)$$

which have solutions $W(n) = O(n \log n)$ and $D(n) = O(\log^2 n)$.

Planar Convex Hull

The convex-hull problem takes a set of points in k dimensions and returns the smallest convex region that contains all the points. In two dimensions the problem is called the planar convex-hull problem, and it returns the set of points that form the corners of the region. These points are a subset of the original points. We will describe two parallel algorithms for the planar convex-hull problem. They are both based on divide-and-conquer, but one does most of the work before the divide step, and the other does most of the work after.

QuickHull

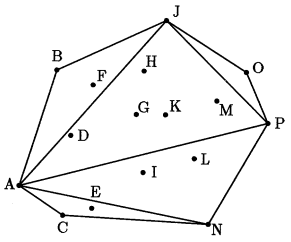
The parallel *QuickHull* algorithm is based on the sequential version [71], so named because of its similarity to the QuickSort algorithm. As with QuickSort, the strategy is to pick a "pivot" element, split the data into two sets based on the pivot, and recurse on each of the sets. Also as with QuickSort, the pivot element is not guaranteed to split the data into equal-sized sets, and in the worst case the algorithm requires $O(n^2)$ work. In practice, however, the algorithm is often very efficient, probably the most practical of the convex hull algorithms. At the end of the section we briefly describe how the splits can be made so that the work is guaranteed to be bounded by $O(n \log n)$.

The QuickHull algorithm is based on the recursive function SUBHULL, which is expressed as follows.

ALGORITHM: SUBHULL(P, p_1, p_2)
1 $P' := \{p \in P \mid \text{LEFT\_OF?}(p, (p_1, p_2))\}$
2 **if** ($|P'| < 2$)
3 **then return** $[p_1] + + P'$
4 **else**
5 $i := \text{MAX\_INDEX}(\{\text{DISTANCE}(p, (p_1, p_2)) : p \in P'\})$
6 $p_m := P'[i]$
7 **in parallel do**
8 $H_l := \text{SUBHULL}(P', p_1, p_m)$
9 $H_r := \text{SUBHULL}(P', p_m, p_2)$
10 **return** $H_l + + H_r$

This function takes a set of points P in the plane and two points p_1 and p_2 that are known to lie on the convex hull, and returns all the points that lie on the hull clockwise from p_1 to p_2, inclusive of p_1, but not of p_2. For example in Fig. 47.14 SUBHULL($[A, B, C, \ldots, P]$, A, P) would return the sequence $[A, B, J, O]$.

[2] The depth of finding the minimum or maximum of a set of numbers can actually be improved to $O(\log \log n)$ with concurrent reads [78].



[A B C D E F G H I J K L M N O P]
A [B D F G H J K M O] P [C E I L N]
A [B F] J [O] P N [C E]
A B J O P N C

FIGURE 47.14 An example of the *QuickHull* algorithm.

The function SUBHULL works as follows. Line 1 removes all the elements that cannot be on the hull because they lie to the right of the line from p_1 to p_2. Determining which side of a line a point lies on can easily be calculated with a few arithmetic operations. If the remaining set P' is either empty or has just one element, the algorithm is done. Otherwise the algorithm finds the point p_m farthest from the line (p_1, p_2). The point p_m must be on the hull since as a line at infinity parallel to (p_1, p_2) moves toward (p_1, p_2), it must first hit p_m. In Line 5 the function MAX_INDEX returns the index of the maximum value of a sequence, which is then used to extract the point p_m. Once p_m is found, SUBHULL is called twice recursively to find the hulls from p_1 to p_m, and from p_m to p_2. When the recursive calls return, the results are appended.

The following function uses SUBHULL to find the full convex hull.

ALGORITHM: QUICKHULL(P)
1 $X := \{x : (x, y) \in P\}$
2 $x_{\min} := P[\text{MIN\_INDEX}(X)]$
3 $x_{\max} := P[\text{MAX\_INDEX}(X)]$
4 **return** SUBHULL($P, x_{\min}, x_{\max}$) $+ +$ SUBHULL($P, x_{\max}, x_{\min}$)

We now consider the cost of the parallel QuickHull, and in particular the SUBHULL routine, which does all the work. The call to MAX_INDEX uses $O(n)$ work and $O(\log n)$ depth. Hence, the cost of everything other than the recursive calls is $O(n)$ work and $O(\log n)$ depth. If the recursive calls are balanced so that neither recursive call gets much more than half of the data then the number of levels of recursion will be $O(\log n)$. This will lead to the algorithm running in $O(\log^2 n)$ depth. Since the sum of the sizes of the recursive calls can be less than n (e.g., the points within the triangle AJP will be thrown out when making the recursive calls to find the hulls between A and J and between J and P), the work can be as little as $O(n)$, and often is in practice. As with QuickSort, however, when the recursive calls are badly partitioned the number of levels of recursion can be as bad as $O(n)$ with work $O(n^2)$. For example, consider the case when all the points lie on a circle and have the following unlikely distribution. The points x_{min} and x_{max} appear on opposite sides of the circle. There is one point that appears half way between x_{min} and x_{max} on the sphere and this point becomes the new x_{max}. The remaining points are defined recursively. That is, the points become arbitrarily close to x_{min} (see Fig. 47.15).

Kirkpatrick and Seidel [49] have shown that it is possible to modify QuickHull so that it makes provably good partitions. Although the technique is shown for a sequential algorithm, it is easy to parallelize. A simplification of the technique is given by Chan et al. [25]. Their algorithm admits even more parallelism and leads to an $O(\log^2 n)$-depth algorithm with $O(n \log h)$ work where h is the number of points on the convex hull.

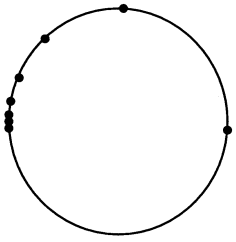


FIGURE 47.15 Contrived set of points for worst-case QuickHull.

MergeHull

The MergeHull algorithm [68] is another divide-and-conquer algorithm for solving the planar convex hull problem. Unlike QuickHull, however, it does most of its work after returning from the recursive calls. The function is expressed as follows.

ALGORITHM: MERGEHULL(P)
1 **if** ($|P| < 3$) **then return** P
2 **else**
3 **in parallel do**
4 H_L = MERGEHULL($P[0..|P|/2)$)
5 H_R = MERGEHULL($P[|P|/2..|P|)$)
6 **return** JOIN_HULLS(H_L, H_R)

This function assumes the input P is presorted according to the x coordinates of the points. Since the points are presorted, H_L is a convex hull on the left and H_R is a convex hull on the right. The JOIN_HULLS routine is the interesting part of the algorithm. It takes the two hulls and merges them into one. To do this it needs to find lower and upper points l_1 and u_1 on H_L and l_2 and u_2 on H_R such that l_1, l_2 and u_1, u_2 are successive points on H (see Fig. 47.16). The lines b_1 and b_2 joining these upper and lower points are called the upper and lower bridges, respectively. All the points between l_1 and u_1 and between u_2 and l_2 on the "outer" sides of H_L and H_R are on the final convex hull, while the points on the "inner" sides are not on the convex hull. Without loss of generality we only consider how to find the upper bridge b_1. Finding the lower bridge b_2 is analogous.

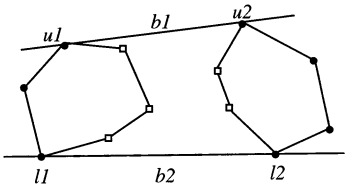

FIGURE 47.16 Merging two convex hulls.

To find the upper bridge one might consider taking the points with the maximum y values on H_L and H_R. This approach does not work in general, however, since u_1 can lie as far down as the point with the minimum x or maximum x value (see Fig. 47.17). Instead there is a nice solution due to Overmars and van Leeuwen [68] based on a dual binary search. Assume that the points on the convex hulls are given in order (e.g., clockwise). At each step the binary search algorithm will eliminate half of the remaining points from consideration in either H_L or H_R or both. After at most $\log |H_L| + \log |H_R|$ steps the search will be left with only one point in each hull, and these will be the desired points u_1 and u_2. Figure 47.18 illustrates the rules for eliminating part of H_L or H_R on each step.

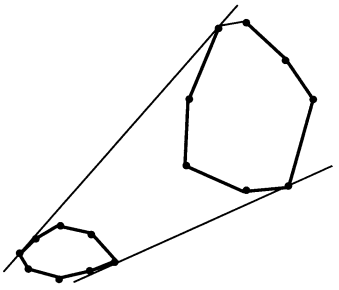

FIGURE 47.17 A bridge that is far from the top of the convex hull.

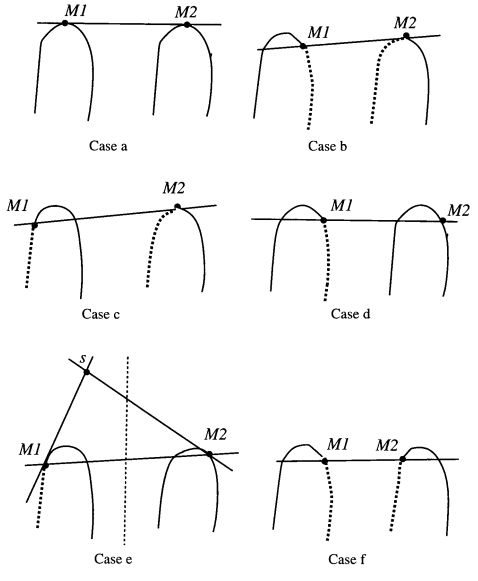

FIGURE 47.18 Cases used in the binary search for finding the upper bridge for the MergeHull. The points $M1$ and $M2$ mark the middle of the remaining hulls. In case (a), all of H_L and H_R lie below the line through $M1$ and $M2$. In this case, the line segment between $M1$ and $M2$ is the bridge. In the remaining cases, dotted lines represent the parts of the hulls H_L and H_R that can be eliminated from consideration. In cases (b) and (c), all of H_R lies below the line through $M1$ and $M2$, and either the left half of H_L or the right half of H_L lies below the line. In cases (d) through (f), neither H_L nor H_R lies entirely below the line. In the case (e), the region to eliminate depends on which side of a line separating H_L and H_R the intersection of the tangents appears. The mirror images of cases (b) through (e) are also used. Case (f) is actually an instance of case (d) and its mirror image.

We now consider the cost of the algorithm. Each step of the binary search requires only constant work and depth since we need only to consider the two middle points M_1 and M_2, which can be found in constant time if the hull is kept sorted. The cost of the full binary search to find the upper bridge is therefore bounded by $D(n) = W(n) = O(\log n)$. Once we have found the upper and lower bridges we need to remove the points on H_L and H_R that are not on H and append the remaining convex hull points. This requires linear work and constant depth. The overall costs of MERGEHULL are therefore

$$D(n) = D(n/2) + O(\log n) = O(\log^2 n) \tag{47.13}$$

$$W(n) = 2W(n/2) + O(n) = O(n \log n) \tag{47.14}$$

This algorithm can be improved to run in $O(\log n)$ depth using one of two techniques. The first involves modifying the search for the bridge points so that it runs in constant depth with linear work [12]. This

involves sampling every $\sqrt{n}$th point on each hull and comparing all pairs of these two samples to narrow the search down to regions of size $\sqrt{n}$ in constant depth. The regions can then be finished in constant depth by comparing all pairs between the two regions. The second technique [1, 11] uses divide-and-conquer to separate the point set into $\sqrt{n}$ regions, solves the convex hull on each region recursively, and then merges all pairs of these regions using the binary-search method. Since there are $\sqrt{n}$ regions and each of the searches takes $O(\log n)$ work, the total work for merging is $O((\sqrt{n})^2 \log n) = O(n \log n)$ and the depth is $O(\log n)$. This leads to an overall algorithm that runs in $O(n \log n)$ work and $O(\log n)$ depth. The algorithms above require concurrent reads (**CREW**). The same bounds can be achieved with exclusive reads (EREW) [66].

47.8 Numerical Algorithms

There has been an immense amount of work on parallel algorithms for numerical problems. Here we briefly discuss some of the problems and results. We suggest the following sources for further information on parallel numerical algorithms [75, Chapters 12-14], [45, Chapter 8], [53, Chapters 5, 10 and 11] and [18].

Matrix Operations

Matrix operations form the core of many numerical algorithms and led to some of the earliest work on parallel algorithms. The most basic matrix operation is matrix multiplication. The standard triply nested loop for multiplying two dense matrices is highly parallel since each of the loops can be parallelized:

ALGORITHM: MATRIX_MULTIPLY(A, B)
1 $(l, m) := dimensions(A)$
2 $(m, n) := dimensions(B)$
3 **in parallel for** $i \in [0..l)$ **do**
4 **in parallel for** $j \in [0..n)$ **do**
5 $R_{ij} := sum(\{A_{ik} * B_{kj} : k \in [0..m)\})$
6 **return** R

If $l = m = n$, this routine does $O(n^3)$ work and has depth $O(\log n)$, due to the depth of the summation. This has much more parallelism than is typically needed, and most of the research on parallel matrix multiplication has concentrated on what subset of the parallelism to use so that communication costs can be minimized. Sequentially it is known that matrix multiplication can be performed using less than $O(n^3)$ work. Strassen's algorithm [82], for example, requires only $O(n^{2.81})$ work. Most of these more efficient algorithms are also easy to parallelize because they are recursive in nature (Strassen's algorithm has $O(\log n)$ depth using a simple parallelization).

Another basic matrix operation is to invert matrices. Inverting dense matrices has proven to be more difficult to parallelize than multiplying dense matrices, but the problem still supplies plenty of parallelism for most practical purposes. When using Gauss–Jordan elimination, two of the three nested loops can be parallelized, leading to an algorithm that runs with $O(n^3)$ work and $O(n)$ depth. A recursive block-based method using matrix multiplication leads to the same depth, although the work can be reduced by using a more efficient matrix-multiplication algorithm. There are also more sophisticated, but less practical, work-efficient algorithms with depth $O(\log^2 n)$ [28, 70].

Parallel algorithms for many other matrix operations have been studied, and there has also been significant work on algorithms for various special forms of matrices, such as tridiagonal, triangular, and sparse matrices. Iterative methods for solving sparse linear systems has been an area of significant activity.

Fourier Transform

Another problem for which there is a long history of parallel algorithms is the discrete Fourier transform (DFT). The fast Fourier transform (FFT) algorithm for solving the DFT is quite easy to parallelize and, as with matrix multiply, much of the research has gone into reducing communication costs. In fact the butterfly network topology is sometimes called the FFT network, since the FFT has the same communication pattern as the network [55, Section 3.7]. A parallel FFT over complex numbers can be expressed as follows:

ALGORITHM: $\mathrm{FFT}(A)$
1 $n := |A|$
2 **if** $(n = 1)$ **then return** A
3 **else**
4 **in parallel do**
5 $\mathrm{EVEN} := \mathrm{FFT}(\{A[2i] : i \in [0..n/2)\})$
6 $\mathrm{ODD} := \mathrm{FFT}(\{A[2i+1] : i \in [0..n/2)\})$
7 **return** $\{\mathrm{EVEN}[j] + \mathrm{ODD}[j] e^{2\pi ij/n} : j \in [0..n/2)\} + +\{\mathrm{EVEN}[j] - \mathrm{ODD}[j] e^{2\pi ij/n} : j \in [0..n/2)\}$

The algorithm simply calls itself recursively on the odd and even elements and then puts the results together. This algorithm does $O(n \log n)$ work, as does the sequential version, and has a depth of $O(\log n)$.

47.9 Research Issues and Summary

Recent work on parallel algorithms has focused on solving problems from domains such as pattern matching, data structures, sorting, computational geometry, combinatorial optimization, linear algebra, and linear and integer programming. For pointers to this work, see Section "Further Information."

Algorithms have also been designed specifically for the types of parallel computers that are available today. Particular attention has been paid to machines with limited communication bandwidth. For example, there is a growing library of software developed for the BSP model [40, 62, 85].

The parallel computer industry has been through a period of financial turbulence, with several manufacturers failing or discontinuing sales of parallel machines. In the past few years, however, a large number of inexpensive small-scale parallel machines have been sold. These machines typically consist of 4 to 8 commodity processors connected by a bus to a shared-memory system. As these machines reach the limit in size imposed by the bus architecture, manufacturers have reintroduced parallel machines based on the hypercube network topology (e.g., [54]).

47.10 Defining Terms

CREW: This refers to a shared memory model that allows for concurrent reads (CR) but only exclusive writes (EW) to the memory.

CRCW: A shared memory model that allows for concurrent reads (CR) and concurrent writes (CW) to the memory.

Depth: The longest chain of sequential dependencies in a computation.

EREW: A shared memory model that allows for only exclusive reads (ER) and exclusive writes (EW) to the memory.

Graph contraction: Contracting a graph by removing a subset of the vertices.

List contraction: Contracting a list by removing a subset of the nodes.

Multiprefix: A generalization of the scan (**prefix sums**) operation in which the partial sums are grouped by keys.

Multiprocessor model: A model of parallel computation based on a set of communicating sequential processors.

Pipelined divide-and-conquer: A divide-and-conquer paradigm in which partial results from recursive calls can be used before the calls complete. The technique is often useful for reducing the depth of an algorithm.

Pointer jumping: In a linked structure, replacing a pointer with the pointer it points to. Used for various algorithms on lists and trees.

PRAM model: A multiprocessor model in which all processors can access a shared memory for reading or writing with uniform cost.

Prefix sums: A parallel operation in which each element in an array or linked-list receives the sum of the previous elements.

Random sampling: Using a randomly selected sample of the data to help solve a problem on the whole data.

Recursive doubling: The same as pointer jumping.

Scan: A parallel operation in which each element in an array receives the sum of all the previous elements.

Shortcutting: Same as pointer jumping.

Tree contraction: Contracting a tree by removing a subset of the nodes.

Symmetry breaking: A technique to break the symmetry in a structure such as a graph which can locally look the same to all the vertices. Usually implemented with randomization.

Work: The total number of operations taken by a computation.

Work-depth model: A model of parallel computation in which one keeps track of the total work and depth of a computation without worrying about how it maps onto a machine.

Work-efficient: A parallel algorithm is work-efficient if asymptotically (as the problem size grows) it requires at most a constant factor more work than the best known sequential algorithm (or the optimal work).

Work-preserving: A translation of an algorithm from one model to another is work-preserving if the work is the same in both models, to within a constant factor.

Further Information

In a chapter of this length, it is not possible to provide comprehensive coverage of the subject of parallel algorithms. Fortunately, there are several excellent textbooks and surveys on parallel algorithms including [4, 5, 6, 18, 30, 31, 35, 45, 48, 53, 55, 67, 75, 80].

There are many technical conferences devoted to the subjects of parallel computing and computer algorithms, so keeping abreast of the latest research developments is challenging. Some of the best work in parallel algorithms can be found in conferences such as the ACM Symposium on Parallel Algorithms and Architectures, the IEEE International Parallel Processing Symposium, the IEEE Symposium on Parallel and Distributed Processing, the International Conference on Parallel Processing, the International Symposium on Parallel Architectures, Algorithms, and Networks, the ACM Symposium on the Theory of Computing, the IEEE Symposium on Foundations of Computer Science, the ACM–SIAM Symposium on Discrete Algorithms, and the ACM Symposium on Computational Geometry.

In addition to parallel algorithms, this chapter has also touched on several related subjects, including the modeling of parallel computations, parallel computer architecture, and parallel programming languages. More information on these subjects can be found in [7, 43, 44, 86], and [21, 34], respectively. Other topics likely to interest the reader of this chapter include distributed algorithms [59] and VLSI layout theory and computation [57, 84].

Distributed Computing: A Glimmer of a Theory

Eli Gafni
U.C.L.A.

48.1 Introduction

What Is the Area About?

Distributed computing theory develops computability and complexity theories for models whose computation involves many processors interacting in certain limited unpredictable manner through some communication objects, where a **processor** is shorthand for a sequential piece of code that includes instructions, some of which involve access to the communication objects.

One of the defining characteristics of the models tackled by distributed computing is a **nondeterminism** due to run-time events whose possibility of occurrence or the order in which they might occur is unpredictable. Moreover, distributed computing takes as its primary domain models whose nondeterminism gives their processors differing views of the world. Thus, for example, distributed computing will examine a model in which the failure of a processor is noticeable to some of its processors but not to others, but it will not examine a model in which the outcome of a flip of a coin (i.e., a randomized outcome) is made available to all processors simultaneously. In the parlance of knowledge [20], distributed computing studies systems in which the current state of a processor is not common knowledge, even when the input is known to all of the processors.

Research in distributed computing has focused on a number of models distinguished by the different communication objects and different timing constraints. Among those investigated most extensively are the asynchronous message-passing model, the asynchronous shared-memory model, asynchronous models in which at most t processors may fail-stop, and synchronous models with Byzantine, omission, or fail-stop failures.

What Is this Chapter About?

Here I argue that in the chaos that has characterized the field of distributed computing theory, we have begun to see signs of an underlying order. In the 1980s, as Lynch and Lamport [25] have observed, "the field seemed to consist of a collection of largely unrelated results about individual models." They were right at the time. Researchers concentrated on obtaining efficient solutions to problems, and although this was and is an important and productive line of research, most of the ideas leading to efficiency seem ad hoc and are closely tied to a specific model and, at times, to a specific problem instance. Few of the ideas leading to efficient solutions supply a methodology that can be applied in other contexts.

Furthermore, the arguments that have led to the most fundamental impossibility results of the field seem to share no common thread. One fundamental negative result, FLP impossibility [16], states that no agreement can be reached in an asynchronous system in which even a single processor may fail-stop unannounced. The original arguments that led to this result were procedural and very much tied to the properties of the operations specific to the model. Concurrently, the impossibility of reaching Byzantine agreement in time equal to the number of faults was proven [15] through the use of a **chain** of compatible views that led from a run in which one decision has to be taken to a run in which another decision has to be taken. Consequently, the argument went, there must be a link in the chain at which incompatible decisions are taken by different processors in the same run. At about the same time, the procedural inductive proof of the nonexistence of a solution to the so-called two-armies problem was replaced by a slick proof using a newly developed knowledge theory [20, 18]. Although the connection between the latter two impossibility results, one in the context of synchronous systems and the other in the context of asynchronous systems, was at the time vaguely understood, the connection between them and FLP impossibly seemed nonexistent.

In recent years tools have been developed, and research has been fruitful in making connections between results and models in a way that parallels what has been done in complexity theory. Where complexity theory is not much help in supplying a receipt to determine whether a specific problem at hand is $\Theta(n^2)$ or $\Theta(n^3)$ other then referral to some generic problems that have been thoroughly investigated, distributed computing can similarly provide only hints in the form of pointers to similar problems, in determining time and message complexity of a specific problem. Where complexity theory has tool and techniques to categorize problems in a "broad-brush," e.g., P vs. NP, distributed computing theory has over recent years built a formidable machinery to classify problems by the models in which they are solvable.

Problems have been identified that are analogous to **complete** problems. They characterize a model. The problem is solvable in the characterized model, and any model in which the problem is solvable, has a set of solvable problems that is a superset of the problems solvable in the characterized model. Collections of models, whose set of solvable problems is identical, have been identified, where in some models the level of the unpredictability of the possible order of events is lesser than in others. A problem is then checked for solvability in the model that exhibit the least unpredictability, if one exists. It provides, on the one hand, short uncluttered impossibility argument, or on the other hand, it provides a succinct protocol. Such a protocol may be viewed as written in a high-level programming language, with a guaranteed automatic compilation of the protocol to a protocol in the target model.

Some starts that stalled, and some partial successes in the direction indicated above occurred in the 1980s. Knowledge theory [20] was developed, showed some promise for certain problems, but eventually led, in my opinion, to no major breakthrough, in the understanding of distributed computing. A way of coaching 1-resilient models within graph theory led to a complete characterization of these models [9], providing an automatic impossibility proof on one hand or a protocol on the other, to the question of a problem

solvability in the model. This raised the hope that protocol derivation, or the realization of its nonexistence, can in general be automated. And finally, a helpful instance of the "high-level-programming," mentioned above, was discovered with the realization of the equivalence between message passing systems and shared memory systems on the one hand, and between shared memory and atomic-snapshot shared-memory on the other. These instances of model equivalence allowed the investigation of the power of message-passing systems, within the much less detailed model of atomic-snapshot shared-memory.

The break-through was enabled when researchers started to zooming on complete problems. Herlihy [19] showed that the number processor that can achieve consensus characterizes and differentiates certain models. While consensus takes n input values and allows a single output, Chaudhuri proposed to check for models that allow several but less than n outputs. In 1993 three teams were able to show that her problems are also complete for certain models. The techniques employed resulted in the revelation of a connection between distributed computing and topology, be it algebraic [22], combinatorial [5], or point-set topology [29].

Extensive research effort followed. If by "theory" one means a body of tightly related results, building one upon the other, and readily providing explanations to many observable phenomena, then, as I will attempt to show in this chapter, a theory of distributed computing has emerged.

The survey in this chapter has a narrow focus. The advances outlined above are presented. The utility of the "modern tools" that result in are demonstrated in deriving past results. The next section, on models, discusses distributed systems in general and defines the various notions of emulation and tasks which are central to this chapter. We then embark upon a sequence of emulations. We start with the asynchronous shared-memory model for two and three processors, characterizing them for fail-stop and Byzantine failures and, via transformation, we apply all these results to the message-passing model. Then we investigate the shared-memory model in the synchronous domain, and we show how an impossibility result in the asynchronous model translates into lower bound on complexity in the synchronous model. The next step is to link the two models through the notion of failure detectors, and the new notion of an iterated model, and to explicate the utility of characterizing a synchronous system as an asynchronous one with a (weak) failure detector [12]. The concluding section raises some of the major questions that, in my opinion, are facing this emerging theory of distributed computing. Obviously, the chapter leaves unaddressed many of the very large number of techniques developed in distributed computing; in most cases, how they may be incorporated into the framework reported here is not yet clear. The reader is encouraged to look up this wealth of techniques in the excellent textbook by Lynch [26], and two of the surveys by Lamport and Lynch [25], and Attiya [6].

48.2 Models

An asynchronous distributed computation model is the set of all sequential interleaving of communication actions performed by sequential processes or processors on shared communication objects. A communication action may be thought of as the invocation of a remote procedure call by a processor at an object. An object may be thought of as a processor that executes the remote procedure call, changes its state, and responds to the invoking processor by returning a value. The returned value causes the invoking processor to change its state, which in turn determines the next parameter for the next access to a communication object. In this chapter we assume that processors never halt, and therefore after each return of an invocation, they enter a state in which a new invocation is enabled. In the network model, processors access unidirectional point-to-point communication channels. A single communication object is associated with two processors, called sender and receiver, respectively. The sender can invoke an action **send**(m) on the object. The effect of the action is to place a message m in the buffer of the object. After placing the message in its buffer the object responds by returning an *ok* to the sender. The receiver invokes an action **receive** which moves a message from the buffer of the object to the receiver, if such a message exists, or the object

responds by notifying exception otherwise. In the shared memory model, communication objects are read/write registers on which the action of read and write can be invoked.

In this chapter we assume that communication objects do not fail. Yet, in light of the view of a communication object as a "restricted" processor, it is not surprising that when communication failures are taken into account [3], they give rise to results reminiscent of processor failures.

Given a **protocol** — the instantiation of processors with codes — and the initial conditions of processors and objects, we define a space R of **runs** to be a subset of the infinite sequences of processors names. Since we assume that a processor has a single enabled invocation at a time, such a sequence when interpreted as the order in which enabled invocations were executed completely determines the evolution of the computation. Before the system starts all runs in which the processor has its current input are possible. As the system evolves, the local state of the processor excludes some runs. Thus with a local state of a processor we associate a **view** — the set of all runs in R that are not excluded by the local state. By making processors maintain their history in local memory we may assume that consecutive views of a processor are monotonically nondecreasing. Thus, with each run $r \in R$ of a protocol p we can associate a limit view $\lim(V_i(r, p))$ of processor P_i. A protocol f is **full-information** if for all i, r, and p we have $\lim(V_i(r, f)) \subseteq \lim(V_i(r, p))$. Intuitively, a full-information protocol does not economize on the size of its local state, or the size of the parameter to its object invocation. Models which are **oblivious,** that is, the sequence of communication objects a processor will access is the same for all protocols, possess a full-information protocol. All the models in this chapter do. In the rest of this chapter, a protocol stands for the full-information one, and correspondingly a model is associated with a single protocol — its full-information protocol. One can define the notion of full-information protocol with respect to a specific protocol in a nonoblivious model, but we will not need this notion here. A sequence of runs $r_1, r_2, \ldots$ converges to a run r, if r_k and r share a longer and longer prefix as k increases.

It can be observed from the definition of a view, that two views of the same processor, are either disjoint, or related by containment. Given an intermediate view $V_i(r)$ of a processor P_i in run r, we say that a processor **outputs** its view in r if for all P_j which have infinitely many distinct views in r, $\lim(V_j(r)) \subseteq V_i(r)$. Processor P_i is **faulty** in r if it outputs finitely many views. Processor P_i is **participating** in r if it outputs any nontrivial view. Otherwise it is **sleeping** in r. A model A with n processors with communication object O_A **wait-free emulates** a model B with n processors and communication objects O_B if there is a map m from runs R_A in A to runs R_B in B such that

1. The sets of sleeping processors and faulty processors in r and $m(r)$ are identical.
2. The map m is continuous with respect to prefixes. That is if $r_1, r_2, \ldots$ in A converges to r, then $m(r_1), m(r_2), \ldots$ in B converges to $m(r)$. This captures the idea that the map does not predict the future.
3. The map m does not utilize detailed information about the past of a run, if this detailed information is not available through processors' views. Formally, for all P_j nonfaulty and for all r in A, $m(\lim(V_j(r))) \subseteq \lim(V_j(m(r)))$

We say that A **nonblocking** emulates B if we relax the first condition by allowing the mapping m to fail any nonfaulty processor as long as an infinite sequence is mapped into an infinite sequence. Two models are wait-free (nonblocking) equivalent if they wait-free (nonblocking) emulate each other.

A specification of a problem Π on n processors, is a relation from runs to sets of "output-sequences." Each output in the sequence is associate with a unique processor. A model with n processors wait-free solves Π if there exists a map from views to outputs, such the map of the projection of a run on views that are output in the run, is an output-sequence that relates to the run. A problem Π on n processors is non-blocking solvable in a model, if the relaxed problem $\bar{\Pi}$ is wait-free solvable, where $\bar{\Pi}$ takes each element in Π and closes the output-sequence set with respect to removal of infinite suffixes of processors' outputs (as long as the sequence remains infinite).

A **task** is a relaxation of a problem Π such that only bounded prefixes of output-sequences matter. That is to say that past some number of outputs any output is acceptable. Since the notion of participating set is invariant over models, the runs that are distinguished by different output requirements in a task are those that differ in their participating set. Thus in this chapter we employ the notion of task in this restricted sense. In the **consensus** task a processor first outputs its private value, which is either 0 or 1, and then outputs a consensus value. Consensus values agree, and match the input of at least one of the participating processors. In the **election** task a processor outputs its ID and then outputs an election value which is an ID of a participating processor. All election values agree. A run with a single participating processor is a **solo-execution** of that processor.

A model is t**-resilient** if we require that it solves a problem only over runs in which at most t processors are faulty.

A **synchronous** model is one which progresses in rounds. In each round all the communication actions enabled by the beginning of the round are executed by the end of the round.

48.3 Asynchronous Models

Two-Processor Shared-Memory Model

Consider a two-processor single-writer/multi-reader (SWMR) shared-memory system. In such a system, there are two processors P_1 and P_0, and two shared-memory cells C_1 and C_0. Processor P_i writes exclusively to C_i, but it can read the other cell. Both shared-memory cells are initialized to $\perp$. W.l.o.g. computation proceeds with each processor alternately writing to its cell and reading the cell of the other processor.

Can this two-processor system 1-resiliently (wait-free in this case, since for $n = 2$, $n - 1 = 1$) elect one of the processors as the leader? No one-step full-information protocol, and consequently no one-step protocol at all, for solving this problem exists. Consider the state of processor P_1 after writing and reading. It could have read what processor P_0 wrote (denoted by $P_1 : w_0$), or it could have missed what processor P_0 wrote (denoted by $P_1 : \perp$). Thus, we have four possible views, two for each processor, after one step.

In the graph whose nodes are these views, two views are connected by an undirected edge if there is an execution that gives rise to the two views. The resulting graph appears in Fig. 48.1. Since a processor has a single view in an execution, edges connect nodes labeled by distinct processor IDs. The two nodes of distinct IDs which do not share an edge are $P_1 : \perp$ and $P_0 : \perp$. This follows from the fact that in shared memory in which processors first write and then read, the processor that writes second must read the value of the processor that writes first.

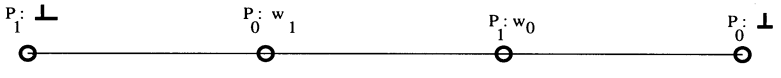

FIGURE 48.1 One-step view graph.

The edge $\{P_1 : \perp, P_0 : w_1\}$ corresponds to the execution: P_1 writes, P_1 reads, P_0 writes, P_0 reads. If we could map the view of a processor after one step into an output, then processor P_1 in this edge is bound to elect P_1, since the possibility of a solo execution by the processor has not yet been eliminated. Similarly, in the edge $\{P_0 : \perp, P_1 : w_0\}$, processor P_0 is bound to elect P_0. Thus, no matter what processor is elected by P_1 and P_0 in the views $P_1 : w_0$ and $P_0 : w_1$, respectively, we are bound to create an edge where at one end P_1 is elected and at the other end P_0 is elected. Because there is an execution in which both processors are elected, we must conclude that there is no one-step 1-resilient protocol for election with two processors.

To confirm that no k-step full-information protocol exists, we could draw the graph of the views after k steps, and observe that the graph contains a path connecting the views $\{P_1 : \perp\}$ and $\{P_0 : \perp\}$.

It is not easy to see that indeed the observation above holds. Given that our goal is an argument that will generalize to more than two processors, we have to be able to get a handle on the general explicit structure of the shared-memory model for any number of processors. This has been an elusive challenge. Instead, we turn to iterated shared memory, a model in which the structure of the graph of a k-step two-processor full-information protocol is easily verified to be a path. We then argue that for two processors, the shared-memory model and the iterated shared-memory model are nonblocking equivalent. We then show that this line of argumentation generalizes to any number of processors.

Two-Processor Iterated Shared-Memory Model

For any model M in which the notion of one-shot use of the model exists, one can define the iterated counterpart $\bar{M}$ of M. In $\bar{M}$, the processors go through a sequence of stages of one-shot use of M in which the output of the $(k-1)$th stage is in turn the input to the kth stage.

To iterate the two-processor SWMR shared-memory model, we take two sequences of cells: $C_{1,1}, C_{1,2}, C_{1,3}, \ldots$, and $C_{0,1}, C_{0,2}, C_{0,3}, \ldots$. Processor P_1 writes its input to $C_{1,1}$ and then reads $C_{0,1}$. Inductively, P_1 then takes its view after reading $C_{0,(k-1)}$, writes this view into $C_{1,k}$, reads $C_{0,k}$, and so on.

The iterated model is related to the notion of a **communication-closed layer** [14]. This accounts for why algorithms in the iterated model are easy both to understand and to prove correct: one may imagine that there is a barrier synchronization after each stage such that no processor proceeded to the current stage until all processors had executed (asynchronously) the previous stage.

In an execution, if the view of P_1 after reading $C_{0,(k-1)}$ is X and the corresponding view for P_0 is Y, then the graph of the views after the kth stage, given the view after the $k-1$'st stage, appears in Fig. 48.2. This graph is the same as the graph for the one-shot SWMR shared-memory model when X is the input to P_1 (and stands therefore for w_1) and Y is the input to P_0 (and stands therefore for w_0). To get the graph of all the possible views after the kth stage, we inductively take the graph after the $(k-1)$th stage, replace each edge with a path of three edges, and label the nodes appropriately. Thus, after k stages, we get a path of 3^k edges. At one end of this path is a view that is bound to output P_1, at the other a view bound to be output P_0, which leads to the conclusion that there is no k-stage protocol in the model for any k.

FIGURE 48.2 One-step view graph after the kth stage with input X,Y.

It is easy to see that the shared-memory model nonblocking implements its iterated version by dividing cell C_i into a sequence of on-demand virtual cells $C_{i,1}, C_{i,2}, C_{i,3}, \ldots$. Processors then "pretend" to read only the appropriate cell. To the see that a non-blocking emulation in the reverse direction is also possible we consider processors to $WriteRead$ sequence numbers. Processor P_1 keeps an estimate v_{p_0} of the last sequence number P_0 wrote. To $WriteRead_1(v)$, processor P_1 writes the pair v_{p_0}, v into the next cell in the sequence. It then read the other. If it contains $\perp$, or it contains the same pair it has written, then the operation terminates, and P_1 returns the pair it wrote to its cell. Otherwise, it updates v_{p_0} to the maximum between the value it held and the value it read, and continues [8].

Characterization of Solvability for Two Processors

What tasks can two processors in shared memory solve 1-resiliently? They can solve, for instance, the following task. Processor P_1 in a solo execution outputs 1, and processor P_0 in a solo execution outputs 10. In every case, the two processors must output values between 1 and 10 whose absolute difference is exactly 1. This task can be solved easily, since in the iterated shared-memory model, after three stages the path contains

10 nodes and these nodes can be associated one-to-one with the integers 1 through 10. The task may be represented using domino pieces. There is an infinite number of pieces, each labeled P_1, x on one side and P_0, y on the other side, where all x and y are real numbers and $|x - y| = 1,\ 1 \leq x \leq 10,\ 1 \leq y \leq 10$. The task is solvable iff one can create a domino path with the pieces such that one side of the path is labeled P_1, 1 and the other side P_0, 10. It is easy to see that if processor P_0 had to output 11 (rather than 10) in a solo execution, the problem would not be solvable.

A generalized version is solvable if processors in solo executions output their integer inputs (which come, for the moment, from a bounded domain of integers) and the tuples of inputs are such that one input value is odd and the other is even. To see that the input (1,8) is solvable, take the output from the second stage of the iterated shared-memory model and fold three consecutive view edges on a single output edge. In algebraic and combinatorial topology, an edge is called a **1-simplex,** a node is called a **0-simplex,** an edge that is subdivided into a path is called a **one-dimensional subdivided simplex,** and a graph is called a **complex.** Thus, for a problem to be solvable 1-resiliently by two processors, the output complex must contain a subdivided simplex in which the labels on the two boundary nodes are the processors with their corresponding solo-execution outputs and the ID labels on the path alternate (colored subdivided simplex).

What if we want to solve the infinite version of the task where the possible integer inputs are not bounded? In this case, the difficulty is that we cannot place an *a priori* upper bound on the number of iterated steps we need to take in the iterated model. One solution is to map the infinite line to a semicircle, then do the appropriate convergence on the semicircle, and map back. Another solution, denoted by Π, proceeds as follows. Processor P_1 with input k_1 takes k_1 steps if it reads $\perp$ continuously. Otherwise, after P_1 reads a value for P_0, it stops once it reads $\perp$ or reads that P_0 has read a value from P_1. Clearly, if the input values are k_1 and k_2, then the view complex is a path of length $k_1 + k_2$ that can be folded into the interval $[k_1, k_2]$ with enough views to cover all the integers (see [4]).

In the case of shared memory (not iterated), if a processor halts once it takes some number of steps or once it observes the other processor take one step, we say that the processor halts within a unit of time. Consider the full-information version of Π (a protocol in the iterated model). An execution of the full-information protocol can be interpreted as an execution of a nonblocking emulation of the atomic-snapshot shared-memory model. If we take this view, then Π translates into a unit-time algorithm.

This conclusion, in fact, holds true for any task that is solvable 1-resiliently by two processors. It is easy to see that by defining the unit as any desirable $\epsilon > 0$, we can get two processors to output real numbers that are within an ϵ-ball (ϵ-agreement). To solve any problem, we fix an embedding of a path that may account for the solvability of the task. Consequently, there exists an ϵ such that for any interval I of length ϵ, all the simplexes that overlap the interval have a common intersection. Processors then conduct ϵ-agreement on the path, and each processor adopts as an output the node of its label which is closest to its ϵ-agreement output.

This view of convergence does not generalize easily to more than two processors. Therefore, we propose another interpretation for the two-processor convergence process [8]. After an $\epsilon/2$-agreement as above, P_i observes the largest common intersection s_i of the simplexes overlapping the ϵ-length interval that is centered around P_i's ϵ-agreement value. It must be that $s_1 \cup s_2$ is a simplex and that $s_1 \cap s_2 \neq \emptyset$. P_i posts s_i in shared memory. It then takes the intersection of the s_j's it observes posted. If a node labeled by P_i's ID is in the intersection, P_i outputs that node. Otherwise, P_i sees only one node, v, in the intersection, and v has a label different from P_i's ID. In this case, P_i outputs one of the nodes labeled by its own ID which appear in a simplex along with v (these nodes are said to be "in the **link** of v").

Thus, since solvability amounts to ϵ-agreement, and ϵ-agreement can be achieved 1-resiliently within a unit of time, we conclude that any task 1-resiliently solvable by two processors can be solved within a unit of time.

Three-Processor 2-Resilient Model

We consider now the three-processor 2-resilient SWMR shared-memory model. W.l.o.g. processors alternate between writing and reading the other two cells one by one. Obviously, we cannot elect a leader (since two processors cannot), but perhaps we can solve the $(3, 2)$ set-consensus problem in which processors elect at most two leaders (i.e., each processor outputs an ID of a participating processor, and the union of the outputs is of cardinality at most 2).

The structure of the full-information protocol of the one-shot shared-memory model for three processors is not as easy to identify as that for two processors. Two-processor executions have many hidden properties that are lost when we have three processors. For example, in a two-processor execution, when a processor reads the value of the other processor's cell, then in conjunction with the value it has last written to its own cell, the processor has an instantaneous view of how the memory looks, as if it read both cell in a single atomic operation. Such an instantaneous copy is called an **atomic snapshot** (or, for short, a snapshot) [1]. In a three-processor system, this property is lost; we cannot interpret a read operation as returning a snapshot.

To get the effect of processor P_1 reading cells C_2 and C_0 instantaneously, we have P_1 read C_2 and C_0 repeatedly until the values the processor reads do not change over two consecutive repetitions. If all values written are distinct, then the values the processor reads reside simultaneously in the memory in an instant that is after the first of the two consecutive repetitions and before the second of the repetitions. Thus, P_1 may safely return these values.

Clearly, three processors can 2-resiliently nonblocking implement one-shot snapshot memory—a memory in which a processor writes its cell and then obtains a vector of values for all cells, and this vector is a snapshot. Yet, a one-shot snapshot may give processors the following views: $P_1 : w_1, w_2, w_0$, $P_2 : w_1, w_2, w_0$, $P_0 : \perp, w_2, w_0$. This is the result of the execution: P_2 writes, P_0 writes, P_0 takes a snapshot, P_1 writes, P_1 and P_2 take a snapshot. Can we require that the set of processors S_i that return at most i values return snapshots only of values written by processors from S_i? In the example above, we have $S_2 = \{P_0\}$, but P_0 returns a value from P_2 which is not in S_2. A snapshot whose values are restricted in this way is called an **immediate snapshot** [7, 29]. A recursive distributed procedure will return immediate snapshots (program for P_i):

1. Procedure-immediate-snapshot $ISN(P_i, k)$.
2. Write input to cell $C_{k,i}$.
3. For $j = 1$ to n, read cell $C_{k,j}$.
4. If the number of values ($\neq \perp$) is k, then return everything read; else, call immediate snapshot $ISN(P_i, k-1)$.

We assume that all cells are initialized to $\perp$ and that in a system with n processors, P_i starts by calling immediate snapshot $ISN(P_i, n)$.

It is not difficult to prove that the view complex of a one-shot immediate snapshot is a subdivided simplex. Simple extension of the algorithm outlined for two processors shows that, in general, the iterated immediate-snapshot model nonblocking implements the shared-memory atomic-snapshot model [8]. The view complex for three processors is shown in Fig. 48.3.

We now argue by way of example that after the first stage in the iterated immediate-snapshot model, processors cannot elect two leaders. By definition, the view $P_i : w_i$ has to be mapped to P_i. The views $P_i : w_i, w_j$ are mapped to P_i or P_j. The rest are mapped to any processor ID. Such a mapping of views to processor IDs constitutes a Sperner coloring of the subdivided simplex [28]. The Sperner Lemma then says that there must be a triangle colored by the three colors. Since a triangle is at least one execution, we have proven that no election of two leaders is possible. The argument we made about the coloring of a path by two processors' IDs is just the one-dimensional instance of the Sperner Lemma. By the recursive properties of iterated models, we conclude that the structure of a k-step three-processor 2-resilient iterated immediate snapshot is the structure of a subdivided triangle.

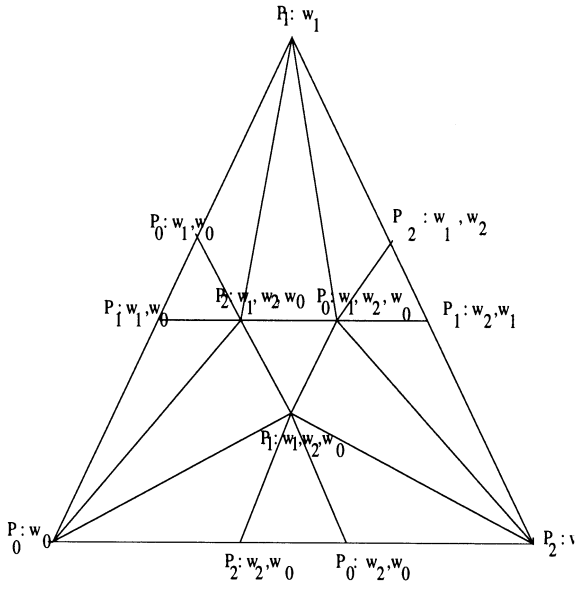

FIGURE 48.3 Three-processor one-shot immediate-snapshot view complex.

What nontrivial tasks can we solve? For one, the task of producing a one-shot immediate snapshot is far from trivial. In general, we can solve anything that the view complex of a sufficiently large number of iterations of one-shot immediate snapshots can map to, color and boundary preserving, simplicially. This includes any subdivided triangle A [23].

We show algorithmically how any three processors converge to a triangle on a colored subdivided triangle A. Embedding a reasonably large-enough complex of the iterated immediate snapshots embedded over A yields two-dimensional ϵ-agreement over A, since triangles of the view complex can be inscribed in smaller and smaller circles as a function of the number of iterations we take. Thus, as we did for two processors, we may argue now that an $\epsilon > 0$ exists such that for any ϵ-ball in A, all simplexes that overlap the ball have a common intersection. P_i then conducts $\epsilon/2$-agreement and posts the largest such intersection s_i of the simplexes overlapping the $\epsilon/2$-radius ball whose center is P_i's $\epsilon/2$-agreement value. P_i takes the intersection of the s_is posted and, if P_i's color is present, adopts the value of that A node. Otherwise, P_i removes a node of P_i's color, if one exists, from the union of the simplexes P_i observed to get a simplex x_i and then starts a new ϵ-agreement from a node of P_i's color in the link of x_i.

As we argued for two processors, when there are three processors, at least one processor will terminate after the first ϵ-agreement. If two processors show up for the second agreement, they have identified the processor that will not proceed; the link is at worst a closed path. The convergence of the remaining two processors is interpreted to take place on one side of the closed path rather than on the other, and the decision about on which side convergence takes place is made according to a predetermined rule that is a function of the starting nodes. The convergence of two processors on a path was outlined in the previous section.

To see that ϵ-agreement for three processors is solvable 2-resiliently on a triangle within a unit of time, we notice that if we again take an iterated algorithm with the stopping rule that processors halt once they reach some bound or once they learn that they read from each other, as in the case of two processors, it can easily be argued inductively that we get a subdivided simplex "growing from the center." As we increase the bound on the solo and pairs executions, we "add a layer" around the previous subdivided simplex. Thus, we have a mesh that becomes as fine as we need and results in ϵ-agreement. Our stopping rule, when converted via nonblocking emulation of shared memory by iterated shared memory, results in a unit-time algorithm. Since we have seen that solving a task amounts to ϵ-agreement on the convex hull,

we conclude that in the snapshot model, an algorithm exists for any wait-free solvable task such that at least one processor can obtain an output within a unit of time (see [4]).

Now, if we view three-processor tasks as a collection of triangular domino pieces that can be reshaped into triangles of any size we want, we see that again the question of solvability amounts to a tiling problem. Where in the two-processor case we had two distinct domino ends that we had to tile in between, we now have three distinct domino corners, corresponding to solo executions, and three distinct domino sides, corresponding to executions in which only two processors participated. To solve a three-processor task, we have to pack the domino pieces together to form a subdivided triangle that complies with the boundary conditions on the sides. Unfortunately, this two-dimensional tiling problem is undecidable in general [17].

Three-Processor 1-Resilient Model

What kind of three-processor tasks are 1-resiliently solvable [9]? It stands to reason that such systems are more powerful than two-processor 1-resiliency. Perhaps the two nonfaulty processors can gang up on the faulty one and decide.

In light of our past reasoning, the natural way to answer this question is to ask what the analogue to the one-shot immediate snapshot is in this situation. A little thought shows that the analogue comprises two stages of the wait-free one-shot immediate snapshot where the nodes that correspond to solo executions have been removed. (We need to two stages because one stage with solo executions removed is a task that is not solvable 1-resiliently by three processors.) This structure can be solved as a task by the three-processor 1-resilient model, and the iteration of this structure is a model that can nonblocking implement a shared-memory model of the three-processor 1-resilient model.

An inductive argument shows that this structure is connected, and consequently consensus is impossible. Furthermore, the link of any node is connected. If we have a task satisfying these conditions, the convergence argument of the previous section shows how to solve the task. We start at possibly only two nodes because one processor may wait on one of the other two. By simple connectivity, we can converge so that at least one processor terminates. The other two can converge on the link of the terminating processor since this link is connected.

Thus a task is solvable 1-resiliently in a system with three processors if it contains paths with connected links, connecting solo executions of two processors. Checking whether this holds amounts to a reachability problem and therefore is decidable.

Models with Byzantine Failure

What if a processor not only may fail to take further steps but also may write anything to its cell in the asynchronous SWMR memory? Such a processor is said to fail in a Byzantine fashion. Byzantine failures have been dealt with in the asynchronous model within the message passing system [10]. Here we define it for the shared-memory environment and show that the essential difficulty is actually in transforming a message-passing system to a shared-memory one with write-once cells.

Why a Byzantine failure is not more harmful than a regular fail-stop failure when in a write-once cells shared-memory environment? If we assume that cell C_i is further subdivided into sub-cells $C_{i1}, C_{i2}, \ldots$ and that these subcells are write-once only, we can nonblocking emulate iterated snapshot shared memory in which a processor writes and then reads all cells in a snapshot. All processors now have to comply with writing in the form of snapshots—namely, they must write a set of values from the previous stage, otherwise what they write will be trivially discarded. Yet, faulty processors may post snapshots that are inconsistent with the snapshots posted by other, nonfaulty processors. We observe that we can resolve inconsistent snapshots by letting their owners to revise these snapshots to snapshots that are the union of the inconsistent ones. This allows processors to affirm some snapshots and not affirm others. A processor that observes another snapshot that is inconsistent with its own snapshot will suggests the union snapshot

if its snapshot has not been affirmed yet. This processor waits with a snapshot consistent with the others until one of its snapshots has been affirmed. It then writes one of its affirmed snapshots as a final one. Thus, all other processors may check that a processor's final snapshot have been affirmed.

A processor affirms a snapshot by observing it to be consistent with the rest and writing an affirmation for it. If we wait for at least $n/2 + 1$ affirmations (discard a processor which affirms two inconsistent snapshots as faulty), then it can be seen that no inconsistent snapshots will be affirmed. In other words, we have transformed Byzantine failure to fail-stop at the cost of nonblocking emulating the original algorithm if it was not written in the iterated style.

The next problem to be addressed is how to nonblocking emulate subdivision to a write-once subcell of a cell C_i when a processor may overwrite the values previously written to the cell. The following procedure nonblocking emulates a read of $C_{i,k}$:

1. If read $C_{i,k} \neq \perp$ or if read $f + 1$ processors claiming a value $v \neq \perp$ for $C_{i,k}$, claim v for $C_{i,k}$.
2. If read $2f + 1$ processors claiming v for $C_{i,k}$ or if read $f + 1$ processors wrote Confirm(v) for $C_{i,k}$, write Confirm(v) for $C_{i,k}$.
3. If read $2f + 1$ processors claiming Confirm(v) for $C_{i,k}$, accept v for $C_{i,k}$.

Clearly, once a processor accepts a value, all processors will accept that value eventually and so a value may not change.

Since the availability of write-once cells allows Byzantine agreement we conclude that like Byzantine agreement the implementation of write-once cells requires that less of a third of the processors fail. In hindsight, we recognize that Bracha discovered in 1987 that a shared-memory system with Byzantine failure and write-once cells can be nonblocking implemented on a message-passing system with the same failures as the shared-memory system provided that $3f < n$ [10]. It took another three years for researchers to independently realize the simpler transformation from message passing to shared memory for fail-stop faults [2].

Message-Passing Model

Obviously, shared memory can nonblocking emulate message passing. The conceptual breakthrough made by Attiya, Bar-Noy, and Dolev (ABD) [2] was to realize that for $2f < n$, message passing can f-resiliently wait-free emulate f-resilient shared memory, as follows. To emulate a write, a processor takes the latest value it is to write, sends the value to all of the processors, and waits for acknowledgment from a majority. To read, a processor asks for the latest value for the cell from a majority of the processors and then writes it. A processor keeps an estimate of the latest value for a cell; this estimate is the value with the highest sequence number that the processor has ever observed for the cell. Since two majorities intersect, the emulation works.

All results of shared memory now apply verbatim, by either the fail-stop or the Byzantine transformation, to message passing. To derive all the above directly in message passing is complex, because, in one way or the other, hidden ABD or Bracha transformations sit there and obscure the real issues. The ABD and Bracha transformations have clarified why shared memory is a much cleaner model than message passing to think and argue about.

From Safe-Bits to Atomic Snapshots

We now show that in retrospect the result of the research conducted during the second part of the 1980s on the power of shared-memory made out of safe-bits is not surprising.

We started this section with a SWMR shared-memory model. Can such a model be nonblocking implemented from the most basic primitives? Obviously, this is a question about the power of models, specifically about relaxing the atomicity of read-write shared-memory registers. This problem was raised

by Lamport [24] in 1986, and quite a few researchers have addressed it since then. Here we show that the nonblocking version of the problem can be answered trivially.

The primitive Lamport considers is a single-writer/single-reader safe-bit. A **safe-bit** is an object to which the writer writes a bit and from which the reader can read provided that the interval of operation execution of reading does not overlap with writing.

We now show how a stage of the iterated immediate-snapshot model can be nonblocking implemented by safe-bits. We assume an unlimited number of safe-bits, all initialized to 0, per pair of processors. To write a value, a processor writes it in unary, starting at a location known to the reader. To read, a processor counts the number of 1s it encounters until it meets a 0.

We observe that the recursive program for one-shot immediate snapshot itself consists of stages. At most k processors arrive at the immediate-snapshot stage called k (notice that these stages run from n down to 1). All we need is for at least one out of the k processors to remain trapped at stage k. The principle used to achieve this is the flag principle, namely, if k processors raise a flag and then count the number of flags raised, at least one processor will see k flags. For this principle to hold, we do not need atomic variables. Processors first write to all the other processors that they are at stage k and only then start the process of reading, so the last processor to finish writing will always read k flags.

Given that a processor writes its input to all other processors before it starts the immediate-snapshot stage, when one processor encounters another in the immediate snapshot and needs to know the other processor's input, the input is already written.

This shows that any task solvable by the most powerful read-write objects can be solved by single-writer/single-reader safe-bits. Can one nonblocking emulate by safe-bits any object that can be read-write emulated? The ingenious transformations cited in the introduction have made it clear that the answer to this question is "yes." Nonetheless, the field still awaits a theory that will allow us to deal with wait-free emulation in the same vein as we have dealt with nonblocking emulation here.

Geometric Protocols

What if we draw a one-dimensional immediate snapshot complex on a plan and repeat subdivide it forever? We can then argue that each point in our drawing corresponds to an infinite run with respect to views that are outputed. Obviously such a construction can be done for any dimension. We obtain an embedding of the space of runs in the Euclidean unit simplex. Such an embedding was the quest that eluded the authors of [29]. An embedding gives rise to "geometric-protocols."

Consider the problem of 2-processors election when we are given that the infinite symmetric run will not happen. One may work out an explicit protocol (which is not trivial). Geometrically, we take an embedding, and a processor waits until its view is completely on one side of the symmetric run. It then decides according to the solo execution that side contains.

48.4 Synchronous Systems

Shared-Memory Model

In retrospect, given the iterated-snapshots model in which conceptually processors go in lock-step, and its equivalence to the asynchronous shared memory, it is hard to understand the dichotomy between synchrony and asynchrony. In one case, the synchronous, we consider processors that are not completely coordinated because of various type of failures. In the other case, the asynchronous, processors are not coordinated because of speed mismatch. Why is this distinction of such fundamental importance? In fact, we argue that it is not. To exemplify this we show how one can derive a result in one model from a result in the other.

We consider the SWMR shared-memory model where its computation evolves in rounds. In other words, all communication events in the different processors and communication objects proceed in lockstep. At

the beginning of a round, processors write their cells and then read all cells in any order. Anything written in the round by a processor is read by all processors. This model may be viewed as a simple variant of the parallel RAM (PRAM) model, in which processors read all cells, rather than just one cell, in a single round.

With no failures, asynchronous systems can emulate synchronous ones. What is the essential difference between synchronous and asynchronous systems when failures are involved? A 1-resilient asynchronous system can "almost" emulate a round of the synchronous system. It falls short because one processor (say, if we are dealing with the synchronous shared-memory system below) misbehaves—but this processor does not really misbehave: what happens is that some of the other processors miss it because they read its cell too early, and they cannot wait on it, since one processor is allowed to fail-stop. If we call this processor faulty, we have the situation where we have at most one fault in a round, but the fault will shift all over the place and any processor may look faulty sooner or later. In contrast, in a synchronous system, a faulty behavior is attributed to some processor, and we always assume that the number of faults is less than n, the number of processors in the system.

We now introduce the possibility of faults into the synchronous system, and we will examine three types of faults. The first type is the analogue of fail-stop: a processor dies in the middle of writing, and the last value it wrote may have been read by some processors and not read by the others.

The algorithm to achieve consensus is quite easy. Each processor writes an agreement proposal at each round and then, at the next round, proposes the plurality of values it has read (with a tie-breaking rule common to all processors). At the first round, processors propose their initial value. After $t + 1$ rounds, where t is an upper bound on the number of faults, a processor decides on the value it would have proposed at round $t + 2$. The algorithm works because, by the pigeon principle, there is a **clean round,** namely, a round at which no processor dies. At the clean round, all processors take the plurality of common information, which results in a unanimous proposal at the next round. This proposal will be sustained to the end. Various techniques exist that can lead to early termination in executions with fewer faults than expected.

The next type of fault is omission [27]: a processor may be resurrected from fail-stop and continue to behave correctly, only to later die again to be perhaps resurrected again, and so on.

We reduce omission failure to fail-stop. A processor P_i that fails to read a value of P_j at round k goes into a protocol introduced in the next section to commit P_j as faulty. Such a protocol has the property that if P_i succeeds, then all processors will consider P_j faulty in the next round. Otherwise P_i obtain a value for P_j. We see that if a correct processor P_i fails to read a value from P_j, all processors will stop reading cell C_j at the next round, which is exactly the effective behavior of a fail-stop processor.

The last type of fault is Byzantine. We assume $n = 3f + 1$. Here, in addition to omitting a value, a processor might not obey the protocol and instead write anything (but not different values ($\neq \perp$) to different processors). We want to achieve the effect of true shared memory, in which if a correct processor reads a value, then all other processors can read the same value after the correct processor has done so.

We encountered the same difficulty in the asynchronous case, with the difference that in the asynchronous case things happen "eventually." If we adopt the same algorithm, whatever must happen eventually (asynchronous case) translates into happening in some finite number of rounds (synchronous case). Moreover, if something that is supposed to happen for a correct processor in the asynchronous case does not happen for a processor in the synchronous case within a prescribed number of rounds, the other processors infer that the processor involved is faulty and announce it as faulty. Thus, the asynchronous algorithm for reading a value which we gave in the previous section translates to (code for processor P_i):

1. Round 1: $v := read(cell)$.
2. Round 2: Write v, read values for v from all nonfaulty processors.
3. Round 3: If $2f + 1$ for value $v \neq \perp$ in Round 2, write $confirm(v)$; else, write $v := faulty$, read cells.

4. Round 4: If $2f + 1$ for v in Round 3 or if $f + 1$ for $confirm(v)$, write $confirm(v)$; else, $v := faulty$. If $2f + 1$ $confirm(v)$ up to now, then $accept(v)$. If $v = faulty$ and $accept(v)$, consider the processor that wrote v faulty.

A little thought shows that the "eventual" of the asynchronous case translates into a single round in the synchronous case. If a value is accepted, it will be accepted by all correct processors in the next round. If a value is not accepted by the end of the third round, then all correct processors propose $v := faulty$. In any case, at the end of the fourth round, either a real value or $v = faulty$ or both will be accepted. After a processor P_i is accepted as faulty, at the next round (which may be at the next phase) all processors will accept it as faulty and will ignore it. Thus, ignoring for the moment the problem that a faulty processor may write incorrect values, we have achieved the effect of write-once shared memory with fail-stop.

To deal with the issue of a faulty processor writing values a correct processor would not write, we can check on previous writes and see whether the processor observes its protocol. Here we do not face the difficulty we faced in the asynchronous case: a processor cannot avoid reading a value of a correct processor, and a processor may or may not (either is possible) read a value from a processor that failed. Nevertheless, a processor's value may be inconsistent with the values of correct processors. We notice that correct processors are consistent among themselves. Processors then can draw a "conflict" graph and, by eliminating edges to remove conflicts, declare the corresponding processors faulty. Since an edge contains at least one faulty processor, we can afford the cost of failing a correct processor.

We now argue a lower bound of $f + 1$ rounds for consensus for any of our three failure modes. It suffices to prove this bound for fail-stop failure, because fail-stop is a special case of omission failure and of Byzantine failure. Suppose an $(m < t + 1)$-rounds consensus algorithm exists for the fail-stop type of failure. We emulate the synchronous system by a 1-resilient asynchronous system in iterated atomic-snapshot shared memory. At a round, there is a unique single processor whose value other processors may fail to read. We consider such a processor to be faulty. We have seen that, without any extra cost, if a correct processor fails to read a value of processor P_j, then all correct processors will consider P_j faulty in the next round, which amounts to fail-stop. Thus, the asynchronous system emulates m rounds of the synchronous system. At each simulated round, there is at most one fault, for a total of at most f faults. This means that the emulated algorithm should result in consensus in the 1-resilient asynchronous system, which is impossible.

We can apply the same logic for set consensus and show that with f faults and k-set consensus, we need at least $\lfloor f/k \rfloor + 1$ rounds. This involves simulating the algorithm in a k-resilient asynchronous atomic-snapshot shared-memory system in which k-set consensus is impossible. (The first algorithm in this section automatically solves k-set consensus in the prescribed number of rounds; see [11]).

Notice that the above impossibility result for the asynchronous model translated into a lower bound on round complexity in the synchronous model. We now present the failure-detector framework, a framework in which speed mismatch is "transformed" into failure, and thus unifying synchrony and asynchrony.

48.5 Failure Detectors: A Bridge Between Synchronous and Asynchronous Systems

In the preceding section, we have seen that a 1-resilient asynchronous system looks like a synchronous system in which at each round a single but arbitrary processor may fail. Thus, synchronous systems can achieve consensus because in this setting when one processor considers another processor faulty, it is indeed the case, and one processor is never faulty. In the asynchronous setting, the processor considered faulty in a round is not faulty, only slow; we make a mistake in declaring it faulty.

Chandra and Toueg [13] have investigated the power of systems via the properties of their of augmenting subsystem called **failure-detector** (FD) that issues faulty declarations. The most interesting FDs are those with properties called S and $\diamond S$.

FD S can be described as follows:

- All processors that take finitely many steps in the underlying computation (faulty processors) will eventually be declared forever faulty by all the local FDs of processors that took infinitely many steps (correct processors), and
- Some correct processor is never declared faulty by the local FDs of correct processors.

In $\diamond S$, these properties hold eventually. Chandra, Hadzilacos, and Toueg [12] then showed that of all the FDs that provide for consensus, $\diamond S$ is the weakest: any FD that provides for consensus can nonblocking emulate $\diamond S$.

Thus, in a sense, if we take a system with timing constraints and call it synchronous if the constraints provide for consensus, then we have an alternative way of checking on whether the constraints provide for nonblocking emulation of $\diamond S$.

In many systems, this alternative technique is natural. For instance, consider a system in which the pending operations stay pending for at most some bounded but otherwise unknown real time and the processors can delay themselves for times that grow longer and longer without bound (of course, a delay operation is not pending until the prescribed delay time has elapsed). It is easy to see that this system can nonblocking implement $\diamond S$ and, as a result, achieve consensus. Thus, we have a variety of consensus algorithms from which to choose. In fact, we can transform any synchronous consensus algorithm for omission to an algorithm for $\diamond S$. The transformation proceeds in two stages. We first transform a synchronous omission algorithm A to an algorithm B for consensus in S. We accomplish this by nonblocking emulating A round by round, where each processor waits on the others until either the expected value is observed or the processor waited on is declared faulty by the FD. Such failure can be considered omission failure. Since in S, one of the processors is never declared faulty, we get that the number of omission faults is less than n, and the emulation results in consensus.

To transform a consensus algorithm A in S to a consensus algorithm B for $\diamond S$, we use a layer algorithm called Eventual. We assume A is safe in the sense that when running A in $\diamond S$, the liveness conditions that result in consensus are weakened but the safety conditions that make processors in A over S agree or preserve validity (output has to be one of the inputs) are maintained.

Algorithm Eventual has the property that a processor's output consists of either committing to some input value or adopting one.

1. If all processors start with the same input, then all commit to that input.
2. If one processor commits to an input value, then all other processors commit to or adopt that value.

The consensus algorithm B for shared memory with $\diamond S$ is to run alternately with A followed by Eventual. The output of A is the input to Eventual, and the output of Eventual is the input to A. When a processor commits to a value in Eventual, it outputs it as the output of B. Algorithm Eventual is simple. Processors repeatedly post their input values and take snapshots until the number of postings exceeds n. If a processor observes only a single value, it commits to that value; otherwise, it adopts a plurality value.

The notion of FDs is very appealing. It unifies synchronous and asynchronous systems. In the FD framework, all systems are of the same type but each system possesses FDs with distinctive properties. Research into the question of how this unified view can be exploited in distributed computing—for example, it might enable understanding of the "topology" of FDs—has hardly begun.

Another direction of possible research is to enrich the semantics of failure-detector. If we take the iterated snapshot system we may consider attaching a separate failure detector subsystem to each layer. A processor which is "late" arriving to a layer is declared faulty by that layer subsystem. We may now investigate the power of such system as a function of the properties of their failure detectors. We can for instance model a **t-resilient system** as a system in which at most t processors will be declared faulty at a layer. When one

considers such a system, the dichotomy of systems between synchronous and asynchronous is completely blurred. The traditional failure detector of Chandra and Toueg cannot capture such a property.

48.6 Research Issues and Summary

In this chapter, we have considered a body of fairly recent research in distributed computing whose results are related and draw upon one another. We have argued that a unified view of these results derives from the synergy between the application of results from topology and the use of the interpretive power of distributed computing to derive transformations that make topology apply.

Many interesting and important questions, aside from matters of complexity, remain. The most practical of these questions concern computations that are amenable to algorithms whose complexity is a function of the concurrency rather than the size of the system. Such algorithms are usually referred to as **fast.** Examples of tasks that can be solved by application of fast algorithms are numerous, but a fundamental understanding of exactly what, why, and how computations are amenable to such algorithms is lacking. Extension of the theory presented in this chapter to nonterminating tasks and to long-lived objects is next on the list of questions.

48.7 Defining Terms

t-Resilient system: A system in which at most t processors are faulty.

0-Simplex: A singleton set. item[1-Dimensional subdivided simplex:] An embedding of 1-simplex that is partitioned into 1-simplexes (a path).

1-Simplex: A set consisting of two elements.

Atomic snapshot: An atomic read operation that returns the entire shared memory.

Chain-of-runs: A sequence of runs in which two consecutive runs are indistinguishable to a processor.

Cleanround: A round in which no new faulty behavior is exhibited.

Communication-closed-layers: A distributed program partitioned to layers that communicate remotely only among themselves and communicate locally unidirectionally.

Complete problem: A problem in a model that characterizes the set of all other problems in the model in the sense that they are reducible to it.

Complex: A set of simplexes that is closed under subset.

Consensus problem: A decision task in which all processors agree on a single input value.

Election: A consensus over the IDs as inputs.

Failure-detector: An oracle that updates a processor on the operational status of the rest of the processors.

Fast solution: A solution to a problem whose complexity depends on the number of participating processors rather than the size of the entire system.

Faulty processor: A processor whose view is output finitely many times in a run.

Full-information protocol: A protocol that induces the finest partition of the set of runs, compared to any other protocol in the model.

Immediate snapshots: A restriction of the atomic snapshots that achieves a certain closure property that atomic snapshots do not have.

Link (of a simplex in a complex): The set of all simplexes in a complex that are contained in a simplex with the given simplex.

Nonblocking (emulation): An emulation that may increase the set of faulty processors.

Oblivious (to a parameter): Not a function of that parameter.

Outputs: Map over views that are eventually known to all nonfaulty processors.

Participating (set of processors): Processors in a run that are not sleeping.

Processor: A sequential piece of code.

Protocol: A set of processors whose codes refer to common communication objects.

Run: An infinite sequence of global "instantaneous-description" of a system, such that one element is the preceding one after the application of a pending operation.

Safe-bit: A single-writer single-reader register bit whose read is defined and returns the last value written only if does not overlap a write operation to the register.

Sleeping (in a run): A processor whose state in a run does not change.

Solo-execution: A run in which only a single processor is not sleeping.

Task: A relation from inputs and set of participating processors to outputs.

View: A set of runs compatible with a processor's local state.

Wait-free (solution): A solution to a nontermination problem in which a processor that is not faulty outputs infinitely many output values.

Acknowledgment

I am grateful to Hagit Attiya for detailed illuminating comments on an earlier version of this chapter.

Further Information

Current research on the theoretical aspects of distributed computing is reported in the proceedings of the annual ACM Symposium on Principles of Distributed Computing (PODC) and the annual International Workshop on Distributed Algorithms on Graphs (WDAG). Relatively recent books and surveys are [6, 21, 26].
