Preface

The purpose of *Algorithms and Theory of Computation Handbook* is to be a comprehensive treatment of the subject for computer scientists, engineers, and other professionals in related scientific and engineering disciplines. Its focus is to provide a compendium of fundamental topics and techniques for professionals, including practicing engineers, students, and researchers. The handbook is organized around the main subject areas of the discipline, and also contains chapters from applications areas that illustrate how the fundamental concepts and techniques come together to provide elegant solutions to important practical problems.

The contents of each chapter were chosen so that the computer professional or engineer has a high probability of finding significant information on a topic of interest. While the reader may not find in a chapter all the specialized topics, nor will the coverage of each topic be exhaustive, the reader should be able to obtain sufficient information for initial inquiries and a number of references to the current in-depth literature. Each chapter contains a section on "Research Issues and Summary" where the reader is given a summary of research issues in the subject matter of the chapter, as well as a brief summary of the chapter. Each chapter also contains a section called "Defining Terms" that provides a list of terms and definitions that might be useful to the reader. The last section of each chapter is called "Further Information" and directs the reader to additional sources of information in the chapter's subject area; these are the sources that contain more detail than the chapter can possibly provide. As appropriate, they include information on societies, seminars, conferences, databases, journals, etc.

It is a pleasure to extend my thanks to the people and organizations who made this handbook possible. My sincere thanks go to the chapter authors; it has been an honor and a privilege to work with such a dedicated and talented group. Purdue University and the universities and research laboratories with which the authors are affiliated deserve credit for providing the computing facilities and intellectual environment for this project. It is also a pleasure to acknowledge the support of CRC Press and its people: Bob Stern, Jerry Papke, Nora Konopka, Jo Gilmore, Suzanne Lassandro, Susan Fox, and Dr. Clovis L. Tondo. Special thanks are due to Bob Stern for suggesting to me this project and continuously supporting it thereafter. Finally, my wife Karen and my children Christina and Nadia deserve credit for their generous patience during the many weekends when I was in my office, immersed in this project.

Algorithm Design and Analysis Techniques[1]

Edward M. Reingold
University of Illinois at Urbana-Champaign

We outline the basic methods of algorithm design and analysis that have found application in the manipulation of discrete objects such as lists, arrays, sets, graphs, and geometric objects such as points, lines, and polygons. We begin by discussing **recurrence relations** and their use in the analysis of algorithms. Then we discuss some specific examples in algorithm analysis, **sorting** and **priority queues.** In the next three sections, we explore three important techniques of algorithm design—**divide-and-conquer, dynamic programming,** and **greedy heuristics.** Finally, we examine establishing lower bounds on the cost of any algorithm for a problem.

1.1 Analyzing Algorithms

It is convenient to classify algorithms based on the relative amount of time they require: how fast does the time required grow as the size of the problem increases? For example, in the case of arrays, the "size of the problem" is ordinarily the number of elements in the array. If the size of the problem is measured by a variable n, we can express the time required as a function of n, $T(n)$. When this function $T(n)$ grows rapidly, the algorithm becomes unusable for large n; conversely, when $T(n)$ grows slowly, the algorithm remains useful even when n becomes large.

[1]Supported in part by the National Science Foundation, grant numbers CCR-93-20577 and CCR-95-30297. The comments of Tanya Berger-Wolf, Ken Urban, and an anonymous referee are gratefully acknowledged.

We say an algorithm is $\Theta(n^2)$ if the time it takes quadruples (asymptotically) when n doubles; an algorithm is $\Theta(n)$ if the time it takes doubles when n doubles; an algorithm is $\Theta(\log n)$ if the time it takes increases by a constant, independent of n, when n doubles; an algorithm is $\Theta(1)$ if its time does not increase at all when n increases. In general, an algorithm is $\Theta(T(n))$ if the time it requires on problems of size n grows proportionally to $T(n)$ as n increases. Table 1.1 summarizes the common growth rates encountered in the analysis of algorithms.

TABLE 1.1 Common Growth Rates of Times of Algorithms

Rate of Growth	Comment	Examples
$\Theta(1)$	Time required is constant, independent of problem size	Expected time for hash searching
$\Theta(\log \log n)$	Very slow growth of time required	Expected time of interpolation search of n elements
$\Theta(\log n)$	Logarithmic growth of time required—doubling the problem size increases the time by only a constant amount	Computing x^n; binary search of an array of n elements
$\Theta(n)$	Time grows linearly with problem size—doubling the problem size doubles the time required	Adding/subtracting n-digit numbers; linear search of an n-element array
$\Theta(n \log n)$	Time grows worse than linearly, but not much worse—doubling the problem size somewhat more than doubles the time required	Merge sort or heapsort of n elements; lower bound on comparison-based sorting of n elements
$\Theta(n^2)$	Time grows quadratically—doubling the problem size quadruples the time required	Simple-minded sorting algorithms
$\Theta(n^3)$	Time grows cubically—doubling the problem size results in an 8-fold increase in the time required	Ordinary matrix multiplication
$\Theta(c^n)$	Time grows exponentially—increasing the problem size by 1 results in a c-fold increase in the time required; doubling the problem size *squares* the time required	Some traveling salesman problem algorithms based on exhaustive search

The analysis of an algorithm is often accomplished by finding and solving a recurrence relation that describes the time required by the algorithm. The most commonly occurring families of recurrences in the analysis of algorithms are linear recurrences and divide-and-conquer recurrences. In the following subsection we describe the "method of operators" for solving linear recurrences; in the next subsection we describe how to obtain an asymptotic solution to divide-and-conquer recurrences by transforming such a recurrence into a linear recurrence.

Linear Recurrences

A *linear recurrence with constant coefficients* has the form

$$c_0 a_n + c_1 a_{n-1} + c_2 a_{n-2} + \cdots + c_k a_{n-k} = f(n) \,, \tag{1.1}$$

for some constant k, where each c_i is constant. To solve such a recurrence for a broad class of functions f (that is, to express a_n in closed form as a function of n) by the *method of operators*, we consider two basic operators on sequences: $\mathcal{S}$, which shifts the sequence left,

$$\mathcal{S}\,\langle a_0, a_1, a_2, \ldots\rangle = \langle a_1, a_2, a_3, \ldots\rangle \;,$$

and C, which, for any constant C, multiplies each term of the sequence by C:

$$C\,\langle a_0, a_1, a_2, \ldots\rangle = \langle Ca_0, Ca_1, Ca_2, \ldots\rangle \;.$$

These basic operators on sequences allow us to construct more complicated operators by sums and products of operators. The sum $(A + B)$ of operators A and B is defined by

$$(A + B)\,\langle a_0, a_1, a_2, \ldots\rangle = A\,\langle a_0, a_1, a_2, \ldots\rangle + B\,\langle a_0, a_1, a_2, \ldots\rangle \;.$$

The product AB is the composition of the two operators:

$$(AB)\,\langle a_0, a_1, a_2, \ldots\rangle = A\,(B\,\langle a_0, a_1, a_2, \ldots\rangle)\ .$$

Thus, for example,

$$\left(\mathcal{S}^2 - 4\right)\langle a_0, a_1, a_2, \ldots\rangle = \langle a_2 - 4a_0, a_3 - 4a_1, a_4 - 4a_2, \ldots\rangle\ ,$$

which we write more briefly as

$$\left(\mathcal{S}^2 - 4\right)\langle a_i\rangle = \left\langle a_{i+2} - 4a_i\right\rangle\ .$$

With the operator notation, we can rewrite Eq. (1.1) as

$$P(\mathcal{S})\,\langle a_i\rangle = \langle f(i)\rangle\ ,$$

where

$$P(\mathcal{S}) = c_0\mathcal{S}^k + c_1\mathcal{S}^{k-1} + c_2\mathcal{S}^{k-2} + \cdots + c_k$$

is a polynomial in $\mathcal{S}$.

Given a sequence $\langle a_i\rangle$, we say that the operator A *annihilates* $\langle a_i\rangle$ if $A\langle a_i\rangle = \langle 0\rangle$. For example, $\mathcal{S}^2 - 4$ annihilates any sequence of the form $\langle u2^i + v(-2)^i\rangle$, with constants u and v. Here are two important facts about annihilators:

FACT 1.1 *The sum and product of operators are associative, commutative, and product distributes over sum. In other words, for operators A, B, and C,*

$$\begin{array}{lcllcl} (A+B)+C & = & A+(B+C) & (AB)C & = & A(BC)\ , \\ A+B & = & B+A & AB & = & BA\ , \end{array}$$

and

$$A(B+C) = AB + AC\ .$$

As a consequence, if A annihilates $\langle a_i\rangle$, then A annihilates $B\langle a_i\rangle$ for any operator B. This implies that the product *of two annihilators annihilates the* sum *of the sequences annihilated by the two operators—that is, if A annihilates $\langle a_i\rangle$ and B annihilates $\langle b_i\rangle$, then AB annihilates $\langle a_i + b_i\rangle$.*

FACT 1.2 *The operator $(\mathcal{S} - c)$, when applied to $\langle c^i \times p(i)\rangle$ with $p(i)$ a polynomial in i, results in a sequence $\langle c^i \times q(i)\rangle$ with $q(i)$ a polynomial of degree one less than $p(i)$. This implies that the operator $(\mathcal{S} - c)^{k+1}$ annihilates $\langle c^i \times$ (a polynomial in i of degree $k)\rangle$.*

These two facts mean that determining the annihilator of a sequence is tantamount to determining the sequence; moreover, it is straightforward to determine the annihilator from a recurrence relation. For example, consider the Fibonacci recurrence

$$\begin{array}{rcl} F_0 & = & 0 \\ F_1 & = & 1 \\ F_{i+2} & = & F_{i+1} + F_i\ . \end{array}$$

The last line of this definition can be rewritten as $F_{i+2} - F_{i+1} - F_i = 0$, which tells us that $\langle F_i\rangle$ is annihilated by the operator

$$\mathcal{S}^2 - \mathcal{S} - 1 = (\mathcal{S} - \phi)\,(\mathcal{S} + 1/\phi)\ ,$$

where $\phi = (1+\sqrt{5})/2$. Thus we conclude from Fact 1.1 that $\langle F_i \rangle = \langle a_i + b_i \rangle$ with $(\mathcal{S} - \phi)\langle a_i \rangle = \langle 0 \rangle$ and $(\mathcal{S} - 1/\phi)\langle b_i \rangle = \langle 0 \rangle$. Fact 1.2 now tells us that

$$F_i = u\phi^i + v(-\phi)^{-i} ,$$

for some constants u and v. We can now use the initial conditions $F_0 = 0$ and $F_1 = 1$ to determine u and v: These initial conditions mean that

$$\begin{aligned} u\phi^0 + v(-\phi)^{-0} &= 0 \\ u\phi^1 + v(-\phi)^{-1} &= 1 \end{aligned}$$

and these linear equations have the solution

$$u = v = 1/\sqrt{5} ,$$

and hence

$$F_i = \phi^i/\sqrt{5} + (-\phi)^{-i}/\sqrt{5} .$$

In the case of the similar recurrence,

$$\begin{aligned} G_0 &= 0 \\ G_1 &= 1 \\ G_{i+2} &= G_{i+1} + G_i + i , \end{aligned}$$

the last equation tells us that

$$\left(\mathcal{S}^2 - \mathcal{S} - 1\right)\langle G_i \rangle = \langle i \rangle ,$$

so the annihilator for $\langle G_i \rangle$ is $(\mathcal{S}^2 - \mathcal{S} - 1)(\mathcal{S} - 1)^2$, since $(\mathcal{S} - 1)^2$ annihilates $\langle i \rangle$ (a polynomial of degree 1 in i) and hence the solution is

$$G_i = u\phi^i + v(-\phi)^{-i} + \text{(a polynomial of degree 1 in i)} ,$$

that is,

$$G_i = u\phi^i + v(-\phi)^{-i} + wi + z .$$

Again, we use the initial conditions to determine the constants u, v, w, and z.

In general, then, to solve the recurrence (1.1), we factor the annihilator

$$P(\mathcal{S}) = c_0\mathcal{S}^k + c_1\mathcal{S}^{k-1} + c_2\mathcal{S}^{k-2} + \cdots + c_k ,$$

multiply it by the annihilator for $\langle f(i) \rangle$, write down the form of the solution from this product (which is the annihilator for the sequence $\langle a_i \rangle$), and then use the initial conditions for the recurrence to determine the coefficients in the solution.

Divide-and-Conquer Recurrences

The divide-and-conquer paradigm of algorithm construction that we discuss in Section 1.3 leads naturally to divide-and-conquer recurrences of the type

$$T(n) = g(n) + uT(n/v) ,$$

for constants u and v, $v > 1$, and sufficient initial values to define the sequence $\langle T(0), T(1), T(2), \ldots \rangle$. The growth rates of $T(n)$ for various values of u and v are given in Table 1.2. The growth rates in this table

TABLE 1.2 Rate of Growth of the Solution to the Recurrence $T(n) = g(n) + uT(n/v)$, the Divide-and-Conquer Recurrence Relations

$g(n)$	u, v	Growth Rate of $T(n)$
$\Theta(1)$	$u = 1$	$\Theta(\log n)$
	$u \neq 1$	$\Theta(n^{\log_v u})$
$\Theta(\log n)$	$u = 1$	$\Theta[(\log n)^2]$
	$u \neq 1$	$\Theta(n^{\log_v u})$
$\Theta(n)$	$u < v$	$\Theta(n)$
	$u = v$	$\Theta(n \log n)$
	$u > v$	$\Theta(n^{\log_v u})$
$\Theta(n^2)$	$u < v^2$	$\Theta(n^2)$
	$u = v^2$	$\Theta(n^2 \log n)$
	$u > v^2$	$\Theta(n^{\log_v u})$

Note: The variables u and v are Positive Constants, Independent of n, and $v > 1$.

are derived by transforming the divide-and-conquer recurrence into a linear recurrence for a subsequence of $\langle T(0), T(1), T(2), \ldots \rangle$.

To illustrate this method, we derive the penultimate line in Table 1.2. We want to solve

$$T(n) = n^2 + v^2 T(n/v) \ ,$$

so we want to find a subsequence of $\langle T(0), T(1), T(2), \ldots \rangle$ that will be easy to handle. Let $n_k = v^k$; then,

$$T(n_k) = n_k^2 + v^2 T(n_k/v) \ ,$$

or

$$T\left(v^k\right) = v^{2k} + v^2 T\left(v^{k-1}\right) \ .$$

Defining $t_k = T(v^k)$,

$$t_k = v^{2k} + v^2 t_{k-1} \ .$$

The annihilator for t_k is then $(\mathcal{S} - v^2)^2$, and thus

$$t_k = v^{2k}(ak + b) \ ,$$

for constants a and b. Since $n_k = v^k$, $k = \log_v n_k$, so we can express the solution for t_k in terms of $T(n)$,

$$T(n) \approx t_{\log_v n} = v^{2\log_v n}\left(a\log_v n + b\right) = an^2 \log_v n + bn^2 \ ,$$

or

$$T(n) = \Theta\left(n^2 \log n\right) \ .$$

1.2 Some Examples of the Analysis of Algorithms

In this section we introduce the basic ideas of algorithms analysis by looking at some practical problems of maintaining a collection of n objects and retrieving objects based on their relative size. For example, how can we determine the smallest of the elements? Or, more generally, how can we determine the kth largest of the elements? What is the running time of such algorithms in the worst case? Or, on the average, if all $n!$ permutations of the input are equally likely? What if the set of items is dynamic—that is, the set changes through insertions and deletions—how efficiently can we keep track of, say, the largest element?

Sorting

How do we rearrange an array of n values `x[1]`, `x[2]`, ..., `x[n]` so that they are in perfect order—that is, so that `x[1]` $\leq$ `x[2]` $\leq \ldots \leq$ `x[n]`? The simplest way to put the values in order is to mimic what we might do by hand: take item after item and insert each one into the proper place among those items already inserted:

```
 1    void insert (float x[], int i, float a) {
 2      // Insert a into x[1] ... x[i]
 3      // x[1] ... x[i-1] are sorted;  x[i] is unoccupied
 4      if (i == 1 || x[i-1] <= a)
 5        x[i] = a;
 6      else {
 7        x[i] = x[i-1];
 8        insert(x, i-1, a);
 9      }
10    }
11
12    void insertionSort (int n, float x[]) {
13      // Sort  x[1] ... x[n]
14      if (n > 1) {
15        insertionSort(n-1, x);
16        insert(x, n, x[n]);
17      }
18    }
```

To determine the time required in the worst case to sort n elements with `insertionSort`, we let t_n be the time to sort n elements and derive and solve a recurrence relation for t_n. We have

$$t_n = \begin{cases} \Theta(1) & \text{if } n = 1, \\ t_{n-1} + s_{n-1} + \Theta(1) & \text{otherwise}, \end{cases}$$

where s_m is the time required to insert an element in place among m elements using `insert`. The value of s_m is also given by a recurrence relation:

$$s_m = \begin{cases} \Theta(1) & \text{if } m = 1, \\ s_{m-1} + \Theta(1) & \text{otherwise}. \end{cases}$$

The annihilator for $\langle s_i \rangle$ is $(\mathcal{S}-1)^2$, so $s_m = \Theta(m)$. Thus the annihilator for $\langle t_i \rangle$ is $(\mathcal{S}-1)^3$, so $t_n = \Theta(n^2)$. The analysis of the average behavior is nearly identical; only the constants hidden in the Θ-notation change.

We can design better sorting methods using the divide-and-conquer idea of the next section. These algorithms avoid $\Theta(n^2)$ worst-case behavior, working in time $\Theta(n \log n)$. We can also achieve time $\Theta(n \log n)$ by using a clever way of viewing the array of elements to be sorted as a tree: consider `x[1]` as the root of the tree and, in general, `x[2*i]` is the root of the left subtree of `x[i]` and `x[2*i+1]` is the root of the right subtree of `x[i]`. If we further insist that parents be greater than or equal to children, we have a **heap**; Fig. 1.1 shows a small example.

A heap can be used for sorting by observing that the largest element is at the root, that is, `x[1]`; thus to put the largest element in place, we swap `x[1]` and `x[n]`. To continue, we must restore the heap property which may now be violated at the root. Such restoration is accomplished by swapping `x[1]` with its larger child, if that child is larger than `x[1]`, and the continuing to swap it downward until either it reaches the bottom or a spot where it is greater or equal to its children. Since the tree-cum-array has height $\Theta(\log n)$, this restoration process takes time $\Theta(\log n)$. Now, with the heap in `x[1]` to `x[n-1]` and

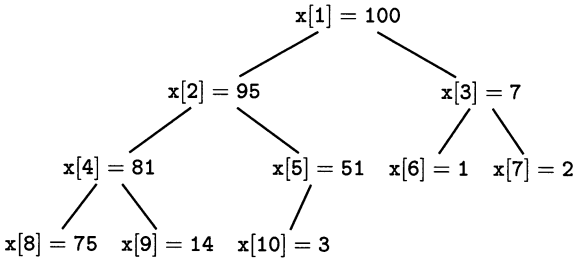

FIGURE 1.1 A heap—that is, an array, interpreted as a binary tree.

`x[n]` the largest value in the array, we can put the second largest element in place by swapping `x[1]` and `x[n-1]`; then we restore the heap property in `x[1]` to `x[n-2]` by propagating `x[1]` downward—this takes time $\Theta(\log(n-1))$. Continuing in this fashion, we find we can sort the entire array in time

$$\Theta\left(\log n + \log(n-1) + \cdots + \log 1\right) .$$

To evaluate this sum, we bound it from above and below, as follows. By ignoring the smaller half of the terms, we bound it from below:

$$\begin{aligned} \log n + \log(n-1) + \cdots + \log 1 &\geq \underbrace{\log \frac{n}{2} + \log \frac{n}{2} + \cdots + \log \frac{n}{2}}_{\frac{n}{2} \text{ times}} \\ &= \frac{n}{2} \log n \\ &= \Theta(n \log n) ; \end{aligned}$$

and by overestimating all of the terms we bound it from above:

$$\begin{aligned} \log n + \log(n-1) + \cdots + \log 1 &\leq \underbrace{\log n + \log n + \cdots + \log n}_{n \text{ times}} \\ &= n \log n \\ &= \Theta(n \log n) . \end{aligned}$$

The initial creation of the heap from an unordered array is done by applying the above restoration process successively to `x[n/2]`, `x[n/2-1]`, ..., `x[1]`, which takes time $\Theta(n)$.

Hence, we have the following $\Theta(n \log n)$ sorting algorithm:

```
1     void heapify (int n, float x[], int i) {
2       // Repair heap property below x[i] in x[1] ... x[n]
3       int largest = i;  // largest of x[i], x[2*i], x[2*i+1]
4       if (2*i <= n && x[2*i] > x[i])
5         largest = 2*i;
6       if (2*i+1 <= n && x[2*i+1] > x[largest])
7         largest = 2*i+1;
8       if (largest != i) {
9         // swap x[i] with larger child and repair heap below
10        float t = x[largest]; x[largest] = x[i]; x[i] = t;
11        heapify(n, x, largest);
12      }
13    }
```

```
14
15      void makeheap (int n, float x[]) {
16        // Make x[1] ... x[n] into a heap
17        for (int i=n/2; i>0; i--)
18          heapify(n, x, i);
19      }
20
21      void heapsort (int n, float x[]) {
22        // Sort  x[1] ... x[n]
23        float t;
24        makeheap(n, x);
25        for (int i=n; i>1; i--) {
26          // put x[1] in place and repair heap
27          t = x[1]; x[1] = x[i]; x[i] = t;
28          heapify(i-1, x, 1);
29        }
30      }
```

We will see in Section 1.6 that no sorting algorithm can be guaranteed always to use time less than $\Theta(n \log n)$. Thus, in a theoretical sense, heapsort is "asymptotically optimal" (but there are algorithms that perform better in practice).

Priority Queues

Aside from its application to sorting, the heap is an interesting data structure in its own right. In particular, heaps provide a simple way to implement a *priority queue*—a priority queue is an abstract data structure that keeps track of a dynamically changing set of values allowing the following operations:

`create`: Create an empty priority queue.

`insert`: Insert a new element into a priority queue.

`decrease`: Decrease the value of an element in a priority queue.

`minimum`: Report the smallest element in a priority queue.

`deleteMinimum`: Delete the smallest element in a priority queue.

`delete`: Delete an element in a priority queue.

`merge`: Merge two priority queues.

A heap can implement a priority queue by altering the heap property to insist that parents are less than or equal to their children, so that the smallest value in the heap is at the root, that is, in the first array position. Creation of an empty heap requires just the allocation of an array, an $\Theta(1)$ operation; we assume that once created, the array containing the heap can be extended arbitrarily at the right end. Inserting a new element means putting that element in the $(n+1)$st location and "bubbling it up" by swapping it with its parent until it reaches either the root or a parent with a smaller value. Since a heap has logarithmic height, insertion to a heap of n elements thus requires worst-case time $O(\log n)$. Decreasing a value in a heap requires only a similar $O(\log n)$ "bubbling up." The smallest element of such a heap is always at the root, so reporting it takes $\Theta(1)$ time. Deleting the minimum is done by swapping the first and last array positions, bubbling the new root value downward until it reaches its proper location, and truncating the array to eliminate the last position. Delete is handled by decreasing the value so that it is the least in the heap and then applying the `deleteMinimum` operation; this takes a total of $O(\log n)$ time.

The merge operation, unfortunately, is not so economically accomplished—there is little choice but to create a new heap out of the two heaps in a manner similar to the `makeheap` function in heap sort. If there are a total of n elements in the two heaps to be merged, this re-creation will require time $O(n)$.

There are better data structures than a heap for implementing priority queues, however. In particular, the *Fibonacci heap* provides an implementation of priority queues in which the delete and `deleteMinimum` operations take $O(\log n)$ time and the remaining operations take $\Theta(1)$ time, *provided we consider the time required for a sequence of priority queue operations, rather than the individual times of each operation.* That is, we must consider the cost of the individual operations *amortized over the sequence of operations*: Given a sequence of n priority queue operations, we will compute the total time $T(n)$ for all n operations. In doing this computation, however, we do not simply add the costs of the individual operations; rather, we subdivide the cost of each operation into two parts, the *immediate cost* of doing the operation and the *long-term savings* that result from doing the operation—the long-term savings represent costs *not* incurred by later operations as a result of the present operation. The immediate cost minus the long-term savings give the **amortized cost** of the operation.

It is easy to calculate the immediate cost (time required) of an operation, but how can we measure the long-term savings that result? We imagine that the data structure has associated with it a bank account; at any given moment the bank account must have a nonnegative balance. When we do an operation that will save future effort, we are making a deposit to the savings account and when, later on, we derive the benefits of that earlier operation we are making a withdrawal from the savings account. Let $\mathcal{B}(i)$ denote the balance in the account after the ith operation, $\mathcal{B}(0) = 0$. We define the amortized cost of the ith operation to be

$$\begin{aligned}\text{amortized cost of } i\text{th operation} &= (\text{immediate cost of } i\text{th operation}) \\ &\quad + (\text{change in bank account}) \\ &= (\text{immediate cost of } i\text{th operation}) + (\mathcal{B}(i) - \mathcal{B}(i-1)) .\end{aligned}$$

Since the bank account $\mathcal{B}$ can go up or down as a result of the ith operation, the amortized cost may be less than or more than the immediate cost. By summing the previous equation, we get

$$\begin{aligned}\sum_{i=1}^{n}(\text{amortized cost of } i\text{th operation}) &= \sum_{i=1}^{n}(\text{immediate cost of } i\text{th operation}) \\ &\quad + (\mathcal{B}(n) - \mathcal{B}(0)) \\ &= (\text{total cost of all } n \text{ operations}) + \mathcal{B}(n) \\ &\geq \text{total cost of all } n \text{ operations} \\ &= T(n) ,\end{aligned}$$

because $\mathcal{B}(i)$ is nonnegative. Thus defined, the sum of the amortized costs of the operations gives us an upper bound on the total time $T(n)$ for all n operations.

It is important to note that the function $\mathcal{B}(i)$ is not part of the data structure, but is just our way to measure how much time is used by the sequence of operations. As such, we can choose *any rules* for $\mathcal{B}$, provided $\mathcal{B}(0) = 0$ and $\mathcal{B}(i) \geq 0$ for $i \geq 1$. Then, the sum of the amortized costs defined by

$$\text{amortized cost of } i\text{th operation} = (\text{immediate cost of } i\text{th operation}) + (\mathcal{B}(i) - \mathcal{B}(i-1))$$

bounds the overall cost of the operation of the data structure.

Now, to apply this method to priority queues. A *Fibonacci heap* is a list of heap-ordered trees (not necessarily binary); since the trees are heap ordered, the minimum element must be one of the roots and we keep track of which root is the overall minimum. Some of the tree nodes are *marked*. We define

$$\begin{aligned}\mathcal{B}(i) &= (\text{number of trees after the } i\text{th operation}) \\ &\quad + K \times (\text{number of marked nodes after the } i\text{th operation}) ,\end{aligned}$$

where K is a constant that we will define precisely during the discussion below.

The clever rules by which nodes are marked and unmarked, and the intricate algorithms that manipulate the set of trees, are too complex to present here in their complete form, so we just briefly describe the simpler operations and show the calculation of their amortized costs:

`create`: To create an empty Fibonacci heap we create an empty list of heap-ordered trees. The immediate cost is $\Theta(1)$; since the numbers of trees and marked nodes are zero before and after this operation, $\mathcal{B}(i) - \mathcal{B}(i-1)$ is zero and the amortized time is $\Theta(1)$.

`insert`: To insert a new element into a Fibonacci heap we add a new one-element tree to the list of trees constituting the heap and update the record of what root is the overall minimum. The immediate cost is $\Theta(1)$. $\mathcal{B}(i) - \mathcal{B}(i-1)$ is also 1 since the number of trees has increased by 1, while the number of marked nodes is unchanged. The amortized time is thus $\Theta(1)$.

`decrease`: Decreasing an element in a Fibonacci heap is done by cutting the link to its parent, if any, adding the item as a root in the list of trees, and decreasing its value. Furthermore, the marked parent of a cut element is itself cut, and this process of cutting marked parents propagates upward in the tree. Cut nodes become unmarked, and the unmarked parent of a cut element becomes marked. The immediate cost of this operation is no more than kc, where c is the number of cut nodes and $k > 0$ is some constant. Now, letting $K = k + 1$, we see that if there were t trees and m marked elements before this operation, the value of $\mathcal{B}$ before the operation was $t + Km$. After the operation, the value of $\mathcal{B}$ is $(t+c) + K(m-c+2)$, so $\mathcal{B}(i) - \mathcal{B}(i-1) = (1-K)c + 2K$. The amortized time is thus no more than $kc + (1-K)c + 2K = \Theta(1)$ since K is constant.

`minimum`: Reporting the minimum element in a Fibonacci heap takes time $\Theta(1)$ and does not change the numbers of trees and marked nodes; the amortized time is thus $\Theta(1)$.

`deleteMinimum`: Deleting the minimum element in a Fibonacci heap is done by deleting that tree root, making its children roots in the list of trees. Then, the list of tree roots is "consolidated" in a complicated $O(\log n)$ operation that we do not describe. The result takes amortized time $O(\log n)$.

`delete`: Deleting an element in a Fibonacci heap is done by decreasing its value to $-\infty$ and then doing a `deleteMinimum`. The amortized cost is the sum of the amortized cost of the two operations, $O(\log n)$.

`merge`: Merging two Fibonacci heaps is done by concatenating their lists of trees and updating the record of which root is the minimum. The amortized time is thus $\Theta(1)$.

Notice that the amortized cost of each operation is $\Theta(1)$ except `deleteMinimum` and `delete`, both of which are $O(\log n)$.

1.3 Divide-and-Conquer Algorithms

One approach to the design of algorithms is to decompose a problem into subproblems that resemble the original problem, but on a reduced scale. Suppose, for example, that we want to compute x^n. We reason

that the value we want can be computed from $x^{\lfloor n/2 \rfloor}$ because

$$x^n = \begin{cases} 1 & \text{if } n = 0, \\ (x^{\lfloor n/2 \rfloor})^2 & \text{if } n \text{ is even}, \\ x \times (x^{\lfloor n/2 \rfloor})^2 & \text{if } n \text{ is odd}. \end{cases}$$

This recursive definition can be translated directly into

```
1     int power (int x, int n) {
2      // Compute the n-th power of x
3       if (n == 0)
4         return 1;
5       else {
6         int t = power(x, floor(n/2));
7         if ((n % 2) == 0)
8           return t*t;
9         else
10          return x*t*t;
11      }
12    }
```

To analyze the time required by this algorithm, we notice that the time will be proportional to the number of multiplication operations performed in lines 8 and 10, so the divide and conquer recurrence

$$T(n) = 2 + T(\lfloor n/2 \rfloor) ,$$

with $T(0) = 0$, describes the rate of growth of the time required by this algorithm. By considering the subsequence $n_k = 2^k$, we find, using the methods of the previous section, that $T(n) = \Theta(\log n)$. Thus above algorithm is considerably more efficient than the more obvious

```
1     int power (int k, int n) {
2      // Compute the n-th power of k
3       int product = 1;
4       for (int i = 1; i <= n; i++)
5         // at this point power is k*k*k*...*k (i times)
6         product = product * k;
7       return product;
8     }
```

which requires time $\Theta(n)$.

An extremely well-known instance of divide-and-conquer algorithm is **binary search** of an ordered array of n elements for a given element—we "probe" the middle element of the array, continuing in either the lower or upper segment of the array, depending on the outcome of the probe:

```
1     int binarySearch (int x, int w[], int low, int high) {
2       // Search for x among sorted array w[low..high]. The integer
3       // returned is either the location of x in w, or the location
4       // where x belongs.
5       if (low > high) // Not found
6         return low;
7       else {
8         int middle = (low+high)/2;
9         if (w[middle] < x)
```

```
10            return binarySearch(x, w, middle+1, high);
11          else if (w[middle] == x)
12            return middle;

13          else
14            return binarySearch(x, w, low, middle-1);
15        }
16      }
```

The analysis of binary search in an array of n elements is based on counting the number of probes used in the search, since all remaining work is proportional to the number of probes. But, the number of probes needed is described by the divide-and-conquer recurrence

$$T(n) = 1 + T(n/2) \ ,$$

with $T(0) = 0$, $T(1) = 1$. We find from Table 1.2 (the top line) that $T(n) = \Theta(\log n)$. Hence, binary search is much more efficient than a simple linear scan of the array.

To multiply two very large integers x and y, assume that x has exactly $n \geq 2$ decimal digits and y has at most n decimal digits. Let $x_{n-1}, x_{n-2}, \ldots, x_0$ be the digits of x and $y_{n-1}, y_{n-2}, \ldots, y_0$ be the digits of y (some of the most significant digits at the end of y may be zeros, if y is shorter than x), so that

$$x = 10^{n-1}x_{n-1} + 10^{n-2}x_{n-2} + \cdots + x_0 \ ,$$

and

$$y = 10^{n-1}y_{n-1} + 10^{n-2}y_{n-2} + \cdots + y_0 \ .$$

We apply the divide-and-conquer idea to multiplication by chopping x into two pieces, the most significant (leftmost) l digits and the remaining digits:

$$x = 10^l x_{\text{left}} + x_{\text{right}} \ ,$$

where $l = \lfloor n/2 \rfloor$. Similarly, chop y into two corresponding pieces:

$$y = 10^l y_{\text{left}} + y_{\text{right}} \ ,$$

because y has at most the number of digits that x does, y_{left} might be 0. The product $x \times y$ can be now written

$$\begin{aligned} x \times y &= \left(10^l x_{\text{left}} + x_{\text{right}}\right) \times \left(10^l y_{\text{left}} + y_{\text{right}}\right) , \\ &= 10^{2l} x_{\text{left}} \times y_{\text{left}} \\ &\quad + 10^l \left(x_{\text{left}} \times y_{\text{right}} + x_{\text{right}} \times y_{\text{left}}\right) \\ &\quad + x_{\text{right}} \times y_{\text{right}} \ . \end{aligned}$$

If $T(n)$ is the time to multiply two n-digit numbers with this method, then

$$T(n) = kn + 4T(n/2) \ ;$$

the kn part is the time to chop up x and y and to do the needed additions and shifts; each of these tasks involves n-digit numbers and hence $\Theta(n)$ time. The $4T(n/2)$ part is the time to form the four needed subproducts, each of which is a product of about $n/2$ digits.

The line for $g(n) = \Theta(n)$, $u = 4 > v = 2$ in Table 1.2 tells us that $T(n) = \Theta(n^{\log_2 4}) = \Theta(n^2)$, so the divide-and-conquer algorithm is no more efficient than the elementary-school method of multiplication. However, we can be more economical in our formation of subproducts:

$$\begin{aligned} x \times y &= \left(10^n x_{\text{left}} + x_{\text{right}}\right) \times \left(10^n y_{\text{left}} + y_{\text{right}}\right), \\ &= 10^{2n} A + 10^n C + B \ , \end{aligned}$$

where

$$\begin{aligned} A &= x_{\text{left}} \times y_{\text{left}} \\ B &= x_{\text{right}} \times y_{\text{right}} \\ C &= \left(x_{\text{left}} + x_{\text{right}}\right) \times \left(y_{\text{left}} + y_{\text{right}}\right) - A - B \ . \end{aligned}$$

The recurrence for the time required changes to

$$T(n) = kn + 3T\,(n/2) \ .$$

The kn part is the time to do the two additions that form $x \times y$ from A, B, and C and the two additions and the two subtractions in the formula for C; each of these six additions/subtractions involves n-digit numbers. The $3T(n/2)$ part is the time to (recursively) form the three needed products, each of which is a product of about $n/2$ digits. The line for $g(n) = \Theta(n)$, $u = 3 > v = 2$ in Table 1.2 now tells us that

$$T(n) = \Theta\left(n^{\log_2 3}\right) \ .$$

Now

$$\log_2 3 = \frac{\log_{10} 3}{\log_{10} 2} \approx 1.5849625\cdots \ ,$$

which means that this divide-and-conquer multiplication technique will be faster than the straightforward $\Theta(n^2)$ method for large numbers of digits.

Sorting a sequence of n values efficiently can be done using the divide-and-conquer idea. Split the n values arbitrarily into two piles of $n/2$ values each, sort each of the piles separately, and then merge the two piles into a single sorted pile. This sorting technique, pictured in Fig. 1.2, is called *merge sort*. Let $T(n)$ be the time required by merge sort for sorting n values. The time needed to do the merging is proportional to the number of elements being merged, so that

$$T(n) = cn + 2T\,(n/2) \ ,$$

because we must sort the two halves (time $T(n/2)$ for each half) and then merge (time proportional to n). We see by Table 1.2 that the growth rate of $T(n)$ is $\Theta(n \log n)$, since $u = v = 2$ and $g(n) = \Theta(n)$.

1.4 Dynamic Programming

In the design of algorithms to solve optimization problems, we need to make the optimal (lowest cost, highest value, shortest distance, and so on) choice among a large number of alternative solutions; dynamic programming is an organized way to find an optimal solution by systematically exploring all possibilities without unnecessary repetition. Often, dynamic programming leads to efficient, polynomial-time algorithms for problems that appear to require searching through exponentially many possibilities.

Like the divide-and-conquer method, dynamic programming is based on the observation that many optimization problems can be solved by solving similar subproblems and then composing the solutions

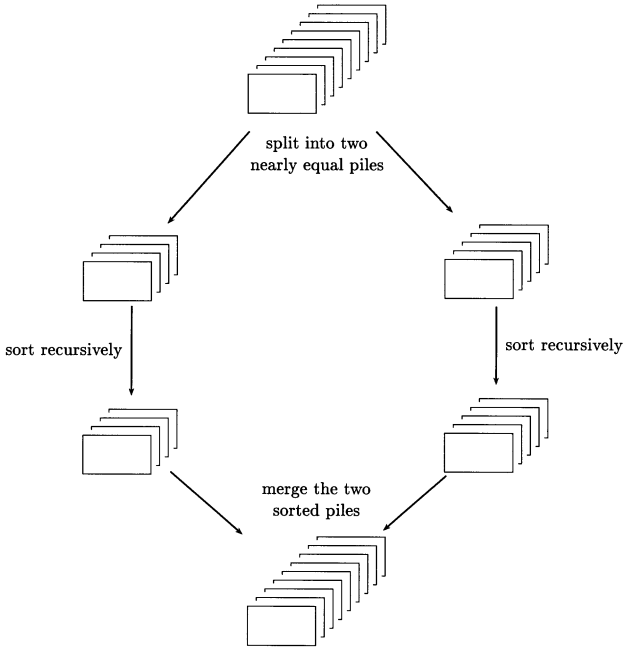

FIGURE 1.2 Schematic description of merge sort.

of those subproblems into a solution for the original problem. In addition, the problem is viewed as a sequence of decisions, each decision leading to different subproblems; if a wrong decision is made, a suboptimal solution results, so all possible decisions need to be accounted for.

As an example of dynamic programming, consider the problem of constructing an optimal search pattern for probing an ordered sequence of elements. The problem is similar to searching an array—in the previous section we described binary search in which an interval in an array is repeatedly bisected until the search ends. Now, however, suppose we know the frequencies with which the search will seek various elements (both in the sequence and missing from it). For example, if we know that the last few elements in the sequence are frequently sought—binary search does not make use of this information—it might be more efficient to begin the search at the right end of the array, not in the middle. Specifically, we are given an ordered sequence $x_1 < x_2 < \cdots < x_n$ and associated frequencies of access $\beta_1, \beta_2, \ldots, \beta_n$, respectively; furthermore, we are given $\alpha_0, \alpha_1, \ldots, \alpha_n$ where α_i is the frequency with which the search will fail because the object sought, z, was missing from the sequence, $x_i < z < x_{i+1}$ (with the obvious meaning when $i = 0$ or $i = n$). What is the optimal order to search for an unknown element z? In fact, how should we describe the optimal search order?

We express a search order as a **binary search tree**, a diagram showing the sequence of probes made in every possible search. We place at the root of the tree the sequence element at which the first probe is made, say x_i; the left subtree of x_i is constructed recursively for the probes made when $z < x_i$ and the right subtree of x_i is constructed recursively for the probes made when $z > x_i$. We label each item in the tree with the frequency that the search ends at that item. Figure 1.3 shows a simple example. The search of sequence $x_1 < x_2 < x_3 < x_4 < x_5$ according to the tree of Fig. 1.3 is done by comparing the unknown element z with x_4 (the root); if $z = x_4$, the search ends. If $z < x_4$, z is compared with x_2 (the root of the left subtree); if $z = x_2$, the search ends. Otherwise, if $z < x_2$, z is compared with x_1 (the root of the left subtree of x_2); if $z = x_1$, the search ends. Otherwise, if $z < x_1$, the search ends unsuccessfully at the leaf labeled α_0. Other results of comparisons lead along other paths in the tree from the root downward. By its nature, a binary search tree is *lexicographic* in that for all nodes in the tree, the elements in the left subtree of the node are smaller and the elements in the right subtree of the node are larger than the node.

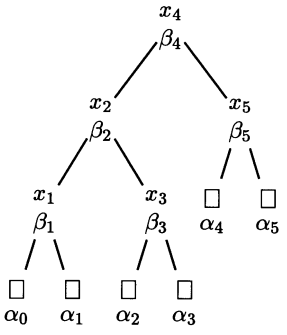

FIGURE 1.3 A binary search tree.

Because we are to find an optimal search pattern (tree), we want the cost of searching to be minimized. The cost of searching is measured by the *weighted path length* of the tree:

$$\sum_{i=1}^{n} \beta_i \times [1 + \text{ level } (\beta_i)] + \sum_{i=0}^{n} \alpha_i \times \text{ level } (\alpha_i) \ ,$$

defined formally as

$$W\left(\square\right) = 0 \ ,$$
$$W\left(T = \begin{array}{c} \bullet \\ T_l \quad T_r \end{array}\right) = W\left(T_l\right) + W\left(T_r\right) + \sum \alpha_i + \sum \beta_i \ ,$$

where the summations $\sum \alpha_i$ and $\sum \beta_i$ are over all α_i and β_i in T. Since there are exponentially many possible binary trees, finding the one with minimum weighted path length could, if done naïvely, take exponentially long.

The key observation we make is that a **principle of optimality** holds for the cost of binary search trees: subtrees of an optimal search tree must themselves be optimal. This observation means, for example, if the tree shown in Fig. 1.3 is optimal, then its left subtree must be the optimal tree for the problem of searching the sequence $x_1 < x_2 < x_3$ with frequencies $\beta_1, \beta_2, \beta_3$ and $\alpha_0, \alpha_1, \alpha_2, \alpha_3$. (If a subtree in Fig. 1.3 were *not* optimal, we could replace it with a better one, reducing the weighted path length of the entire tree because of the recursive definition of weighted path length.) In general terms, the principle of optimality states that subsolutions of an optimal solution must themselves be optimal.

The optimality principle, together with the recursive definition of weighted path length, means that we can express the construction of an optimal tree recursively. Let $C_{i,j}$, $0 \le i \le j \le n$, be the cost of an optimal tree over $x_{i+1} < x_{i+2} < \cdots < x_j$ with the associated frequencies $\beta_{i+1}, \beta_{i+2}, \ldots, \beta_j$ and $\alpha_i, \alpha_{i+1}, \ldots, \alpha_j$. Then,

$$\begin{aligned} C_{i,i} &= 0 \ , \\ C_{i,j} &= \min_{i<k\le j} \left(C_{i,k-1} + C_{k,j}\right) + W_{i,j} \ , \end{aligned}$$

where

$$\begin{aligned} W_{i,i} &= \alpha_i \ , \\ W_{i,j} &= W_{i,j-1} + \beta_j + \alpha_j \ . \end{aligned}$$

These two recurrence relations can be implemented directly as recursive functions to compute $C_{0,n}$, the cost of the optimal tree, leading to the following two functions:

```
 1     int W (int i, int j) {
 2       if (i == j)
 3         return alpha[j];
 4       else
 5         return W(i,j-1) + beta[j] + alpha[j];
 6     }
 7
 8     int C (int i, int j) {
 9       if (i == j)
10         return 0;
11      else {
12         int minCost = MAXINT;
13        int cost;
14         for (int k = i+1; k <= j; k++) {
15           cost = C(i,k-1) + C(k,j) + W(i,j);
16           if (cost < minCost)
17             minCost = cost;
18         }
19         return minCost;
20       }
21     }
```

These two functions correctly compute the cost of an optimal tree; the tree itself can be obtained by storing the values of `k` when `cost < minCost` in line 16.

However, the above functions are unnecessarily time consuming (requiring exponential time) because the same subproblems are solved repeatedly. For example, each call `W(i,j)` uses time $\Theta(j - i)$ and such calls are made repeatedly for the same values of `i` and `j`. We can make the process more efficient by caching the values of `W(i,j)` in an array as they are computed and using the cached values when possible:

```
 1     int w[n][n];
 2     for (int i = 0; i < n; i++)
 3       for (int j = 0; j < n; j++)
 4         w[i][j] = MAXINT;
 5
 6     int W (int i, int j) {
 7       if (w[i][j] == MAXINT)
 8         if (i == j)
 9           w[i][j] = alpha[j];
10         else
11           w[i][j] =  W(i,j-1) + beta[j] + alpha[j];
12       return w[i][j];
13     }
```

In the same way, we should cache the values of `C(i,j)` in an array as they are computed:

```
 1     int c[n][n];
 2     for (int i = 0; i < n; i++)
 3       for (int j = 0; j < n; j++)
 4         c[i][j] = MAXINT;
 5
 6     int C (int i, int j) {
```

```
 7       if (c[i][j] == MAXINT)
 8         if (i == j)
 9            c[i][j] = 0;
10         else {
11           int minCost = MAXINT;
12           int cost;
13           for (int k = i+1; k <= j; k++) {
14             cost = C(i,k-1) + C(k,j) + W(i,j);
15             if (cost < minCost)
16               minCost = cost;
17           }
18           c[i][j] = minCost;
19         }
20       return c[i][j];
21    }
```

The idea of caching the solutions to subproblems is crucial to making the algorithm efficient. In this case, the resulting computation requires time $\Theta(n^3)$; this is surprisingly efficient, considering that an optimal tree is being found from among exponentially many possible trees.

By studying the pattern in which the arrays `C` and `W` are filled in, we see that the main diagonal `c[i][i]` is filled in first, then the first upper super-diagonal `c[i][i+1]`, then the second upper super-diagonal `c[i][i+2]`, and so on until the upper right corner of the array is reached. Rewriting the code to do this directly, and adding an array `R[][]` to keep track of the roots of subtrees, we obtain

```
 1     int w[n][n];
 2     int R[n][n];
 3     int c[n][n];
 4
 5     // Fill in the main diagonal
 6     for (int i = 0; i < n; i++) {
 7       w[i][i] = alpha[i];
 8       R[i][i] = 0;
 9       c[i][i] = 0;
10     }
11
12     int minCost, cost;
13     for (int d = 1; d < n; d++)
14       // Fill in d-th upper super-diagonal
15       for (i = 0; i < n-d; i++) {
16         w[i][i+d] = w[i][i+d-1] + beta[i+d] + alpha[i+d];
17         R[i][i+d] = i+1;
18         c[i][i+d] = c[i][i] + c[i+1][i+d] + w[i][i+d];
19         for (int k = i+2; k <= i+d; k++) {
20           cost = c[i][k-1] + c[k][i+d] + w[i][i+d];
21           if (cost < c[i][i+d]) {
22             R[i][i+d] = k;
23             c[i][i+d] = cost;
24           }
25         }
26       }
```

which more clearly shows the $\Theta(n^3)$ behavior.

As a second example of dynamic programming, consider the **traveling salesman problem** in which a salesman must visit n cities, returning to his starting point, and is required to minimize the cost of the trip. The cost of going from city i to city j is $C_{i,j}$. To use dynamic programming we must specify an optimal tour in a recursive framework, with subproblems resembling the overall problem. Thus we define

$$T(i; j_1, j_2, \ldots, j_k) = \begin{cases} \text{cost of an optimal tour from city } i \text{ to city 1 that} \\ \text{goes through each of the cities } j_1, j_2, \ldots, j_k \\ \text{exactly once, in any order, and through no other} \\ \text{cities.} \end{cases}$$

The principle of optimality tells us that

$$T(i; j_1, j_2, \ldots, j_k) = \min_{1 \le m \le k} \left\{ C_{i,j_m} + T(j_m; j_1, j_2, \ldots, j_{m-1}, j_{m+1}, \ldots, j_k) \right\} ,$$

where, by definition,

$$T(i; j) = C_{i,j} + C_{j,1} .$$

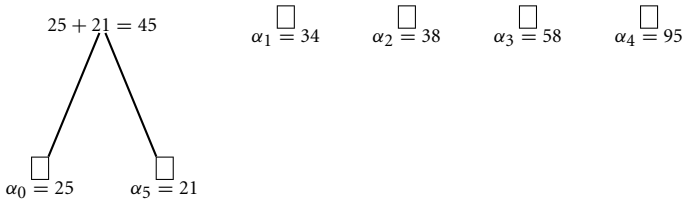
We can write a function T that directly implements the above recursive definition, but as in the optimal search tree problem, many subproblems would be solved repeatedly, leading to an algorithm requiring time $\Theta(n!)$. By caching the values $T(i; j_1, j_2, \ldots, j_k)$, we reduce the time required to $\Theta(n^2 2^n)$, still exponential, but considerably less than without caching.

1.5 Greedy Heuristics

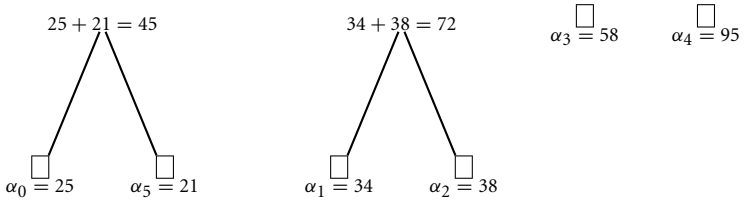
Optimization problems always have an objective function to be minimized or maximized, but it is not often clear what steps to take to reach the optimum value. For example, in the optimum binary search tree problem of the previous section, we used dynamic programming to examine systematically all possible trees; but perhaps there is a simple rule that leads directly to the best tree—say by choosing the largest β_i to be the root and then continuing recursively. Such an approach would be less time-consuming than the $\Theta(n^3)$ algorithm we gave, but it does not necessarily give an optimum tree (if we follow the rule of choosing the largest β_i to be the root, we get trees that are no better, on the average, than a randomly chosen trees). The problem with such an approach is that it makes decisions that are *locally optimum*, though perhaps not *globally optimum*. But, such a "greedy" sequence of locally optimum choices does lead to a globally optimum solution in some circumstances.

Suppose, for example, $\beta_i = 0$ for $1 \le i \le n$, and we remove the lexicographic requirement of the tree; the resulting problem is the determination of an optimal prefix code for $n + 1$ letters with frequencies $\alpha_0, \alpha_1, \ldots, \alpha_n$. Because we have removed the lexicographic restriction, the dynamic programming solution of the previous section no longer works, but the following simple greedy strategy yields an optimum tree: Repeatedly combine the two lowest-frequency items as the left and right subtrees of a newly created item whose frequency is the sum of the two frequencies combined. Here is an example of this construction; we start with five leaves with weights

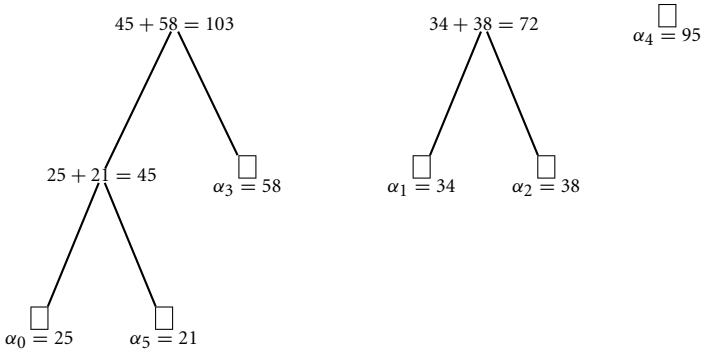
First, combine leaves $\alpha_0 = 25$ and $\alpha_5 = 21$ into a subtree of frequency $25 + 21 = 45$:



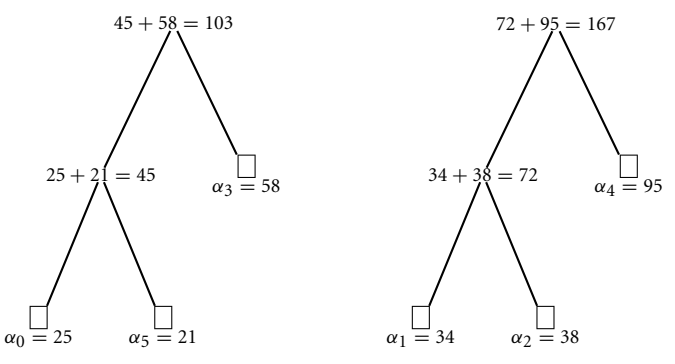
Then combine leaves $\alpha_1 = 34$ and $\alpha_2 = 38$ into a subtree of frequency $34 + 38 = 72$:



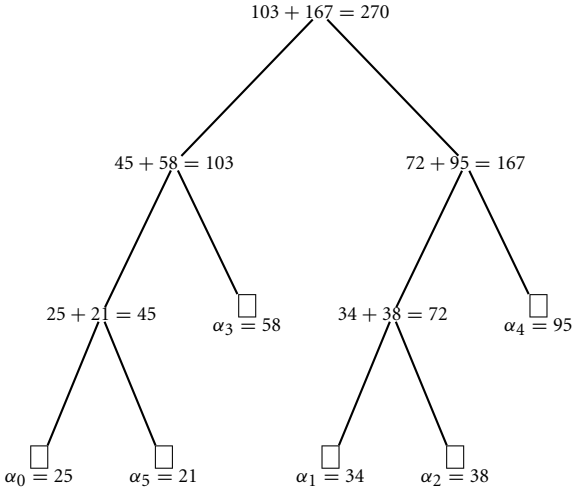
Next, combine the subtree of frequency $\alpha_0 + \alpha_5 = 45$ with $\alpha_3 = 58$:



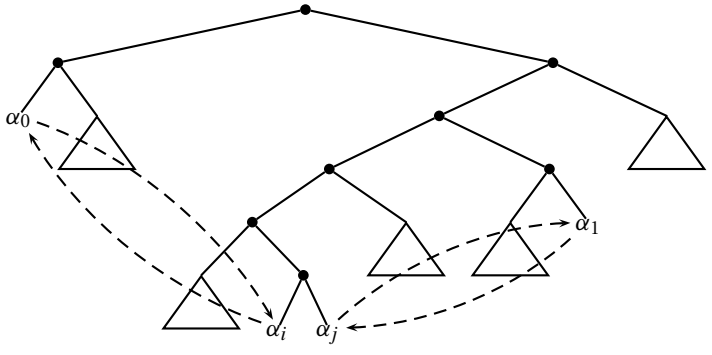
Then, combine the subtree of frequency $\alpha_1 + \alpha_2 = 72$ with $\alpha_4 = 95$:



Finally, combine the only two remaining subtrees:



How do we know that the above-outlined process leads to an optimum tree? The key to proving that the tree is optimum is to assume, by way of contradiction, that it is not optimum. In this case, the greedy strategy must have erred in one of its choices, so let us look at the *first* error this strategy made. Since all previous greedy choices were not errors, and hence lead to an optimum tree, we can assume that we have a sequence of frequencies $\alpha_0, \alpha_1, \ldots, \alpha_n$ such that the first greedy choice is erroneous—without loss of generality assume that α_0 and α_1 are two smallest frequencies, those combined erroneously by the greedy strategy. For this combination to be erroneous, there must be no optimum tree in which these two αs are siblings, so consider an optimum tree, the locations of α_0 and α_1, and the location of the two deepest leaves in the tree, α_i and α_j:



By interchanging the positions of α_0 and α_i and α_1 and α_j (as shown), we obtain a tree in which α_0 and α_1 are siblings. Because α_0 and α_1 are the two lowest frequencies (because they were the greedy algorithm's choice) $\alpha_0 \leq \alpha_i$ and $\alpha_1 \leq \alpha_j$, thus the weighted path length of the modified tree is no larger than before the modification since $\text{level}(\alpha_0) \geq \text{level}(\alpha_i)$, $\text{level}(\alpha_1) \geq \text{level}(\alpha_j)$ and hence

$$\text{level}\,(\alpha_i) \times \alpha_0 + \text{level}\,(\alpha_j) \times \alpha_1 \leq \text{level}\,(\alpha_0) \times \alpha_0 + \text{level}\,(\alpha_1) \times \alpha_1\,.$$

In other words, the first so-called mistake of the greedy algorithm was in fact not a mistake, since there is an optimum tree in which α_0 and α_1 are siblings. Thus we conclude that the greedy algorithm never makes a first mistake—that is, it never makes a mistake at all!

The greedy algorithm above is called *Huffman's algorithm*. If the subtrees are kept on a priority queue by cumulative frequency, the algorithm needs to insert the $n + 1$ leaf frequencies onto the queue, and the

repeatedly remove the two least elements on the queue, unite those to elements into a single subtree, and put that subtree back on the queue. This process continues until the queue contains a single item, the optimum tree. Reasonable implementations of priority queues will yield $O(n \log n)$ implementations of Huffman's greedy algorithm.

The idea of making greedy choices, facilitated with a priority queue, works to find optimum solutions to other problems too. For example, a **spanning tree** of a weighted, connected, undirected graph $G = (V, E)$ is a subset of $|V| - 1$ edges from E connecting all the vertices in G; a spanning tree is minimum if the sum of the weights of its edges is as small as possible. *Prim's algorithm* uses a sequence of greedy choices to determine a minimum spanning tree: Start with an arbitrary vertex $v \in V$ as the spanning-tree-to-be. Then, repeatedly add the cheapest edge connecting the spanning-tree-to-be to a vertex not yet in it. If the vertices not yet in the tree are stored in a priority queue implemented by a Fibonacci heap, the total time required by Prim's algorithm will be $O(|E| + |V| \log |V|)$. But why does the sequence of greedy choices lead to a minimum spanning tree?

Suppose Prim's algorithm does *not* result in a minimum spanning tree. As we did with Huffman's algorithm, we ask what the state of affairs must be when Prim's algorithm makes its first mistake; we will see that the assumption of a first mistake leads to a contradiction, proving the correctness of Prim's algorithm. Let the edges added to the spanning tree be, in the order added, $e_1, e_2, e_3, \ldots$, and let e_i be the first mistake. In other words, there is a minimum spanning tree $T_{\min}$ containing $e_1, e_2, \ldots, e_{i-1}$, but no minimum spanning tree containing $e_1, e_2, \ldots, e_i$. Imagine what happens if we add the edge e_i to $T_{\min}$: since $T_{\min}$ is a spanning tree, the addition of e_i causes a cycle containing e_i. Let $e_{\max}$ be the highest-cost edge on that cycle not among $e_1, e_2, \ldots, e_i$. There must be such an $e_{\max}$ because $e_1, e_2, \ldots, e_i$ are acyclic, since they are in the spanning tree constructed by Prim's algorithm. Moreover, because Prim's algorithm always makes a greedy choice—that is, chooses the lowest-cost available edge—the cost of e_i is no more than the cost of any edge available to Prim's algorithm when e_i is chosen; the cost of $e_{\max}$ is at least that of one of those unchosen edges, so it follows that the cost of e_i is no more than the cost of $e_{\max}$. In other words, the cost of the spanning tree $T_{\min} - \{e_{\max}\} \cup \{e_i\}$ is at most that of $T_{\min}$; that is, $T_{\min} - \{e_{\max}\} \cup \{e_i\}$ is also a minimum spanning tree, contradicting our assumption that the choice of e_i is the first mistake. Therefore, the spanning tree constructed by Prim's algorithm must be a minimum spanning tree.

We can apply the greedy heuristic to many optimization problems, and even if the results are not optimal, they are often quite good. For example, in the n-city traveling salesman problem, we can get near-optimal tours in time $O(n^2)$ when the intercity costs are symmetric ($C_{i,j} = C_{j,i}$ for all i and j) and satisfy the triangle inequality($C_{i,j} \leq C_{i,k} + C_{k,j}$ for all i, j, and k). The *closest insertion algorithm* starts with a "tour" consisting of a single, arbitrarily chosen city, and successively inserts the remaining cities to the tour, making a greedy choice about which city to insert next and where to insert it: the city chosen for insertion is the city not on the tour but closest to a city on the tour; the chosen city is inserted adjacent to the city on the tour to which it is closest.

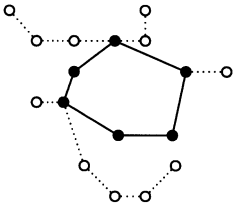
Given an $n \times n$ symmetric distance matrix C that satisfies the triangle inequality, let I_n of length $|I_n|$ be the "closest insertion tour" produced by the closest insertion heuristic and let O_n be an optimal tour of length $|O_n|$. Then

$$\frac{|I_n|}{|O_n|} < 2 .$$

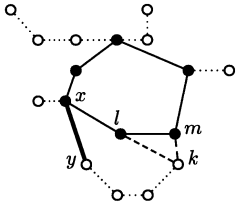
This bound is proved by an incremental form of the optimality proofs for greedy heuristics we have seen above: we ask not where the first error is, but by how much we are in error at each greedy insertion to the tour—we establish a correspondence between edges of the optimal tour O_n and cities inserted on the closest insertion tour. We show that at each insertion of a new city to the closest insertion tour, the additional length added by that insertion is at most twice the length of corresponding edge of the optimal tour O_n.

To establish the correspondence, imagine the closest insertion algorithm keeping track not only of the current tour, but also of a spider-like configuration including the edges of the current tour (the body of

the spider) and pieces of the optimal tour (the legs of the spider). We show the current tour in solid lines and the pieces of optimal tour as dotted lines:



Initially, the spider consists of the arbitrarily chosen city with which the closest insertion tour begins and the legs of the spider consist of all the edges of the optimal tour *except* for one edge eliminated arbitrarily. As each city is inserted into the closest insertion tour, the algorithm will delete from the spider-like configuration one of the dotted edges from the optimal tour. When city k is inserted between cities l and m, the edge deleted is the one attaching the spider to the leg that contains the city inserted (from city x to city y), shown here in bold:



Now,

$$C_{k,m} \leq C_{x,y} \ ,$$

because of the greedy choice to add city k to the tour and not city y. By the triangle inequality,

$$C_{l,k} \leq C_{l,m} + C_{m,k} \ ,$$

and by symmetry we can combine these two inequalities to get

$$C_{l,k} \leq C_{l,m} + C_{x,y} \ .$$

Adding this last inequality to the first one above,

$$C_{l,k} + C_{k,m} \leq C_{l,m} + 2C_{x,y} \ ,$$

that is,

$$C_{l,k} + C_{k,m} - C_{l,m} \leq 2C_{x,y} \ .$$

Thus adding city k between cities l and m adds no more to I_n than $2C_{x,y}$. Summing these incremental amounts over the cost of the entire algorithm tells us

$$|I_n| \leq 2\,|O_n| \ ,$$

as we claimed.

1.6 Lower Bounds

In Subsection "Sorting" and Section 1.3 we saw that we could sort faster than naïve $\Theta(n^2)$ worst-case behavior algorithms: we designed more sophisticated $\Theta(n \log n)$ worst-case algorithms. Can we do still better? No, $\Theta(n \log n)$ is a **lower bound** on sorting algorithms based on comparisons of the items being sorted. More precisely, let us consider only sorting algorithms described by decision boxes of the form

$$x_i : x_j$$

and outcome boxes such as

$$\boxed{x_1 < x_2 < x_3}$$

Such diagrams are called *decision trees*. Figure 1.4 shows a decision tree for sorting the three elements x_1, x_2, and x_3.

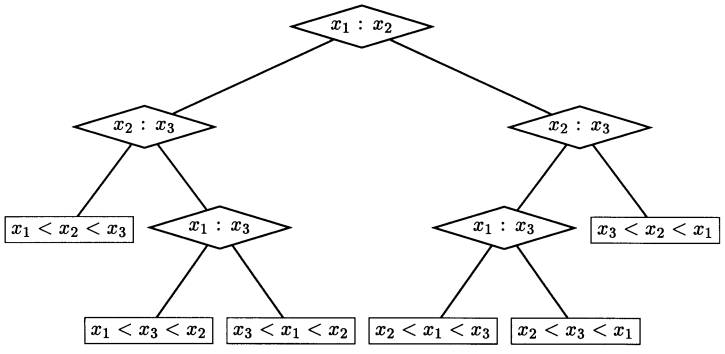


FIGURE 1.4 A decision tree for sorting the three elements x_1, x_2, and x_3.

Restricting ourselves to sorting algorithms represented by decision trees eliminates algorithms not based on comparisons of the elements, but it also appears to eliminate from consideration any of the common sorting algorithms, such as insertion sort, heapsort, and mergesort, all of which use index manipulations in loops, auxiliary variables, recursion, and so on. Furthermore, we have not allowed the algorithms to consider the possibility that some of the elements to be sorted may have equal values. These objections to modeling sorting algorithms on decision trees are serious, but can be countered by arguments that we have not been too restrictive.

For example, disallowing elements that are equal can be defended, because we certainly expect any sorting algorithm to work correctly in the special case that all of the elements are different; we are just examining an algorithm's behavior in this special case—a lower bound in a special case gives a lower bound on the general case. The objection that such normal programming techniques as auxiliary variables, loops, recursion, and so on are disallowed can be countered by the observation that *any* sorting algorithm based on comparisons of the elements can be stripped of its programming implementation to yield a decision tree. We expand all loops and all recursive calls, ignoring data moves and keeping track only of the comparisons between elements and nothing else. In this way, all common sorting algorithms can be described by decision trees.

We make an important observation about decision trees and the sorting algorithms represented as decision trees: *If a sorting algorithm correctly sorts all possible input sequences of n items, then the corresponding decision tree has n! outcome boxes.* This observation follows by examining the correspondence between permutations and outcome boxes. Since the decision tree arose by tracing through the algorithm for all

possible input sequences (that is, permutations), an outcome box must have occurred as the result of some input permutation or it would not be in the decision tree. Moreover, it is impossible that there are two different permutations corresponding to the same outcome box—such an algorithm cannot sort all input sequences correctly. Since there are $n!$ permutations of n elements, the decision tree has $n!$ leaves (outcome boxes).

To prove the $\Theta(n \log n)$ lower bound, define the *cost* of the ith leaf in the decision tree, $c(i)$, to be the number of element comparisons used by the algorithm when the input permutation causes the algorithm to terminate at the ith leaf. In other words, $c(i)$ is the *depth* of the ith leaf. This measure of cost ignores much of the work in the sorting process, but the overall work done will be proportional to the depth of the leaf at which the sorting algorithm terminates; because we are concerned only with lower bounds with in the Θ-notation, this analysis suffices.

Kraft's inequality tells us that for any tree with N leaves,

$$\sum_{i=1}^{N} \frac{1}{2^{c(i)}} \leq 1 \, . \tag{1.2}$$

We can prove this inequality by induction on the height of the tree: When the height is zero, there is one leaf of depth zero and the inequality is trivial. When the height is non-zero, the inequality applies inductively to the left and right subtrees; the edges from the root to these subtrees increases the depth of each leaf by one, so the sum over each of the two subtrees is 1/2 and the inequality follows.

We use Kraft's inequality by letting h be the height of a decision tree corresponding to a sorting algorithm applied to n items. Then h is the depth of the deepest leaf, that is, the worst-case number of comparisons of the algorithm: $h \geq c(i)$, for all i. Therefore,

$$\begin{aligned} \frac{N}{2^h} &= \sum_{i=1}^{N} \frac{1}{2^h} \\ &\leq \sum_{i=1}^{N} \frac{1}{2^{c(i)}} \\ &\leq 1 \, , \end{aligned}$$

and so

$$N \leq 2^h \, .$$

However, we saw that $N = n!$, so this last inequality can be rewritten as

$$2^h \geq n! \, .$$

But

$$n! \geq \left(\frac{n}{2}\right)^{n/2} \, ,$$

so that

$$h \geq \log_2 n! = \Theta(n \log n) \, ,$$

which is what we wanted to prove.

We can make an even stronger statement about sorting algorithms that can be modeled by decision trees: It is impossible to sort in *average time* better than $\Theta(n \log n)$, if each of the $n!$ input permutations is equally likely to be the input. The average number of decisions in this case is

$$\frac{1}{N} \sum_{i=1}^{N} c(i) \, .$$

Suppose this is less than $\log_2 N$; that is, suppose

$$\sum_{i=1}^{N} c(i) < N \log_2 N \ .$$

By the arithmetic/geometric mean inequality, we know that

$$\frac{1}{m} \sum_{i=1}^{m} u_i \geq \left(\prod_{i=1}^{m} u_i \right)^{1/m} \ . \tag{1.3}$$

Applying this inequality, we have

$$\begin{aligned} \sum_{i=1}^{N} \frac{1}{2^{c(i)}} &\geq N \left(\prod_{i=1}^{N} \frac{1}{2^{c(i)}} \right)^{1/N} \\ &= N \left(2^{-\sum_{i=1}^{N} c(i)} \right)^{1/N} \\ &> N \left(2^{-N \log_2 N} \right)^{1/N} , \end{aligned}$$

by assumption,

$$\begin{aligned} &= N \left(N^{-N} \right)^{1/N} \\ &= 1 , \end{aligned}$$

contradicting Kraft's inequality.

The lower bounds on sorting are called *information theoretic* lower bounds, because the rely on the amount of "information" contained in a single decision (comparison); in essence, the best a comparison can do is divide the set of possibilities into two equal parts. Such bounds also apply to many searching problems—for example, such arguments prove that binary search is, in a sense, optimal.

Information theoretic lower bounds do not always give useful results. Consider the **element uniqueness problem,** the problem of determining if there are any duplicate numbers in a set of n numbers, $x_1, x_2, \ldots, x_n$. Since there are only two possible outcomes, yes or no, the information theoretic lower bound says that a single comparison should be sufficient to answer the question. Indeed, that is true: Compare the product

$$\prod_{1 \leq i < j \leq n} \left(x_i - x_j \right) \tag{1.4}$$

to zero. If the product is non-zero, there are no duplicate numbers; if it is zero there are duplicates.

Of course, the cost of the one comparison is negligible compared to the cost of computing the product (1.4). It takes $\Theta(n^2)$ arithmetic operations to determine the product, but we are ignoring this dominant expense. The resulting lower bound is ridiculous.

To obtain a sensible lower bound for the element uniqueness problem, we define an **algebraic computation tree** for inputs $x_1, x_2, \ldots, x_n$ as a tree in which every leaf is either "yes" or "no." Every internal node either is a binary node (that is, with two children) based on a comparison of values computed in the ancestors of that binary node, or is a unary node (that is, with one child) that computes a value based on constants and values computed in the ancestors of that unary node, using the operations of addition, subtraction, multiplication, division, and square roots. An algebraic computation tree thus describes functions that take n numbers and compute a yes-or-no answer using intermediate algebraic results. The cost of an algebraic computation tree is its height.

By a complicated argument based on algebraic geometry, one can prove that any algebraic computation tree for the element uniqueness problem has depth at least $\Theta(n \log n)$. This is a much more sensible, satisfying lower bound on the problem. It follows from this lower bound that a simple sort-and-scan algorithm is essentially optimal for the element uniqueness problem.

1.7 Defining Terms

Algebraic computation tree: A tree combining simple algebraic operations with comparisons of values.

Amortized cost: The cost of an operation considered to be spread over a sequence of many operations.

Average-case cost: The sum of costs over all possible inputs divided by the number of possible inputs.

Binary search tree: A binary tree that is lexicographically arranged so that, for every node in the tree, the nodes to its left are smaller and those to its right are larger.

Binary search: Divide-and-conquer search of a sorted array in which the middle element of the current range is probed so as to split the range in half.

Divide-and-conquer: A paradigm of algorithm design in which a problem is solved by reducing it to subproblems of the same structure.

Dynamic programming: A paradigm of algorithm design in which an optimization problem is solved by a combination of caching subproblem solutions and appealing to the "principle of optimality."

Element uniqueness problem: The problem of determining if there are duplicates in a set of numbers.

Greedy heuristic: A paradigm of algorithm design in which an optimization problem is solved by making locally optimum decisions.

Heap: A tree in which parent–child relationships are consistently "less than" or "greater than."

Information theoretic bounds: Lower bounds based on the rate at which information can be accumulated.

Kraft's inequality: The statement that $\sum_{i=1}^{N} 2^{-c(i)} \leq 1$, where the sum is taken over the N leaves of a binary tree and $c(i)$ is the depth of leaf i.

Lower bound: A function (or growth rate) below which solving a problem is impossible.

Merge sort: A sorting algorithm based on repeated splitting and merging.

Principle of optimality: The observation, in some optimization problems, that components of a globally optimum solution must themselves be globally optimal.

Priority queue: A data structure that supports the operations of creation, insertion, minimum, deletion of the minimum, and (possibly) decreasing the value an element, deletion, or merge.

Recurrence relation: The specification of a sequence of values in terms of earlier values in the sequence.

Sorting: Rearranging a sequence into order.

Spanning tree: A connected, acyclic subgraph containing all of the vertices of a graph.

Traveling salesman problem: The problem of determining the optimal route through a set of cities, given the intercity travel costs.

Worst-case cost: The cost of an algorithm in the most pessimistic input possibility.

Further Information

General discussions of the analysis of algorithms and data structures can be found in [1, 4], and [10]; [9] has a more elementary treatment. Both [3] and [7] contain detailed treatments of recurrences, especially in regard to the analysis of algorithms. Sorting and searching techniques are explored in depth in [5, 6] discusses algorithms for problems such as computing powers, evaluating polynomials, and multiplying large numbers. Reference [12] discusses many important graph algorithms, including several for finding minimum spanning trees. Our discussion of Fibonacci heaps is from [2]; our discussion of the heuristics for the traveling salesman problem is from [11]. A detailed discussion of the lower bound of the element-uniqueness problem is presented in [8, vol. 1, pp. 75–79], along with much other material on algebraic computation trees.

Searching

Ricardo Baeza-Yates

Universidad de Chile

2.1 Introduction

Searching is one of the main applications in computers as well as in other fields, including daily life. The basic problem consists in finding a given object in a set of objects of the same kind. Databases are perhaps the best example where searching is the main task involved, and also where its performance is crucial.

We use the *dictionary problem* as a generic example of searching for a key in a set of keys. Formally, we are given a set S of n distinct keys[1] $x_1, \ldots, x_n$, and we have to implement the following operations, for a given key x:

$$\begin{aligned} \texttt{Search}: &\quad x \in S? \\ \texttt{Insert}: &\quad S \leftarrow S \cup \{x\} \\ \texttt{Delete}: &\quad S \leftarrow S - \{x\} \end{aligned}$$

Although for simplicity we treat the set S as just a set of keys, in practice it would consist of a set of records, one of whose fields would be designated as the key. Extending the algorithms to cover this case is straightforward.

[1] We will not consider in detail the case of nondistinct keys. Most of the algorithms work in that case too, or can be extended without much effort, but the performance may not be the same, especially in degenerate cases.

Searches have always two possible outcomes. A search can be *successful* or *unsuccessful*, depending on whether the key was found or not in the set. We will use the letter U to denote the cost of an unsuccessful search, and S to denote the cost of a successful search. In particular, we will use the name U_n (respectively, S_n) to denote the random variable "cost of an unsuccessful (respectively, successful) search for a random element in a table built by random insertions." Unless otherwise noted, we assume that the elements to be accessed are chosen with uniform probability. The notations C'_n and C_n have been used in the literature to denote the expected values of U_n and S_n, respectively [22]. We use the notation $\mathbf{E}X$ to denote the expected value of the random variable X.

In this chapter we cover the most basic searching algorithms which work on fixed size arrays or tables and linked lists. They include techniques to search an array (unsorted or sorted), **self-organizing strategies** for arrays and lists, and hashing. In particular, hashing is a widely used method to implement dictionaries. We cover here the basic algorithms, and we provide pointers to the related literature. With the exception of hashing, we emphasize the SEARCH operation, because updates require $O(n)$ time. We also include a summary of other related searching problems.

2.2 Sequential Search

Consider the simplest problem: search for a given element in a set of n integers. If the numbers are given one by one (this is called an *on-line* problem) the obvious solution is to use sequential search. That is, we compare every element, and in the worst case we need n comparisons (either it is the last element or it is not present). Under the traditional RAM model, this algorithm is optimal. This is the algorithm used to search in an unsorted array storing n elements, and is advisable when n is small or when we do not have enough time or space to store the elements (for example in a very fast communication line). Clearly, $U_n = n$. If finding an element in any position has the same probability, then $\mathbf{E}S_n = \frac{n+1}{2}$.

Randomized Sequential Search

We can improve the worst case of sequential search in a probabilistic sense if the element belongs to the set (successful search) and we have all the elements in advance (*off-line* case). Consider the following **randomized algorithm.** We flip a coin. If it is a heads, we search the set from 1 to n. Otherwise, from n to 1. The worst case for each possibility is n comparisons. However, we have two algorithms and not only one. Suppose that the element we are looking for is in position i and that the coin is fair (that is, the probability of heads or tails is the same). So, the number of comparisons to find the element is i if it is heads, or $n - i + 1$ if it is tails. So, averaging over both algorithms (note that we are not averaging over all possible inputs), the expected worst case is

$$\frac{1}{2} \times i + \frac{1}{2} \times (n - i + 1) = \frac{n+1}{2}$$

which is independent of where the element is! This is better than n. In other words, an adversary would have to place the element in the middle position because he/she does not know which algorithm will be used.

Self-Organizing Heuristics

If the probability of retrieving each element is not the same, we can improve a successful search by ordering the elements by decreasing probability of access, either in an array or a linked list. Let p_i be the probability of accessing element i, and assume without loss of generality that $p_i > p_{i+1}$. Then, we have that the

optimal static order (OPT) has

$$\mathbf{E}S_n^{OPT} = \sum_{i=1}^{n} i\ p_i$$

However, most of the time we do not know the accessing probabilities and in practice they may change over time. For that reason, there are several heuristics to *reorganize* dynamically the order of the list. The most common ones are *move-to-front* (MF) where we promote the accessed element to the first place of the list, and *transpose* (T) where we advance the accessed element one place in the list (if it is not the first). These two heuristics are *memoryless* in the sense that they work only with the element currently accessed. MF is best suited for a linked list while T can also be applied to arrays. A good heuristic if access probabilities do not change much with time is the *count* (C) heuristic. In this case every element keeps a counter with the number of times it has been accessed and advances in the list one or more positions when its count is larger than previous elements in the list. The main disadvantage of C is that we need $O(n)$ extra space to store the counters if they fit in a word. Other more complex heuristics have been proposed, which are hybrids of the basic ones or/and use limited memory. They can also be extended to double-linked lists or more complex data structures as search trees.

Using these heuristics is advisable for small n, when space is severely limited, or when the performance obtained is good enough.[2] Evaluating how good a self-organizing strategy is with respect to the optimal order is not easily defined, as the order of the list is dynamic and not static. One possibility is to use the asymptotic expected successful search time, that is, the expected search time achieved by the algorithm after a very large sequence of independent accesses averaged over all possible initial configurations and sequences according to stable access probabilities. In this case, we have that

$$\mathbf{E}S_n^T \leq \mathbf{E}S_n^{MF} \leq \frac{\pi}{2}\mathbf{E}S_n^{OPT} \approx 1.57\mathbf{E}S_n^{OPT}$$

and $\mathbf{E}S_n^C = \mathbf{E}S_n^{OPT}$.

Another possible analysis is to use the worst-case search cost, but usually this is not fair because many times the worst-case situation does not repeat very often. A more realistic solution is to consider the **amortized cost**. That is, the average number of comparisons over a worst-case sequence of executions. Then, a costly single access can be amortized with cheaper accesses that follow after. In this case, starting with an empty list, we have

$$S^{MF} \leq 2S^{OPT}$$

and

$$S^{C} \leq 2S^{OPT}$$

while S^T can be as bad as $O(mS^{OPT})$ for m operations. If we consider a nonstatic optimal algorithm, that is, an algorithm that knows the sequence of accesses in advance and can rearrange the list with every access to minimize the search cost, then the results change. Under the assumption that the access cost function is convex, that is, if $f(i)$ is the cost of accessing the i-th element, then $f(i) - f(i-1) \geq f(i+1) - f(i)$. In this case we usually have $f(i) = i$, and then only MF satisfies the inequality

$$S^{MF} \leq 2S^{OPT}$$

for this new notion of optimal algorithm. In this case, T and C may cost $O(m)$ times the cost of the optimal algorithm for m operations. Another interesting measure is how fast a heuristic converges to the asymptotic behavior. For example, T converges more slowly than MF but it is more stable. However, MF it is more robust as seen in the amortized case.

---

[2] Also when linked lists are an internal component of other algorithms, like hashing with chaining, which is explained later.

2.3 Sorted Array Search

In the off-line case we can search faster if we allow some time to preprocess the set and the elements can be ordered. Certainly, if we sort the set (using $O(n \log n)$ comparisons in the worst-case) and we store it in an array, we can use the well-known binary search. Binary search uses divide and conquer to quickly discard half of the elements by comparing the searched key with the element in the middle of the array, and if not equal, following the search recursively either on the first half or the second half (if the searched key was smaller or larger, respectively). Using binary search we can solve the problem using at most $U_n = \lceil \log_2(n+1) \rceil$ comparisons. Therefore, if we do many searches we can amortize the cost of the initial sorting.

On average, a successful search is also $O(\log n)$. In practice we do not have three-way comparisons, so it is better to search recursively until we have discarded all but one element and then comparing for equality. Binary search is optimal for the RAM comparison model in the worst and the average case. However, by assuming more information about the set or changing the model, we can improve the average or the worst case, as shown in the next sections.

Parallel Binary Search

Suppose now that we change the model by having p processors with a shared memory. That is, we use a *parallel RAM* (PRAM) model. Can we speed up binary search? First, we have to define how the memory is accessed in a concurrent way. The most used model is CREW, that is, concurrent read, but exclusive write (otherwise it is difficult to know the final value of a memory cell after a writing operation). In a **CREW PRAM**, we can use the following simple parallel binary search. We divide the sorted set in $p+1$ segments (then, there are p internal segment boundaries). Processor i compares the key to the element stored in the i-th boundary and writes in a variable c_i a 0 if it is greater or a 1 if it is smaller (in case of equality the search ends). All the processors do this in parallel. After this step, there is an index j such that $c_j = 0$ and $c_{j+1} = 1$ (we assume that $c_0 = 0$ and $c_{p+1} = 1$), which indicates in what segment the key should be. Then, processor i compares c_i and c_{i+1} and if they are different writes the new boundaries where the search continues recursively (see Fig. 2.1). This step is also done in parallel (processor 1 and p take care of the extreme cases). When the segment is of size p or less, each processor compares one element and the search ends. Then, the worst-case number of parallel key comparisons is given by

$$U_n = 1 + U_{\frac{n}{p+1}}, \quad U_i = 1 \ (i \leq p)$$

which gives $U_n = \log_{p+1} n + O(p)$. That is, $U_n = O(\log n / \log(p+1))$. Note that for $p = 1$ we obtain the binary search result, as expected. It is possible to prove that is not possible to do it better. In the PRAM model, the optimal speed-up is when the work done by p processors is p times the work of the optimal sequential algorithm. In this case, the total work is $p \log n / \log p$, which is larger than $\log n$. In other words, searching in a sorted set cannot be solved with optimal speed-up. If we restrict the PRAM model also to exclusive reads (EREW), then $U_n = O(\log n - \log p)$, which is even worse. This is because, at every recursive step, if all the processors cannot read the new segment concurrently, we slow down all the process.

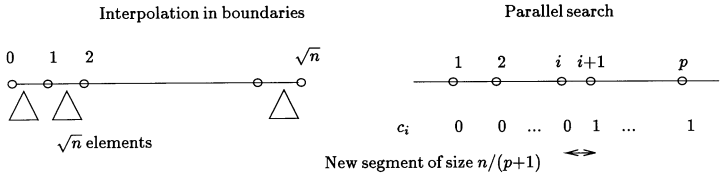

FIGURE 2.1 Binary interpolation (left) and parallel binary (right) search.

Interpolation Search

Assume now that the distribution of the n integers is uniform over a fixed range of $M >> n$ integers. Then, instead of using binary search to divide the set, we can linearly interpolate the position of the searched element with respect to the smallest and the largest element. In this way, on average, it is possible to prove that $O(\log\log n)$ comparisons are needed if the element is in the set. The proof is quite involved and mathematical [29], but there are some variations of interpolation search that have a simpler analysis. The main fact behind the $O(\log\log n)$ complexity is that when we do the first interpolation, with very high probability the searched element is at distance $O(\sqrt{n})$. So, the expected number of comparisons is given by the recurrence

$$\mathbf{E}S_n = a + \mathbf{E}S_{b\sqrt{n}}, \quad \mathbf{E}S_1 = 1$$

for some constants a and b, which gives $\mathbf{E}S_n = O(\log\log n)$. A simple variation is the following, which is called binary interpolation search [28]. Imagine that we divide the ordered set in $\sqrt{n}$ segments of size approximately $\sqrt{n}$. Then, we use interpolation search on the $\sqrt{n}+1$ keys that are segment boundaries (including the first and the last key as shown in Fig. 2.1, left) to find in what segment the key is. After we know the segment, we apply the same algorithm recursively in it. We can think that we have a $\sqrt{n}$-ary search tree where in each node we use interpolation search to find the right pointer. By a simple probabilistic analysis it is possible to show that on average less than 2.5 comparisons are needed to find in what segment is the key. So, we can use the previous recurrence with $a = 2.5$ and $b = 1$, obtaining less than $2.5\log_2\log_2 n$ comparisons on average.

2.4 Hashing

If the keys are drawn from a universe $U = \{0, \ldots, u-1\}$, where u is a reasonably small natural number, a simple solution is to use a table $T[0..u-1]$, indexed by the keys. Initially, all the table elements are initialized to a special value **empty**. When element x is inserted, the corresponding record is stored in the entry $T[x]$.

In the case when all we need to know is whether a given element is present or not, it is enough for $T[x]$ to take only two values: 0 (**empty**) and 1 (**not empty**), and the resulting data structure is called a *bit vector*.

Using this approach, all three basic operations (INSERT, SEARCH, DELETE) take time $\Theta(1)$ in the worst case.

When the size of the universe is much larger, as is the case for character strings, the same approach could still work in principle, as strings can be interpreted as (possibly very large) natural numbers, but the size of the table would make it impractical. A solution is to map the keys onto a relatively small integer range, using a function called a **hash function.**

The resulting data structure, called *hash tables*, makes it possible to use keys drawn from an arbitrarily large universe as "subscripts," much in the way small natural numbers are used as subscripts for a normal array. They are the basis for the implementation of the "associative arrays" available in some languages.

More formally, suppose we want to store our set of size n in a table of size m. (The ratio $\alpha = n/m$ is called the *load factor* of the table.) Assume we have a *hash function* h that maps each key $x \in U$ to an integer value $h(x) \in [0..m-1]$. The basic idea is to store key x in location $T[h(x)]$.

Typically, hash functions are chosen so that they generate "random looking" values. For example, the following is a function that usually works well:

$$h(x) = x \bmod m$$

where m is a prime number.

The preceding function assumes that x is an integer. In most practical applications, x is a character string instead. Strings are sequences of characters, each of which has an internal representation as a small

natural number (e.g., using the ASCII coding). If a string x can be written as $c_k c_{k-1} \ldots c_1 c_0$, where each c_i satisfies $0 \leq c_i < C$, then we can compute h as

$$h \leftarrow 0; \quad \textbf{for } i \textbf{ in } 0..k \textbf{ do } h \leftarrow (h * C + c_i) \textbf{ mod } m$$

There is one important problem that needs to be solved. As keys are inserted in the table, it is possible that we may have *collisions* between different keys hashing to the same table slot. If the hash function distributes the elements uniformly over the table, the number of collisions cannot be too large on the average (after all, the expected number of elements per slot is α), but the well known *birthday paradox* makes it very likely that there will be at least one collision, even for a lightly loaded table.

There are two basic methods for handling collisions in a hash table: **chaining** and **open addressing.**

Chaining

The simplest chaining method stores elements in the table as long as collisions do not occur. When there is a collision, the incoming key is stored in an *overflow area*, and the corresponding record is appended at the end of a linked list that stores all elements that hashed to that same location (see Fig. 2.2). The original hash table is then called the *primary area*. Figure 2.2 shows the result of inserting keys $A, B, \ldots, I$ in a

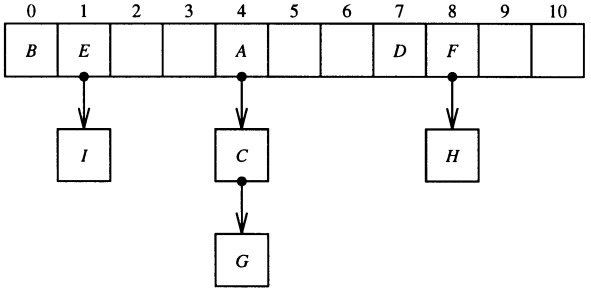

FIGURE 2.2 Hashing with separate chaining.

hash table using chaining to resolve collisions, with the following hash function:

x	A	B	C	D	E	F	G	H	I
$h(x)$	4	0	4	7	1	8	4	8	1

If the hash function maps elements uniformly, and if the elements are drawn at random from the universe, the expected values for these performance measures U_n and S_n are

$$\mathbf{E}U_n = e^{-\alpha} + \alpha + \Theta\left(\frac{1}{m}\right)$$

and

$$\mathbf{E}S_n = 1 + \frac{\alpha}{2} + \Theta\left(\frac{1}{m}\right)$$

Note that the search cost is basically independent of the number of elements, and that it depends on the load factor instead. By making the latter low enough, we can have hash tables with very efficient average search times.

The worst case, on the other hand, can be very bad: if all the keys happen to hash to the same location, the search cost is $\Theta(n)$. The probability of this happening is, of course, exceedingly small, so a more

realistic measure of the worst case may be the expected length of the longest chain in a table. This can be shown to be $\Theta\left(\frac{\log m}{\log\log m}\right)$ [16].

Deletions are handled simply by removing the appropriate element from the list. When the element happened to be in the primary area, the first remaining element in the chain must be promoted to the primary area.

The need for an overflow area can be eliminated by storing these records in table locations that happen to be empty. The resulting method, called *coalesced hashing*, has slightly larger search times, because of unrelated chains fusing accidentally, but it is still efficient even for a full table ($\alpha = 1$):

$$\begin{aligned} \mathbf{E}U_n &= 1 + \frac{1}{4}\left(e^{2\alpha} - 1 - 2\alpha\right) + \Theta\left(\frac{1}{m}\right) \\ \mathbf{E}S_n &= 1 + \frac{1}{8\alpha}\left(e^{2\alpha} - 1 - 2\alpha\right) + \frac{\alpha}{4} + \Theta\left(\frac{1}{m}\right) \end{aligned}$$

Deletions require some care, as simply declaring a given location **empty** may confuse subsequent searches. If the rest of the chain contains an element that hashes to the now empty location, it must be moved there, and the process must be repeated for the new vacant location, until the chain is exhausted. In practice, this is not as slow as it sounds, as chains are usually short.

The preceding method can be generalized by allocating an overflow area of a given size, and storing the colliding elements there as long as there is space. Once the overflow area (called the *cellar* in this method) becomes full, the empty slots in the primary area begin to be used. This data structure was studied by Vitter and Chen [35]. By appropriately tuning the relative sizes of the primary and of the overflow areas, this method can outperform the other chaining algorithms. Even at a load of 100%, an unsuccessful search requires only 1.79 probes.

Vitter and Chen's analysis of coalesced hashing is very detailed, and also very complex. An alternative approach to this problem has been used by Siegel [32] to obtain a much simpler analysis that leads to more detailed results.

Open Addressing

This is a family of methods that avoids the use of pointers, by computing a new hash value every time there is a collision.

Formally, this can be viewed as using a sequence of hash functions $h_0(x), h_1(x), \ldots$. An insertion probes that sequence of locations until finding an empty slot. Searches follow that same probe sequence, and are considered unsuccessful as soon as they hit an empty location.

The simplest way to generate the probe sequence is by first evaluating the hash function, and then scanning the table sequentially from that location (and wrapping around the end of the table). This is called *linear probing*, and is reasonably efficient if the load factor is not too high, but, as the table becomes full, it is too slow to be practical:

$$\begin{aligned} \mathbf{E}U_n &= \frac{1}{2}\left(1 + \frac{1}{1-\alpha}\right) + \Theta\left(\frac{1}{m}\right) \\ \mathbf{E}S_n &= \frac{1}{2}\left(1 + \frac{1}{(1-\alpha)^2}\right) + \Theta\left(\frac{1}{m}\right) \end{aligned}$$

Note that these formulae break down for $\alpha = 1$. For a full table, the unsuccessful and the successful search costs are $\Theta(m)$ and $\Theta(\sqrt{m})$, respectively.

A better method for generating the probe sequences is *double hashing*. In addition to the original hash function $h(x)$, a second hash function $s(x) \in [1..m-1]$ is used, to provide a "step size." The probe sequence is then generated as

$$h_0(x) = h(x); \quad h_{i+1}(x) = (h_i(x) + s(x)) \bmod m$$

Figure 2.3 shows the result of inserting keys $A, B, \ldots, I$ using the following hash functions:

x	A	B	C	D	E	F	G	H	I
$h(x)$	4	0	4	7	1	8	4	8	1
$s(x)$	5	1	4	2	5	3	9	2	9

Analyzing double hashing is quite hard [18, 26], and for this reason most mathematical analyses are instead done assuming one of two simplified models:

- *Uniform probing:* the locations are chosen at random from the set $[0..m-1]$, without replacement, or
- *Random probing:* the locations are chosen at random from the set $[0..m-1]$, with replacement.

0	1	2	3	4	5	6	7	8	9	10
B	E	G	F	A		I	D	C		H

FIGURE 2.3 Open addressing with double hashing.

For both models, it can be shown that

$$\begin{aligned} \mathbf{E}U_n &= \frac{1}{1-\alpha} + \Theta\left(\frac{1}{m}\right) \\ \mathbf{E}S_n &= \frac{1}{\alpha}\ln\frac{1}{1-\alpha} + \Theta\left(\frac{1}{m}\right) \end{aligned}$$

Again, for a full table the above expressions are useless, but we can prove that the search costs are $\Theta(m)$ and $\Theta(\log m)$, respectively.

Deletions cannot be done by simply erasing the given element, because searches would stop there and miss any element located beyond that point in its probe sequence. The solution of marking the location as "dead" (i.e., still occupied for the purposes of searching, but free for the purposes of insertion) works at the expense of deteriorating the search time.

An interesting property of collision resolution in *open addressing* hash tables is that when two keys collide (one incoming key and one that is already in the table), *either* of them may validly stay in that location, and the other one has to try its next probe location. The traditional insertion method does not use this degree of freedom, and simply assigns locations to the keys in a "first-come-first-served" (FCFS) fashion.

Several methods have been proposed, that make use of this flexibility to improve the performance of open addressing hash tables. Knuth and Amble [21] used it to resolve collisions in favor of the element with the smallest key, with the result that the table obtained is the same as if the keys had been inserted in increasing order. This implies that all keys encountered in a successful search are in increasing order, a fact that can be used to speed up unsuccessful searches.

If we restrict ourselves to methods that arbitrate collisions based only on the past history (i.e., no lookahead), it can be shown that the expected successful search cost does not depend on the rule used (assuming random probing). However, the *variance* of the successful search cost does depend on the method used, and can be decreased drastically with respect to that of the standard FCFS method.

A smaller variance is important because of at least two reasons. First, a method with a low variance becomes more predictable, and less subject to wide fluctuations in its response time. Second, and more important, the usual method of following the probe sequence sequentially may be improved by replacing it by an optimal search algorithm that probes the most likely location first, then the second most likely,

and so on. A reasonable approximation for this is a "mode-centered" search, that probes the most likely location first, and then moves away from it symmetrically.

Perhaps the simplest heuristic in this class is "last-come-first-served" (LCFS) [30], which does exactly the opposite from what the standard method does: in the case of a collision, the location is assigned to the incoming key.

For a full table (assuming random probing), the variance of the standard (FCFS) method is $\Theta(m)$. The LCFS heuristic reduces this to $\Theta(\log m)$.

Another heuristic, that is much more aggressive in trying to decrease inequalities between the search costs of individual elements is the "Robin Hood" (RH) method [9]. In the case of a collision, it awards the location to the element that has the largest retrieval cost. For a full table (assuming random probing), the variance of the cost of a successful search for Robin Hood hashing is ≤ 1.833, and using the optimal search strategy brings the expected retrieval cost down to ≤ 2.57 probes.

These variance reduction techniques can be applied also to linear probing. It can be shown [31] that, for a full table, both LCFS and RH decrease the variance from the $\Theta(m^{3/2})$ of the standard FCFS method to $\Theta(m)$. In the case of linear probing, it can be shown that, for any given set of keys, the Robin Hood arrangement minimizes the variance of the search time.

If we wish to decrease the expected search cost itself, and not just the variance, we must look ahead in the respective probe sequences of the keys involved in a collision. The simplest scheme would be to resolve the collision in favor of the key that would have to probe the most locations before finding an empty one. This idea can be applied recursively, and Brent [7] and Gonnet and Munro [15] used this to obtain methods that decreased the expected search cost to 2.4921 and to 2.13414 probes, respectively, for a full table.

Gonnet and Munro [15] considered also the possibility of moving keys *backward* in their probe sequences to find the *optimal* table arrangement for a given set of keys. This problem is mostly of theoretical interest, and there are actually two versions of it, depending on whether the average search cost or the maximum search cost are minimized. Simulation results show that the optimal average search cost for a full table is approximately 1.83 probes.

Choosing a Hash Function

The traditional choice of hash functions suffers from two problems. First, collisions are very likely to occur, and the method has to plan for them. Second, a malicious adversary, knowing the hash function, may generate a set of keys that will make the worst-case be $\Theta(n)$.

If the set of keys is known in advance, we may be able to find a *perfect hash function*, i.e., a hash function that produces no collisions for that set of keys. Many methods have been proposed for constructing perfect hash functions, beginning with the work of Fredman, Komlós and Szemerédi [14]. Mehlhorn [27] proved a matching upper and lower bound of $\Theta(n)$ bits for the program size of a perfect hash function.

Fox et al. [12, 13] provide algorithms for finding a *minimal* perfect hash function (i.e., for a full table), which runs in expected linear time on the number of keys involved. Their algorithms have been successfully used on sets sizes of the order of one million keys.

An approach to deal with the worst-case problem was introduced by Carter and Wegman [8]. They use a class of hash functions, and choose one function at random from the class for each run of the algorithm. In order for the method to work, the functions must be such that no pair of keys collide very often. Formally, a set $\mathcal{H}$ of hash functions is said to be *universal* if for each pair of distinct keys, the number of hash functions $h \in \mathcal{H}$ is exactly $|\mathcal{H}|/m$. This implies that for a randomly chosen h, the probability of a collision between x and y is $1/m$, the same as if h assigned truly random hash values for x and y. Cormen, Leiserson and Rivest [10] show that, if keys are composed of $r+1$ "bytes" $x_0, \ldots, x_r$, each less than m, and $a = \langle a_0, \ldots, a_r \rangle$ is a sequence of elements chosen at random from $[0..m-1]$, then the set of functions $h_a(x) = \Sigma_{0 \leq i \leq r} a_i x_i \bmod m$ is universal.

Hashing in Secondary Storage

All the hashing methods we have covered can be extended to secondary storage. In this setting, keys are usually stored in *buckets*, each holding a number of keys, and the hash function is used to select a bucket, not a particular key. Instead of the problem of collisions, we need to address the problem of bucket *overflow*. The analysis of the performance of these methods is notoriously harder than that of the main memory version, and few exact results exist [34].

However, for most practical applications, simply adapting the main memory methods is not enough, as they usually assume that the size of the hash table (m) is fixed in advance. Files need to be able to grow on demand, and also to shrink if we want to maintain an adequate memory utilization.

Several methods are known to implement *extendible* hashing (also called *dynamic* hash tables). The basic idea is to use an unbounded hash function $h(x) \geq 0$, but to use only its d rightmost bits, where d is chosen to keep overflow low or zero.

Fagin et al. [11] use the rightmost d bits from the hash function to access a *directory* of size 2^d, whose entries are pointers to the actual buckets holding the keys. Several directory entries may point to the same bucket.

Litwin [25] and Larson [23, 24] studied schemes that do not require a directory. Their methods work by gradually doubling the table size, scanning buckets from left to right. To do this, bucket splitting must be delayed until it is that bucket's turn to be split, and overflow records must be held temporarily using chaining or other similar method.

2.5 Related Searching Problems

Searching in an Unbounded Set

In most cases we search in a bounded set. We can also search in an *unbounded set*. Consider the following game: one person thinks about a positive number and another person has to guess it with questions of the type: *the number x is less than, equal to, or larger than the number that you are thinking?* This problem was considered in [4].

A first obvious solution is to use the sequence $1, 2, \ldots, n$ (that is, sequential search), using n questions. We can do better by using the "gambler" strategy. That is, we use the sequence $1, 2, 4, \ldots, 2^m$, until we have $2^m \geq n$. In the worst case we have $m = \lfloor \log n \rfloor + 1$. Next, we can use binary search in the interval $2^{m-1} + 1$ to 2^m to search for n, using in the worst case $m - 1$ questions. Hence, the total number of questions is $2m - 1 = 2\lfloor \log n \rfloor + 1$. This algorithm is depicted in Fig. 2.4. That is, only twice a binary search in a finite set of n elements. Can we do better? We can think that what we did is to search the exponent m using sequential search. So, we can use this algorithm, A_1, to search for m using $2\lfloor \log m \rfloor + 1$ questions, and then use binary search, with a total number of questions of $\log n + 2 \log \log n + O(1)$ questions. We could call this algorithm A_2.

In general, we can define algorithm A_k, which uses A_{k-1} to find m and then use binary search. The complexity of such algorithm is

$$S_n^k = \log n + \log \log n + \cdots + \log^{(k-1)} n + 2 \log^{(k)} n + O(1)$$

questions, where $\log^{(i)} n$ denotes log applied i times. Of course, if we could know the value of n in advance, there is an optimal value for k of $O(\log^* n)$,[3] because if k is too large, we go too far. However, we do not know n a priori!

[3] $\log^* n$ is the number of times that we have to apply the log function before we reach a value less than or equal to 0.

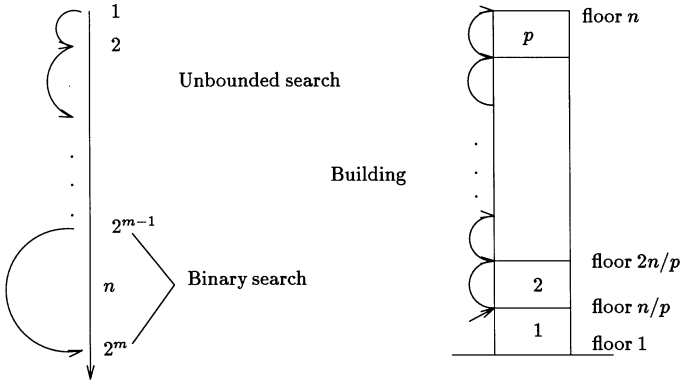

FIGURE 2.4 A_1 unbounded search (left) and the person problem (right).

Searching with Bounded Resources

Most of the time we assume that we can perform an unbounded number of questions when searching. However, in many real situations, we search with bounded resources. For example, gasoline when using a car. As an example, we use a variable cost searching problem, initially proposed in [5, Section 3.2], with some changes, but maintaining the same philosophy. Given a building of n floors and k persons, we want to answer the following problem: which is the largest floor from where a person can jump and does not break a leg? We assume that a person with a broken leg cannot jump again.[4]

Suppose that the answer is floor j. So, we have j floors that will give us a positive answer and $n - j$ floors that give us a negative answer. However, we can only afford up to k negative answers to solve the problem (in general $k < n - j$). So, we have a bounded resource: persons.

If we have just one person, the solution is easy, since we are forced to use sequential search to find j. Any other strategy does not work, because if the person fails, we do not solve the problem. If we have many persons (more precisely $k > \log n$), we can use binary search. In both cases, the solution is optimal in the worst case.

If we have two persons, a first solution would be to start using binary search with the first person, and then use the second sequentially in the remaining segment. In the worst case, the first person fails in the first jump, giving a $n/2$ jumps algorithm. The problem is that both persons do not perform the same amount of work. We can balance the work by using the following algorithm: the first person tries sequentially every n/p floors for a chosen p, that is n/p, $2n/p$, etc. When his/her leg breaks, the second person has a segment of approximately n/p floors to check (see Fig. 2.4). In the worst case the number of floors is p (first person) plus n/p (second person). So we have

$$U_n^2 = p + n/p + O(1)$$

Balancing the work, we have $p = n/p$, which implies $p = \sqrt{n}$, giving $U_n^2 = 2\sqrt{n} + O(1)$. Note that to succeed, any algorithm has to do sequential search in some segment with the last person.

We can generalize the above algorithm to k persons using the partitioning idea recursively. Every person except the last one partitions the remaining segment in p parts and the last person uses sequential search. In the worst case, every person (except the last one) has to perform p jumps. The last one does sequential search on a segment of size n/p^{k-1}. So, the total cost is approximately

$$U_n^k = (k-1)p + \frac{n}{p^{k-1}}$$

[4]This is a theoretical example, do not try to solve this problem in practice!

Balancing the work for every person, we must have $p = n/p^{k-1}$, obtaining $p = n^{1/k}$ (same as using calculus!). Then, the final cost is

$$U_n^k = kn^{1/k}$$

If we consider $k = \log_2 n$, we have

$$U_n^k = kn2^{\log_2(n^{1/k})} = \log_2 n 2^{\frac{\log_2 n}{k}} = 2\log_2 n$$

which is almost like binary search. In fact, taking care of the partition boundaries, and using an optimal partition (related to binomial trees), we can save k jumps, which gives the same as binary search. So we have a continuum from sequential to binary search as k grows.

We can mix the previous two cases to have unbounded search with limited resources. The solution mixes the two approaches already given and can be a nice exercise for interested readers.

Searching with Nonuniform Access Cost

In the traditional RAM model we assume that any memory access has the same cost. However, this is not true if we consider the memory hierarchy of a computer: registers, cache and main memory, secondary storage, etc. As an example of this case, we use the *hierarchical memory* model introduced in [1]. That is, the access cost to position x is given by a function $f(x)$. The traditional RAM model is when $f(x)$ is a constant function. Based in access times of current devices, possible values are $f(x) = \log x$ or $f(x) = x^\alpha$ with $0 < \alpha \leq 1$.

Given a set of n integers in a hierarchical memory, two problems are discussed. First, given a fixed order (sorted data), what is the optimal worst-case search algorithm. Second, what is the optimal ordering (implicit structure) of the data to minimize the worst-case search time. This ordering must be described using constant space.

In both cases, we want to have the n elements in n contiguous memory locations starting at some position and only using a constant amount of memory to describe the searching procedure. In our search problem, we consider only successful searches, with the probability of searching for each one of the n elements being the same.

Suppose that the elements are sorted. Let $S(i, j)$ be the optimal worst-case cost to search for an element which is between positions i and j of the memory. We can express the optimal worst-case cost as

$$S(i, j) = \min_{k=i,\ldots,j} \{f(k) + \max(S(i, k-1), S(k+1, j))\}$$

for $i \geq j$ or 0 otherwise. We are interested in $S(1, n)$. This recurrence can be solved using dynamic programming in $O(n^2)$ time. This problem was considered in [20], where it is shown that for logarithmic or polynomial $f(x)$, the optimal algorithm needs $O(f(n)\log n)$ comparisons. In particular, if $f(x) = x^\alpha$, a lower and upper bound of

$$\frac{n^\alpha \log n}{1+\alpha}$$

for the worst-case cost of searching is given in [20].

In our second problem, we can order the elements to minimize the searching cost. A first approach is to store the data as the implicit complete binary search tree induced by a binary search in the sorted data, such that the last level is compacted to the left (*left complete binary tree*). That is, we store the root of the tree in position 1 and in general the children of the element in position i in positions $2i$ and $2i+1$ like in a heap. Nevertheless, there are better addressing schemes that balance as much as possible every path of the search tree.

Searching with Partial Information

In this section we use a nonuniform cost model plus an unbounded domain. In addition the algorithm does not know all the information of the domain and learns about it while searching. In this case we are searching for an object in some space under the restriction that for each new "probe" we must pay costs proportional to the distance of the probe position relative to our current probe position and we wish to minimize this cost. This is meant to model the cost in real terms of a robot (or human) searching for an object when the mobile searcher must move about to find the object. It is also the case for many searching problems on secondary memory devices as disk and tapes. This another example of an **on-line algorithm.**

An on-line algorithm is called *c-competitive* if the solution to the problem related to the optimal solution when we have all the information at the beginning (off-line case) is bounded by

$$\frac{\text{Solution (on-line)}}{\text{Optimal (off-line)}} \leq c$$

Suppose that a person wants to find a bridge over a river. We can abstract this problem as finding some distinguished point on a line. Assume that the point is n (unknown) steps away along the line and that the person does not know how far away the point is. What is the minimum number of steps it must make to find the point, as a function of n?

The optimal way to find the point (up to lower order terms) is given by linear spiral search [3]: execute cycles of steps where the function determining the number of steps to walk before the i^{th} turn starting from the origin is 2^i for all $i \geq 1$. That is, we first walk one step to the left, we return to the origin, then two steps to the right, returning again to the origin, then four steps to the left, etc. The total distance walked is $2\Sigma_{i=1}^{\lfloor \log n \rfloor + 1} 2^i + n$, which is no more than 9 times the original distance. That is, this is a 9-competitive algorithm, and this constant cannot be improved.

2.6 Research Issues and Summary

Sequential and binary search are present in many forms in most programs, as they are basic tools for any data structure (either in main memory or in secondary storage). Hashing provides an efficient solution when we need good average search cost. We also covered several variants generalizing the model of computation (randomized, parallel, bounded resources) or the data model (unbounded, nonuniform access cost, and partial knowledge).

As for research issues, we list here some of the most important problems that still deserve more work. Regarding hashing, faster and practical algorithms to find perfect hashing functions are still needed. The hierarchical memory model has been extended to cover nonatomic accesses (that is, access by blocks) and other variations. This model still has several open problems. Searching with partial information led to research on more difficult problems such as motion planning.

2.7 Defining Terms

Amortized cost: Worst-case cost of a sequence of operations, averaged over the number of operations.

Chaining: A family of hashing algorithms that solve collisions by using pointers to link elements.

CREW PRAM: Computer model that has many processors sharing a memory where many can read at the same time, but only one can write at the same time in a given memory cell.

Hash function: Function that maps keys onto table locations, by performing arithmetic operations on the keys. Keys that hash to the same location are said to *collide*.

On-line algorithm: Algorithm that process the input sequentially.

Open addressing: A family of collision resolution strategies based on computing alternative hash locations for the colliding elements.

Randomized algorithm: Algorithm that makes some random (or pseudo-random) choices.

Self-organizing strategies: Heuristic that reorders a list of elements according to how the elements are accessed.

Universal hashing: A scheme that chooses randomly from a set of hash functions.

Further Information

Additional algorithms and references for the first four sections can be found in [17] and in many algorithms textbooks. More information on self-organizing heuristics can be found on Hester and Hirschberg's survey [19]. The amortized-case analysis is presented in [6, 33]. More information on searching with partial information is given in [3]. More information on searching nonatomic objects is covered in [2].

Many chapters of this handbook extend the material presented here. Another example of amortized analysis of algorithms is given in Chapter 1. Analysis of the average case is covered in Chapter 14. Randomized, on-line, and parallel algorithms are covered in Chapters 15, 10, and 47, respectively. Searching and updating more complex data structures is explained in Chapters 4 and 5. Searching for strings and subtrees is covered in Chapters 11 and 13, respectively. The use of hashing functions in cryptography is covered in Chapter 8.

Sorting and Order Statistics

Vladimir Estivill-Castro
University of Newcastle

3.1 Introduction

Sorting is the computational process of rearranging a given sequence of items from some total order into ascending or descending order. Because sorting is a task in the very core of Computer Science, efficient algorithms were developed early. The first practical and industrial applications of computers had many uses for sorting. It is still a very frequently occurring problem, often appearing as a preliminary step to some other computational tasks. A related application to sorting is computing *order statistics,* for example, finding the median, the smallest or the largest of a set of items. Although finding order statistics is immediate once the items are sorted, sorting can be avoided and faster algorithms have been designed for finding the kth largest element, the most practical of which is derived from the structure of a sorting method.

Sorting usually involves data consisting of records in one or several files. One or several fields of the records are used as the criteria for sorting (often a small part of the record) and are called the *key.* Usually, the objective of the sorting method is to rearrange the records so that their keys are arranged in numerical or alphabetical order.

In many applications of sorting, elementary sorting algorithms are the best alternative. There are several reasons for this. Sorting programs are often used once (or only a few times) rather than repeated many times, one after another. Simple methods are always suitable for small files, say less than a 100 elements. The increasing speeds in every time less expensive computers are enlarging the size for which basic methods are adequate. More advanced algorithms require more careful programming, and their correctness or efficiency is more fragile to thorough understanding of their mechanisms. Also, sophisticated methods may not take advantage of existing order in the input, which may already be sorted, while elementary methods usually do. Finally, elementary sorting algorithms usually have a very desirable property, named *stability;* that is, they preserve the relative order of items with equal keys. This is usually expected in applications generating reports from already sorted files, but with a different key. For example, long distance phone calls are usually recorded in a log in chronological order by the date and time the call

was made. When reporting bills to customers, the carrier sorts by customer name, but the result should preserve the chronological order of the calls made by each particular customer.

Advanced methods are the choice in applications involving a large number of items. Also, they can be used to build a robust, general-purpose sorting routine. Elementary methods should not be used for large, randomly permuted files. An illustrative trade-off between a sophisticated technique that results in generally better performance over the simplicity of the programming is the sorting of keys and pointers to records rather than the entire records. Once the keys are sorted, the pointers to the complete records are used in a simple pass over the file to rearrange the data in the desired order. To apply this technique we must construct the auxiliary sequence of keys and pointers (or in the case of long keys, the keys can be kept with the records as well). However, many exchanges and data moves are saved until the final destination of each record is known. In addition, less space is required if, as is common in practice, keys are only a small part of the data record. When keys are a quarter or more of their records, this technique is not worth the programming effort.

When the file to be sorted is small enough that all the data fits in main memory (usually an array of records or keys), the sorting process is called **internal sorting**. **External sorting** corresponds to the situation when the file to be sorted is so large that the data does not entirely fit in main memory; then, the sorting process must be performed with clever use of input/output operations, since these operations, account for most of the computational time. Currently, the sorting of files that are too large to be held in main memory is performed on disk drives, rather than tapes. The availability of large main memories and new technologies for disk drives have modified the models for external sorting [17, 20].

Sorting algorithms can also be divided into two large groups according to what they require about the data to perform the sorting. The first group is usually called *comparison-based.* Methods of this class only use the fact that the universe of keys is linearly ordered. That is, given two items, they only need to query what is the order between these two items. Because of this property, the implementation of **comparison-based algorithms** can be generic with respect to the data type of the keys, and a comparison routine can be supplied as a parameter to the sorting procedure. The second group of algorithms assumes further that keys are restricted to a certain domain or representation and use knowledge of this information to dissect subparts, bytes, or bits of the keys.

Sorting is also ideal for introducing issues regarding algorithmic complexity. For comparison-based algorithms, it is possible to precisely define an abstract model of computation (namely, *decision trees*) and show lower bounds on the number of comparisons any sorting method would require to sort a sequence with n items (in the worst case and in the average case). A comparison-based sorting algorithm that requires $O(n \log n)$ comparisons is said to be *optimal,* because this matches the $\Omega(n \log n)$ lower bounds. Thus, in theory, no other algorithm could be faster. The fact that algorithms that are not comparison-based can result in faster implementations illustrates the relevance of the model of computation with respect to theoretical claims of optimality and the effect that a stronger assumption on the data has for designing a faster algorithm [1, 14].

Sorting illustrates *randomization* (the fact that the algorithm makes a random choice). Randomization has practical value for sorting algorithms. In particular, it provides an easy protection for sophisticated algorithms from special input that may be simple (like almost sorted) but harmful to the efficiency of the method. The most notable example is the use of randomization for the selection of the pivot in *Quicksort.*

In what follows, we will assume that the goal is to sort into ascending order, since sorting in descending order is symmetrical, or can be achieved by sorting in ascending order and reversing the result (in linear time, which is usually affordable). Also, we make no distinction between the records to be sorted and their keys, assuming that some provision has been made for handling this as suggested before. Through our presentation the keys may not all be different, since one of the main applications of sorting is to bring together records with matching keys. We will present algorithms in pseudocode in the style introduced by Cormen et al. [5], or when more specific detail is convenient, we will use PASCAL code. When appropriate, we will indicate possible trade-offs between clarity and efficiency of the code. We believe that efficiency should not be pursued at the extreme, and certainly not above clarity. The costs of programming and

code maintenance are usually larger than slight efficiency gains by tricky coding. For example, there is a conceptually simple remedy to make every sorting routine **stable**. The idea is to precede it with the construction of new keys and sort according to lexicographical order of the new keys. The new key for the ith item is the pair (k_i, i), where k_i is the original sorting key. This requires the extra management of the composed keys and adds to the programming effort the risk of a faulty implementation. Today, this could probably be solved by simply choosing a competitive stable sort, perhaps at the expense of slightly more space or time.

3.2 Underlying Principles

Divide-and-conquer is a natural, top-down approach for the design of an algorithm for the abstract problem of sorting a sequence $X = \langle x_1, x_2, \ldots, x_n \rangle$ of n items. It consists of dividing the problem into smaller subproblems hoping that the solutions of the subproblems are easier to find and then composing the partial solutions into the solution of the original problem. A prototype of this idea is *Mergesort;* where the input sequence $X = \langle x_1, x_2, \ldots, x_n \rangle$ is split into two sequences $X_L = \langle x_1, x_2, \ldots, x_{\lfloor n/2 \rfloor} \rangle$ the left subsequence) and $X_R = \langle x_{\lfloor n/2 \rfloor + 1}, \ldots, x_n \rangle$ (the right subsequence). Finding solutions recursively for sequences of more than one item and terminating the recursion with sequences with only one item (since these are always sorted) provides a solution for the two subproblems. The overall solution is found by describing a method to merge two sorted sequences. In fact, internal sorting algorithms are variations of two forms of using divide-and-conquer:

Conquer form. Divide is simple (usually requiring constant time), conquer is sophisticated.

Divide form. Divide is sophisticated, conquer is simple (usually requiring constant time).

Again, *Mergesort* is an illustration of the conquer from. The core of the method is in the merging of the two sorted sequences, hence its name.

The prototype for the **divide form** is *Quicksort* [10]. Here, one item x_p (called the *pivot*) is selected from the input sequence X and its key is used to create two subproblems $X_{\leq}$ and $X_{\geq}$, where $X_{\leq}$ contains items in X with keys less or equal than the pivot's, while items in $X_{\geq}$ have keys larger or equal than the pivot's. Now, recursively applying the algorithm for $X_{\leq}$ and $X_{\geq}$ results in a global solution (with a trivial conquer step that places $X_{\leq}$ before $X_{\geq}$).

Sometimes we may want to conceptually simplify the **conquer form** by not dividing into two problems of roughly the same size, but rather divide X into $X' = \langle x_1, \ldots, x_{n-1} \rangle$ and $X'' = \langle x_n \rangle$. This is conceptually simpler in two ways. First, X'' is a trivial subproblem, because it has only one item and thus it is already sorted. Therefore, in a sense we have one subproblem less. Second, the merging of the solutions of X' and X'' is simpler than the merging of two sequences of almost equal length, because we just need to place x_n in its proper position amongst the sorted items from X'. Because the method is based upon inserting into an already sorted sequence, sorting algorithms with this idea are called **insertion sorts**.

Insertion sorts vary according to how the sorted list for the solution of X' is represented by a data structure that supports insertions. The simplest alternative is to have the sorted list stored in an array, and this method is named *Insertion Sort* or *Straight Insertion Sort* [12]. However, if the sorted list is represented by a *level-linked-tree* with a *finger,* the method has been named *A-sort* [14] or *Local Insertion Sort* [13].

The complementary simplification in the divide form makes one subproblem trivial by selecting a pivot so $X_{\leq}$ or $X_{\geq}$ consist of just one item. This is achieved if we select the pivot as the item with the smallest or with the largest key in the input. The algorithms under this scheme are called **selection sorts**, and they vary according to the data structured used to represent X so that repeated extraction of the maximum (minimum) key is efficient. This is typically the requirement of the *priority queue* abstract data type with the keys as the priorities. When the priority queue is implemented as an array and the smallest key is found

by scanning this array, the method is *Selection Sort.* However, if the priority queue is an array organized into a heap, then the method is called *Heapsort.*

Using divide-and-conquer does not necessarily mean that the division must be into two subproblems. It may divide into several subproblems. For example, if the keys can be manipulated with other operations besides comparisons, *Bucket Sort* uses an interpolation formula on the keys to partition the records between m buckets. The buckets are sets of records, which are usually implemented as *queues.* The queues are usually implemented as linked lists that allow insertion and removal in constant time in first-in first-out order, as the abstract data type queue requires. The buckets represent subproblems to be sorted recursively. Finally, all the buckets are concatenated together. *Shellsort* divides the problem of sorting X into several problems consisting of the interlaced subsequences of X that consist of items d positions apart. Thus, the first subproblem is $\langle x_1, x_{1+d}, x_{1+2d}, \ldots \rangle$ while the second subproblem is $\langle x_2, x_{2+d}, x_{2+2d}, \ldots \rangle$. *Shellsort* solves the subproblems by applying *Insertion Sort;* however, rather than using a **multiway merge** to combine these solutions, it reapplies itself to the whole input but with a smaller d. Careful selection of the sequence of values of d results in a very practical sorting method.

We have used divide-and-conquer to conceptually depict the landscape of sorting algorithms (refer to Fig. 3.1). Nevertheless, in practice, sorting algorithms are usually not implemented as recursive programs. Instead, a nonrecursive equivalent analog is implemented (although computations may be performed in different order). In applications, the nonrecursive version is more efficient since the administration of the recursion is avoided. For example, a straightforward nonrecursive version of *Mergesort* proceeds as follows. First, the pairs of lists $\langle x_{2i-1} \rangle$ and $\langle x_{2i} \rangle$ (for $i = 1, \ldots \lfloor n/2 \rfloor$) are merged to form sorted lists of length two. Next, the pairs of lists $\langle x_{4i-1}, x_{4i-2} \rangle$ and $\langle x_{4i-1}, x_{4i} \rangle$ (for $i = 1, \ldots \lfloor n/4 \rfloor$) are merged to form sorted lists of length four. The process builds sorted lists twice as long in each round until the input is sorted. Similarly, *Insertion Sort* has a practical iterative version illustrated in Fig. 3.2.

```

FIGURE 3.2 The sentinel version of *insertion sort.*

Placing a sorting method in the landscape provided by divide-and-conquer allows easy computation of its time requirements, at least under the O notation. For example, algorithms of the conquer form have a divide part that takes $O(1)$ time to derive two subproblems of roughly equal size. The solutions of subproblems may be combined in $O(n)$ time. This results in the following recurrence for the time $T(n)$

to solve a problem of size n:

$$T(n) = \begin{cases} 2T(\lceil n/2 \rceil) + O(n) + O(1) & \text{if } n > 1\,, \\ O(1) & n = 1\,. \end{cases} \tag{3.1}$$

It is not hard to see that each level of recursion takes linear time and that there are at most $O(\log n)$ levels (since n is roughly divided by 2 at each level). This results in $T(n) = O(n \log n)$ time overall. If the divide form splits into one problem of size $n-1$ and one trivial problem, the recurrence is as follows:

$$T(n) = \begin{cases} 2T(n-1) + O(1) + O(conquer(n-1)) & \text{if } n > 1\,, \\ O(1) & n = 1\,, \end{cases} \tag{3.2}$$

where $conquer(n-1)$ is the time required for the conquer step. It is not hard to see that there are $O(n)$ levels of recursion (since n is decremented by one at each level). Thus, the solution to the recurrence is $T(n) = O(n) + \Sigma_{i=1}^{n} O(conquer(i))$. In the case of *Insertion Sort,* the worst case for $conquer(i)$ is $O(i)$, for $i = 1, \ldots, n$. Thus, we have that *Insertion Sort* is $O(n^2)$. However, *Local Insertion Sort* assures $conquer(i) = O(\log i)$ and results in an algorithm that requires $O(n \log n)$ time. We will not purse this analysis any further, confident that the reader will be able to find enough information here or in the references to identify the time and space complexity of the algorithms presented, at least up to the O notation.

Naturally, one may ask why there are so many sorting algorithms if they all solve the same problem and fit a general framework. It turns out that, when implemented, each has different properties that makes them more suitable for different objectives.

First, comparison-based sorting algorithms are ranked by their theoretical performance in the comparison-based model of computation. Thus, an $O(n \log n)$ algorithm should always be preferred over an $O(n^2)$ algorithm if files are large. However, theoretical bounds may be for the worst case, or the expected case (where the analysis assumes that the keys are pairwise different and all possible permutations of items are equally likely). Thus, an $O(n^2)$ algorithm should be preferred over an $O(n \log n)$ algorithm if the file is small, or if we know that the file is already almost sorted. Particularly, if in such a case, the $O(n^2)$ algorithm turns into an $O(n)$ algorithm. For example, *Insertion Sort* requires exactly $Inv(X) + n - 1$ comparisons and $Inv(X) + 2n - 1$ data moves, where $Inv(X)$ is the number of *inversions* in a sequence $X = \langle x_1, x_2, \ldots, x_n \rangle$; that is, the number of pairs (i, j) where $i < j$ and $x_i > x_j$. On the other hand, if *Quicksort* is not carefully implemented, it may degenerate to $\Omega(n^2)$ performance for nearly sorted inputs.

If the theoretical complexities are equivalent, other aspects come into play. Naturally, the next criteria is the size of the constant hidden under the O notation (as well as the size of hidden minor terms when the file is small). These constants are affected by implementation aspects. The most significant are now listed.

- The relative costs of swaps, comparisons, and other operations in the computer at hand (and for the data types of the keys and records). Usually, swaps are more costly than comparisons, which in turn are more costly than other arithmetic operations; however, comparisons may be just as costly as swaps or an order of magnitude less costly, depending on the length of keys, records, and strategies to rearrange the records.
- The length of the machine code, so code remains in memory, under an operating system that administers paging or in the cache of the microprocessor.
- Similarly, the locality of references to data or the capacity to place frequently compared keys in a CPU register.

Finally, there may be restrictions that force the choice of one sorting method over another. These include limitations like the data structure holding the data may be a linked list instead of an array, or the space available may be seriously restricted. There may be need for stability, or the programming tool may lack recursion. In practice, a hybrid sort is usually the best answer.

3.3 State of the Art and Best Practices

Comparison-Based Internal Sorting

Insertion Sort

Figure 3.2 presented *Insertion Sort.* This algorithm uses sequential search to find the location, one item at a time, in a portion already sorted of the input array. It is mainly used to sort small arrays.

Besides being one of the simplest sorting algorithms, which results in simple code, it has many desirable properties. From the programming point of view, its loop is very short (usually taking advantage of memory management in the CPU cache or main memory), the key of the inserted element may be placed in a CPU register and access to data exhibits as much locality as it is perhaps possible. Also, if a minimum possible key value is known, a *sentinel* can be placed at the beginning of the array to simplify the inner loop, resulting in faster execution. Another alternative is to place the item being inserted, itself as a sentinel each time. From the applicability point of view, it is stable; recall this means records with equal keys remain in the same relative order after the sort. Its $\Theta(n^2)$ expected-case complexity and worst-case behavior makes it only suitable for small files, and thus, it is usually applied in *Shellsort* to sort the interleaved sequences. However, the fact that it is **adaptive** with respect to the measure of disorder Inv makes it suitable for almost sorted files with respect to this measure. Thus, it is commonly used to sort roughly sorted data produced by implementations of *Quicksort* that do not follow recursion calls once the subarray is small. This idea helps *Quicksort* implementations achieve better performance, since the administration of recursive calls for small files is more time consuming than using *Insertion Sort* to complete the sorting.

Insertion Sort also requires only constant space; that is, space for a few local variables (refer to Fig. 3.2). From the point of view of quadratic sorting algorithms, it is a clear winner. Investigations of theoretical interest have looked at comparison-based algorithms where space requirements are constant, and data moves are linear. Only in this case, *Insertion Sort* is not the answer, since *Selection Sort* achieves this with the equivalent number of comparisons. Thus, when records are very large and no provision is taken for avoiding the expensive data moves (by sorting a set of indices rather than the data directly), *Selection Sort* should be used.

Shellsort

One idea toward improving the performance of *Insertion Sort* is to observe than each element, when inserted into the sorted portion of the array, travels a distance equal to the number of elements to its left which are greater than itself (the number of elements inverted with it). However, this traveling is done in steps of just adjacent elements and not by exchanges between elements far apart. The idea behind *Shellsort* [12] is to use *Insertion Sort* to sort interleaved sequences formed by items d positions apart, thus allowing for exchanges as far as d positions apart. After this, elements far apart are closer to their final destinations, so d is reduced to allow exchanges of closer positions. To assure the output is sorted, the final value for d is one.

There are many proposals for the *increment sequence* [9]; the sequence of values of d. Some proposals are $\langle 2^k - 1, 2^{k-1} - 1, \ldots, 7, 3, 1\rangle$, $\langle 2^p 3^q, \ldots, 9, 8, 6, 4, 3, 2, 1\rangle$, and $\langle S_i, \ldots, 40, 13, 4, 1\rangle$ where $S_i = 3S_{i-1} + 1$. It is possible that better sequences exist; however, the improvement that they may produce in practice is almost not visible. *Shellsort* is guaranteed to be clearly below the quadratic behavior of *Insertion Sort.* The exact theoretical complexity remains elusive but large experiments conjecture $O(n(\log n)^2)$, $O(n^{1.25})$, and $O(n \log n \log\log n)$ comparisons are required for various increment sequences. Thus, it will certainly be much faster than quadratic algorithms, and for medium-size files it would remain competitive with $O(n \log n)$ algorithms.

From the programming point of view, *Shellsort* is simple to program. It is *Insertion Sort* inside the loop for the increment sequence. It is important not to use the version of *Insertion Sort* with sentinels, since for the rounds with large d many sentinels would be required. Not using a sentinel demands two exit points for the most inner loop. This can be handled with a clean use of a **goto**, but in languages which short-cut

logical connectives (typically C) this feature can be used to avoid gotos. Figure 3.3 shows pseudocode for *Shellsort.*

```
SHELLSORT(X, n);
1  d ← n ;
2  repeat
3        if d < 5
4        then d ← 1
5        else d ← (5 * d − 1) div 11;
6        for j ← d + 1 to n
7        do i ← j − d;
8            t ← X[j];
9            while t < X[i]
10           do X[i + d] ← X[i];
11               i ← i − d;
12               if i < d
13               then goto 14;
14           X[i + d] ← t; ▷ part of the for j loop
15 until d ≤ 1;
```

FIGURE 3.3 *Shellsort* with increment sequence $\langle \lfloor n\alpha \rfloor, \lfloor \lfloor n\alpha \rfloor \alpha \rfloor, \ldots, \rangle$ with $\alpha = 0.4545 < 5/11$.

Unfortunately, *Shellsort* loses some of the virtues of *Insertion Sort.* It is no longer stable, and its behavior in nearly sorted files is adaptive but not as marked as for *Insertion Sort.* However, its space requirements remain constant, and its coding is straightforward and usually results in a short program loop. It does not have a bad case and is a good candidate for a library sorting routine. The usual recommendation when facing a sorting problem is to first try out *Shellsort* because a correct implementation is easy to achieve. Only if this proves to be insufficient for the application at hand should a more sophisticated method be attempted.

Heapsort

The *priority queue* abstract data type is an object that allows the storage of items with a key indicating their priority as well as retrieval of the item with the largest key. Given a data structure for this abstract data type, a sorting method can be constructed as follows. Insert each data item in the priority queue with the sorting key as the priority key. Repeatedly extract the item with the largest key in the priority queue to obtain the items sorted in reverse order.

One immediate implementation of the priority queue is as an unsorted list (either as an array or as a linked list). Insertion in the priority queue is trivial; the item is just appended to the list. Extraction of the item with the largest key is achieved by scanning the list to find the largest item. If this implementation of a priority queue is used for sorting, the algorithm is called *Selection Sort.* Its time complexity is $\Theta(n^2)$, and as was already mentioned, its main virtue is that data moves are minimal.

A second implementation of a priority queue is to keep a list of the items sorted in descending order by their priorities. Now, extraction of the item with largest priority requires constant time, since it is known that the largest item is at the front of the list. However, inserting a new item into the priority queue implies scanning the sorted list for the position of the new item. Using this implementation of a priority queue for sorting we observe that we obtain *Insertion Sort* once more.

The above implementations of a queue offer constant time for either insertion or extraction of the item with maximum key in exchange for linear time for the other operation. Thus, in applications of priority queues where the balance of operations is uneven, they may result in efficient methods. However, for sorting, n items are inserted and n are extracted; thus, a balance is required between the insert and extract

operations. This is achieved by implementing the priority queue as a *heap* [1, 12] that shares the space with the array of data to be sorted. An array $A[1..n]$ satisfies the heap property if $A[\lfloor k/2 \rfloor] \geq A[k]$, for $2 \leq k \leq n$. In this case, $A[\lfloor k/2 \rfloor]$ is called the *parent* of $A[k]$ while $A[2k]$ and $A[2k+1]$ are called the *children* of $A[k]$. However, an item may have no children or only one child, in which case its called a *leaf.* The heap is constructed using all the elements in the array and is located in the lower part of the array. The sorted array is incrementally constructed from the item with largest key towards the element with smallest key. *Heapsort* operates in two phases. The first phase builds the heap using all the elements, and careful programming guarantees that this requires $O(n)$ time. The second phase repeatedly extracts the item with largest key from the heap. Since the heap shrinks by one element, the space created is used to place the element just extracted. Each of the n updates in the heap takes $O(\log i)$ comparisons, where i is the number of items currently in the heap. In fact, the second phase of *Heapsort* exchanges the first item of the array (the item with largest key) with the item in the last position of the heap, and sinks the new item at the top of the heap to reestablish the heap property.

Heapsort can be efficiently implemented around a procedure *sink* for repairing the heap property (refer to Fig. 3.4). Procedure *sink*$(k, limit)$ moves down the heap, if necessary, exchanging the item at position k with the largest of its two children, and stopping when the item at position k is no longer smaller than one of its children (or when $k > limit$); refer to Fig. 3.5. Observe that the loop in *sink* has two distinct exits, when item k has no children and when the heap property is reestablished. For our pseudocode, we have decided to avoid the use of gotos. However, the reader can refer to our use of a goto in Fig. 3.3 for an idea to construct an implementation that actually saves some data moves. Using procedure *sink,* the code for *Heapsort* is simple. From the applicability point of view, *Heapsort* has the disadvantage that it is not stable. However, it is guaranteed to execute in $O(n \log n)$ time in the worst case and no extra space.

```
HEAPSORT(X, n);
1 for i ← n div 2 downto 2
2 do SINK(i, n)
3 for i ← n downto 2
4 do SINK(1, i)
5      t ← X[1]
6      X[1] ← X[i]
7      X[i] ← t
```

FIGURE 3.4 The pseudocode for *Heapsort.*

```
SINK(k, limit);
1 while 2 * k ≤ limit
2 do j ← 2k
3    if j < limit
4    then ▷ two children
5           if X[j] < X[j + 1]
6           then j ← j + 1
7    if X[k] < X[j]
8    then t ← X[j]
9           X[j] ← X[k]
10          X[k] ← t
11          k ← j
12   else k ← limit + 1 ▷ force loop exit
```

FIGURE 3.5 The sinking of one item into a heap.

It is worth revising the analysis of *Heapsort.* First, let us look at *sink.* In each pass around its loop, *sink* at least doubles the value of k, and *sink* terminates when k reaches $limit$ (or before, if the heap property is reestablished earlier). Thus, in the worst case $sink$ requires $O(h)$ time where h is the height of the heap. The loop in lines 1 and 2 for *Heapsort* constitute the core of the first phase (in our code, the head construction is completed after the first execution of line 4). A call to *sink* is made for each node. The first $\lfloor n/2 \rfloor$ calls to *sink* are for heaps of height 1, the next $\lfloor n/4 \rfloor$ are for heaps of height 2, and so on. Summing over the heights, we have that the phase for building the heap requires

$$O\left(\sum_{i=1}^{\log n} i\,\frac{n}{2^i}\right) = O(n) \tag{3.3}$$

time. Now, the core of the second phase is the loop from line 3. These are n sinks plus a constant for the three assignments. The ith of the sinks is in a heap of height $O(\log i)$. Thus, this is $O(n \log n)$ time. We conclude that the first phase of *Heapsort* (building the priority queue) requires $O(n)$ time. This is useful when building a priority queue. The second phase, and, thus, the algorithm, requires $O(n \log n)$ time.

Heapsort does not use any extra storage, nor does it require a language supplying recursion. For some, it may be surprising that *Heapsort* destroys the order in an already sorted array to re-sort it. Thus, *Heapsort* does not take advantage of existing order in the input, but it compensates this with the fact that its running time has very small variance across the universe of permutations. Intuitively, items at the leaves of the heap have small keys, which makes the sinking usually travel down to a leaf. Thus, almost all of the n updates in the heap takes at least $\Omega(\log i)$ comparisons, making the number of comparisons vary very little from one input permutation to another. Although its average case performance may not be as good as *Quicksort,* it is rather simple to obtain an implementation that is robust. It is a very good choice for an internal sorting algorithm. Sorting by selection with an array having a heap property is also used for external sorting.

Quicksort

For many applications a more realistic measure of the time complexity of an algorithm is its expected time. In sorting, a classical example is *Quicksort* [10, 18], which has an optimal expected time complexity of $O(n \log n)$ under the decision tree model, while there are sequences that force it to perform $\Omega(n^2)$ operations (in other words, its worse-case time complexity is quadratic). If the worst-case sequences are very rare, or the algorithm exhibits a small variance around its expected case, then this type of algorithm is suitable in practice.

Several factors have made *Quicksort* a very popular choice for implementing a sorting routine. *Quicksort* is a simple divide-and-conquer concept, the partitioning can be done in a very short loop and is also conceptually simple, its memory requirements can be guaranteed to be only logarithmic on the size of the input, the pivot can be placed in a register and, most importantly, the expected number of comparisons is almost half of the worst-case optimal competitors, most notably *Heapsort.* In their presentation, many introductory courses on algorithms favor *Quicksort.* However, it is very easy to implement *Quicksort* in such a way that it seems correct and extremely efficient for many sorting situations. However, it may be hiding $O(n^2)$ behavior for a simple case (for example, sorting n equal keys). Users of such library routine will be satisfied with it initially, only to find out later that on something that seems a simple sorting task, the implementation is consuming too much time to finish the sort.

Fine tuning of *Quicksort* is a delicate issue [3]. Many of the improvements proposed may be compensated by reduced applicability of the method or more fragile and less clear code. Although the partitioning is conceptually simple, much care is required to avoid common pitfalls. Among these, we must assure that the selection and placement of the pivot maintains the assumption about the distribution of input sequences. That is, the partitioning must guarantee that all permutations of smaller sequences are equally likely when permutations of n items are equally likely. The partitioning must also handle extreme cases, which occur far more frequently in practice than the uniformity assumption for the theoretical analysis. These extreme

cases include the case in which the file is already sorted (either in ascending or descending order) and its subcase, the case in which the keys are all equal, as well as the case in which many keys replicated. One very common application of sorting is bringing together items with equal keys [3].

Recall that *Quicksort* is a prototype of divide-and-conquer with the core of the work performed during the divide phase. The standard *Quicksort* algorithm selects from a fixed location in the array a splitting element or *pivot* to partition a sequence in two parts. After partitioning, the items of the subparts are in correct order with respect to each other. Most partition schemes result in *Quicksort* not being stable. Figure 3.6 presents a version for partitioning that is correct and assures $O(n \log n)$ performance even if all keys are equal; it does not require sentinels and the indices i and j never go out of bounds from the subarray. The drawback of using fixed location pivots for the partition is when the input is sorted (in descending or ascending order). In these cases, the choice of pivot drives *Quicksort* to $O(n^2)$ performance. This is still the case for the routine presented here. However, we have accounted for repeated key values, so if there are e key values equal to the pivot's, then $\lceil e/2 \rceil$ end up in the right subfile. If all keys are always different, the partition can be redesigned so that it leaves the pivot in its correct position and out of further consideration. Figure 3.7 presents the global view of *Quicksort*. The second subfile is never empty (i.e., $p < r$), and thus, this *Quicksort* always terminates.

```
PARTITION(X, l, r)
1 pivot ← X[l]
2 i ← l − 1
3 j ← r + 1
4 while TRUE
5       do repeat j ← j − 1
6          until X[j] ≤ pivot
7          repeat i ← i + 1
8          until X[i] ≥ pivot
9          if i < j
10           then exchange X[i] ↔ X[j]
11           else return j
```

FIGURE 3.6 A simple and robust partitioning.

```
QUICKSORT(X, l, r)
1 if l < r
2   then split ← PARTITION(X, l, r)
3        QUICKSORT(X, l, split)
4        QUICKSORT(X, split + 1, r)
```

FIGURE 3.7 Pseudocode for *Quicksort*. An array is sorted with the call QUICKSORT $(X, 1, n)$.

The most popular variants to protect *Quicksort* from worst-case behavior are the following. The splitting item is selected as the median of a small sample, typically three items (the first, middle, and last element of the subarray). Many results show that this can reduce the expected average running time by about 5% to 10% (depending on the cost of comparisons and how many keys are different). This approach assures that a worst case happens with negligible low probability. For this method, the partitioning can accommodate the elements used in the sample so then no sentinels are required, but there is still the danger of many or all equal keys.

Another proposal delays selection of the splitting element; instead, a pair of elements that determine the range for the median is used. As the array is scanned, every time an element falls between the pair,

one of the values is updated to maintain the range as close to the median as possible. At the end of the partitioning two elements are in their final positions, dividing the interval. This method is fairly robust, but it enlarges the inner loop deteriorating performance, there is a subtle loss of randomness, and it also complicates the code significantly. Correctness for many equal keys remains a delicate issue.

Other methods are not truly comparison-based; for example, they use pivots that are arithmetic averages of the keys. These methods reduce the applicability of the routine and may loop forever on equal keys.

Randomness can be a useful tool in algorithm design, especially if some bias in input is suspected. A randomized version of *Quicksort* is practical because there are many ways in which the algorithm can proceed with good performance and only a few worst cases. Some authors find displeasing the need to use a pseudo-random generator for a problem as well studied as sorting. However, we find that the simple partitioning routine presented if Fig. 3.7 is robust to many of the aspects that make partitioning difficult to code and can remain simple and robust while handling worst case performance with the use of randomization. The randomized version of *Quicksort* is extremely solid and easy to code; refer to Fig. 3.8. Moreover, the inner loop of *Quicksort* remains extremely short; it is inside partition and consists of modifying an integer by 1 (increment or decrement, a very efficient operation in current hardware) and comparing a key with the key of the pivot (this value, along with the indexes i and j, can be placed in a register of the CPU). Also, access to the array exhibits a lot of locality of reference. By using the randomized version, the space requirements become $O(\log n)$ without the need to sort recursively the smallest of the two subfiles produced by the partitioning. If ever in practice the algorithm is taking too long, just halting it and running it again will provide a new seed with extremely high probability of reasonable performance.

```
ROUGHLY QUICKSORT(X, l, r)
1 while r − l > 10
2       do i ← RANDOM(l, r)
3          exchange X[i] ↔ X[l]
4          split ← PARTITION(X, l, r)
5          ROUGHLY QUICKSORT(X, l, split)
6          l ← split + 1
```

FIGURE 3.8 Randomized and tuned version of *Quicksort*.

Further improvements can now be made to tune up the code presented here (of course, sacrificing some simplicity). One of the recursive calls can be eliminated by **tail recursion removal**, and thus the time for half of the procedure calls is saved. Finally, it is not necessary to use a technique such as *Quicksort* itself to sort the very small subarrays produced in the final recursive calls. It is about 15% to 20% more efficient to sort small files of less than 10 items by a final call to *Insertion Sort* to complete the sorting. Figure 3.8 illustrates the tuned hybrid version of *Quicksort* that incorporates these improvements. To sort a file, first a call is made as ROUGHLY QUICKSORT$(X, 1, n)$ immediately followed by the call INSERTION SORT(X, n). Obviously both calls should be packed under a call for *Quicksort* to avoid accidentally forgetting to make both calls. However, for testing purposes, it is good practice to call them separately. Otherwise, we may receive the impression the implementation of the *Quicksort* part is correct, while *Insertion Sort* is actually doing the sorting.

It is worth revising the analysis of *Quicksort*. We will do this for the randomized version. This version has no bad inputs. For the same input, each run has different behavior. The analysis computes the expected time for each input, and it shows that this is $O(n \log n)$ time.

Suppose that $i \leftarrow$ RANDOM(l, r) returns an integer in $[l, \ldots, r]$ with uniform probability. That is, Prob$[i = k] = 1/(r - l + 1)$, for all $k \in [l \ldots r]$. Let $T_{RQ}(X)$ be the number of comparisons performed by *Randomized Quicksort* on an input X. Because the algorithm is randomized, $T_{RQ}(X)$ is a random variable, and we will be interested in its expected value. For the analysis, we evaluate the largest expected value of $T_{RQ}(X)$ over all inputs with n different key values. Thus, we estimate $E[T_{RQ}(n)] =$

$\max\{E[T_{RQ}(X)] \mid \|X\| = n\}$. The largest subproblem for a recursive call is $n-1$. Thus, the recursive form of the algorithm allows the following derivation, where c is a constant.

$$E\left[T_{RQ}(n)\right] = \sum_{i=1}^{n-1} \text{Prob}[i=k] E\left[\begin{array}{l}\sharp \text{ of comparisons when subproblems} \\ \text{are of sizes } i \text{ and } n-i\end{array}\right] + cn \tag{3.4}$$

$$\leq cn + \frac{1}{n}\sum_{i=1}^{n-1}\left(E\left[T_{RQ}(i)\right] + E\left[T_{RQ}(n-i)\right]\right) \tag{3.5}$$

$$= cn + \frac{2}{n}\sum_{i=1}^{n-1} E\left[T_{RQ}(i)\right]. \tag{3.6}$$

Since $E[T_{RQ}(0)] \leq b$ and $E[T_{RQ}(1)] \leq b$ for some constant b, then it is not hard to verify by induction that $E[T_{RQ}(n)] \leq kn\log_e n = O(n\log n)$, for all $n \geq 2$, which is the required result. Moreover, recurrence (3.6) can be solved exactly to obtain an expression for the constant hidden under the O notation.

Mergesort

Mergesort is not only a prototype of the conquer form in divide-and-conquer, as we saw earlier. *Mergesort* has two properties that can make it a better choice over *Heapsort* and *Quicksort* in many applications. The first of these properties is that *Mergesort* is naturally a stable sorting algorithm, while additional efforts are required to obtain stable versions of *Heapsort* and *Quicksort*. The second property is that access to the data is sequential; thus, data does not have to be in an array. This makes *Mergesort* an ideal method to sort linked lists. It is possible to use a divide form for obtaining a *Quicksort* version for lists that is also stable. However, the methods for protection against quadratic worst cases still make *Mergesort* a more fortunate choice. The advantages of *Mergesort* are not without cost. *Mergesort* requires $O(n)$ extra space (for another array or for the pointers in the linked list implementation). It is possible to implement *Mergesort* with constant space, but the gain hardly justifies the added programming effort.

Mergesort is based upon merging two sorted sequences of roughly the same length. Actually, *merging* is a very common special case of sorting, and it is interesting in its own right. Merging two ordered lists is achieved by repeatedly comparing the head elements and moving the one with the smaller key to the output list. Figure 3.9 shows PASCAL code for merging two linked lists. The PASCAL code for linked lists of *Mergesort* is shown in Fig. 3.10. It uses the function for merging of the previous figure. This implementation of *Mergesort* is more general that a sorting procedure for all the items in a linked list. It is a PASCAL function with two parameters, the head of the lists to be sorted and an integer n indicating how many items from the head should be included in the sort. The implementation returns as a result the head of the sorted portion and the head of the original list is a VAR parameter adjusted to point to the $(n+1)$th element of the original sequence. If n is larger or equal to the length of the list, the pointer returned includes the whole list and the VAR parameter is set to nil.

Restricted Universe Sorts

In this section we present algorithms that use other aspects about the keys to carry out the sorting. These algorithms were very popular at some point, and were the standard to sort punched cards. With the emergence of comparison-based sorting algorithms, which provided generality as well as elegant analyses and matching bounds, these algorithms lost popularity. However, their implementations can be much faster than comparison-based sorting algorithms. The choice between comparison-based methods and these types of algorithms may depend on the particular application. For a general sorting routine, many factors must be considered, and the criteria to determine which approach is best should not be limited to just running time. If the keys meet the conditions for using these methods, they are certainly a very

```
type
     list ↑ item;
     item =record k: keytype;
                  next : list;
            end;

function merge(X1,X2:list):list;

good alternative. In fact, today's technology has word lengths and memory sizes that make competitive many of the algorithms presented here. These algorithms were considered useful for only small restricted universes. Large restricted universes can be implemented with current memory sizes and current word sizes for many practical cases. Recent research has shown theoretical improvements on older versions of these methods [2].

Distribution Counting

A special situation of the sorting problem $X = \langle x_1, \ldots, x_n \rangle$ is the sorting of n distinct integers in the range $[1, m]$. If the value of $m = O(n)$, the fact that the x_i are distinct integers allows a very simple sorting method that runs in $O(n)$ time. Use a temporary array $T : [1, m]$ and place each x_i in $T[x_i]$. Scan T to collect the items in sorted order (where T was initialized to hold only 0).

This idea can be extended in many ways; the first is to handle the case when the integers are no longer distinct, and the resulting method is called *Distribution Counting.* The fundamental idea is to determine, for each x_i, its *rank.* The rank is the number of elements less or equal (but before x_i in X) than x_i. The

rank can be used to place x_i directly in its final position in the output array OUT. To compute the rank, we use the fact that the set of possible key values is the integers in $[1, m]$. We count the number E_k of values in X that equal k, for $k = 1, \ldots, m$. Arithmetic sums $\Sigma_{k=1}^{i} E_k$ can be used to find how many x_j are less or equal to x_i. Scanning through X, we can now find the destination of x_i, when x_i is reached. Figure 3.11 presents the pseudocode for the algorithm. Observe that two loops are till n and two till m. From this observation, the $O(n + m) = O(n)$ time complexity follows directly. The method has the disadvantage that extra space is required; however, in practice, we will use this method when m fits our available main memory, and in such cases, this extra space is not a problem.

```
DISTRIBUTION COUNTING(X, m, OUT)
1 for k ← 1 to m
2     do count[k] ← 0
3 for i ← 1 to n
4     do count[X_i] ← count[X_i] + 1
5 for k ← 2 to m
6     do count[k] ← count[k] + count[k − 1]
7 for i ← n downto 1
8     do OUT[count[X_i]] ← X_i
9        count[X_i] ← count[X_i]-1
```

FIGURE 3.11 Pseudocode for *Distribution Counting.*

A very appealing property of *Distribution Counting* is that it is a stable method. Observe that not a single comparison is required to sort. However, we need an array of size m, and the key values must fit the addressing space.

Bucket Sort

Bucket Sort is an extension to the idea of finding out where in the output array each x_i should be placed. However, the keys are not necessarily integers. We assume that we can apply an interpolation formula to the keys to obtain a new key in the real interval $[0, 1)$ which proportionally indicates where x_i should be relative to the smallest and largest possible keys. The interval $[0, 1)$ is partitioned into m equal-sized consecutive subintervals, each with an associated queue. The item x_i is placed in the queue q_j when the interpolation address from its key lies in the jth interval. The queues are sorted recursively, and then concatenated starting from the lower interval. The first-in last-out properties of the queues assure that, if the recursive sorting is stable, the overall sorting is stable. In particular, if *Bucket Sort* is called recursively, the method is stable. However, in practice, it is expected that queues will have very few items after one or two partitions. Thus, it is convenient to switch to an alternative stable sorting methods to sort the items in each bucket, most preferable *Insertion Sort.* For the insertion into the queues, an implementation that allows insertion in constant time should be used. Usually, linked lists with a pointer to their last item is the best alternative. This also assures that the catenation of the queues is efficient.

The method has an excellent average case time complexity, namely, it is linear (when $m = \Theta(n)$). However, the assumption is a uniform distribution of the interpolated keys in $[0, 1)$. In the worst scenario, the method may send every item into one bucket only, resulting in quadratic performance. The difficulty lies in finding the interpolation function. These functions work with large integers (like the maximum key) and must be carefully programmed to avoid integer overflow.

However, the method has been specialized so that k rounds of it sort k-tuples of integers in $[1, m]$ in $O(k(n + m))$ time, and also to sort strings of characters with excellent results [1]. Namely, strings of characters are sorted in $O(m + L)$ where L it the total length of the strings. In this cases, the alphabet of characters defines a restricted universe and the interpolation formula is just a displacement from the

```
BUCKET SORT(X)
1 for i ← 0 to m − 1
2     do Queue[i] ← empty
3 for i ← 1 to n
4     do insert x_i into Queue[⌊interpol(x_i)m⌋]
5 for i ← 0 to m − 1
6     do Sort(Queue[i])
7 for i ← 1 to m − 1
8     do Concatenate Queue[i] at the back of Queue[0]
9 return Queue[0]
```

FIGURE 3.12 The code for *Bucket Sort.*

smallest value. Moreover, the number of buckets can be made equal to the different values of the universe. These specializations are very similar to radix sorting, which we discuss next.

Radix Sort

Radix sort refers to a family of sorting methods where the keys are interpreted as representation in some base (usually a power of 2) or as strings over a given small alphabet. The radix sorts examine the digits of this representation in as many rounds as the length of the key to achieve the sorting. Thus, radix sorts perform several passes over the input, in each pass, performing decisions by one digit only.

The sorting can be done from the most significant digit toward the least significant digit or the other way around. The radix sort version that goes from most significant digit toward least significant digit is called *Top-Down Radix Sort*, *MSD Radix Sort*, or *Radix Exchange Sort* [9, 12, 19]. It resembles *Bucket Sort*, and from the perspective of divide-and-conquer is a method of the divide form. The most significant digit is used to split the items into groups. Next, the algorithm is applied recursively to the groups separatedly, with the first digit out of consideration. The sorted groups are collected by the order of increasing values of the splitting digit. Recursion is terminated by groups of size one. If we consider the level of recursion as rounds over the string of digits of the key, the algorithm keeps the invariant that after the ith pass, the input is sorted according to the first i digits of the keys.

The radix sort version that proceeds from the least significant digit toward the most significant digit is usually called *Bottom-Up Radix Sort*, *Straight Radix Sort*, *LSD Radix sort*, or just *Radix Sort* [9, 12, 19]. It could be considered as doing the activities of each round in different order. Split the items into groups according to the digit under consideration, group the items in order of increasing values of the splitting digit. Apply the algorithm recursively to all the items, but considering the next more significant digit. At first, it may not seem clear why this method is correct. It has a dual invariant to the *Top-Down Sort*; however, after the ith pass, the input is sorted according to the last i digits of the keys. Thus, for this *Bottom-Up* version to work, it is crucial that the insertion of items into their groups is made in the first-in first-out order of a queue. For the *Top-Down* version, this is only required to ensure stability. Both methods are stable though.

The *Top-Down* version has several advantages and disadvantages with respect to the *Bottom-Up* version. In the *Top-Down* version, the algorithm only examines the distinguishing prefixes, while the entire set of digits of all keys are examined by the *Bottom-Up* version. However, *Top-Down* needs space to keep track of the recursive calls generated, while the *Bottom-Up* version does not. If the input digits have a random distribution, then both versions of radix sort are very effective. However, in practice this assumption regarding the distribution is not the case. For example, if the digits are the bits of characters, the first leading bits of all lower case letters are the same in most character encoding schemes. Thus, *Top-Down Radix Sort* deteriorates with files with many equal keys (similar to *Bucket Sort*).

The *Bottom-Up* version is like a *Distribution Counting* on the digit that is being used. In fact, this is the easiest way to implement it. Thus, the digits can be processed more naturally as groups of digits (and allowing a larger array for the distribution counting). This is an advantage of the *Bottom-Up* version over the *Top-Down* version.

It should be pointed out that radix sorts can be considered linear in the size of the input, since each digit of the keys is examined only once. However, other variants of the analysis are possible; these include modifying the assumptions regarding the distribution of keys or according to considerations of the word size of the machine. Some authors think that the n keys require $\log n$ bits to be represented and stored in memory. From this perspective, radix sorts require $\log n$ passes with $\Omega(n)$ operations on them, still amounting to $O(n \log n)$ time. In any case, radix sorts, are reasonable methods for a sorting routine, or for a hybrid one. One hybrid method proposed by Sedgewick [19] consist of using the *Bottom-up* version of radix sort, but for the most significant half of the digits of the keys. This makes the file almost sorted, so the sort can be finished by *Insertion Sort.* The result is a linear sorting methods for most current word sizes on randomly distributed keys.

Order Statistics

The kth *order statistic* of a sequence of n items is the kth largest item. In particular, the smallest element is the first order statistic while the largest element is the nth order statistic. Finding the smallest or largest item in a sequence, can easily be achieved in linear time. For the smallest item, we just have to scan the sequence, remembering the smallest item seen so far. Obviously, we can also find the first and second statistic in linear time by the same procedure, just remembering the two smallest items seen so far. However, as soon as $\log n$ statistics are required, it is best to sort the sequence and retrieve any order statistic required directly.

A common request is to find jointly the smallest and largest items of a sequence of n item. Scanning through the sequence remembering the smallest and largest items seen so far requires that each new item be compared with what is being remembered; thus, $2n + O(1)$ comparisons are required. A better alternative for this case is to from $\lfloor n/2 \rfloor$ pairs of items, and perform the comparisons within pairs. We find the smallest item among the smaller items of the pairs, while the largest is found among the larger items of the pairs (a final comparison may be required for an element left out when n is odd). This results in $\lfloor 3n/2 \rfloor + O(1)$ comparison, which in some applications is worth the effort.

The fact that the smallest and largest items can be retrieved in $O(n)$ time without the need of sorting made the quest for linear algorithms for the kth order statistic a very interesting one for some time. Still, today there are many theoreticians researching the possibility of linear selection of the median (the $\lfloor n/2 \rfloor$th item) with a smaller constant factor. As a matter of fact, selection of the k largest item is another illustration of the use of average complexity to reflect a practical situation more accurately than worst-case analysis. The theoretical worst-case linear algorithms are so complex that very few authors dare to present pseudocode for them. This is perfectly justified, because nobody should implement worst-case algorithms in light of very efficient algorithms in the expected case, which are far easier conceptually as well as simpler in programming effort terms.

Lets consider divide-and-conquer approaches to finding the kth largest element. If we take the conquer form, as in *Mergesort*, it seems difficult to imagine how the kth largest item of the left subsequence and the kth largest item of the right subsequence relate to the kth largest item of the overall subsequence. However, if we take the divide form, as in *Quicksort*, we see that partitioning divides the input and conceptually splits by the correct rank of the pivot. If the position of the pivot is $i \geq k$, we only need to search for the kth largest element of the $X_{\leq}$ subsequence. Otherwise, we have found i items that we can remove from further consideration, since they are smaller than the kth largest. We just need to find the $k - i$ largest in the subsequence $X_{\geq}$. This approach to divide-and-conquer results in only one subproblem to be pursued recursively. The analysis results in an algorithm that requires $O(n)$ time in the expected case. Such a method requires, again, careful protection against the worst cases. Moreover, it is more likely that a file

that is being analyzed for its order statistics has being inadvertently sorted before, setting up a potential worst case for a selection method whose selection of the pivot is not adequate. In the algorithm presented in Fig. 3.13 we use the same partitioning algorithm as in the section for *Quicksort*; refer to Fig. 3.7.

```
SELECT(X, l, r, k)
1 if r = l
2    then return X[l]
3 i ← RANDOM(l, r)
4 exchange X[i] ↔ X[l]
5 split ← PARTITION(X, l, r)
6 if k ≤ split
7    then return SELECT(X, l, split, k)
8    else return SELECT(X, split + 1, r, k)
```

FIGURE 3.13 Randomized version for selection of the kth largest.

External Sorting

There are many situations where external sorting is required for the maintenance of a well-organized database. Files are often maintained in sorted order with respect to some attribute to facilitate searching and processing. External sorting is used not only to produce organized output, but also to efficiently implement complex operations such as a relational join. External sorting consists of two phases: a *run-creation phase* and a *merge phase*. During the first phase, the file to be sorted is divided into smaller sorted sequences called *initial runs* or *strings* [12]. These runs are created by bringing into main memory a fragment of the file. During the second phase, one or more activations of *multiway-merge* are used to combine the initial runs into a single run [16].

Currently, the sorting of files that are too large to be held in main memory is performed on disk drives [16]; see Fig. 3.14. Situations where only one disk drive is available are now uncommon, since this usually results into very slow sorting processes and complex algorithms while the problem can easily be solved with another disk drive (which are more affordable today). In each pass (one for run-creation and one or more for merging) the input file is read from the *IN* disk drive. The output of one pass is the input of the next, until a single run is formed; thus, the *IN* and *OUT* disks swap roles after each pass. While one of the input buffers, say I_i, $i \in \{0, f-1\}$, is being filled, the sorting process reads records from some of the other input buffers $I_0, \ldots, I_{i-1}, I_{i+1}, \ldots, I_{f-1}$. The output file of each pass is written using *double buffering*. While one of the output buffers, say O_i, $i \in \{0, 1\}$, is being filled, the other buffer O_{1-i} is being written to disk. The roles of O_i and O_{1-i} are interchanged when one buffer is full and the other is empty. In practice, several data records are read in a I/O operation forming a **physical block**, while the capacity of buffers defines the size of *logical blocks*. For the description of external sorting methods, the use of logical blocks is usually sufficient and we will just name them *blocks*.

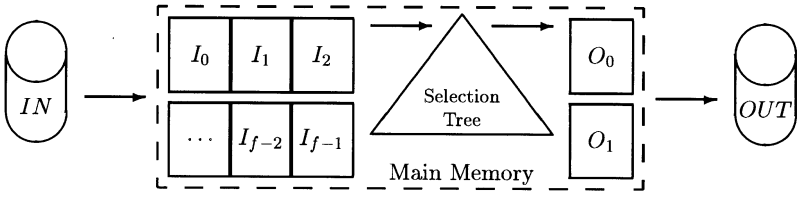

FIGURE 3.14 The model for a pass of external sorting.

During the run-creation phase the number f of input buffers is 2 and reading is sequential using double-buffering. During a merge pass, the next block to be read is normally from a different run and the disk arm must be repositioned. Thus, reading is normally not sequential. Writing during the merge is, however, faster than reading, since normally it is performed sequentially and no seeks are involved (except for the minimum seek for the next cylinder when the current cylinder is full). In each pass, the output is written sequentially to disk. Scattered writing during a pass in anticipation of saving seeks because of some sequential reading of the next pass has been shown to be counterproductive [20]. Thus, in the two-disk model (see Fig. 3.14) the writing during the merge will completely overlap with the reading and its time requirements are a minor concern. In contrast to the run-creation phase in which reading is sequential, merging may require a seek each time a data block is read.

Replacement selection usually produces runs that are larger than the available main memory; the larger the initial runs, the faster the overall sorting. Replacement selection allows full overlapping of I/O with sequential reading and writing of data, and it is standard for the run creation phase. The classic result on the performance of replacement selection establishes that, when all input files are assumed to be equally likely, the asymptotic expected length of the resulting runs is twice the size of available main memory [12]. Other researchers have modified replacement selection such that, asymptotically, the expected length of an initial run is more than twice the size of available main memory. These methods have received limited acceptance because they require more sophisticated I/O operations and prevent full overlapping; hence, the possible benefits hardly justify the added complexity of the methods. Similarly, any attempt to design a new run-creation method that profits from the existing order in the input file will almost certainly have inefficient overlapping of I/O operations. More recently, it has been mathematically confirmed that the lengths of the runs created by replacement selection increase as the order in the input file increases [6].

During the run-creation phase *Replacement Selection* consists of a *selection tree.* This structure is a binary tree where nodes hold the smaller of their two children. It is called selection tree because the item at the root of the tree holds the smallest key. By tracing the path up of the smallest key from its place at a leaf to the root, we have selected the smallest item among those in the leaves. If we replace the smallest item with another value at the corresponding leaf, we only are required to update the path to the root. Performing the comparisons along this path updates the root as the new smallest item. Selection trees are different from heaps (ordered to extract the item with smallest keys) in that selection trees have fixed size. During the selection phase, the selection tree is initialized with the first P elements of the input file (where P is the available internal memory). Repeatedly, the smallest item is removed from the selection tree and placed in the output stream, the next item from the input file is inserted in its place as a leaf in the selection tree. The name *Replacement Selection* comes from the fact that the new item from the input file replaces the item just selected to the output stream. To make certain that items enter and leave the selection tree in the proper order, the comparisons are not only with respect to the sorting keys, but also with respect to the current run being output. Thus, the selection tree uses lexicographically the composite keys (r, key), where r is the *run-number* of the item, and key is the sorting key. The run number of an item entering the selection tree is known by comparing it to the item which it is replacing. If it is smaller than the item just sent to the output stream, the run number is one more than the current run number; otherwise, it is the same run number as the current run.

The Merge

In the merging phase of external sorting, blocks from each run are read into main memory, and the records from each block are extracted and merged into a single run. Replacement selection (implemented with a *selection tree*) is also used as the process to merge several runs into one [12]. Here, however, each leaf is associated with each of the runs being merged. The *order* of the merge is the number of leaves in the selection tree. Because main memory is a critical resource here, items in the selection tree are not replicated, but rather a tree of losers is used [12].

There are many factors involved in the performance of disk drives. For example, larger main memories implies larger data blocks and the *block-transfer rate* is now significant with respect to *seek time* and *rotational latency.* Using a larger block size reduces the total number of reads (and seeks) and reduces the overhead of the merging phase. Now, a merge pass requires at least as many buffers as the order ω of the merge. On one hand, using only one buffer for each run, maximizes block size, and if we perform a seek for each block, it reduces the total number of seeks. However, we cannot overlap I/O. On the other hand, using more buffers, say, two buffers for each run, increases the overlap of I/O, but reduces the block size and increases the total number of seeks. Note that because the amount of main memory is fixed during the merge phase, the number of buffers is inversely proportional to their size.

Salzberg [17] found that, for almost all situations, the use of $f = 2\omega$ buffers assigned as pairs to each merging stream outperforms the use of ω fixed buffers. Recently, it has been shown that double buffering cannot take advantage of nearly-sorted data [7]. Double buffering does not guarantee full overlap of I/O during merging. When buffers are not fixed to a particular run, but can be reassigned to another run during the merge, they are called *floating buffers* [11]. Using twice as many floating buffers as the order of the merge provides maximum overlap of I/O [11]. Zheng and Larson [20] combined Knuth's [12] *forecasting* and floating-buffers techniques and proposed six to ten times as many floating input buffers as the order of the merge. In fact, techniques based on floating buffers not only ensure full overlap of I/O during merging, but also require less main memory. Moreover, it was also demonstrated that techniques based on floating buffers profit significantly from nearly-sorted files [7].

Floating Buffers

The *consumption sequence* is the particular order in which the merge consumes blocks from the runs being merged. This sequence can be precomputed by extracting the highest key (the last key) from each data block (during the previous pass) and sorting them. The time taken to compute the consumption sequence can be overlapped with the output of the last run and the necessary space for the subsidiary internal sort is also available then; thus, the entire consumption sequence can be computed during the previous pass with negligible overhead. The floating-buffers technique exploits the knowledge of the consumption sequence to speed up reading.

We illustrate double buffering and floating buffers with a merging example of four runs that are placed sequentially as shown in Fig. 3.15. Let $C = \langle C_1, C_2, \ldots, C_T \rangle$ be the consumption sequence, where C_i identifies a data block with respect to its location on the disk. For example, consider

$$C = \langle 1, 8, 13, 18, 2, 9, 14, 19, 3, 10, 4, 5, 15, 11, 12, 16, 17, 20, 6, 21, 7, 22, 23 \rangle .^{1}$$

Double buffering uses twice as many buffers as runs, and a seek is required each time a block is needed from a different run. Moreover, even when a block is needed from the same run, this may not be known at exactly the right time; therefore, the disk will continue to rotate and every read has rotational latency. In the example, double buffering reads one block from each run (with a seek in each case) and then it reads a second block from each run (again with a seek in each case). Next, the disk arm travels to block 3 to read a new block from the first run (one more seek). Afterward, the arm moves to block 10 to get a new block from the second run. Then, it moves to block 4 and reads block 4 and block 5, but a seek is not required for reading block 5 since the run-creation phase places blocks from the same run sequentially on the disk. In total, double buffering performs 19 seeks.

[1] Alternatively, the consumption sequence can be specified as $C = \langle c_1, c_2, \ldots, c_T \rangle$ where c_i is the run from which the ith block should be read. For this example, $C = \langle 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 1, 1, 3, 2, 2, 3, 3, 4, 1, 4, 1, 4, 4 \rangle$.

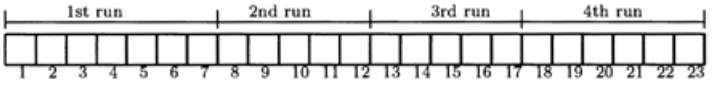

FIGURE 3.15 An example of four runs (written sequentially) on a disk.

We now consider the effect of using only seven buffers (of the same size as before) managed as floating buffers [11]. In this case, we use only three more buffers than the number of runs but we use knowledge of the consumption sequence. The seven buffers are used as follows: four buffers contain a block from each run that are currently being consumed by the merge, two buffers contain look-ahead data, and one buffer is used for reading new data. In the previous example, after the merging of the two data blocks 1 and 7, the buffers are as follows:

block 24	block 2	empty	block 8	block 15	block 23	block 16
buffer 1	buffer 2	buffer 3	buffer 4	buffer 5	buffer 6	buffer 7

Data from buffers 2, 4, 5, and 6 are consumed by the merge and are placed in an output buffer. At the same time, one data block is read into buffer 3. As soon as the merge needs a new block from run 3, it is already in buffer 7 and the merge releases buffer 5. Thus, the system enters a new state in which we merge buffers 2, 4, 6, and 7, and we read a new block into buffer 5. Figure 3.16 shows the merge when the blocks are read in the following order:

$$\langle \underline{1, 2, 8, 9}, \underline{13, 18}, \underline{14, 19}, \underline{3, 4, 5}, \underline{10, 11, 12}, \underline{15, 16, 17}, \underline{6, 7}, \underline{20, 21, 22, 23} \rangle \ . \tag{3.7}$$

The letter e denotes an empty buffer and b_i denotes a buffer that holds data block i. Reading activity is

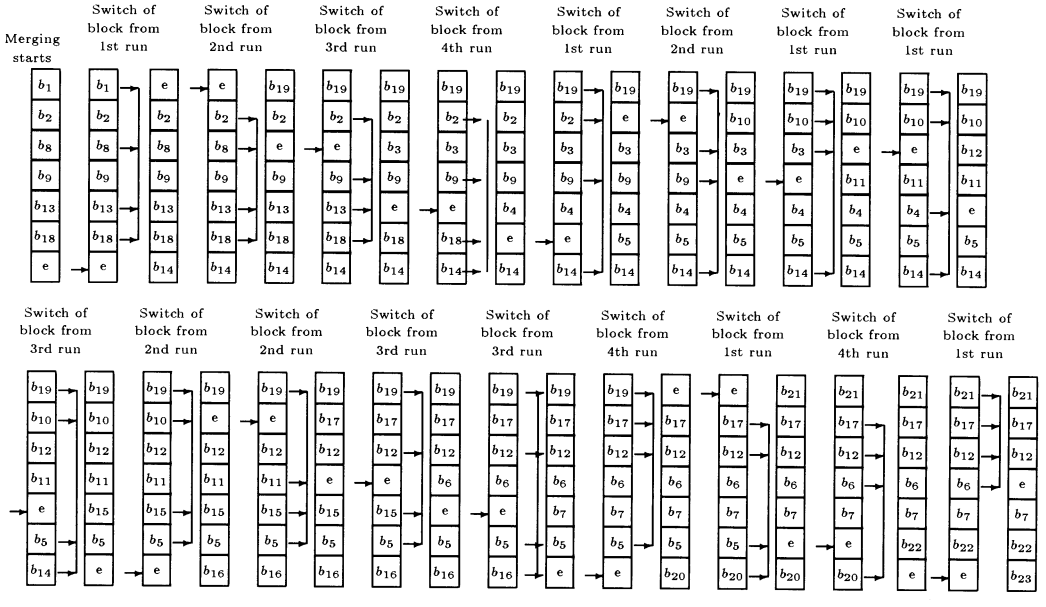

FIGURE 3.16 Merging with seven floating buffers.

indicated by an arrow into a buffer and merging activity is indicated by an arrow out of a buffer. The ordered sequence in which the blocks are read from the disk into main memory is called the *reading sequence.* A reading sequence is *feasible* if every time the merge needs a block, it is already in main memory and reading never has to wait because there is no buffer space available in main memory. Note that the consumption

sequence (with two or more floating buffers for each run) is always a feasible reading sequence [11]. In the example of Fig. 3.16, not only is the new reading sequence feasible and provides just-in-time blocks for the merge, but also it requires only 11 seeks and uses even less memory than double buffering!

Computing a Feasible Reading Sequence

In the previous subsection, we have illustrated that that floating buffers can save both main memory and the overhead due to seeks. There are, however, two important aspects in using floating buffers. First, floating buffers are effective when knowledge of the consumption sequence is used to compute reading sequences [20]. The consumption sequence is computed by the previous pass (and for the first pass, during the run-creation phase). The consumption sequence is the consumption order of data-blocks in the next pass. Thus, the buffer size for the next pass must be known by the previous pass. Overall, the buffer size and the number f of input floating buffers for each pass must be chosen before starting the sorting.

Before sorting we usually know the length $|X_I|$ of the file, and assuming it is in random order, we can expect, after run-creation, initial runs of twice the size P of the available main memory. That is, $E[Runs(X_O)] = |X_I|/2P$. Now, we can decide the number of merge passes (most commonly only one) and the order ω of these merge passes. Zheng and Larson [20] follow this approach and recommend the number f of floating buffers to be between 6ω and 10ω. Once the value of f is chosen, the buffer size is determined, and where to partition the input into data blocks is defined. The justification for this strategy is that current memory sizes allow it and an inaccurate estimate of the number of initial runs or their sizes seems not to affect performance [20]. It has been shown that if the input is nearly sorted, the fact that the technique just described may choose f much larger that 10ω does not affect floating buffers. Moreover, for nearly sorted files, reading during the merge becomes almost sequential, and over 80% of seeks can be avoided [7].

The second difficulty consists of computing feasible reading sequences that minimize the number of seeks. Zheng and Larson [20] have related the problem of finding the optimal feasible reading sequence to the traveling salesman problem; thus, research has concentrated on approximation algorithms.

To describe precisely the problem finding a feasible reading sequence with fewer seeks we will partition, into what we call *groups,* the blocks in a read sequence that are adjacent and belong to the same run. The groups are indicated by underlining in sequence (3.7). A seek is needed at the beginning of each group, because the disk head has to move to a different run. Inside a group, we read blocks from a single run sequentially, as placed by the run-creation phase or a previous merge pass. Note that there is no improvement in reading data blocks from the same run in different order than in the consumption sequence. For long groups, a seek may be required from one cylinder to the next, but such a seek takes minimum time because the reading is sequential. Moreover, in this case the need to read a block from the next cylinder is known early enough to avoid rotational latency. Thus, we want to minimize the number of groups while maintaining feasibility.

We now describe *group shifting,* an algorithm that computes a feasible reading sequence with fewer seeks. Group shifting starts with a consumption sequence $C = \langle C_1, \ldots, C_T \rangle$ as the initial feasible reading sequence. It scans the groups in the sequence twice. The first scan produces a feasible reading sequence that is the input for the next. A scan builds a new feasible reading sequence incrementally. The first ω groups of the new reading sequence are the first ω groups of the previous reading sequence because, for $i = 1, \ldots, \omega$, the optimal feasible reading sequence for the first i groups consists of the first i groups of the consumption sequence. In each scan, the groups of the previous sequence are analyzed in the order they appear. During the first scan an attempt is made to move each group in turn forward and catenate it with the previous group from the same run while preserving feasibility. A single group that results from the catenation of groups B_j and B_k is denoted by $(B_j B_k)$. During the second scan an attempt is made to move back the previous group from the same run under analysis, while preserving feasibility. We summarize the new algorithm in Fig. 3.17.

```
GROUP-SHIFTING (C = ⟨C_1, ..., C_T⟩ original consumption sequence for a merge pass of order ω).
1 N ← ⟨C_1, C_2, ..., C_ω⟩
2 b ← ω
3 while b < T
4 doLet B the (b + 1)th group in C and
5    let the sequence N be N = ⟨B_1, B_2, ..., B_p⟩,
6    where B_l is the last group in N from the same run as B.
7    if group B can be moved forward and joined to B_l preserving feasibility,
8    then N ← ⟨B_1, ..., B_{l-1}, (B_l B), B_{l+1}, ..., B_p⟩,
9    else  append B to N.
10 M ← first ω groups in N
11 b ← ω
12 while b < |N|
13 do Let B be the (b + 1)th group in N and
14    let the sequence M be M = ⟨B_1, B_2, ..., B_p⟩,
15    where B_l is the last group in M from the same run as B.
16    if group B_l can be shifted to the end of M and joined to group B preserving feasibility,
17    then M ← ⟨B_1, ..., B_{l-1}, B_{l+1}, ..., B_p, (B_l B)⟩,
18    else append B to M
19 return M
```

FIGURE 3.17 The algorithm for reducing seeks during the merging phase with floating buffers.

For an example of a forward move during the first scan, consider $b = 4$, $M^b = \langle 1, 8, 13, 18\rangle$, and group $b + 1$ is 2. Then, $M^{b+1} = \langle 1, 2, 8, 13, 28\rangle$. As an example of a backward move during the second scan, consider $b = 18$,

$M^b = \langle 1, 2, 8, 9, 13, 18, 14, 19, 3, 4, 5, 10, 11, 12, 15, 16, 17, 20, 21, 6, 7\rangle$, and group $b + 1$ is 22, 23. Moving 20, 21 over 6, 7 gives the optimal sequence of Fig. 3.16.

The algorithm uses the following fact to test that feasibility is preserved. Let $C = \langle C_1, \ldots, C_T\rangle$ be the consumption sequence for ω runs with T data blocks. A read sequence $R = \langle R_1, \ldots, R_T\rangle$ is feasible for $f > \omega + 1$ floating buffers if and only if, for all k such that $f \leq k \leq T$, we have $\{C_1, C_2, \ldots, C_{k-f+\omega}\} \subset \{R_1, R_2, \ldots, R_{k-1}\}$.

3.4 Research Issues and Summary

We now look at some of the research issues on sorting from the practical point of view. In the area of internal sorting, advances in data structures for the abstract data type *dictionary* or for the abstract data type *priority queue* may result in newer or alternative sorting algorithms. The implementation of dictionaries by variants of binary search trees where the items can easily (in linear time) be recovered in sorted order with an *in-order* traversal, results in an immediate sorting algorithm. We just insert the items to be sorted into the tree implementing the dictionary using the sorting keys as the dictionary keys. Later, we extract the sorted order from the tree. An insertion sort is obtained for each representation of the dictionary. Some interesting advances, at the theoretical level, but perhaps at the practical level, have been obtained by using data structures like *Fusion Trees* [8]. Although these algorithms are currently somewhat complicated and they make use of dissecting keys and careful packing of information in memory words, the increase in the word size of computers is making them practically feasible.

Another area of research is the more careful study of the alternatives offered by radix sorts. Careful analyses have emerged for these methods and they take into consideration the effect of non-uniform distributions. Moreover, simple combinations of *Top-Down* and *Bottom-up* have resulted in hybrid Radix Sorting algorithms with very good performance [2]. In practical experiments, Andersson and Nilsson observed that their proposed *Forward Radix Sort* defeats some of the best alternatives offered by the comparison-based approach.

A third area of research with possible practical implications is the area of adaptive sorting. When the sorting algorithm takes advantage of existing order in the input, the time taken by the algorithm to sort is

a smoothly growing function of the size of the sequence and the disorder in the sequence. In this case, we say that the algorithm is *adaptive* [14]. Adaptive sorting algorithms are attractive because nearly sorted sequences are common in practice [12, 14, 18]; thus, we have the possibility of improving on algorithms that are oblivious to the existing order in the input.

So far we presented *Insertion Sort* as an example of this type of algorithm. Adaptive algorithms have received attention for comparison-based sorting. Many theoretical algorithms have been found for many *measures of disorder* [6, 13]. However, from the practical point of view, these algorithms usually involve more machinery. This additional overhead is unappealing because of its programming effort. Thus, room remains for providing adaptive sorting algorithms that are simple for the practitioner. Adaptive algorithms currently in use are Cook and Kim's *CKsort* [4], *Natural Mergesort* [12], *Skipsort* [6], and *Splaysort* [15]. Some of these algorithms have been shown to be far more efficient in nearly sorted inputs for just a small overhead on randomly permuted files, but they have not received wide acceptance.

Finally, let us summarize the alternatives when facing a sorting problem. First we must determine if our situation is in the area of external sorting. A model with two disk drives is recommended in this case. Use replacement selection for run creation and for merging, using floating buffers during the second phase. It is possible to tune the sorting for just one pass during the second phase.

If the situation is internal sorting of a small file, then *Insertion Sort* does the job. If we are sorting integers, or character strings or some other restricted universe, then *Distribution Counting*, *Bucket Sort*, and *Radix Sort* are very good choices. If we are after a stable methods, **restricted universe sorts** are also good options. If we need something more general, the next level up is *Shellsort*, and finally the tuned versions of $O(n \log n)$ comparison-based sorting algorithms. If we have serious grounds to suspect the inputs are nearly sorted, we should consider adaptive algorithms. Whenever the sorting key is a small portion of the data records, we should try to avoid expensive data moves by sorting a file of keys and indexes. Always preserve a clear and simple code.

3.5 Defining Terms

Adaptive: A sorting algorithm that can take advantage of existing order in the input, reducing its requirements for computational resources as a function of the amount of disorder in the input.

Comparison-based algorithm: A sorting methods that uses comparisons, and nothing else about the sorting keys, to rearrange the input into ascending or descending order.

Conquer form: An instantiation of the divide-and-conquer paradigm for the structure of an algorithm where the bulk of the work is combining the solutions of subproblems into a solution for the original problem.

Divide form: An instantiation of the divide-and-conquer paradigm for the structure of an algorithm where the bulk of the work is dividing the problem into subproblems.

External sorting: The situation when the file to be sorted is too large to fit in main memory.

Insertion sort: The family of sorting algorithms where one item is analyzed at a time and inserted into a data structure holding a representation of a sorted list of previously analyzed items.

Internal sorting: The situation when the file to be sorted is small enough to fit in main memory.

Multiway merge: The mechanism by which ω sorted runs are merged into a single run. The input runs are usually organized in pairs and merged using the standard method for merging two sorted sequences. The results are paired again, and merged, until just one run is produced. The parameter ω is called the order of the merge.

Restricted universe sorts: Algorithms that operate on the basis that the keys are members of a restricted set of values. They may not require comparisons of keys to perform the sorting.

Selection sorts: The family of sorting algorithms where the data items are retrieved from a data structure, one item at a time, in sorted order.

Sorting arrays: The data to be sorted is placed in an array and access to individual items can be done randomly. The goal of the sorting is that the ascending order matches the order of indices in the array.

Sorting liked lists: The data to be sorted is a sequence represented as a linked list. The goal is to rearrange the pointers of the linked list so that the linked list has the data in sorted order.

Stable: A sorting algorithm where the relative order of items with equal keys in the input sequence is always preserved in the sorted output.

Brown University

4.1 Introduction

The study of data structures, i.e., methods for organizing data that are suitable for computer processing, is one of the classic topics of computer science. At the hardware level, a computer views storage devices such as internal memory and disk as holders of elementary data units (bytes), each accessible through its address (an integer). When writing programs, instead of manipulating the data at the byte level, it is convenient to organize them into higher level entities, called *data structures.*

Containers, Elements, and Locators

Most data structures can be viewed as **containers** that store a collection of objects of a given type, called the *elements* of the container. Often a total order is defined among the elements (e.g., alphabetically ordered names, points in the plane ordered by x-coordinate). We assume that the elements of a container can be accessed by means of variables called **locators**. When an object is inserted into the container, a locator is

[1]The material in this chapter was previously published in *The Computer Science and Engineering Handbook,* Allen B. Tucker, Editor-in-Chief, CRC Press, Boca Raton, FL, 1997.

returned, which can be later used to access or delete the object. A locator is typically implemented with a pointer or an index into an array.

A data structure has an associated repertory of operations, classified into *queries,* which retrieve information on the data structure (e.g., return the number of elements, or test the presence of a given element), and *updates,* which modify the data structure (e.g., insertion and deletion of elements). The performance of a data structure is characterized by the space requirement and the time complexity of the operations in its repertory. The *amortized* time complexity of an operation is the average time over a suitably defined **sequence** of operations.

However, efficiency is not the only quality measure of a data structure. Simplicity and ease of implementation should be taken into account when choosing a data structure for solving a practical problem.

Abstract Data Types

Data structures are concrete implementations of **abstract data types** (ADTs). A *data type* is a collection of objects. A data type can be mathematically specified (e.g., real number, directed graph) or concretely specified within a programming language (e.g., `int` in C, `set` in Pascal). An ADT is a mathematically specified data type equipped with operations that can be performed on the objects. Object-oriented programming languages, such as C++, provide support for expressing ADTs by means of *classes.* ADTs specify the data stored and the operations to be performed on them.

Main Issues in the Study of Data Structures

The following issues are of foremost importance in the study of data structures.

Static vs. Dynamic A *static* data structure supports only queries, while a dynamic data structure supports also updates. A *dynamic* data structure is often more complicated than its static counterpart supporting the same repertory of queries. A *persistent* data structure (see, e.g., [9]) is a dynamic data structure that supports operations on past versions. There are many problems for which no efficient dynamic data structures are known. It has been observed that there are strong similarities among the classes of problems that are difficult to parallelize and those that are difficult to dynamize (see, e.g., [32]). Further investigations are needed to study the relationship between parallel and incremental complexity [26].

Implicit vs. Explicit Two fundamental data organization mechanisms are used in data structures. In an *explicit* data structure, pointers (i.e., memory addresses) are used to link the elements and access them (e.g., a singly linked list, where each element has a pointer to the next one). In an *implicit* data structure, mathematical relationships support the retrieval of elements (e.g., array representation of a **heap**, see "Time Complexity"). Explicit data structures must use additional space to store pointers. However, they are more flexible for complex problems. Most programming languages support pointers and basic implicit data structures, such as arrays.

Internal vs. External Memory In a typical computer, there are two levels of memory: internal memory (RAM) and external memory (disk). The internal memory is much faster than external memory but has much smaller capacity. Data structures designed to work for data that fit into internal memory may not perform well for large amounts of data that need to be stored in external memory. For large-scale problems, data structures need to be designed that take into account the two levels of memory [1]. For example, two-level indices such as B-trees [6] have been designed to efficiently search in large databases.

Space vs. Time Data structures often exhibit a trade-off between space and time complexity. For example, suppose we want to represent a set of integers in the range $[0, N]$ (e.g., for a set of social security numbers $N = 10^{10} - 1$) such that we can efficiently query whether a given

element is in the set, insert an element, or delete an element. Two possible data structures for this problem are an N-element bit-array (where the bit in position i indicates the presence of integer i in the set), and a balanced **search tree** (such as a 2-3 tree or a red-black tree). The bit-array has optimal time complexity, since it supports queries, insertions, and deletions in constant time. However, it uses space proportional to the size N of the range, irrespectively of the number of elements actually stored. The balanced search tree supports queries, insertions, and deletions in logarithmic time but uses optimal space proportional to the current number of elements stored.

Theory vs. Practice A large and ever-growing body of theoretical research on data structures is available, where the performance is measured in asymptotic terms ("big-Oh" notation). While asymptotic complexity analysis is an important mathematical subject, it does not completely capture the notion of efficiency of data structures in practical scenarios, where constant factors cannot be disregarded and the difficulty of implementation substantially affects design and maintenance costs. Experimental studies comparing the practical efficiency of data structures for specific classes of problems should be encouraged to bridge the gap between the theory and practice of data structures.

Fundamental Data Structures

The following four data structures are ubiquitously used in the description of discrete algorithms, and serve as basic building blocks for realizing more complex data structures. They are covered in detail in the textbooks listed in "Further Information" and in the additional references provided.

Sequence A sequence is a container that stores elements in a certain linear order, which is imposed by the operations performed. The basic operations supported are retrieving, inserting, and removing an element given its position. Special types of sequences include stacks and queues, where insertions and deletions can be done only at the head or tail of the sequence. The basic realization of sequences are by means of arrays and linked lists. Concatenable queues (see, e.g., [18]) support additional operations such as splitting and splicing, and determining the sequence containing a given element. In external memory, a sequence is typically associated with a file.

Priority Queue A **priority queue** is a container of elements from a totally ordered universe that supports the basic operations of inserting an element and retrieving/removing the largest element. A key application of priority queues is to sorting algorithms. A heap is an efficient realization of a priority queue that embeds the elements into the ancestor/descendant partial order of a binary tree. A heap also admits an implicit realization where the nodes of the tree are mapped into the elements of an array (see "Time Complexity"). Sophisticated variations of priority queues include min-max heaps, pagodas, deaps, binomial heaps, and Fibonacci heaps. The buffer tree is efficient external-memory realization of a priority queue.

Dictionary A **dictionary** is a container of elements from a totally ordered universe that supports the basic operations of inserting/deleting elements and searching for a given element. **Hash tables** provide an efficient implicit realization of a dictionary. Efficient explicit implementations include skip lists [31], tries, and balanced search trees (e.g., **AVL-trees**, red-black trees, 2-3 trees, 2-3-4 trees, weight-balanced trees, biased search trees, splay trees). The technique of fractional cascading [3] speeds up searching for the same element in a collection of dictionaries. In external memory, dictionaries are typically implemented as B-trees and their variations.

Union-Find A union-find data structure represents a collection disjoint sets and supports the two fundamental operations of merging two sets and finding the set containing a given element.

There is a simple and optimal union-find data structure (rooted tree with path compression) whose time complexity analysis is very difficult to analyze. See, e.g., [15].

Examples of fundamental data structures used in three major application domains are mentioned below.

Graphs and Networks adjacency matrix, adjacency lists, link-cut tree [34], dynamic expression tree [5], topology tree [14], SPQR-tree [8], sparsification tree [11]. See also, e.g., [12, 23, 35].

Text Processing string, suffix tree, Patricia tree. See, e.g., [16].

Geometry and Graphics binary space partition tree, chain tree, trapezoid tree, range tree, segment-tree, interval-tree, priority-search tree, hull-tree, quad-tree, R-tree, grid file, metablock tree. See, e.g., [4, 10, 13, 23, 27, 28, 30].

Organization of the Chapter

The rest of this chapter focuses on three fundamental abstract data types: sequences, priority queues, and dictionaries. Examples of efficient data structures and algorithms for implementing them are presented in detail in Sections 4.2, 4.3, and 4.4, respectively. Namely, we cover arrays, singly-and doubly-linked lists, heaps, search trees, (a, b)-**trees**, AVL-trees, **bucket arrays**, and hash tables.

4.2 Sequence

Introduction

A *sequence* is a container that stores elements in a certain order, which is imposed by the operations performed. The basic operations supported are:

- INSERTRANK: insert an element in a given position;
- REMOVE: remove an element.

Sequences are a basic form of data organization, and are typically used to realize and implement other data types and data structures.

Operations

Using locators (see "Containers, Elements, and Locators"), we can define a more complete repertory of operations for a sequence S:

SIZE(N) return the number of elements N of S;

HEAD(c) assign to c a locator to the first element of S; if S is empty, c is a null locator;

TAIL(c) assign to c a locator to the last element of S; if S is empty, a null locator is returned;

LOCATERANK(r, c) assign to c a locator to the r-th element of S; if $r < 1$ or $r > N$, where N is the size of S, c is a null locator;

PREV(c', c'') assign to c'' a locator to the element of S preceding the element with locator c'; if c' is the locator of the first element of S, c'' is a null locator;

NEXT(c', c'') assign to c'' a locator to the element of S following the element with locator c'; if c' is the locator of the last element of S, c'' is a null locator;

INSERTAFTER(e, c', c'') insert element e into S after the element with locator c', and return a locator c'' to e;

INSERTBEFORE(e, c', c'') insert element e into S before the element with locator c', and return a locator c'' to e;

INSERTHEAD(e, c) insert element e at the beginning of S, and return a locator c to e;

INSERTTAIL(e, c) insert element e at the end of S, and return a locator c to e;

INSERTRANK(e, r, c) insert element e in the r-th position of S; if $r < 1$ or $r > N + 1$, where N is the current size of S, c is a null locator;

REMOVE(c, e) remove from S and return element e with locator c;

MODIFY(c, e) replace with e the element with locator c.

Some of the above operations can be easily expressed by means of other operations of the repertory. For example, operations HEAD and TAIL can be easily expressed by means of LOCATERANK and SIZE.

Implementation with an Array

The simplest way to implement a sequence is to use a (one-dimensional) array, where the i-th element of the array stores the i-th element of the list, and to keep a variable that stores the size N of the sequence. With this implementation, accessing elements takes $O(1)$ time, while insertions and deletions take $O(N)$ time.

Table 4.1 shows the time complexity of the implementation of a sequence by means of an array.

TABLE 4.1 Performance of a Sequence Implemented with an Array

Operation	Time
SIZE	$O(1)$
HEAD	$O(1)$
TAIL	$O(1)$
LOCATERANK	$O(1)$
PREV	$O(1)$
NEXT	$O(1)$
INSERTAFTER	$O(N)$
INSERTBEFORE	$O(N)$
INSERTHEAD	$O(N)$
INSERTTAIL	$O(1)$
INSERTRANK	$O(N)$
REMOVE	$O(N)$
MODIFY	$O(1)$

Note: We denote with N the number of elements in the sequence at the time the operation is performed. The space complexity is $O(N)$.

Implementation with a Singly-Linked List

A sequence can also be implemented with a singly-linked list, where each element has a pointer to the next one. We also store the size of the sequence, and pointers to the first and last element of the sequence.

With this implementation, accessing elements takes $O(N)$ time, since we need to traverse the list, while some insertions and deletions take $O(1)$ time.

Table 4.2 shows the time complexity of the implementation of sequence by means of singly-linked list.

TABLE 4.2 Performance of a Sequence Implemented with a Singly-Linked List

Operation	Time
SIZE	$O(1)$
HEAD	$O(1)$
TAIL	$O(1)$
LOCATERANK	$O(N)$
PREV	$O(N)$
NEXT	$O(1)$
INSERTAFTER	$O(1)$
INSERTBEFORE	$O(N)$
INSERTHEAD	$O(1)$
INSERTTAIL	$O(1)$
INSERTRANK	$O(N)$
REMOVE	$O(N)$
MODIFY	$O(1)$

Note: We denote with N the number of elements in the sequence at the time the operation is performed. The space complexity is $O(N)$.

Implementation with a Doubly-Linked List

Better performance can be achieved, at the expense of using additional space, by implementing a sequence with a doubly-linked list, where each element has pointers to the next and previous elements. We also store the size of the sequence, and pointers to the first and last element of the sequence.

Table 4.3 shows the time complexity of the implementation of sequence by means of a doubly-linked list.

TABLE 4.3 Performance of a Sequence Implemented with a Doubly-Linked List

Operation	Time
SIZE	$O(1)$
HEAD	$O(1)$
TAIL	$O(1)$
LOCATERANK	$O(N)$
PREV	$O(1)$
NEXT	$O(1)$
INSERTAFTER	$O(1)$
INSERTBEFORE	$O(1)$
INSERTHEAD	$O(1)$
INSERTTAIL	$O(1)$
INSERTRANK	$O(N)$
REMOVE	$O(1)$
MODIFY	$O(1)$

Note: We denote with N the number of elements in the sequence at the time the operation is performed. The space complexity is $O(N)$.

4.3 Priority Queue

Introduction

A *priority queue* is a container of elements from a totally ordered universe that supports the following two basic operations:

- INSERT: insert an element into the priority queue;
- REMOVEMAX: remove the largest element from the priority queue.

Here are some simple applications of a priority queue:

Scheduling A scheduling system can store the tasks to be performed into a priority queue, and select the task with highest priority to be executed next.

Sorting To sort a set of N elements, we can insert them one at a time into a priority queue by means of N INSERT operations, and then retrieve them in decreasing order by means of N REMOVEMAX operations. This two-phase method is the paradigm of several popular sorting algorithms, including *Selection-Sort, Insertion-Sort,* and *Heap-Sort.*

Operations

Using locators, we can define a more complete repertory of operations for a priority queue Q:

SIZE(N) return the current number of elements N in Q;
MAX(c) return a locator c to the maximum element of Q;
INSERT(e, c) insert element e into Q and return a locator c to e;
REMOVE(c, e) remove from Q and return element e with locator c;
REMOVEMAX(e) remove from Q and return the maximum element e from Q;
MODIFY(c, e) replace with e the element with locator c.

Note that operation REMOVEMAX(e) is equivalent to MAX(c) followed by REMOVE(c, e).

Realization with a Sequence

We can realize a priority queue by reusing and extending the sequence abstract data type (see Section 4.2). Operations SIZE, MODIFY, and REMOVE correspond to the homonymous sequence operations.

Unsorted Sequence

We can realize INSERT by an INSERTHEAD or an INSERTTAIL, which means that the sequence is not kept sorted. Operation MAX can be performed by scanning the sequence with an iteration of NEXT operations, keeping track of the maximum element encountered. Finally, as observed above, operation REMOVEMAX is a combination of MAX and REMOVE. Table 4.4 shows the time complexity of this realization, assuming that the sequence is implemented with a doubly-linked list.

Sorted Sequence

An alternative implementation uses a sequence that is kept sorted. In this case, operation MAX corresponds to simply accessing the last element of the sequence. However, operation INSERT now requires scanning the sequence to find the appropriate position where to insert the new element. Table 4.5 shows the time complexity of this realization, assuming that the sequence is implemented with a doubly-linked list.

TABLE 4.4 Performance of a Priority Queue Realized by an Unsorted Sequence, Implemented with a Doubly-Linked List

Operation	Time
SIZE	$O(1)$
MAX	$O(N)$
INSERT	$O(1)$
REMOVE	$O(1)$
REMOVEMAX	$O(N)$
MODIFY	$O(1)$

Note: We Denote with N the number of elements in the priority queue at the time the operation is performed. The space complexity is $O(N)$.

TABLE 4.5 Performance of a Priority Queue Realized by a Sorted Sequence, Implemented with a Doubly-Linked List

Operation	Time
SIZE	$O(1)$
MAX	$O(1)$
INSERT	$O(N)$
REMOVE	$O(1)$
REMOVEMAX	$O(1)$
MODIFY	$O(N)$

Note: We denote with N the number of elements in the priority queue at the time the operation is performed. The space complexity is $O(N)$.

Realizing a priority queue with a sequence, sorted or unsorted, has the drawback that some operations require linear time in the worst case. Hence, this realization is not suitable in many applications where fast running times are sought for all the priority queue operations.

Sorting

For example, consider the sorting application (see "Introduction" in Section 4.3). We have a collection of N elements from a totally ordered universe, and we want to sort them using a priority queue Q. We assume that each element uses $O(1)$ space, and any two elements can be compared in $O(1)$ time. If we realize Q with an unsorted sequence, then the first phase (inserting the N elements into Q) takes $O(N)$ time. However the second phase (removing N times the maximum element) takes time:

$$O\left(\sum_{i=1}^{N} i\right) = O\left(N^2\right) .$$

Hence, the overall time complexity is $O(N^2)$. This sorting method is known as *Selection-Sort.*

However, if we realize the priority queue with a sorted sequence, then the first phase takes time:

$$O\left(\sum_{i=1}^{N} i\right) = O\left(N^2\right) ,$$

while the second phase takes time $O(N)$. Again, the overall time complexity is $O(N^2)$. This sorting method is known as *Insertion-Sort.*

Realization with a Heap

A more sophisticated realization of a priority queue uses a data structure called *heap.* A heap is a binary tree T whose internal nodes store each one element from a totally ordered universe, with the following properties (see Fig. 4.1):

Level Property: all the levels of T are full, except possibly for the bottommost level, which is left-filled;

Partial Order Property: let μ be a node of T distinct from the root, and let ν be the parent of μ; then the element stored at μ is less than or equal to the element stored at ν.

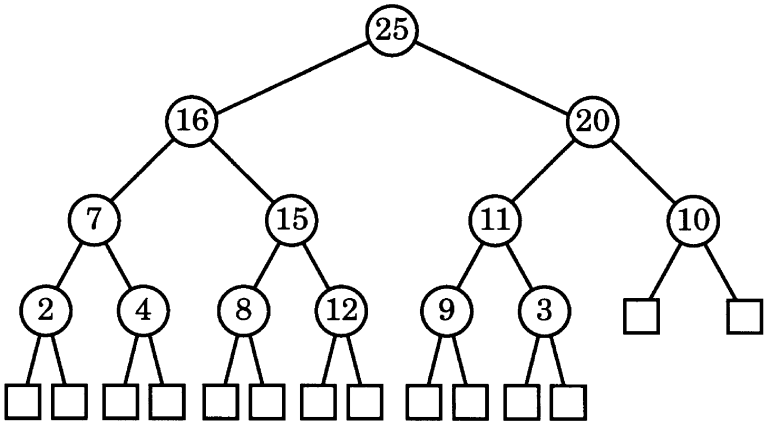

FIGURE 4.1 Example of a heap storing 13 elements.

The leaves of a heap do not store data and serve only as "placeholders." The level property implies that heap T is a minimum-height binary tree. More precisely, if T stores N elements and has height h, then each level i with $0 \leq i \leq h-2$ stores exactly 2^i elements, while level $h-1$ stores between 1 and 2^{h-1} elements. Note that level h contains only leaves. We have

$$2^{h-1} = 1 + \sum_{i=0}^{h-2} 2^i \leq N \leq \sum_{i=0}^{h-1} 2^i = 2^h - 1 \,,$$

from which we obtain

$$\log_2(N+1) \leq h \leq 1 + \log_2 N \,.$$

Now, we show how to perform the various priority queue operations by means of a heap T. We denote with $x(\mu)$ the element stored at an internal node μ of T. We denote with ρ the root of T. We call *last node* of T the rightmost internal node of the bottommost internal level of T.

By storing a counter that keeps track of the current number of elements, SIZE consists of simply returning the value of the counter. By the partial order property, the maximum element is stored at the root, and hence, operation MAX can be performed by accessing node ρ.

Operation INSERT

To insert an element e into T, we add a new internal node μ to T such that μ becomes the new last node of T, and set $x(\mu) = e$. This action ensures that the level property is satisfied, but may violate

the partial-order property. Hence, if $\mu \neq \rho$, we compare $x(\mu)$ with $x(\nu)$, where ν is the parent of μ. If $x(\mu) > x(\nu)$, then we need to restore the partial order property, which can be locally achieved by exchanging the elements stored at μ and ν. This causes the new element e to move up one level. Again, the partial order property may be violated, and we may have to continue moving up the new element e until no violation occurs. In the worst case, the new element e moves up to the root ρ of T by means of $O(\log N)$ exchanges. The upward movement of element e by means of exchanges is conventionally called *upheap.*

An example of a sequence of insertions into a heap is shown in Fig. 4.2.

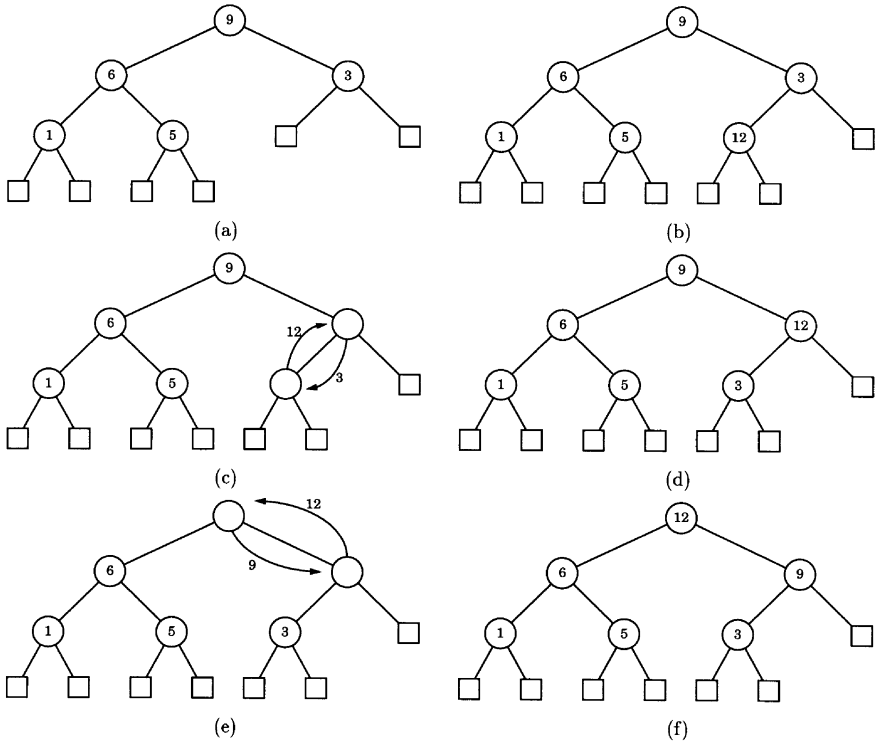

FIGURE 4.2 Example of insertion into a heap.

Operation REMOVEMAX

To remove the maximum element, we cannot simply delete the root of T, because this would disrupt the binary tree structure. Instead, we access the last node λ of T, copy its element e to the root by setting $x(\rho) = x(\lambda)$, and delete λ. We have preserved the level property, but we may have violated the partial order property. Hence, if ρ has at least one nonleaf child, we compare $x(\rho)$ with the maximum element $x(\sigma)$ stored at a child of ρ. If $x(\rho) < x(\sigma)$, then we need to restore the partial order property, which can be locally achieved by exchanging the elements stored at ρ and σ. Again, the partial order property may be violated, and we continue moving down element e until no violation occurs. In the worst case, element e moves down to the bottom internal level of T by means of $O(\log N)$ exchanges. The downward movement of element e by means of exchanges is conventionally called *downheap.*

An example of operation REMOVEMAX in a heap is shown in Fig. 4.3.

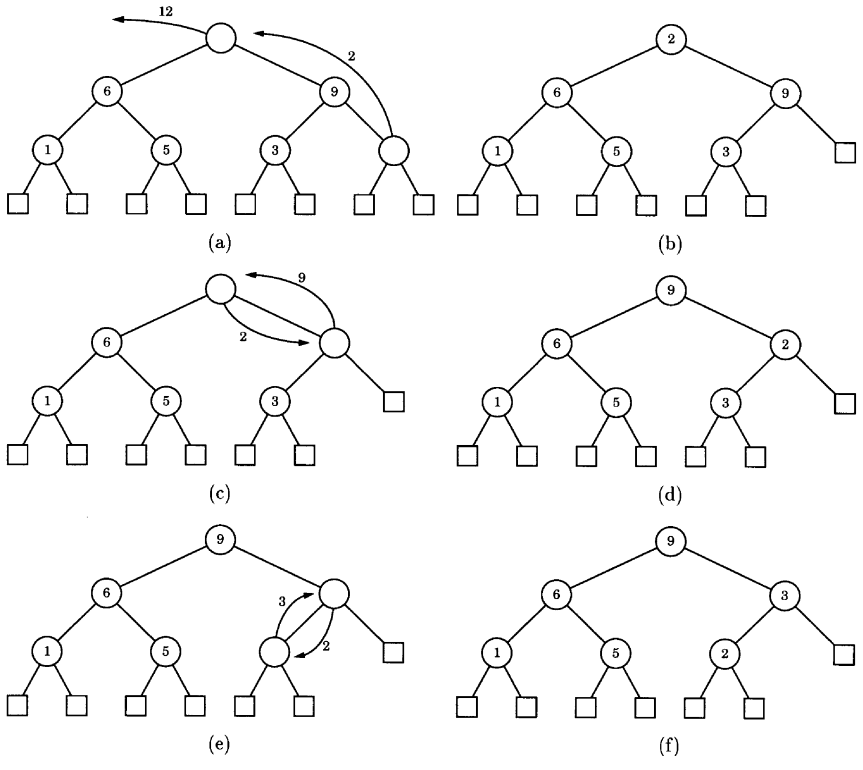

FIGURE 4.3 REMOVEMAX operation in a heap.

Operation REMOVE

To remove an arbitrary element of heap T, we cannot simply delete its node μ, because this would disrupt the binary tree structure. Instead, we proceed as before and delete the last node of T after copying to μ its element e. We have preserved the level property, but we may have violated the partial order property, which can be restored by performing either upheap or downheap.

Finally, after modifying an element of heap T, if the partial order property is violated, we just need to perform either upheap or downheap.

Time Complexity

Table 4.6 shows the time complexity of the realization of a priority queue by means of a heap. We assume that the heap is itself realized by a data structure for binary trees that supports $O(1)$-time access to the children and parent of a node. For instance, we can implement the heap explicitly with a linked structure (with pointers from a node to its parents and children), or implicitly with an array (where node i has children $2i$ and $2i + 1$).

Let N the number of elements in a priority queue Q realized with a heap T at the time an operation is performed. The time bounds of Table 4.6 are based on the following facts:

- In the worst case, the time complexity of upheap and downheap is proportional to the height of T.
- If we keep a pointer to the last node of T, we can update this pointer in time proportional to the height of T in operations INSERT, REMOVE, and REMOVEMAX, as illustrated in Fig. 4.4.
- The height of heap T is $O(\log N)$.

TABLE 4.6 Performance of a Priority Queue Realized by a Heap, Implemented with a Suitable Binary Tree Data Structure

Operation	Time
SIZE	$O(1)$
MAX	$O(1)$
INSERT	$O(\log N)$
REMOVE	$O(\log N)$
REMOVEMAX	$O(\log N)$
MODIFY	$O(\log N)$

Note: We denote with N the number of elements in the priority queue at the time the operation is performed. The space complexity is $O(N)$.

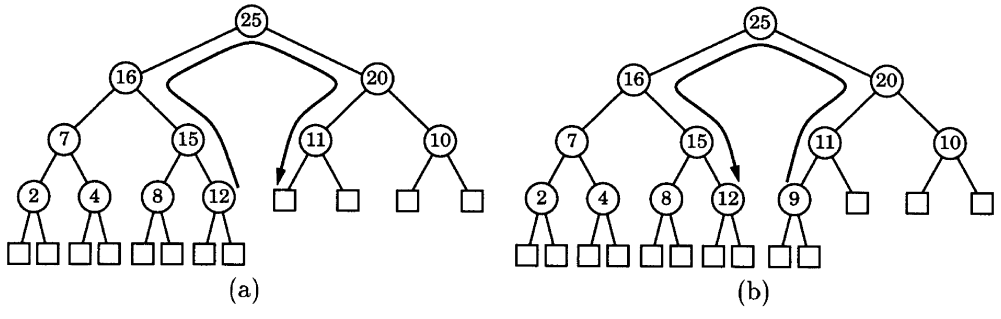

FIGURE 4.4 Update of the pointer to the last node: (a) INSERT; (b) REMOVE or REMOVEMAX.

The $O(N)$ space complexity bound for the heap is based on the following facts:

- The heap has $2N + 1$ nodes (N internal nodes and $N + 1$ leaves).
- Every node uses $O(1)$ space.
- In the array implementation, because of the level property the array elements used to store heap nodes are in the contiguous locations 1 through $2N - 1$.

Note that we can reduce the space requirement by a constant factor implementing the leaves of the heap with null objects, such that only the internal nodes have space associated with them.

Sorting

Realizing a priority queue with a heap has the advantage that all the operations take $O(\log N)$ time, where N is the number of elements in the priority queue at the time the operation is performed. For example, in the sorting application (see "Introduction" in Section 4.3), both the first phase (inserting the N elements) and the second phase (removing N times the maximum element) take time:

$$O\left(\sum_{i=1}^{N} \log i\right) = O(N \log N) .$$

Hence, sorting with a priority queue realized with a heap takes $O(N \log N)$ time. This sorting method is known as *Heap-Sort,* and its performance is considerably better than that of *Selection-Sort* and *Insertion-Sort* (see "Sorting" in Section 4.3), where the priority queue is realized as a sequence.

Realization with a Dictionary

A priority queue can be easily realized with a dictionary (see Section 4.4). Indeed, all the operations in the priority queue repertory are supported by a dictionary. To achieve $O(1)$ time for operation MAX, we can store the locator of the maximum element in a variable, and recompute it after an update operations. This realization of a priority queue with a dictionary has the same asymptotic complexity bounds as the realization with a heap, provided the dictionary is suitably implemented, e.g., with an (a, b)-tree (see "Realization with an (a, b)-Tree") or an AVL-tree (see "Realization with an AVL-Tree"). However, a heap is simpler to program than an (a, b)-tree or an AVL-tree.

4.4 Dictionary

A *dictionary* is a container of elements from a totally ordered universe that supports the following basic operations:

- FIND: search for an element;
- INSERT: insert an element;
- REMOVE: delete an element.

A major application of dictionaries are database systems.

Operations

In the most general setting, the elements stored in a dictionary are pairs (x, y), where x is the *key* giving the ordering of the elements, and y is the auxiliary information. For example, in a database storing student records, the key could be the student's last name, and the auxiliary information the student's transcript. It is convenient to augment the ordered universe of keys with two *special keys:* $+\infty$ and $-\infty$, and assume that each dictionary has, in addition to its *regular elements,* two *special elements,* with keys $+\infty$ and $-\infty$, respectively. For simplicity, we shall also assume that no two elements of a dictionary have the same key. An insertion of an element with the same key as that of an existing element will be rejected by returning a null locator.

Using locators (see "Containers, Elements, and Locators"), we can define a more complete repertory of operations for a dictionary D:

SIZE(N) return the number of regular elements N of D;

FIND(x, c) if D contains an element with key x, assign to c a locator to such an element, otherwise set c equal to a null locator;

LOCATEPREV(x, c) assign to c a locator to the element of D with the largest key less than or equal to x; if x is smaller than all the keys of the regular elements, c is a locator the special element with key $-\infty$; if $x = -\infty$, c is a null locator;

LOCATENEXT(x, c) assign to c a locator to the element of D with the smallest key greater than or equal to x; if x is larger than all the keys of the regular elements, c is a locator to the special element with key $+\infty$; if $x = +\infty$, c is a null locator;

LOCATERANK(r, c) assign to c a locator to the r-th element of D; if $r < 1$, c is a locator to the special element with key $-\infty$; if $r > N$, where N is the size of D, c is a locator to the special element with key $+\infty$;

PREV(c', c'') assign to c'' a locator to the element of D with the largest key less than that of the element with locator c'; if the key of the element with locator c' is smaller than all the keys of the regular elements, this operation returns a locator to the special element with key $-\infty$;

NEXT(c', c'') assign to c'' a locator to the element of D with the smallest key larger than that of the element with locator c'; if the key of the element with locator c' is larger than all the keys of the regular elements, this operation returns a locator to the special element with key $+\infty$;

MIN(c) assign to c a locator to the regular element of D with minimum key; if D has no regular elements, c is a null locator;

MAX(c) assign to c a locator to the regular element of D with maximum key; if D has no regular elements, c is null a locator;

INSERT(e, c) insert element e into D, and return a locator c to e; if there is already an element with the same key as e, this operation returns a null locator;

REMOVE(c, e) remove from D and return element e with locator c;

MODIFY(c, e) replace with e the element with locator c.

Some of the above operations can be easily expressed by means of other operations of the repertory. For example, operation FIND is a simple variation of LOCATEPREV or LOCATENEXT; MIN and MAX are special cases of LOCATERANK, or can be expressed by means of PREV and NEXT.

Realization with a Sequence

We can realize a dictionary by reusing and extending the sequence abstract data type (see Section 4.2). Operations SIZE, INSERT, and REMOVE correspond to the homonymous sequence operations.

Unsorted Sequence

We can realize INSERT by an INSERTHEAD or an INSERTTAIL, which means that the sequence is not kept sorted. Operation FIND(x, c) can be performed by scanning the sequence with an iteration of NEXT operations, until we either find an element with key x, or we reach the end of the sequence. Table 4.7 shows the time complexity of this realization, assuming that the sequence is implemented with a doubly-linked list.

TABLE 4.7 Performance of a Dictionary Realized by an Unsorted Sequence, Implemented with a Doubly-Linked List

Operation	Time
SIZE	$O(1)$
FIND	$O(N)$
LOCATEPREV	$O(N)$
LOCATENEXT	$O(N)$
LOCATERANK	$O(N)$
NEXT	$O(N)$
PREV	$O(N)$
MIN	$O(N)$
MAX	$O(N)$
INSERT	$O(1)$
REMOVE	$O(1)$
MODIFY	$O(1)$

Note: We denote with N the number of elements in the dictionary at the time the operation is performed.

Sorted Sequence

We can also use a sorted sequence to realize a dictionary. Operation INSERT now requires scanning the sequence to find the appropriate position where to insert the new element. However, in a FIND operation, we can stop scanning the sequence as soon as we find an element with a key larger than the search key. Table 4.8 shows the time complexity of this realization by a sorted sequence, assuming that the sequence is implemented with a doubly-linked list.

TABLE 4.8 Performance of a Dictionary Realized by a Sorted Sequence, Implemented with a Doubly-Linked List

Operation	Time
SIZE	$O(1)$
FIND	$O(N)$
LOCATEPREV	$O(N)$
LOCATENEXT	$O(N)$
LOCATERANK	$O(N)$
NEXT	$O(1)$
PREV	$O(1)$
MIN	$O(1)$
MAX	$O(1)$
INSERT	$O(N)$
REMOVE	$O(1)$
MODIFY	$O(N)$

Note: We denote with N the number of elements in the dictionary at the time the operation is performed. The space complexity is $O(N)$.

Sorted Array

We can obtain a different performance trade-off by implementing the sorted sequence by means of an array, which allows constant-time access to any element of the sequence given its position. Indeed, with this realization we can speed up operation FIND(x, c) using the *binary search* strategy, as follows. If the dictionary is empty, we are done. Otherwise, let N be the current number of elements in the dictionary. We compare the search key k with the key x_m of the middle element of the sequence, i.e., the element at position $\lfloor N/2 \rfloor$. If $x = x_m$, we have found the element. Else, we recursively search in the subsequence of the elements preceding the middle element if $x < x_m$, or following the middle element if $x > x_m$. At each recursive call, the number of elements of the subsequence being searched halves. Hence, the number of sequence elements accessed and the number of comparisons performed by binary search is $O(\log N)$. While searching takes $O(\log N)$ time, inserting or deleting elements now takes $O(N)$ time.

Table 4.9 shows the performance of a dictionary realized with a sorted sequence, implemented with an array.

Realization with a Search Tree

A *search tree* for elements of the type (x, y), where x is a key from a totally ordered universe, is a rooted ordered tree T such that

TABLE 4.9 Performance of a Dictionary Realized by a Sorted Sequence, Implemented with an Array

Operation	Time
SIZE	$O(1)$
FIND	$O(\log N)$
LOCATEPREV	$O(\log N)$
LOCATENEXT	$O(\log N)$
LOCATERANK	$O(1)$
NEXT	$O(1)$
PREV	$O(1)$
MIN	$O(1)$
MAX	$O(1)$
INSERT	$O(N)$
REMOVE	$O(N)$
MODIFY	$O(N)$

Note: We denote with N the number of elements in the dictionary at the time the operation is performed. The space complexity is $O(N)$.

- Each internal node of T has at least two children and stores a nonempty set of elements;
- A node μ of T with d children $\mu_1, \cdots, \mu_d$ stores $d-1$ elements $(x_1, y_1) \cdots (x_{d-1}, y_{d-1})$, where $x_1 \leq \cdots \leq x_{d-1}$;
- For each element (x, y) stored at a node in the subtree of T rooted at μ_i, we have $x_{i-1} \leq x \leq x_i$, where $x_0 = -\infty$ and $x_d = +\infty$.

In a search tree, each internal node stores a nonempty collection of keys, while the leaves do not store any key and serve only as "placeholders." An example of search tree is shown in Fig. 4.5(a). A special type of search tree is a **binary search tree**, where each internal node stores one key and has two children.

We will recursively describe the realization of a dictionary D by means of a search tree T, since we will use dictionaries to implement the nodes of T. Namely, an internal node μ of T with children $\mu_1, \cdots, \mu_d$ and elements $(x_1, y_1) \cdots (x_{d-1}, y_{d-1})$ is equipped with a dictionary $D(\mu)$ whose regular elements are the pairs $(x_i, (y_i, \mu_i))$, $i = 1, \cdots, d-1$ and whose special element with key $+\infty$ is $(+\infty, (\cdot, \mu_d))$. A regular element (x, y) stored in D is associated with a regular element $(x, (y, v))$ stored in a dictionary $D(\mu)$, for some node μ of T. See the example in Fig. 4.5(b).

Operation FIND

Operation FIND(x, c) on dictionary D is performed by means of the following recursive method for a node μ of T, where μ is initially the root of T [see Fig. 4.5(b)]. We execute LOCATENEXT(x, c') on dictionary $D(\mu)$ and let $(x', (y', v))$ be the element pointed by the returned locator c'. We have three cases:

- $x = x'$: we have found x and return locator c to (x', y');
- $x \neq x'$ and v is a leaf: we have determined that x is not in D and return a null locator c;
- $x \neq x'$ and v is an internal node: we set $\mu = v$ and recursively execute the method.

Operation INSERT

Operations LOCATEPREV, LOCATENEXT, and INSERT can be performed with small variations of the above method. For example, to perform operation INSERT(e, c), where $e = (x, y)$, we modify the

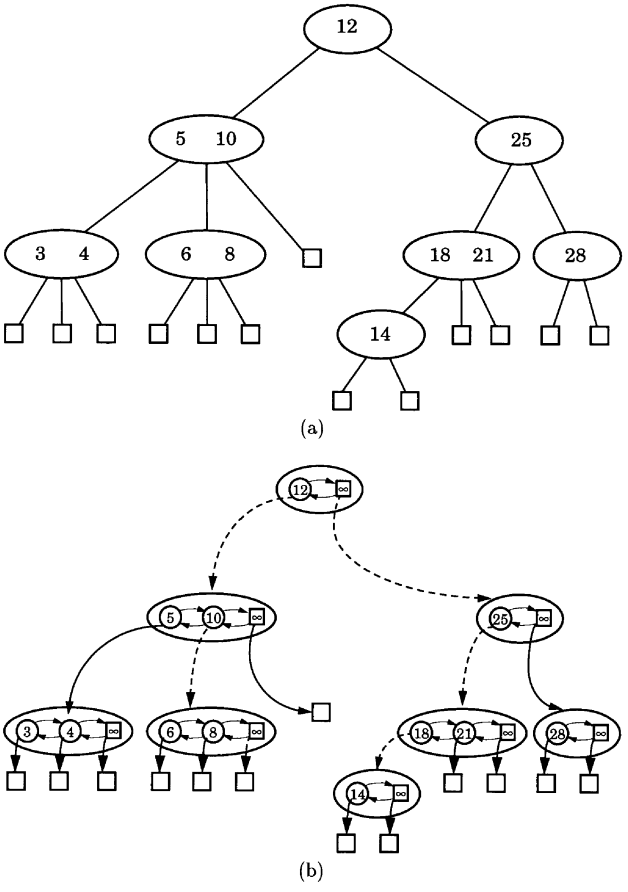

FIGURE 4.5 Realization of a dictionary by means of a search tree. (a) A search tree T. (b) Realization of the dictionaries at the nodes of T by means of sorted sequences. The search paths for elements 9 (unsuccessful search) and 14 (successful search) are shown with dashed lines.

above cases as follows (see Fig. 4.6):

- $x = x'$: an element with key x already exists, and we return a null locator;
- $x \neq x'$ and v is a leaf: we create a new leaf node λ, insert a new element $(x, (y, \lambda))$ into $D(\mu)$, and return a locator c to (x, y).
- $x \neq x'$ and v is an internal node: we set $\mu = v$ and recursively execute the method.

Note that new elements are inserted at the "bottom" of the search tree.

Operation REMOVE

Operation REMOVE(e, c) is more complex (see Fig. 4.7). Let the associated element of $e = (x, y)$ in T be $(x, (y, v))$, stored in dictionary $D(\mu)$ of node μ.

- If node v is a leaf, we simply delete element $(x, (y, v))$ from $D(\mu)$.
- Else (v is an internal node), we find the successor element $(x', (y', v'))$ of $(x, (y, v))$ in $D(\mu)$ with a NEXT operation in $D(\mu)$.
  - If v' is a leaf, we replace v' with v, i.e., change element $(x', (y', v'))$ to $(x', (y', v))$, and delete element $(x, (y, v))$ from $D(\mu)$.

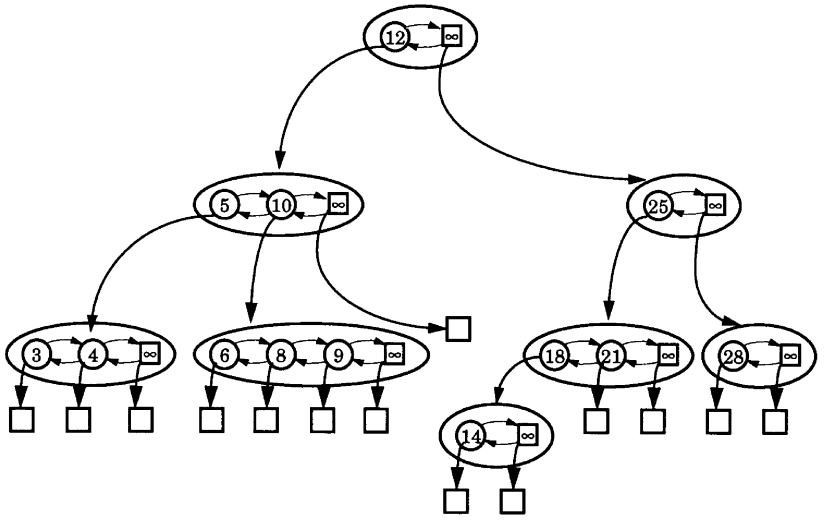

FIGURE 4.6 Insertion of element 9 into the search tree of Fig. 4.5.

– Else (v' is an internal node), while the leftmost child v'' of v' is not a leaf, we set $v' = v''$. Let $(x'', (y'', v''))$ be the first element of $D(v')$ (node v'' is a leaf). We replace $(x, (y, v))$ with $(x'', (y'', v))$ in $D(\mu)$ and delete $(x'', (y'', v''))$ from $D(v')$.

The above actions may cause dictionary $D(\mu)$ or $D(v')$ to become empty. If this happens, say for $D(\mu)$ and μ is not the root of T, we need to remove node μ. Let $(+\infty, (\cdot, \kappa))$ be the special element of $D(\mu)$ with key $+\infty$, and let $(z, (w, \mu))$ be the element pointing to μ in the parent node π of μ. We delete node μ and replace $(z, (w, \mu))$ with $(z, (w, \kappa))$ in $D(\pi)$.

Note that, if we start with an initially empty dictionary, a sequence of insertions and deletions performed with the above methods yields a search tree with a single node. In the next sections, we show how to avoid this behavior by imposing additional conditions on the structure of a search tree.

Realization with an (a, b)-Tree

An (a, b)*-tree,* where a and b are integer constants such that $2 \leq a \leq (b+1)/2$, is a search tree T with the following additional restrictions:

Level Property: all the levels of T are full, i.e., all the leaves are at the same depth;

Size Property: let μ be an internal node of T, and d be the number of children of μ; if μ is the root of T, then $d \geq 2$, else $a \leq d \leq b$.

The height of an (a, b) tree storing N elements is $O(\log_a N) = O(\log N)$. Indeed, in the worst case, the root has two children, and all the other internal nodes have a children.

The realization of a dictionary with an (a, b)-tree extends that with a search tree. Namely, the implementation of operations INSERT and REMOVE need to be modified in order to preserve the level and size properties. Also, we maintain the current size of the dictionary, and pointers to the minimum and maximum regular elements of the dictionary.

Insertion

The implementation of operation INSERT for search trees given in "Operation INSERT" adds a new element to the dictionary $D(\mu)$ of an existing node μ of T. Since the structure of the tree is not changed, the level property is satisfied. However, if $D(\mu)$ had the maximum allowed size $b-1$ before insertion

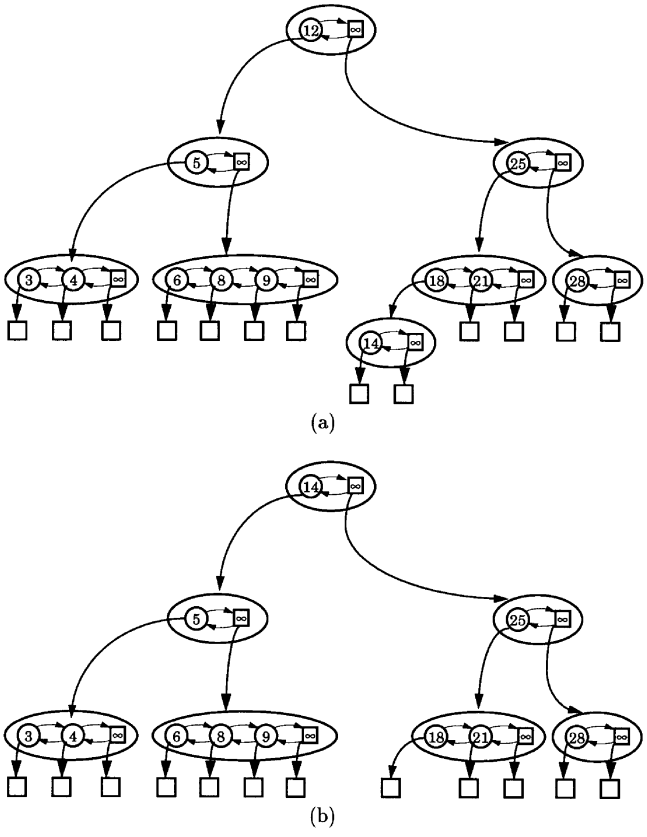

FIGURE 4.7 (a) Deletion of element 10 from the search tree of Fig. 4.6. (b) Deletion of element 12 from the search tree of part a.

(recall that the size of $D(\mu)$ is one less than the number of children of μ), the size property is violated at μ because $D(\mu)$ has now size b. To remedy this *overflow* situation, we perform the following *node-split* (see Fig. 4.8):

- Let the special element of $D(\mu)$ be $(+\infty, (\cdot, \mu_{b+1}))$. Find the median element of $D(\mu)$, i.e., the element $e_i = (x_i, (y_i, \mu_i))$ such that $i = \lceil (b+1)/2 \rceil$.
- Split $D(\mu)$ into:
  - dictionary D', containing the $\lceil (b-1)/2 \rceil$ regular elements $e_j = (x_j, (y_j, \mu_j))$, $j = 1 \cdots i-1$ and the special element $(+\infty, (\cdot, \mu_i))$;
  - element e; and
  - dictionary D'', containing the $\lfloor (b-1)/2 \rfloor$ regular elements $e_j = (x_j, (y_j, \mu_j))$, $j = i+1 \cdots b$ and the special element $(+\infty, (\cdot, \mu_{b+1}))$.
- Create a new tree node κ, and set $D(\kappa) = D'$. Hence, node κ has children $\mu_1 \cdots \mu_i$.
- Set $D(\mu) = D''$. Hence, node μ has children $\mu_{i+1} \cdots \mu_{b+1}$.
- If μ is the root of T, create a new node π with an empty dictionary $D(\pi)$. Else, let π be the parent of μ.
- Insert element $(x_i, (y_i, \kappa))$ into dictionary $D(\pi)$.

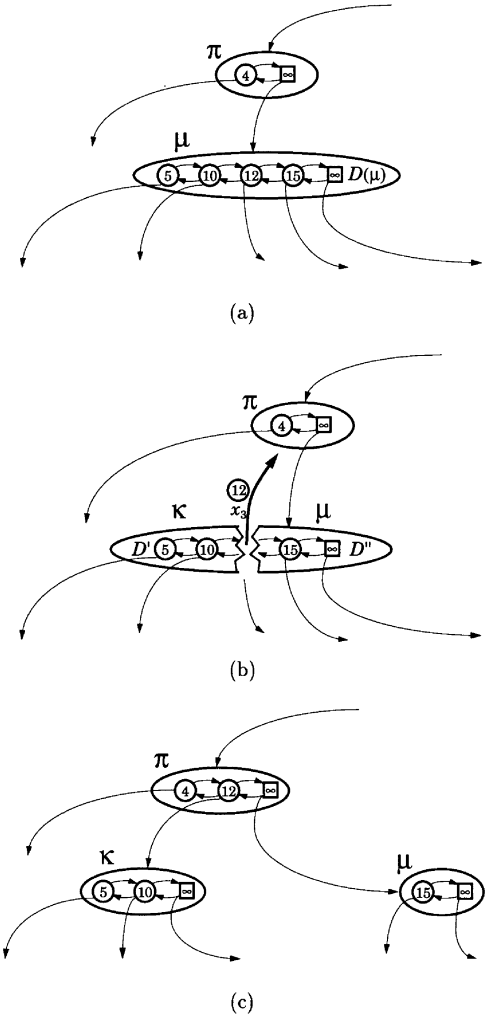

FIGURE 4.8 Example of node-split in a 2-4 tree: (a) initial configuration with an overflow at node μ; (b) split of the node μ into μ' and μ'' and insertion of the median element into the parent node π; (c) final configuration.

After a node-split, the level property is still verified. Also, the size property is verified for all the nodes of T, except possibly for node π. If π has $b + 1$ children, we repeat the node-split for $\mu = \pi$. Each time we perform a node-split, the possible violation of the size property appears at a higher level in the tree. This guarantees the termination of the algorithm for the INSERT operation. We omit the description of the simple method for updating the pointers to the minimum and maximum regular elements.

Deletion

The implementation of operation REMOVE for search trees given in the subsection "REMOVE" removes an element from the dictionary $D(\mu)$ of an existing node μ of T. Since the structure of the tree is not changed, the level property is satisfied. However, if μ is not the root, and $D(\mu)$ had the minimum allowed size $a - 1$ before deletion (recall that the size of the dictionary is one less than the number of children of the node), the size property is violated at μ because $D(\mu)$ has now size $a - 2$. To remedy this *underflow* situation, we perform the following *node-merge* (see Figs. 4.9 and 4.10):

- If μ has a right sibling, let μ'' be the right sibling of μ and $\mu' = \mu$; else, let μ' be the left sibling of μ and $\mu'' = \mu$. Let $(+\infty, (\cdot, \nu))$ be the special element of $D(\mu')$.
- Let π be the parent of μ' and μ''. Remove from $D(\pi)$ the regular element $(x, (y, \mu'))$ associated with μ'.
- Create a new dictionary D containing the regular elements of $D(\mu')$ and $D(\mu'')$, regular element $(x, (y, \nu))$, and the special element of $D(\mu'')$.
- Set $D(\mu'') = D$, and destroy node μ'.
- If μ'' has more than b children, perform a node-split at μ''.

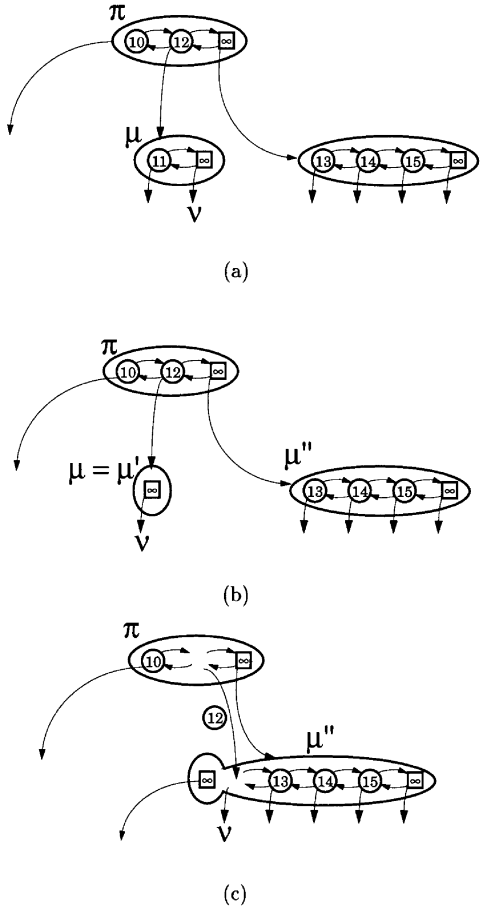

FIGURE 4.9 Example of node merge in a 2-4 tree: (a) initial configuration; (b) the removal of an element from dictionary $D(\mu)$ causes an underflow at node μ; (c) merging node $\mu = \mu'$ into its sibling μ''.

After a node-merge, the level property is still verified. Also, the size property is verified for all the nodes of T, except possibly for node π. If π is the root and has one child (and thus, an empty dictionary), we remove node π. If π is not the root and has fewer than $a - 1$ children, we repeat the node-merge for $\mu = \pi$. Each time we perform a node-merge, the possible violation of the size property appears at a higher level in the tree. This guarantees the termination of the algorithm for the REMOVE operation. We omit the description of the simple method for updating the pointers to the minimum and maximum regular elements.

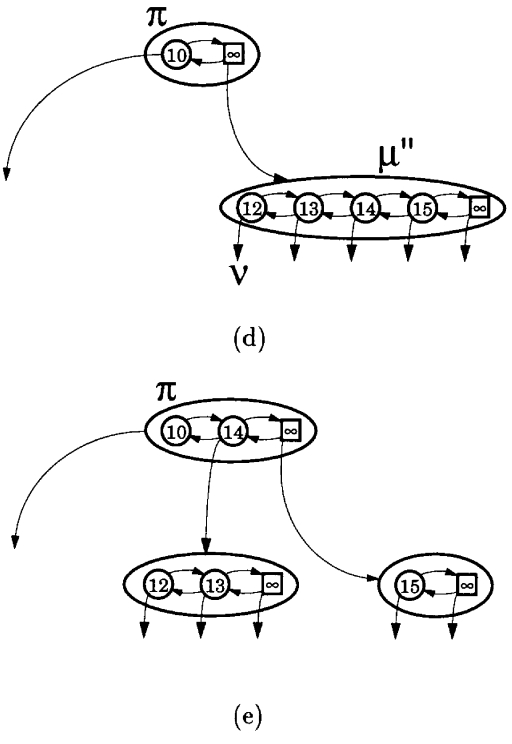

FIGURE 4.10 Example of node merge in a 2-4 tree: (d) overflow at node μ''; (e) final configuration after splitting node μ''.

Complexity

Let T be an (a, b)-tree storing N elements. The height of T is $O(\log_a N) = O(\log N)$. Each dictionary operation affects only the nodes along a root-to-leaf path. We assume that the dictionaries at the nodes of T are realized with sequences. Hence, processing a node takes $O(b) = O(1)$ time. We conclude that each operation takes $O(\log N)$ time.

Table 4.10 shows the performance of a dictionary realized with an (a, b)-tree.

Realization with an AVL-tree

An *AVL-tree* is a search tree T with the following additional restrictions:

Binary Property: T is a binary tree, i.e., every internal node has two children, (left and right child), and stores one key.

Height-Balance Property: For every internal node μ, the heights of the subtrees rooted at the children of μ differ at most by one.

An example of AVL-tree is shown in Fig. 4.11. The height of an AVL-tree storing N elements is $O(\log N)$. This can be shown as follows. Let N_h be the minimum number of elements stored in an AVL-tree of height h. We have $N_0 = 0$, $N_1 = 1$, and

$$N_h = 1 + N_{h-1} + N_{h-2}, \text{ for } h \geq 2 .$$

The above recurrence relation defines the well-known Fibonacci numbers. Hence, $N_h = \Omega(\phi^N)$, where $1 < \phi < 2$.

Note: We denote with N the number of elements in the dictionary at the time the operation is performed. The space complexity is $O(N)$.

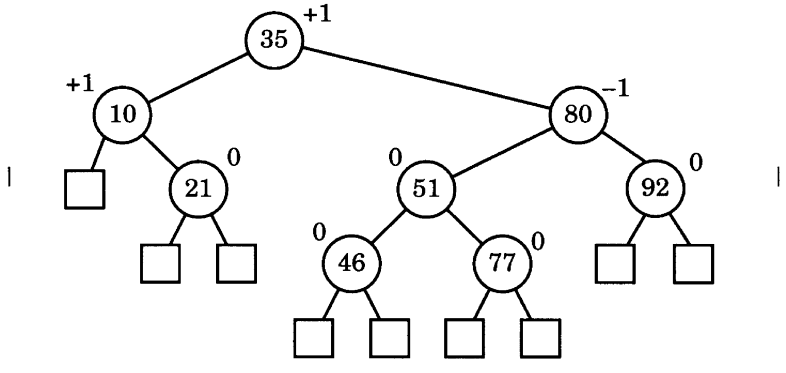

FIGURE 4.11 Example of AVL-tree storing 9 elements. The keys are shown inside the nodes, and the balance factors (see Section "Rebalancing") are shown next to the nodes.

The realization of a dictionary with an AVL-tree extends that with a search tree. Namely, the implementation of operations INSERT and REMOVE need to be modified in order to preserve the binary and height-balance properties after an insertion or deletion.

Insertion

The implementation of INSERT for search trees given in the subsection "Operation INSERT" adds the new element to an existing node. This violates the binary property, and hence, cannot be done in an AVL-tree. Hence, we modify the three cases of the INSERT algorithm for search trees as follows:

- $x = x'$: an element with key x already exists, and we return a null locator c;
- $x \neq x'$ and v is a leaf: we replace v with a new internal node κ with two leaf children, store element (x, y) in κ, and return a locator c to (x, y).
- $x \neq x'$ and v is an internal node: we set $\mu = v$ and recursively execute the method.

We have preserved the binary property. However, we may have violated the height-balance property, since the heights of some subtrees of T have increased by one. We say that a node is balanced if the

difference between the heights of its subtrees is -1, 0, or 1, and is unbalanced otherwise. The unbalanced nodes form a (possibly empty) subpath of the path from the new internal node κ to the root of T. See the example of Fig. 4.12.

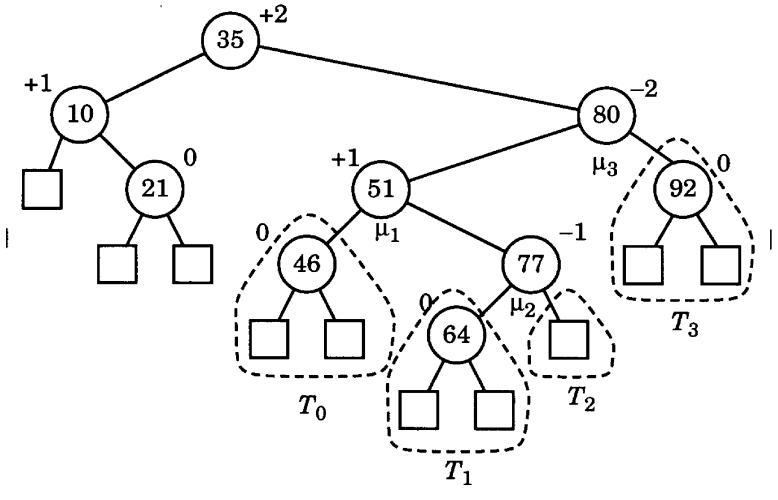

FIGURE 4.12 Insertion of an element with key 64 into the AVL-tree of Fig. 4.11. Note that two nodes (with balance factors $+2$ and -2) have become unbalanced. The dashed lines identify the subtrees that participate in the rebalancing, as illustrated in Fig. 4.14.

Rebalancing

To restore the height-balance property, we *rebalance* the lowest node μ that is unbalanced, as follows.

- Let μ' be the child of μ whose subtree has maximum height, and μ'' be the child of μ' whose subtree has maximum height.
- Let (μ_1, μ_2, μ_3) be the left-to-right ordering of nodes $\{\mu, \mu', \mu''\}$, and (T_0, T_1, T_2, T_3) be the left-to-right ordering of the four subtrees of $\{\mu, \mu', \mu''\}$ not rooted at a node in $\{\mu, \mu', \mu''\}$.
- replace the subtree rooted at μ with a new subtree rooted at μ_2, where μ_1 is the left child of μ_2 and has subtrees T_0 and T_1, and μ_3 is the right child of μ_2 and has subtrees T_2 and T_3.

Two examples of rebalancing are schematically shown in Fig. 4.14. Other symmetric configurations are possible. In Fig. 4.13, we show the rebalancing for the tree of Fig. 4.12.

Note that the rebalancing causes all the nodes in the subtree of μ_2 to become balanced. Also, the subtree rooted at μ_2 now has the same height as the subtree rooted at node μ before insertion. This causes all the previously unbalanced nodes to become balanced. To keep track of the nodes that become unbalanced, we can store at each node a *balance factor,* which is the difference of the heights of the left and right subtrees. A node becomes unbalanced when its balance factor becomes $+2$ or -2. It is easy to modify the algorithm for operation INSERT such that it maintains the balance factors of the nodes.

Deletion

The implementation of REMOVE for search trees given in "Realization with a Search Tree" preserves the binary property, but may cause the height-balance property to be violated. After deleting a node, there can be only one unbalanced node, on the path from the deleted node to the root of T.

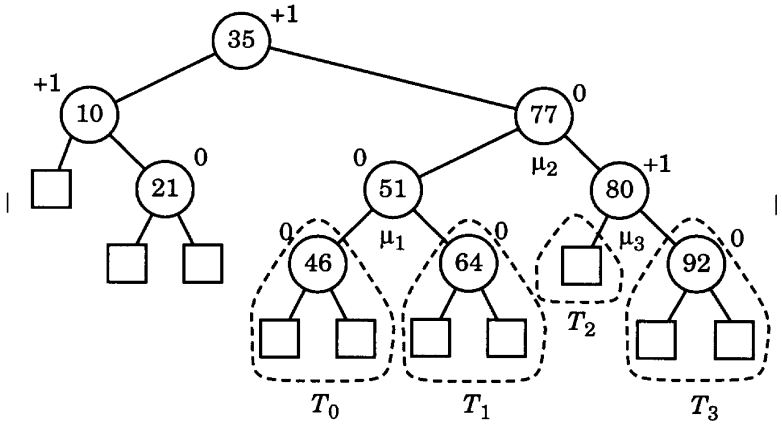

FIGURE 4.13 AVL-tree obtained by rebalancing the lowest unbalanced node in the tree of Fig. 4.11. Note that all the nodes are now balanced. The dashed lines identify the subtrees that participate in the rebalancing, as illustrated in Fig. 4.14.

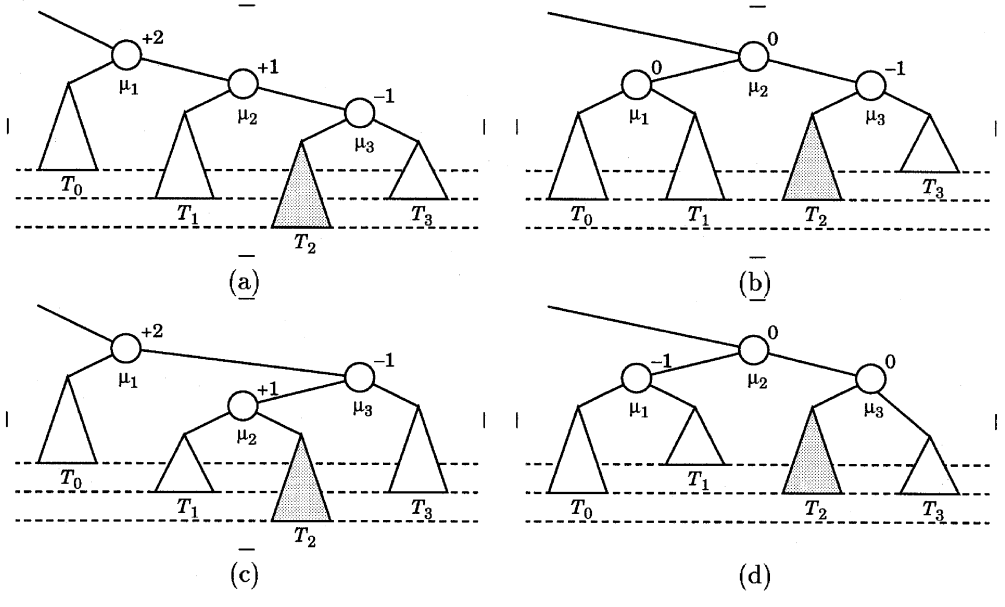

FIGURE 4.14 Schematic illustration of rebalancing a node in the INSERT algorithm for AVL-trees. The shaded subtree is the one where the new element was inserted. (a, b) Rebalancing by means of a "single rotation." (c, d) Rebalancing by means of a "double rotation."

To restore the height-balance property, we *rebalance* the unbalanced node using the above algorithm. Notice, however, that the choice of μ'' may not be unique, since the subtrees of μ' may have the same height. In this case, the height of the subtree rooted at μ_2 is the same as the height of the subtree rooted at μ before rebalancing, and we are done. If instead the subtrees of μ' do not have the same height, then the height of the subtree rooted at μ_2 is one less than the height of the subtree rooted at μ before rebalancing. This may cause an ancestor of μ_2 to become unbalanced, and we repeat the rebalancing step. Balance factors are used to keep track of the nodes that become unbalanced, and can be easily maintained by the REMOVE algorithm.

Complexity

Let T be an AVL-tree storing N elements. The height of T is $O(\log N)$. Each dictionary operation affects only the nodes along a root-to-leaf path. Rebalancing a node takes $O(1)$ time. We conclude that each operation takes $O(\log N)$ time.

Table 4.11 shows the performance of a dictionary realized with an AVL-tree.

TABLE 4.11 Performance of a Dictionary Realized by an AVL-Tree

Operation	Time
SIZE	$O(1)$
FIND	$O(\log N)$
LOCATEPREV	$O(\log N)$
LOCATENEXT	$O(\log N)$
LOCATERANK	$O(\log N)$
NEXT	$O(\log N)$
PREV	$O(\log N)$
MIN	$O(1)$
MAX	$O(1)$
INSERT	$O(\log N)$
REMOVE	$O(\log N)$
MODIFY	$O(\log N)$

Note: We Denote with N the number of elements in the dictionary at the time the operation is performed. The space complexity is $O(N)$.

Realization with a Hash Table

The previous realizations of a dictionary make no assumptions on the structure of the keys, and use comparisons between keys to guide the execution of the various operations.

Bucket Array

If the keys of a dictionary D are integers in the range $[1, M]$, we can implement D with a *bucket array* B. An element (x, y) of D is represented by setting $B[x] = y$. If an integer x is not in D, the location $B[x]$ stores a null value. In this implementation, we allocate a "bucket" for every possible element of D.

Table 4.12 shows the performance of a dictionary realized a bucket array.

The bucket array method can be extended to keys that are easily mapped to integers; e.g., three-letter airport codes can be mapped to the integers in the range $[1, 26^3]$.

Hashing

The bucket array method works well when the range of keys is small. However, it is inefficient when the range of keys is large. To overcome this problem, we can use a *hash function* h that maps the keys of the original dictionary D into integers in the range $[1, M]$, where M is a parameter of the hash function. Now, we can apply the bucket array method using the *hashed value* $h(x)$ of the keys. In general, a *collision* may happen, where two distinct keys x_1 and x_2 have the same hashed value, i.e., $x_1 \neq x_2$ and $h(x_1) = h(x_2)$. Hence, each bucket must be able to accommodate a collection of elements.

TABLE 4.12 Performance of a Dictionary Realized by Bucket Array

Operation	Time
SIZE	$O(1)$
FIND	$O(1)$
LOCATEPREV	$O(M)$
LOCATENEXT	$O(M)$
LOCATERANK	$O(M)$
NEXT	$O(M)$
PREV	$O(M)$
MIN	$O(M)$
MAX	$O(M)$
INSERT	$O(1)$
REMOVE	$O(1)$
MODIFY	$O(1)$

Note: The keys in the dictionary are integers in the range $[1, M]$. The space complexity is $O(M)$.

A hash table of size M for a function $h(x)$ is a bucket array B of size M (primary structure) whose entries are dictionaries (secondary structures), such that element (x, y) is stored in the dictionary $B[h(x)]$. For simplicity of programming, the dictionaries used as secondary structures are typically realized with sequences. An example of hash table is shown in Fig. 4.15.

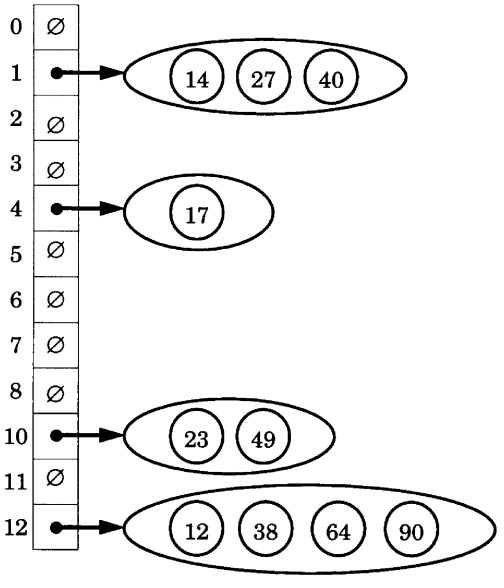

FIGURE 4.15 Example of hash table of size 13 storing 10 elements. The hash function is $h(x) = x \mod 13$.

If all the elements in the dictionary D collide, they are all stored in the same dictionary of the bucket array, and the performance of the hash table is the same as that of the kind of dictionary used as a secondary structures. At the other end of the spectrum, if no two elements of the dictionary D collide, they are stored

in distinct one-element dictionaries of the bucket array, and the performance of the hash table is the same as that of a bucket array.

A typical hash function for integer keys is $h(x) = x \bmod M$. The size M of the hash table is usually chosen as a prime number. An example of hash table is shown in Fig. 4.15.

It is interesting to analyze the performance of a hash table from a probabilistic viewpoint. If we assume that the hashed values of the keys are uniformly distributed in the range $[1, M]$, then each bucket holds on average N/M keys, where N is the size of the dictionary. Hence, when $N = O(M)$, the average size of the secondary data structures is $O(1)$.

Table 4.13 shows the performance of a dictionary realized a hash table. Both the worst-case and average time complexity in the above probabilistic model are indicated.

TABLE 4.13 Performance of a Dictionary Realized by a Hash Table of Size M

	Time	
Operation	**Worst-Case**	**Average**
SIZE	$O(1)$	$O(1)$
FIND	$O(N)$	$O(N/M)$
LOCATEPREV	$O(N+M)$	$O(N+M)$
LOCATENEXT	$O(N+M)$	$O(N+M)$
LOCATERANK	$O(N+M)$	$O(N+M)$
NEXT	$O(N+M)$	$O(N+M)$
PREV	$O(N+M)$	$O(N+M)$
MIN	$O(N+M)$	$O(N+M)$
MAX	$O(N+M)$	$O(N+M)$
INSERT	$O(1)$	$O(1)$
REMOVE	$O(1)$	$O(1)$
MODIFY	$O(1)$	$O(1)$

Note: We denote with N the number of elements in the dictionary at the time the operation is performed. The space complexity is $O(N+M)$. The average time complexity refers to a probabilistic model where the hashed values of the keys are uniformly distributed in the range $[1, M]$.

4.5 Defining Terms

(a, b)-tree: Search tree with additional properties (each node has between a and b children, and all the levels are full); see "Realization with an (a, b)-Tree."

Abstract data type: Mathematically specified data type equipped with operations that can be performed on the objects; see "Abstract Data Types."

AVL-tree: Binary search tree such that the subtrees of each node have heights that differ by at most one; see "Realization with an AVL-Tree."

Binary search tree: Search tree such that each internal node has two children; see "Realization with a Search Tree."

Bucket array: Implementation of a dictionary by means of an array indexed by the keys of the dictionary elements; see "Bucket Array."

Container: Abstract data type storing a collection of objects (elements); see "Containers, Elements, and Locators."

Dictionary: Container storing elements from a sorted universe supporting searches, insertions, and deletions; see Section 4.4.

Hash table: Implementation of a dictionary by means of a bucket array storing secondary dictionaries; see "Hashing."

Heap: Binary tree with additional properties storing the elements of a priority queue; see "Realization with a Heap."

Locator: Variable that allows to access an object stored in a container; see "Containers, Elements, and Locators."

Priority queue: Container storing elements from a sorted universe supporting finding the maximum element, insertions, and deletions; see Section 4.3.

Search tree: Rooted ordered tree with additional properties storing the elements of a dictionary; see "Realization with a Search Tree."

Sequence: Container storing object in a certain order, supporting insertions (in a given position) and deletions; see Section 4.2.

Further Information

Many textbooks and monographs have been written on data structures, e.g., [2, 7, 16, 17, 19, 20, 21, 22, 23, 27, 29, 30, 33, 35, 37].

Recent papers surveying the state-of-the art in data structures include [4, 15, 25, 36].

The LEDA project [24] aims at developing a C++ library of efficient and reliable implementations of sophisticated data structures.

5.1 Introduction

In this chapter, we describe advanced data structures and algorithmic techniques, mostly focusing our attention to two important problems: set union and persistence. We first describe set union data structures. Their discovery required a new set of techniques and tools that have proved useful in other areas as well. We survey algorithms and data structures for set union problems, and attempt to provide a unifying theoretical framework for this growing body of algorithmic tools. **Persistent data structures** maintain information about their past states and find uses in a diverse spectrum of applications. The body of work relating to persistent data structures brings together quite a surprising cocktail of techniques, from real-time computation to techniques from functional programming.

Set Union Data Structures

The *set union problem* consists of maintaining a collection of disjoint sets under an intermixed sequence of the following two kinds of operations:

union(A, B)*:* Combine the two sets A and B into a new set named A.
find(x)*:* Return the name of the set containing element x.

The operations are presented on line, namely each operation must be processed before the next one is known. Initially, the collection consists of n singleton sets $\{1\}, \{2\}, \ldots, \{n\}$, and the name of set $\{i\}$ is i, $1 \leq i \leq n$. Figure 5.1 illustrates an example of set union operations.

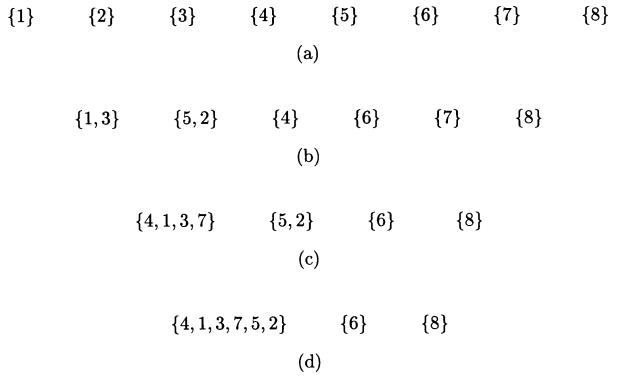

FIGURE 5.1 Examples of set union operations. (a) The initial collection of disjoint sets. (b) The disjoint sets of (a) after performing union(1, 3) and union(5, 2). (c) The disjoint sets of (b) after performing union(1, 7) followed by union(4, 1). (d) The disjoint sets of (c) after performing union(4, 5).

The set union problem has been widely studied, and finds application in a wide range of areas, including Fortran compilers [10, 38], property grammars [78, 79], computational geometry [49, 67, 68], finite state machines [4, 44], string algorithms [5, 48], logic programming and theorem proving [7, 8, 47, 95], and several combinatorial problems such as finding minimum spanning trees [4, 53], solving dynamic edge- and vertex-connectivity problems [98], computing least common ancestors in trees [3], solving off–line minimum problems [34, 45], finding dominators in graphs [83], and checking flow graph reducibility [82].

Several variants of set union have been introduced, in which the possibility of backtracking over the sequences of unions was taken into account [9, 39, 59, 63, 97]. This was motivated by problems arising in logic programming interpreter memory management [40, 60, 61, 96].

Persistent Data Structures

Data structures that one encounters in traditional algorithmic settings are *ephemeral*, i.e., if the data structure is updated then the previous state of the data structure is lost. A *persistent* data structure, on the other hand, preserves old versions of the data structure. Several kinds of persistence can be distinguished based upon what kind of access is allowed to old versions of the data structure. Accesses to a data structure can be of two kinds: *updates*, which change the information content of the data structure, and *queries*, which do not. For the sake of ease of presentation, we will assume that queries do not even change the internal representation of the data, i.e., read-only access to a data structure suffices to answer a query.

In the persistent setting we would like to maintain multiple *versions* of data structures. In addition to the arguments taken by its ephemeral counterparts, a persistent query or update operation takes as

an argument the version of the data structure to which the query or update refers. A persistent update also returns a *handle* to the new version created by the update. We distinguish between three kinds of persistence:

- A *partially* persistent data structure allows updates only to the latest version of the data structure. All versions of the data structure may be queried, however. Clearly, the versions of a partially persistent data structure exhibit a linear ordering as shown in Fig. 5.2(a).
- A *fully* persistent data structure allows all existing versions of the data structure to be queried or updated. However, an update may operate only on a single version at a time—for instance combining two or more old versions of the data structure to form a new one is not allowed. The versions of a fully persistent data structure form a tree, as shown in Fig. 5.2(b).
- A **purely functional language** is one that does not allow any *destructive* operation—one that overwrites data—such as the assignment operation. Purely functional languages are side-effect-free, i.e., invoking a function has no effect other than computing the value returned by the function. In particular, an update operation to a data structure implemented in a purely functional language returns a new data structure containing the updated values, while leaving the original data structure unchanged. Data structures implemented in purely functional languages are therefore persistent in the strongest possible sense, as they allow unrestricted access for both reading and updating all versions of the data structure.
  An example of a purely functional language is pure LISP [64]. Side-effect-free code can also be written in *functional* languages such as ML [70], most existing variants of LISP (e.g., Common LISP [80]) or Haskell [46], by eschewing the destructive operations supported by these languages.

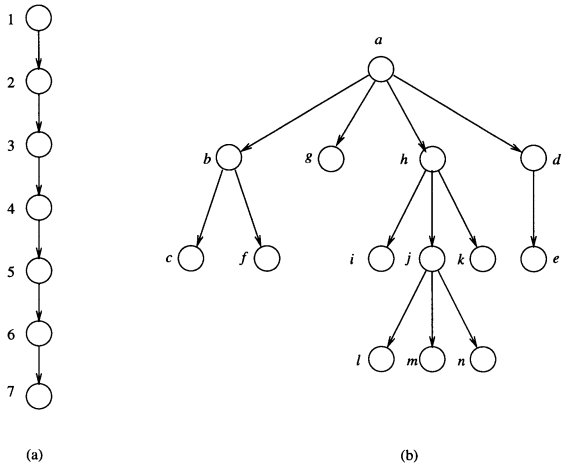

FIGURE 5.2 Structure of versions for (a) partial and (b) full persistence.

This section aims to cover a selection of the major results relating to the above forms of persistence. The body of work contains both *ad hoc* techniques for creating persistent data structures for particular problems, as well as general techniques to make ephemeral data structures persistent. Indeed, early work on persistence [17, 20, 30] focused almost exclusively on the former. Sarnak [75] and Driscoll et al. [28] were the first to offer very efficient general techniques for partial and full persistence. These and related results will form the bulk of the material in this chapter dealing with partial and full persistence. However, the prospect of obtaining still greater efficiency led to the further development of some *ad hoc* persistent

data structures [25, 26, 41]. The results on functional data structures will largely focus on implementations of individual data structures.

There has also been some research into data structures that support *backtrack* or *rollback* operations, whereby the data structure can be reset to some previous state. We do not cover these operations in this section, but we note that fully persistent data structures support backtracking (although sometimes not as efficiently as data structures designed especially for backtracking). Data structures with backtracking for the union–find problem are covered in Section 5.4.

Persistent data structures have numerous applications, including text, program and file editing and maintenance, computational geometry, tree pattern matching and inheritance in object-oriented programming languages. One elegant application of partially persistent search trees to the classical geometric problem of *planar point location* was given by Sarnak and Tarjan [76]. Suppose the Euclidean plane is divided into polygons by a collection of n line segments that intersect only at their endpoints (see Fig. 5.3), and we want to preprocess the collection of line segments so that, given a query point p, we can efficiently determine the polygon to which p belongs. Sarnak and Tarjan achieve this by combining the well-known *plane sweep* technique with a persistent data structure.

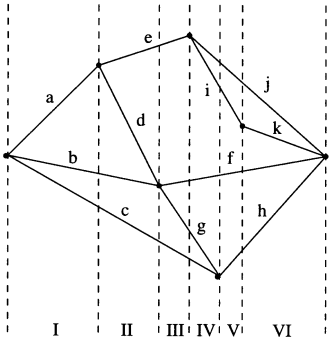

FIGURE 5.3 A planar subdivision.

Imagine moving an infinite vertical line (called the *sweep line*) from left to right across the plane, beginning at the leftmost endpoint of any line segment. As the sweep line moves, we maintain the line segments currently intersecting the sweep line in a balanced binary search tree, in order of their point of intersection with the sweep line (i.e., of two line segments, the one that intersects the sweep line at a higher location is considered smaller). Figure 5.4 shows the evolution of the search tree as the sweep line continues its progress from left to right. Note that the plane is divided into vertical *slabs*, within which the search tree does not change.

Given a query point p, we first locate the slab in which the x-coordinate of p lies. If we could remember what our search tree looked like while the sweep line was in this slab, we could query the search tree using the y-coordinate of p to find the two segments immediately above and below p in this slab; these line segments uniquely determine the polygon in which p lies. However, if we maintained the line segments in a partially persistent search tree as the sweep line moves from left to right, all incarnations of the search tree during this process are available for queries.

Sarnak and Tarjan show that it is possible to perform the preprocessing (which merely consists of building up the persistent tree) in $O(n \log n)$ time. The data structure uses $O(n)$ space and can be queried in $O(\log n)$ time, giving a simple optimal solution to the planar point location problem.

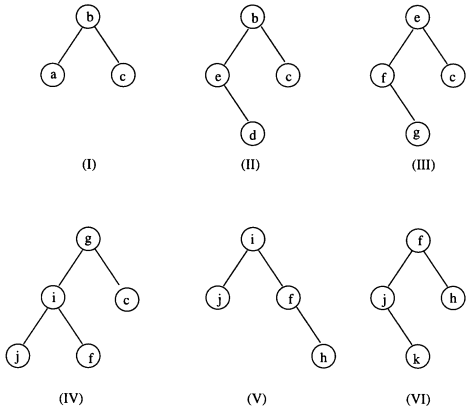

FIGURE 5.4 The evolution of the search tree during the plane sweep.

Models of Computation

Different models of computation have been developed for analyzing data structures. One model of computation is the **random access machine,** whose memory consists of an unbounded sequence of registers, each of which is capable of holding an integer. In this model, arithmetic operations are allowed to compute the address of a memory register. Usually, it is assumed that the size of a register is bounded by $O(\log n)$[1] bits, where n is the input problem size. A more formal definition of random access machines can be found in [4]. Another model of computation, known as the **cell probe model** of computation, was introduced by Yao [99]. In the cell probe, the cost of a computation is measured by the total number of memory accesses to a random access memory with $\lceil \log n \rceil$ bits cell size. All other computations are not accounted for and are considered to be free. Note that the cell probe model is more general than a random access machine, and thus, is more suitable for proving lower bounds. A third model of computation is the **pointer machine** [13, 54, 55, 77, 85]. Its storage consists of an unbounded collection of registers (or records) connected by pointers. Each register can contain an arbitrary amount of additional information but no arithmetic is allowed to compute the address of a register. The only possibility to access a register is by following pointers. This is the main difference between random access machines and pointer machines. Throughout this chapter, we use the terms *random-access algorithms*, *cell-probe algorithms*, and *pointer-based algorithms* to refer to algorithms respectively for random access machines, the cell probe model, and pointer machines.

Among pointer-based algorithms, two different classes were defined specifically for set union problems: *separable pointer algorithms* [85] and *nonseparable pointer algorithms* [69].

Separable pointer algorithms run on a pointer machine and satisfy the **separability** assumption as defined in [85] (see below). A separable pointer algorithm makes use of a linked data structure, namely a collection of records and pointers that can be thought of as a directed graph: each record is represented by a node and each pointer is represented by an edge in the graph. The algorithm solves the set union problem according to the following rules [14, 85]:

(i) The operations must be performed on line, i.e., each operation must be executed before the next one is known.

(ii) Each element of each set is a node of the data structure. There can be also additional (working) nodes.

[1] Throughout this chapter all logarithms are assumed to be to the base 2, unless explicitly otherwise specified.

(iii) (*Separability*). After each operation, the data structure can be partitioned into disjoint subgraphs such that each subgraph corresponds to exactly one current set. The name of the set occurs in exactly one node in the subgraph. No edge leads from one subgraph to another.

(iv) To perform find(x), the algorithm obtains the node v corresponding to element x and follows paths starting from v until it reaches the node which contains the name of the corresponding set.

(v) During any operation the algorithm may insert or delete any number of edges. The only restriction is that rule (iii) must hold after each operation.

The class of *nonseparable pointer algorithms* [69] does not require the separability assumption. The only requirement is that the number of edges leaving each node must be bounded by some constant $c > 0$. More formally, rule (iii) above is replaced by the following rule, while the other four rules are left unchanged:

(iii) There exists a constant $c > 0$ such that there are at most c edges leaving a node.

As we will see later on, often separable and nonseparable pointer-based algorithms admit quite different upper and lower bounds for the same problems.

5.2 The Set Union Problem

As defined in the previous section, the *set union problem* consists of performing a sequence of union and find operations, starting from a collection of n singleton sets $\{1\}, \{2\}, \ldots, \{n\}$. The initial name of set $\{i\}$ is i. As there are at most n items to be united, the number of unions in any sequence of operations is bounded above by $(n - 1)$. There are two invariants which hold at any time for the set union problem: first, the sets are always disjoint and define a partition of $\{1, 2, \ldots, n\}$; second, the name of each set corresponds to one of the items contained in the set itself. Both invariants are trivial consequences of the definition of union and find operations.

A different version of this problem considers the following operation in place of unions:

unite(A,B): Combine the two sets A and B into a new set, whose name is either A or B.

The only difference between union and unite is that unite allows the name of the new set to be arbitrarily chosen (e.g., at run time by the algorithm). This is not a significant restriction in many applications, where one is mostly concerned with testing whether two elements belong to the same set, no matter what the name of the set can be. However, some extensions of the set union problem have quite different time bounds depending on whether unions or unites are considered. In the following, we will deal with unions unless explicitly specified otherwise.

Amortized Time Complexity

In this section we describe algorithms for the set union problem [84, 89] giving the optimal amortized time complexity per operation. We only mention here that the amortized time is the running time per operation averaged over a worst-case sequence of operations, and refer the interested reader to [88] for a more detailed definition of amortized complexity. For the sake of completeness, we first survey some of the basic algorithms that have been proposed in the literature [4, 31, 38]. These are: the *quick-find*, the *weighted quick-find*, the *quick-union*, and the *weighted quick-union* algorithms. The quick-find algorithm performs find operations quickly, while the quick-union algorithm performs union operations quickly. Their weighted counterparts speed these computations up by introducing some weighting rules during union operations.

Most of these algorithms represent sets as rooted trees, following a technique introduced first by Galler and Fischer [38]. There is a tree for each disjoint set, and nodes of a tree correspond to elements of the

corresponding set. The name of the set is stored in the tree root. Each tree node has a pointer to its parent: in the following, we refer to $p(x)$ as the parent of node x.

The quick-find algorithm can be described as follows. Each set is represented by a tree of height 1. Elements of the set are the leaves of the tree. The root of the tree is a special node which contains the name of the set. Initially, singleton set $\{i\}$, $1 \leq i \leq n$, is represented by a tree of height 1 composed of one leaf and one root. To perform a union(A, B), all the leaves of the tree corresponding to B are made children of the root of the tree corresponding to A. The old root of B is deleted. This maintains the invariant that each tree is of height 1 and can be performed in $O(|B|)$ time, where $|B|$ denotes the total number of elements in set B. Since a set can have as many as $O(n)$ elements, this gives an $O(n)$ time complexity in the worst case for each union. To perform a find(x), return the name stored in the parent of x. Since all trees are maintained of height 1, the parent of x is a tree root. Consequently a find requires $O(1)$ time.

A more efficient variant attributed to McIlroy and Morris (see [4]) and known as weighted quick-find uses the freedom implicit in each union operation according to the following weighting rule.

> *Union by size:* Make the children of the root of the smaller tree point to the root of the larger, arbitrarily breaking a tie. This requires that the size of each tree is maintained throughout any sequence of operations.

Although this rule does not improve the worst-case time complexity of each operation, it improves to $O(\log n)$ the amortized bound of a union (see, e.g., [4]).

The quick-union algorithm [38] can be described as follows. Again, each set is represented by a tree. However, there are two main differences with the data structure used by the quick-find algorithm. The first is that now the height of a tree can be greater than 1. The second is that each node of each tree corresponds to an element of a set and therefore there is no need for special nodes. Once again, the root of each tree contains the name of the corresponding set. A union(A, B) is performed by making the tree root of set B child of the tree root of set A. A find(x) is performed by starting from the node x and by following the pointer to the parent until the tree root is reached. The name of the set stored in the tree root is then returned. As a result, the quick-union algorithm is able to support each union in $O(1)$ time and each find in $O(n)$ time.

This time bound can be improved by using the freedom implicit in each union operation, according to one of the following two union rules. This gives rise to two weighted quick-union algorithms.

> *Union by size:* Make the root of the smaller tree point to the root of the larger, arbitrarily breaking a tie. This requires maintaining the number of descendants for each node, in the following referred to as the *size* of a node, throughout all the sequence of operations.
>
> *Union by rank:* [89] Make the root of the shallower tree point to the root of the other, arbitrarily breaking a tie. This requires maintaining the height of the subtree rooted at each node, in the following referred to as the *rank* of a node, throughout all the sequences of operations.

After a union(A, B), the name of the new tree root is set to A. It can be easily proved (see, e.g., [89]) that the height of the trees achieved with either the "union by size" or the "union by rank" rule is never more than $\log n$. Thus, with either rule each union can be performed in $O(1)$ time and each find in $O(\log n)$ time.

A better amortized bound can be obtained if one of the following *compaction rules* is applied to the path examined during a find operation (see Fig. 5.5).

> *Path compression* [45]: Make every encountered node point to the tree root.
>
> *Path splitting* [93, 94]: Make every encountered node (except the last and the next to last) point to its grandparent.
>
> *Path halving* [93, 94]: Make every other encountered node (except the last and the next to last) point to its grandparent.

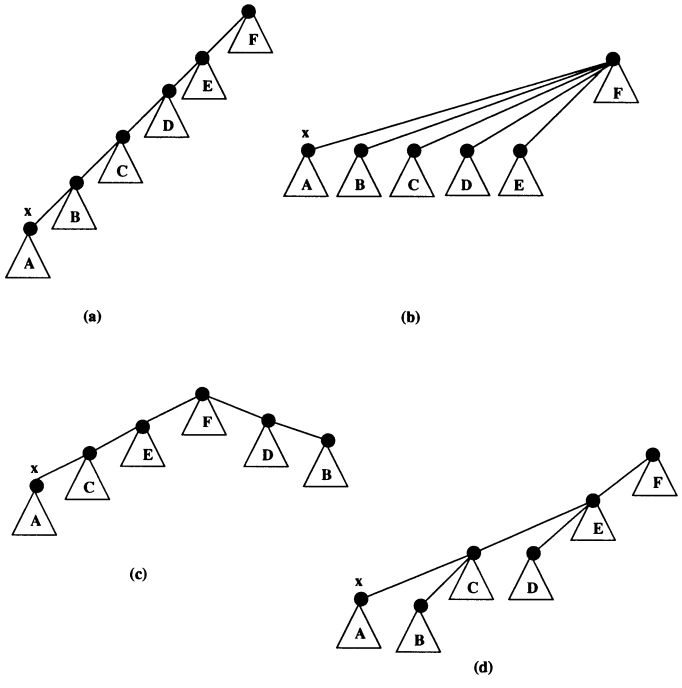

FIGURE 5.5 Illustrating path compaction techniques: (a) the tree before performing a find(x) operation; (b) path compression; (c) path splitting; (d) path halving.

Combining the two choices of a union rule and the three choices of a compaction rule, six possible algorithms are obtained. As shown in [89] they all have an $O(\alpha(m+n,n))$ amortized time complexity, where α is a very slowly growing function, a functional inverse of Ackermann's function [1].

THEOREM 5.1 **[89]** *The algorithms with either linking by size or linking by rank and either compression, splitting or halving run in* $O(n+m\alpha(m+n,n))$ *time on a sequence of at most* $(n-1)$ *unions and m finds.*

No better amortized bound is possible for separable and nonseparable pointer algorithms or in the cell probe model of computation [32, 56, 89].

THEOREM 5.2 **[32, 56, 89]** *Any pointer-based or cell-probe algorithm requires* $\Omega(n+m\alpha(m+n,n))$ *worst-case time for processing a sequence of* $(n-1)$ *unions and m finds.*

Single-Operation Worst-Case Time Complexity

The algorithms that use any union and any compaction rule have still single-operation worst-case time complexity $O(\log n)$ [89], since the trees created by any of the union rules can have height as large as $O(\log n)$. Blum [14] proposed a data structure for the set union problem that supports each union and find in $O(\log n/\log\log n)$ time in the worst case, and showed that this is the actual lower bound for separable pointer-based algorithms.

The data structure used to establish the upper bound is called *k–UF tree*. For any $k \geq 2$, a k–UF tree is a rooted tree such that: (i) the root has at least two children; (ii) each internal node has at least k children; and (iii) all the leaves are at the same level. As a consequence of this definition, the height of a k–UF tree

with n leaves is at most $\lceil \log_k n \rceil$. We refer to the root of a k–UF tree as *fat* if it has more than k children, and as *slim* otherwise. A k–UF tree is said to be *fat* if its root is fat, otherwise it is referred to as *slim*.

Disjoint sets can be represented by k–UF trees as follows. The elements of the set are stored in the leaves and the name of the set is stored in the root. Furthermore, the root also contains the height of the tree and a bit specifying whether it is fat or slim. A find(x) is performed as described in the previous section by starting from the leaf containing x and returning the name stored in the root. This can be accomplished in $O(\log_k n)$ worst-case time. A union(A, B) is performed by first accessing the roots r_A and r_B of the corresponding k–UF trees T_A and T_B. Blum assumed that his algorithm obtained in constant time r_A and r_B before performing a union(A, B). If this is not the case, r_A and r_B can be obtained by means of two finds (i.e., find(A) and find(B)), due to the property that the name of each set corresponds to one of the items contained in the set itself. We now show how to unite the two k–UF *trees* T_A and T_B. Assume without loss of generality that $height(T_B) \leq height(T_A)$. Let v be the node on the path from the leftmost leaf of T_A to r_A with the same height as T_B. Clearly, v can be located by following the leftmost path starting from the root r_A for exactly $height(T_A) - height(T_B)$ steps. When merging T_A and T_B, only three cases are possible, which give rise to three different types of unions.

Type 1: Root r_B is fat (i.e., has more than k children) and v is not the root of T_A. Then r_B is made a sibling of v.

Type 2: Root r_B is fat and v is fat and equal to r_A (the root of T_A). A new (slim) root r is created and both r_A and r_B are made children of r.

Type 3: This deals with the remaining cases, i.e., either root r_B is slim or $v = r_A$ is slim. If root r_B is slim, then all the children of r_B are made the rightmost children of v, and r_B is deleted. Otherwise, all the children of the slim node $v = r_A$ are made the rightmost children of r_B, and r_A is deleted.

THEOREM 5.3 **[14]** *k–UF trees can support each union and find in $O(\log n / \log\log n)$ time in the worst case. Their space complexity is $O(n)$.*

PROOF Each find can be performed in $O(\log_k n)$ time. Each union(A, B) can require at most $O(\log_k n)$ time to locate the nodes r_A, r_B and v as defined above. Both type 1 and type 2 unions can be performed in constant time, while type 3 unions require at most $O(k)$ time, due to the definition of a slim root. Choosing $k = \lceil \log n / \log\log n \rceil$ yields the claimed time bound. The space complexity derives from the fact that a k–UF tree with ℓ leaves has at most $(2\ell - 1)$ nodes. Thus, the forest of k–UF trees requires at most a total of $O(n)$ space to store all the disjoint sets.

Blum showed also that this bound is tight for the class of separable pointer algorithms, while Fredman and Saks [32] showed that the same lower bound holds in the cell probe model of computation.

THEOREM 5.4 **[14, 32]** *Every separable pointer or cell-probe algorithm for the disjoint set union problem has single-operation worst-case time complexity at least $\Omega(\log n / \log\log n)$.*

Special Linear Cases

The six algorithms using either union rule and either compaction rule as described in "Amortized Time Complexity" run in $O(n + m\alpha(m, n))$ time on a sequence of at most $(n - 1)$ union and m find operations. As stated in Theorem 5.2, no better amortized bound is possible for either pointer-based algorithms or in the cell probe model of computation. This does not exclude, however, that a better bound is possible for a special case of set union. Gabow and Tarjan [34] indeed proposed a random-access algorithm that

runs in linear time in the special case where the structure of the union operations is known in advance. Interestingly, Tarjan's lower bound for separable pointer algorithms applies also to this special case, and thus, the power of a random access machine seems necessary to achieve a linear-time algorithm. This result is of theoretical interest as well as being significant in many applications, such as scheduling problems, the off-line minimum problem, finding maximum matching on graphs, VLSI channel routing, finding nearest common ancestors in trees, and flow graph reducibility [34].

The problem can be formalized as follows. We are given a tree T containing n nodes which correspond to the initial n singleton sets. Denoting by $p(v)$ the parent of the node v in T, we have to perform a sequence of union and find operations such that each union can be only of the form union$(p(v), v)$. For such a reason, T is called the *static union tree* and the problem will be referred to as the *static tree set union*. Also the case in which the union tree can dynamically grow by means of new node insertions (referred to as *incremental tree set union*) can be solved in linear time.

THEOREM 5.5 **[34]** *If the knowledge about the union tree is available in advance, each union and find operation can be supported in $O(1)$ amortized time. The total space required is $O(n)$.*

The same algorithm given for the static tree set union can be extended to the incremental tree set union problem. For this problem, the union tree is not known in advance but is allowed to grow only one node at the time during the sequence of union and find operations. This has application in several algorithms for finding maximum matching in general graphs.

THEOREM 5.6 **[34]** *The algorithm for incremental tree set union runs in a total of $O(m + n)$ time and requires $O(n)$ preprocessing time and space.*

Loebl and Nešetřil [58] presented a linear-time algorithm for another special case of the set union problem. They considered sequences of unions and finds with a constraint on the subsequence of finds. Namely, the finds are listed in a *postorder* fashion, where a postorder is a linear ordering of the leaves induced by a drawing of the tree in the plane. In this framework, they proved that such sequences of union and find operations can be performed in linear time, thus, getting $O(1)$ amortized time per operation. A preliminary version of these results was reported in [58].

5.3 The Set Union Problem on Intervals

In this section, we describe efficient solutions to the *set union problem on intervals*, which can be defined as follows. Informally, we would like to maintain a partition of a list $\{1, 2, \ldots, n\}$ in adjacent intervals. A union operation joins two adjacent intervals, a find returns the name of the interval containing x and a split divides the interval containing x (at x itself). More formally, at any time we maintain a collection of disjoint sets A_i with the following properties. The A_i's, $1 \leq i \leq k$, are disjoint sets whose members are ordered by the relation $\leq$, and such that $\cup_{i=1}^{k} A_i = \{1, 2, \ldots, n\}$. Furthermore, every item in A_i is less than or equal to all the items in A_{i+1}, for $i = 1, 2, \ldots, n-1$. In other words, the intervals A_i partition the interval $[1, n]$. Set A_i is said to be adjacent to sets A_{i-1} and A_{i+1}. The set union problem on intervals consists of performing a sequence of the following three operations:

union(S_1, S_2, S)*:* Given the adjacent sets S_1 and S_2, combine them into a new set $S = S_1 \cup S_2$;
find(x)*:* Given the item x, return the name of the set containing x;
split(S, S_1, S_2, x)*:* Partition S into two sets $S_1 = \{a \in S | a < x\}$ and $S_2 = \{a \in S | a \geq x\}$.

Adopting the same terminology used in [69], we will refer to the set union problem on intervals as the *interval union-split-find problem*. After discussing this problem, we consider two special cases:

the *interval union-find problem* and the *interval split-find problem*, where only union-find and split-find operations are allowed, respectively. The interval union-split-find problem and its subproblems have applications in a wide range of areas, including problems in computational geometry such as dynamic segment intersection [49, 67, 68], shortest paths problems [6, 66], and the longest common subsequence problem [5, 48].

Interval Union-Split-Find

In this section we will describe optimal separable and nonseparable pointer algorithms for the interval union-split-find problem. The best separable algorithm for this problem runs in $O(\log n)$ worst-case time for each operation, while nonseparable pointer algorithms require only $O(\log \log n)$ worst-case time for each operation. In both cases, no better bound is possible.

The upper bound for separable pointer algorithms can be easily obtained by means of balanced trees [4, 21], while the lower bound was proved by Mehlhorn et al. [69].

THEOREM 5.7 **[69]** *For any separable pointer algorithm, both the worst-case per operation time complexity of the interval split-find problem and the amortized time complexity of the interval union-split-find problem are* $\Omega(\log n)$.

Turning to nonseparable pointer algorithms, the upper bound can be found in [52, 68, 91, 92]. In particular, van Emde Boas et al. [92] introduced a priority queue which supports among other operations *insert*, *delete*, and *successor* on a set with elements belonging to a fixed universe $S = \{1, 2, \ldots, n\}$. The time required by each of those operation is $O(\log \log n)$. Originally, the space was $O(n \log \log n)$ but later it was improved to $O(n)$. It is easy to show (see also [69]) that the above operations correspond respectively to union, split, and find, and therefore the following theorem holds.

THEOREM 5.8 **[91]** *Each union, find and split can be supported in* $O(\log \log n)$ *worst-case time. The space required is* $O(n)$.

We observe that the algorithm based on van Emde Boas' priority queue is inherently nonseparable. Mehlhorn et al. [69] proved that this is indeed the best possible bound that can be achieved by a nonseparable pointer algorithm:

THEOREM 5.9 **[69]** *For any nonseparable pointer algorithm, both the worst-case per operation time complexity of the interval split-find problem and the amortized time complexity of the interval union-split-find problem are* $\Omega(\log \log n)$.

Notice that Theorems 5.7 and 5.8 imply that for the interval union-split-find problem the separability assumption causes an exponential loss of efficiency.

Interval Union-Find

The interval union-find problem can be seen from two different perspectives: indeed it is a special case of the union-split-find problem, when no split operations are performed, and it is a restriction of the set union problem described in Section 5.2, where only adjacent intervals are allowed to be joined. Consequently, the $O(\alpha(m+n, n))$ amortized bound given in Theorem 5.1 and the $O(\log n / \log \log n)$ single-operation worst-case bound given in Theorem 5.3 trivially extend to interval union–find. Tarjan's proof of the $\Omega(\alpha(m+n, n))$ amortized lower bound for separable pointer algorithms also holds for the interval union–

find problem, while Blum and Rochow [15] have adapted Blum's original lower bound proof for separable pointer algorithms to interval union–find. Thus, the best bounds for separable pointer algorithms are achieved by employing the more general set union algorithms. On the other side, the interval union–find problem can be solved in $O(\log \log n)$ time per operation with the nonseparable algorithm of van Emde Boas [91], while Gabow and Tarjan used the data structure described in "Special Linear Cases" to obtain an $O(1)$ amortized time for interval union–find on a random access machine.

Interval Split–Find

According to Theorems 5.7, 5.8, and 5.9, the two algorithms given for the more general interval union-split-find problem, are still optimal for the single-operation worst-case time complexity of the interval split–find problem. As a result, each split and find operation can be supported in $\Theta(\log n)$ and in $\Theta(\log \log n)$ time, respectively, in the separable and nonseparable pointer machine model.

As shown by Hopcroft and Ullman [45], the amortized complexity of this problem can be reduced to $O(\log^* n)$, where $\log^* n$ is the iterated logarithm function.[2] Their algorithm works as follows. The basic data structure is a tree, for which each node at level i, $i \geq 1$, has at most $2^{f(i-1)}$ children, where $f(i) = f(i-1)2^{f(i-1)}$, for $i \geq 1$, and $f(0) = 1$. A node is said to be complete either if it is at level 0 or if it is at level $i \geq 1$ and has $2^{f(i-1)}$ children, all of which are complete. A node that is not complete is called incomplete. The invariant maintained for the data structure is that no node has more than two incomplete children. Moreover, the incomplete children (if any) will be leftmost and rightmost. As in the usual tree data structures for set union, the name of a set is stored in the tree root.

Initially, such a tree with n leaves is created. Its height is $O(\log^* n)$ and therefore a find(x) will require $O(\log^* n)$ time to return the name of the set. To perform a split(x), we start at the leaf corresponding to x and traverse the path to the root to partition the tree into two trees. It is possible to show that using this data structure, the amortized cost of a split is $O(\log^* n)$ [45]. This bound can be further improved to $O(\alpha(m, n))$ as shown by Gabow [33]. The algorithm used to establish this upper bound relies on a sophisticated partition of the items contained in each set.

THEOREM 5.10 **[33]** *There exists a data structure supporting a sequence of m find and split operations in $O(m\alpha(m, n))$ worst-case time. The space required is $O(n)$.*

La Poutré [56] proved that this bound is tight for (both separable and nonseparable) pointer-based algorithms.

THEOREM 5.11 **[56]** *Any pointer-based algorithm requires $\Omega(n + m\alpha(m, n))$ time to perform $(n - 1)$ split and m find operations.*

Using the power of a random access machine, Gabow and Tarjan were able to achieve $\Theta(1)$ amortized time for the interval split–find problem [34]. This bound is obtained by employing a slight variant of the data structure sketched in "Special Linear Cases."

---

[2] $\log^* n = \min\{i \mid \log^{[i]} n \leq 1\}$, where $\log^{[i]} n = \log \log^{[i-1]} n$ for $i > 0$ and $\log^{[0]} n = n$.

5.4 The Set Union Problem with Deunions

Mannila and Ukkonen [59] defined a generalization of the set union problem, which they called *set union with deunions*. In addition to union and find, the following operation is allowed.

deunion: Undo the most recently performed union operation not yet undone.

Motivations for studying this problem arise in logic programming, and more precisely in memory management of interpreters without function symbols [40, 60, 61, 96]. In Prolog, for example, variables of clauses correspond to the elements of the sets, unifications correspond to unions and backtracking corresponds to deunions [60].

Algorithms for Set Union with Deunions

The set union problem with deunions can be solved by a modification of Blum's data structure described in "Single-Operation Worst-Case Time Complexity." To facilitate deunions, we maintain a *union stack* that stores some bookkeeping information related to unions. Finds are performed as in "Single-Operation Worst-Case Time Complexity." Unions require some additional work to maintain the union stack. We now sketch which information is stored in the union stack. For sake of simplicity we do not take into account names of the sets (namely, we show how to handle unite rather than union operations): names can be easily maintained in some extra information stored in the union stack. Initially, the union stack is empty. When a type 1 union is performed, we proceed as in "Single-Operation Worst-Case Time Complexity" and then push onto the union stack a record containing a pointer to the old root r_B. Similarly, when a type 2 union is performed, we push onto the union stack a record containing a pointer to r_A and a pointer to r_B. Finally, when a type 3 union is performed, we push onto the union stack a pointer to the leftmost child of either r_B or r_A, depending on the two cases.

Deunions basically use the top stack record to invalidate the last union performed. Indeed, we pop the top record from the union stack, and check whether the union to be undone is of type 1, 2, or 3. For type 1 unions, we follow the pointer to r_B and delete the edge leaving this node, thus, restoring it as a root. For type 2 unions, we follow the pointers to r_A and r_B and delete the edges leaving these nodes and their parent. For type 3 unions, we follow the pointer to the node, and move it together with all its right sibling as a child of a new root.

It can be easily showed that this augmented version of Blum's data structure supports each union, find, and deunion in $O(\log n / \log\log n)$ time in the worst case, with an $O(n)$ space usage. This was proved to be a lower bound for separable pointer algorithms by Westbrook and Tarjan [97]:

THEOREM 5.12 **[97]** *Every separable pointer algorithm for the set union problem with deunions requires at least* $\Omega(\log n / \log\log n)$ *amortized time per operation.*

All of the union rules and path compaction techniques described in "Amortized Time Complexity" can be extended in order to deal with deunions using the same bookkeeping method (i.e., the union stack) described above. However, path compression with any one of the union rules leads to an $O(\log n)$ amortized algorithm, as it can be seen by first performing $(n-1)$ unions which build a binomial tree (as defined, for instance, in [89]) of depth $O(\log n)$ and then by repeatedly carrying out a find on the deepest leaf, a deunion, and a redo of that union. Westbrook and Tarjan [97] showed that using either one of the union rules combined with path splitting or path halving yield $O(\log n / \log\log n)$ amortized algorithms for the set union problem with deunions. We now describe their algorithms.

In the following, a union operation not yet undone will be referred to as *live*, and as *dead* otherwise. To handle deunions, again a *union stack* is maintained, which contains the roots made nonroots by live unions. Additionally, we maintain for each node x a *node stack* $P(x)$, which contains the pointers leaving

x created either by unions or by finds. During a path compaction caused by a find, the old pointer leaving x is left in $P(x)$ and each newly created pointer (x, y) is pushed onto $P(x)$. The bottommost pointer on these stacks is created by a union and will be referred to as a *union pointer*. The other pointers are created by the path compaction performed during the find operations and are called *find pointers*. Each of these pointers is associated with a unique union operation, the one whose undoing would invalidate the pointer. The pointer is said to be *live* if the associated union operation is live, and it is said to be *dead* otherwise.

Unions are performed as in the set union problem, except that for each union a new item is pushed onto the union stack, containing the tree root made nonroot and some bookkeeping information about the set name and either size or rank. To perform a deunion, the top element is popped from the union stack and the pointer leaving that node is deleted. The extra information stored in the union stack is used to maintain set names and either sizes or ranks.

There are actually two versions of these algorithms, depending on when dead pointers are removed from the data structure. *Eager algorithms* pop pointers from the node stacks as soon as they become dead (i.e., after a deunion operation). On the other hand, *lazy algorithms* remove dead pointers in a lazy fashion while performing subsequent union and find operations. Combined with the allowed union and compaction rules, this gives a total of eight algorithms. They all have the same time and space complexity, as the following theorem shows.

THEOREM 5.13 **[97]** *Either union by size or union by rank in combination with either path splitting or path halving gives both eager and lazy algorithms which run in $O(\log n / \log\log n)$ amortized time for operation. The space required by all these algorithms is $O(n)$.*

The Set Union Problem with Unlimited Backtracking

Other variants of the set union problem with deunions have been considered such as set union with arbitrary deunions [36, 63], set union with dynamic weighted backtracking [39], and set union with unlimited backtracking [9]. In this chapter, we will discuss only set union with unlimited backtracking and refer the interested readers to the references for the other problems.

As before, we denote a union not yet undone by live, and by dead otherwise. In the set union problem with unlimited backtracking, deunions are replaced by the following more general operation:

backtrack(i): Undo the last i live unions performed. i is assumed to be an integer, $i \geq 0$.

The name of this problem derives from the fact that the limitation that at most one union could be undone per operation is removed.

Note that this problem is more general than the set union problem with deunions, since a deunion can be simply implemented as backtrack(1). Furthermore, a backtrack(i) can be implemented by performing exactly i deunions. Hence, a sequence of m_1 unions, m_2 finds, and m_3 backtracks can be carried out by simply performing at most m_1 deunions instead of the backtracks. Applying either Westbrook and Tarjan's algorithms or Blum's modified algorithm to the sequence of union, find, and deunion operations, a total of $O((m_1 + m_2)\log n / \log\log n)$ worst-case running time will result. As a consequence, the set union problem with unlimited backtracking can be solved in $O(\log n / \log\log n)$ amortized time per operation. Since deunions are a special case of backtracks, this bound is tight for the class of separable pointer algorithms because of Theorem 5.12.

However, using either Westbrook and Tarjan's algorithms or Blum's augmented data structure, each backtrack(i) can require $\Omega(i \log n / \log\log n)$ in the worst case. Indeed, the worst-case time complexity of backtrack(i) is at least $\Omega(i)$ as long as one insists on deleting pointers as soon as they are invalidated by backtracking (as in the eager methods described in "Algorithms for Set Union with Deunions," since in this case at least one pointer must be removed for each erased union. This is clearly undesirable, since i can be as large as $(n - 1)$.

The following theorem holds for the set union with unlimited backtracking, when union operations are taken into account.

THEOREM 5.14 **[37]** *It is possible to perform each union, find and backtrack(i) in $O(\log n)$ time in the worst case. This bound is tight for nonseparable pointer algorithms.*

Apostolico et al. [9] showed that, when unites instead of unions are performed (i.e., when the name of the new set can be arbitrarily chosen by the algorithm), a better bound for separable pointer algorithms can be achieved:

THEOREM 5.15 **[9]** *There exists a data structure which supports each unite and find operation in $O(\log n / \log\log n)$ time, each backtrack in $O(1)$ time, and requires $O(n)$ space.*

No better bound is possible for any separable pointer algorithm or in the cell probe model of computation, as it can be shown by a trivial extension of Theorem 5.4.

5.5 Partial and Full Persistence

In this section we cover general techniques for partial and full persistence. The time complexities of these techniques will generally be expressed in terms of *slowdowns* with respect to the ephemeral query and update operations. The slowdowns will usually be functions of m, the number of versions. A slowdown of $T_q(m)$ for queries means, for example, that a persistent query to a version which is a data structure of size n is accomplished in time $O(T_q(m) \cdot Q(n))$ time, where $Q(n)$ is the running time of an ephemeral query operation on a data structure of size n.

Methods for Arbitrary Data Structures

The Fat Node Method

A very simple idea for making any data structure partially persistent is the *fat node* method, which works as follows. The m versions are numbered by integers from 1 (the first) to m (the last). We will take the convention that if a persistent query specifies version t, for some $1 \leq t \leq m$, then the query is answered according to the state of the data structure as it was after version t was created but before (if ever) version $t + 1$ was begun.

Each memory location μ in the ephemeral data structure can be associated with a set $C(\mu)$ containing pairs of the form $\langle t, v\rangle$, where v is a value and t is a version number, sometimes referred to as the *time stamp* of v. A pair $\langle t, v\rangle$ is present in $C(\mu)$ if and only if (a) memory location μ was modified while creating version t and (b) at the completion of version t, the location μ contained the value v. For every memory location μ in the ephemeral data structure, we associate an auxiliary data structure $A(\mu)$, which stores $C(\mu)$ ordered by time stamp.

In order to perform a persistent query in version t we simulate the operation of the ephemeral query algorithm. Whenever the ephemeral query algorithm attempts to read a memory location μ, we query $A(\mu)$ to determine the value of μ in version t. Let t^* be the largest time stamp in $C(\mu)$ which is less than or equal to t. Clearly, the required value is v^* where $\langle t^*, v^*\rangle \in C(\mu)$. Creating version $m + 1$ by modifying version m is also easy: if memory locations $\mu_1, \mu_2, \ldots$ were modified while creating version $m + 1$, and the values of these locations in version $m + 1$ were $v_1, v_2, \ldots$, we simply insert the pair $\langle m + 1, v_i\rangle$ to $A(\mu_i)$ for $i = 1, 2, \ldots$.

If we implement the auxiliary data structures as red-black trees [21] then it is possible to query $A(\mu)$ in $O(\log |C(\mu)|) = O(\log m)$ time and also to add a new pair to $A(\mu)$ in $O(1)$ amortized time (this is

possible because the new pair will always have a time stamp greater than or equal to any time stamp in $C(\mu)$). In fact, we can even obtain $O(1)$ worst-case slowdown for updates by using a data structure given in [57]. Note that each ephemeral memory modification performed during a persistent update also incurs a space cost of $O(1)$ (in general this is unavoidable). We thus obtain the following theorem.

THEOREM 5.16 **[28]** *Any data structure can be made partially persistent with slowdown $O(\log m)$ for queries and $O(1)$ for updates. The space cost is $O(1)$ for each ephemeral memory modification.*

The fat node method can be extended to full persistence with a little work. Again, we will take the convention that a persistent query on version t is answered according to the state of the data structure as it was after version t was created but before (if ever) it was modified to create any descendant version. Again, each memory location μ in the ephemeral data structure will be associated with a set $C(\mu)$ containing pairs of the form $\langle t, v\rangle$, where v is a value and t is a version (the timestamp). The rules specifying what pairs are stored in $C(\mu)$ are somewhat more complicated. The main difficulty is that the versions in full persistence are only partially ordered. In order to find out the value of a memory location μ in version t, we need to find the deepest ancestor of t in the version tree where μ was modified (this problem is similar to the inheritance problem for object-oriented languages).

One solution is to impose a total order on the versions by converting the version tree into a *version list*, which is simply a pre-order listing of the version tree. Whenever a new version is created, it is added to the version list immediately after its parent, thus inductively maintaining the pre-ordering of the list. We now compare any two versions as follows: the one which is further to the left in the version list is considered smaller.

For example, a version list corresponding to the tree in Fig. 5.6 is $[a, b, c, f, g, h, i, j, l, m, n, o, k, d, e]$, and by the linearization, version f is considered to be less than version m, and version j is considered to be less than version l.

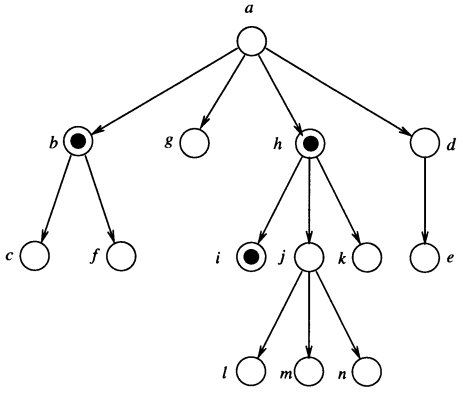

FIGURE 5.6 Navigating in full persistence: an example version tree.

Now consider a particular memory location π which was modified in versions b, h, and i of the data structure, with values B, H, and I being written to it in these versions. The following table shows the value of π in each version in the list (a $\perp$ means that no value has yet been written to π and hence its value may be undefined):

Version	a	b	c	f	g	h	i	j	l	m	n	o	k	d	e
Value	$\perp$	B	B	B	$\perp$	H	I	H	H	H	H	H	H	$\perp$	$\perp$

As can be seen in the above example, if π is modified in versions b, h and i, the version list is divided into

intervals containing respectively the sets $\{a\}, \{b, c, f\}, \{g\}, \{h\}, \{i\}, \{j, l, m, n, o, k\}, \{d, e\}$, such that for all versions in that interval, the value of π is the same. In general, the intervals of the version list for which the answer is the same will be different for different memory locations.

Hence, for each memory location μ, we define $C(\mu)$ to contains pairs of the form $\langle t, v\rangle$, where t is the leftmost version in its interval, and v is the value of μ in version t. Again, $C(\mu)$ is stored in an auxiliary data structure $A(\mu)$ ordered by time-stamp (the ordering among versions is as specified by the version list). In the example above, $C(\pi)$ would contain the following pairs:

$$\langle a, \perp\rangle, \langle b, B\rangle, \langle g, \perp\rangle, \langle h, H\rangle, \langle i, I\rangle, \langle j, H\rangle, \langle d, \perp\rangle .$$

In order to determine the value of some memory location μ in version t, we simply search among the pairs stored in $A(\mu)$, comparing versions, until we find the left endpoint of the interval to which t belongs; the associated value is the required answer.

How about updates? Let μ be any memory location, and firstly notice that if a new version is created in which μ is not modified, the value of μ in this new version will be the same as the value of μ in its parent, and the new version will be added to the version list right after its parent. This will simply enlarge the interval to which its parent belongs, and will also not change the left endpoint of the interval. Hence, if μ is not modified in some version, no change need be made to $A(\mu)$. On the other hand, adding a version where μ is modified creates a new interval containing only the new version, and in addition may split an existing interval into two. In general, if μ is modified in k different versions, $C(\mu)$ may contain up to $2k + 1$ pairs, and in each update, up to two new pairs may need to be inserted into $A(\mu)$. In the above example, if we create a new version p as a child of m and modify π to contain P in this version, then the interval $\{j, l, m, n, o, k\}$ splits into two intervals $\{j, l, m\}$ and $\{n, o, k\}$, and the new interval consisting only of $\{p\}$ is created. Hence, we would have to add the pairs $\langle n, H\rangle$ and $\langle p, P\rangle$ to $C(\pi)$.

Provided we can perform the comparison of two versions in constant time, and we store the pairs in say a red-black tree, we can perform a persistent query by simulating the ephemeral query algorithm, with a slowdown of $O(\log |C(\mu)|) = O(\log m)$, where m is the total number of versions. In the case of full persistence, updates also incur a slowdown of $O(\log m)$, and incur a $O(1)$ space cost per memory modification. Maintaining the version list so that two versions can be compared in constant time to determine which of the two is leftward is known as the *list order* problem, and has been studied in a series of papers [22, 90], culminating in an optimal data structure by Dietz and Sleator [24] which allows insertions and comparisons each in $O(1)$ worst-case time. We conclude:

THEOREM 5.17 **[28]** *Any data structure can be made fully persistent with slowdown $O(\log m)$ for both queries and updates. The space cost is $O(1)$ for each ephemeral memory modification.*

Faster Implementations of the Fat Node Method

For arbitrary data structures, the slowdown produced by the fat node method can be reduced by making use of the power of the RAM model. In the case of partial persistence, the versions are numbered with integers from 1 to m, where m is the number of versions, and special data structures for predecessor queries on integer sets may be used. For instance, the van Emde Boas data structure [91, 92] processes insertions, deletions, and predecessor queries on a set $S \subseteq \{1, \ldots, m\}$ in $O(\log \log m)$ time each. By using dynamic perfect hashing [27] to minimize space usage, the space required by this data structure can be reduced to linear in the size of the data structure, at the cost of making the updates run in $O(\log \log m)$ expected time. We thus obtain:

THEOREM 5.18 **[28, 27]** *Any data structure can be made partially persistent on a RAM with slowdown $O(\log \log m)$ for queries and expected slowdown $O(\log \log m)$ for updates. The space cost is $O(1)$ per ephemeral memory modification.*

At first sight it does not appear possible to use the same approach for full persistence because the versions are not integers. However, it turns out that algorithms for the list order problem work by assigning integer labels to the elements of the version list such that the labels increase monotonically from the beginning to the end of the list. Furthermore, these labels are guaranteed to be in the range $1..m^c$ where m is the number of versions and $c > 1$ is some constant. This means we can once again use the van Emde Boas data structure to search amongst the versions in $O(\log \log m)$ time. Unfortunately, each insertion into the version list may cause many of the integers to be relabeled, and making the changes to the appropriate auxiliary structures may prove expensive. Dietz [23] shows how to combine modifications to the list order algorithms together with standard bucketing techniques to obtain:

THEOREM 5.19 **[23]** *Any data structure can be made fully persistent on a RAM with slowdown $O(\log \log m)$ for queries and expected slowdown $O(\log \log m)$ for updates. The space cost is $O(1)$ per ephemeral memory modification.*

Methods for Linked Data Structures

The methods discussed above, while efficient, are not optimal and some of them are not simple to code. By placing some restrictions on the class of data structures which we want to make persistent, we can obtain some very simple and efficient algorithms for persistence. One such subclass of data structures is that of *linked* data structure.

A linked data structure is an abstraction of pointer-based data structures such as linked lists, search trees, etc. Informally, a linked data structure is composed of a collection of *nodes*, each with a finite number of named fields. Some of these fields are capable of holding an atomic piece of information, while others can hold a pointer to some node (or the value nil). For simplicity we assume the nodes are homogenous (i.e., of the same type) and that all access to the data structure is through a single designated *root* node. Any version of a linked data structure can be viewed as a directed graph, with vertices corresponding to nodes and edges corresponding to pointers.

Queries are abstracted away as *access operations* which consist of a series of *access steps*. The access algorithm has a collection of *accessed* nodes, which initially contains only the root. At each step, the algorithm either reads information from one of the accessed nodes or follows a non-nil pointer from one of the accessed nodes; the node so reached is then added to the set of accessed nodes. In actual data structures, of course, the information read by the query algorithm would be used to determine the pointers to follow as well as to compute an answer to return. Update operations are assumed to consist of an intermixed sequence of access steps as before and *update steps*. An update step either creates an explicitly initialized new node or writes a value to a field of some previously accessed node. We now discuss how one might implement persistent access and update operations.

Path Copying

A very simple but wasteful method for persistence is to copy the entire data structure after every update. *Path copying* is an optimization of this for linked data structures, which copies only "essential" nodes. Specifically, if an update modifies a version v by changing values in a set S of nodes, then it suffices to make copies of the nodes in S, together with all nodes that lie on a path from the root of version v to any node in S. The handle to the new version is simply a pointer to the new root. One advantage of this method is that traversing it is trivial: given a pointer to the root in some version, traversing it is done exactly as in the ephemeral case.

This method performs reasonably efficiently in the case of balanced search trees. Assuming that each node in the balanced search tree contains pointers only to its children, updates in balanced search trees such as AVL trees [2] and red-black trees [21] would cause only $O(\log n)$ nodes to be copied (these would be nodes either on the path from the root to the inserted or deleted item, or nodes adjacent to this path).

Note that this method does not work as well if the search tree only has an amortized $O(\log n)$ update cost, e.g., in the case of splay trees [87, p. 53 ff]. We therefore get the following theorem, which was independently noted by [74, 81].

THEOREM 5.20 *There is a fully persistent balanced search tree with persistent update and query times $O(\log n)$ and with space cost $O(\log n)$ per update, where n is the number of keys in the version of the data structure which is being updated or queried.*

Of course, for many other data structures, path copying may prove prohibitively expensive, and even in the case of balanced search trees, the space complexity is non-optimal, as red-black trees with lazy recoloring only modify $O(1)$ locations per update.

The Node Copying and Split Node Data Structures

An (ephemeral) *bounded-degree* linked data structure is one where the maximum *in-degree*, i.e., the maximum number of nodes that are pointing to any node, is bounded by a constant. Many, if not most, pointer-based data structures have this property, such as linked lists, search trees and so on (some of the data structures covered earlier in this chapter do not have this property). Driscoll et al. [28] showed that bounded-degree linked data structures could be made partially or fully persistent very efficiently, by means of the *node copying* and *split node* data structures respectively.

The source of inefficiency in the fat node data structure is searching among all the versions in the auxiliary data structure associated with an ephemeral node, as there is no bound on the number of such versions. The *node copying* data structure attempts to remedy this by replacing each fat node by a *collection* of "plump" nodes, each of which is capable of recording a bounded number of changes to an ephemeral node. Again, we assume that the versions are numbered with consecutive integers, starting from 1 (the first) to m (the last). Analogously to the fat node data structure, each ephemeral node x is associated with a set $C(x)$ of pairs $\langle t, r\rangle$, where t is a version number, and r is a record containing values for each of the fields of x. The set $C(x)$ is stored in a collection of plump nodes, each of which is capable of storing $2d+1$ pairs, where d is the bound on the in-degree of the ephemeral data structure.

The collection of plump nodes storing $C(x)$ is kept in a linked list $L(x)$. Let X be any plump node in $L(x)$ and let X' the next plump node in the list, if any. Let τ denote the smallest time stamp in X' if X' exists, and let $\tau = \infty$ otherwise. The list $L(x)$ is sorted by time stamp in the sense that all pairs in X are sorted by time stamp and all time stamps in X are smaller than τ. Each pair $\langle t, r\rangle$ in X is naturally associated with a *valid interval*, which is the half-open interval of versions beginning at t, up to, but not including the time stamp of the next pair in X, or τ if no such pair exists. The valid interval of X is simply the union of the valid intervals of the pairs stored in X. The following invariants always hold:

(i) For any pair $p = \langle t, r\rangle$ in $C(x)$, if a data field in r contains some value v then the value of the corresponding data field of ephemeral node x during the entire valid interval of p was also v. Furthermore, if a pointer field in r contains a pointer to a plump node in $L(y)$ or nil then the corresponding field in ephemeral node x pointed to ephemeral node y or contained nil, respectively, during the entire valid interval of p.

(ii) For any pair $p = \langle t, r\rangle$ in $C(x)$, if a pointer field in r points to a plump node Y, then the valid interval of p is contained in the valid interval of Y.

(iii) The handle of version t is a pointer to the (unique) plump node in $L(root)$ whose valid interval contains t.

A persistent access operation on version t is performed by a step-by-step simulation of the ephemeral access algorithm. For any ephemeral node x and version t, let $P(x, t)$ denote the plump node in $L(x)$ whose valid interval contains t. Since the valid intervals of the pairs in $C(x)$ are disjoint and partition

the interval $[1, \infty)$, this is well-defined. We ensure that if after some step, the ephemeral access algorithm would have accessed a set S of nodes, then the persistent access algorithm would have accessed the set of plump nodes $\{P(y, t) | y \in S\}$. This invariant holds initially, as the ephemeral algorithm would have accessed only $root$, and by (iv), the handle of version t points to $P(root, t)$.

If the ephemeral algorithm attempts to read a data field of an accessed node x then the persistent algorithm searches among the $O(1)$ pairs in $P(x, t)$ to find the pair whose valid interval contains t, and reads the value of the field from that pair. By (ii), this gives the correct value of the field. If the ephemeral algorithm follows a pointer from an accessed node x and reaches a node y, then the persistent algorithm searches among the $O(1)$ pairs in $P(x, t)$ to find the pair whose valid interval contains t, and follows the pointer specified in that pair. By invariants (i) and (ii) this pointer must point to $P(y, t)$. This proves the correctness of the simulation of the access operation.

Suppose during an ephemeral update operation on version m of the data structure, the ephemeral update operation writes some values into the fields of an ephemeral node x. Then the pair $\langle m + 1, r \rangle$ is added to $C(x)$, where r contains the field values of x at the end of the update operation. If the plump node $P(x, m)$ is not full then this pair is simply added to $P(x, m)$. Otherwise, a new plump node that contains only this pair is created and added to the end of $L(x)$. For all nodes y that pointed to x in version m, this could cause a violation of (ii). Hence, for all such y, we add a new pair $\langle m + 1, r' \rangle$ to $C(y)$, where r' is identical to the last record in $C(y)$ except that pointers to $P(x, m)$ are replaced by pointers to the new plump node. If this addition necessitates the creation of a new plump node in $L(y)$ then pointers to $P(m, y)$ are updated as above. A simple potential argument in [28] shows that not only does this process terminate, but the amortized space cost for each memory modification is $O(1)$. At the end of the process, a pointer to the last node in $L(root)$ is returned as the handle to version $m + 1$. Hence, we have that:

THEOREM 5.21 **[28]** *Any bounded-degree linked data structure can be made partially persistent with worst-case slowdown $O(1)$ for queries, amortized slowdown $O(1)$ for updates, and amortized space cost $O(1)$ per memory modification.*

Although we will not describe them in detail here, similar ideas were applied by Driscoll et al. in the *split node* data structure which can be used to make bounded-degree linked data structures fully persistent in the following time bounds:

THEOREM 5.22 **[28]** *Any bounded-degree linked data structure can be made fully persistent with worst-case slowdown $O(1)$ for queries, amortized slowdown $O(1)$ for updates, and amortized space cost $O(1)$ per memory modification.*

Driscoll et al. left open the issue of whether the time and space bounds for Theorems 5.21 and 5.22 could be made worst-case rather than amortized. Toward this end, they used a method called *displaced storage of changes* to give a fully persistent search tree with $O(\log n)$ worst-case query and update times and $O(1)$ amortized space per update, improving upon the time bounds of Theorem 5.20. This method relies heavily on the property of balanced search trees that there is a unique path from the root to any internal node, and it is not clear how to extract a general method for full persistence from it. A more direct assault on their open problem was made by [25], which showed that all bounds in Theorem 5.21 could be made worst-case on the RAM model. In the same paper it was also shown that the space cost could be made $O(1)$ worst-case on the pointer machine model, but the slowdown for updates remained $O(1)$ amortized. Subsequently, Brodal [11] fully resolved the open problem of Driscoll et al. for partial persistence by showing that all bounds in Theorem 5.21 could be made worst-case on the pointer machine model. For the case of full persistence it was shown in [26] how to achieve $O(\log \log m)$ worst-case slowdown for updates and queries and a worst-case space cost of $O(1)$ per memory modification, but the open problem

of Driscoll et al. remains only partially resolved in this case. It should be noted that the data structures of [11, 26] are not much more complicated than the original data structures of Driscoll et al.

5.6 Functional Data Structures

In this section we will consider the implementation of data structures in functional languages. Although implementation in a functional language automatically guarantees persistence, the central issue is maintaining the same level of efficiency as in the imperative setting.

The state-of-the-art regarding general methods is quickly summarized. The path-copying method described at the beginning of the previous section can easily be implemented in a functional setting. This means that balanced binary trees (without parent pointers) can be implemented in a functional language, with queries and updates taking $O(\log n)$ worst-case time, and with a suboptimal worst-case space bound of $\Theta(\log n)$. Using the functional implementation of search trees to implement a dictionary which will simulate the memory of any imperative program, it is possible to implement any data structure which uses a maximum of M memory locations in a functional language with a slowdown of $O(\log M)$ in the query and update times, and a space cost of $O(\log M)$ per memory modification.

Naturally, better bounds are obtained by considering specific data structuring problems, and we summarize the known results at the end of this section. First, though, we will focus on perhaps the most fundamental data structuring problem in this context, that of implementing *catenable lists*. A catenable list supports the following set of operations:

makelist(a): Creates a new list containing only the element a.

head(X): Returns the first element of list X. Gives an error if X is empty.

tail(X): Returns the list obtained by deleting the first element of list X without modifying X. Gives an error if X is empty.

catenate(X, Y): Returns the list obtained by appending list Y to list X, without modifying X or Y.

Driscoll et al. [29] were the first to study this problem, and efficient but nonoptimal solutions were proposed in [16, 29]. We will sketch two proofs of the following theorem, due to Kaplan and Tarjan [50] and Okasaki [71]:

THEOREM 5.23 *The above set of operations can be implemented in $O(1)$ time each.*

The result due to Kaplan and Tarjan is stronger in two respects. Firstly, the solution of [50] gives $O(1)$ worst-case time bounds for all operations, while Okasaki's only gives amortized time bounds. Also, Okasaki's result uses "memoization" which, technically speaking, is a side-effect, and hence, his solution is not purely functional. On the other hand, Okasaki's solution is extremely simple to code in most functional programming languages, and offers insight into how to make amortized data structures fully persistent efficiently. In general, this is difficult because in an amortized data structure, some operations in a sequence of operations may be expensive, even though the average cost is low. In the fully persistent setting, an adversary can repeatedly perform an expensive operation as often as desired, pushing the average cost of an operation close to the maximum cost of any operation.

We will briefly cover both these solutions, beginning with Okasaki's. In each case we will first consider a variant of the problem where the *catenate* operation is replaced by the operation *inject*(a, X) which adds a to the end of list X. Note that *inject*(a, X) is equivalent to *catenate*(*makelist*(a), X). Although this change simplifies the problem substantially (this variant was solved quite long ago [43]) we use it to elaborate upon the principles in a simple setting.

Implementation of Catenable Lists in Functional Languages

We begin by noting that adding an element a to the front of a list X, without changing X, can be done in $O(1)$ time. We will denote this operation by $a :: X$. However, adding an element to the end of X involves a destructive update. The standard solution is to store the list X as a pair of lists $\langle F, R\rangle$, with F representing an initial segment of X, and R representing the remainder of X, stored in reversed order. Furthermore, we maintain the invariant that $|F| \geq |R|$.

To implement an *inject* or *tail* operation, we first obtain the pair $\langle F', R'\rangle$, which equals $\langle F, a :: R\rangle$ or $\langle tail(F), R\rangle$, as the case may be. If $|F'| \geq |R'|$, we return $\langle F', R'\rangle$. Otherwise we return $\langle F' +\!\!+ reverse(R'), [\,]\rangle$, where $X +\!\!+ Y$ appends Y to X and $reverse(X)$ returns the reverse of list X. The functions $+\!\!+$ and *reverse* are defined as follows:

$$\begin{aligned} X +\!\!+ Y &= Y \text{ if } X = [\,], \\ &= head(X) :: (tail(X) +\!\!+ Y) \text{ otherwise}. \\ reverse(X) &= rev(X, [\,]), \text{ where:} \\ rev(X, Y) &= Y \text{ if } X = [\,], \\ &= rev(tail(X), head(X) :: Y) \text{ otherwise}. \end{aligned}$$

The running time of $X +\!\!+ Y$ is clearly $O(|X|)$, as is the running time of $reverse(X)$. Although the amortized cost of *inject* can be easily seen to be $O(1)$ in an ephemeral setting, the efficiency of this data structure may be much worse in a fully persistent setting, as discussed above.

If, however, the functional language supports *lazy evaluation* and *memoization* then this solution can be used as is. Lazy evaluation refers to delaying calculating the value of expressions as much as possible. If lazy evaluation is used, the expression $F' +\!\!+ reverse(R')$ is not evaluated until we try to determine its *head* or *tail*. Even then, the expression is not fully evaluated unless F' is empty, and the list $tail(F' +\!\!+ reverse(R'))$ remains represented internally as $tail(F') +\!\!+ reverse(R')$. Note that *reverse* cannot be computed incrementally like $+\!\!+$: once started, a call to *reverse* must run to completion before the first element in the reversed list is available. Memoization involves caching the result of a delayed computation the first time it is executed, so that the next time the same computation needs to be performed, it can be looked up rather than recomputed.

The amortized analysis uses a "debit" argument. Each element of a list is associated with a number of debits, which will be proportional to the amount of delayed work which must be done before this element can be accessed. Each operation can "discharge" $O(1)$ debits, i.e., when the delayed work is eventually done, a cost proportional to the number of debits discharged by an operation will be charged to this operation. The goal will be to prove that all debits on an element will have been discharged before it is accessed. However, once the work has been done, the result is memoized and any other thread of execution which require this result will simply use the memoized version at no extra cost. The debits satisfy the following invariant. For $i = 0, 1, \ldots$, let $d_i \geq 0$ denote the number of debits on the ith element of any list $\langle F, R\rangle$. Then:

$$\sum_{j=0}^{i} d_i \leq \min\{2i, |F| - |R|\}, \text{ for } i = 0, 1, \ldots$$

Note that the first (zeroth) element on the list always has zero debits on it, and so *head* only accesses elements whose debits have been paid. If no list reversal takes place during a *tail* operation, the value of $|F|$ goes down by one, as does the index of each remaining element in the list (i.e., the old $(i + 1)$st element will now be the new ith element). It suffices to pay of $O(1)$ debits at each of the first two locations in the list where the invariant is violated. A new element *inject*ed into list R has no delayed computation associated with it, and is give zero debits. The violations of the invariant caused by an *inject* where no list reversal occurs are handled as above. As a list reversal occurs only if $m = |F| = |R|$ before the operation which caused the reversal, the invariant implies that all debits on the front list have been paid off before

the reversal. Note that there are no debits on the rear list. After the reversal, one debit is placed on each element of the old front list (to pay for the delayed incremental $++$ operation) and $m+1$ debits are placed on the first element of the reversed list (to pay for the reversal), and zero on the remaining elements of the remaining elements of the reversed list, as there is no further delayed computation associated with them. It is easy to verify that the invariant is still satisfied after discharging $O(1)$ debits.

To add catenation to Okasaki's algorithm, a list is represented as a tree whose left-to-right pre-order traversal gives the list being represented. The children of a node are stored in a functional queue as described above. In order to perform $catenate(X, Y)$ the operation $link(X, Y)$ is performed, which adds root of the tree Y is added to the end of the child queue for the root of the tree X. The operation $tail(X)$ removes the root of the tree for X. If its children of the root are $X_1, \ldots, X_m$ then the new list is given by $link(X_1, link(X_2, \ldots, link(X_{m-1}, X_m)))$. By executing the *link* operations in a lazy fashion and using memoization, all operations can be made to run in $O(1)$ time.

Purely Functional Catenable Lists

In this section we will describe the techniques used by Kaplan and Tarjan to obtain a purely functional queue. The critical difference is that we cannot assume memoization in a purely functional setting. This appears to mean that the data structures once again have to support each operation in worst-case constant time. The main ideas used by Kaplan and Tarjan are those of *data-structural bootstrapping* and *recursive slowdown*. Data-structural bootstrapping was introduced by [29] and refers to allowing a data structure to use the same data structure as a recursive sub-structure.

Recursive slowdown can be viewed as running the recursive data structures "at a slower speed." We will now give a very simple illustration of recursive slowdown. Let a 2-queue be a data structure which allows the *tail* and *inject* operations, but holds a maximum of 2 elements. Note that the bound on the size means that all operations on a 2-queue can be can be trivially implemented in constant time, by copying the entire queue each time. A queue Q consists of three components: a front queue $f(Q)$, which is a 2-queue, a rear queue $r(Q)$, which is also a 2-queue, and a center queue $c(Q)$, which is a recursive queue, each element of which is a *pair* of elements of the top-level queue. We will ensure that at least one of $f(Q)$ is non-empty unless Q itself is empty.

The operations are handled as follows An *inject* adds an element to the end of $r(Q)$. If $r(Q)$ is full, then the two elements currently in $r(Q)$ are inserted as a pair into $c(Q)$ and the new element is inserted into $r(Q)$. Similarly, a *tail* operation attempts to remove the first element from $f(Q)$. If $f(Q)$ is empty then we extract the first pair from $c(Q)$, if $c(Q)$ is non-empty and place the second element from the pair into $f(Q)$, discarding the first element. If $c(Q)$ is also empty then we discard the first element from $r(Q)$.

The key to the complexity bound is that only every alternate *inject* or *tail* operation accesses $c(Q)$. Therefore, the recurrence giving the amortized running time $T(n)$ of operations on this data structure behaves roughly like $2T(n) = T(n/2) + k$ for some constant k. The term $T(n/2)$ represents the cost of performing an operation on $c(Q)$, since $c(Q)$ can contain at most $n/2$ pairs of elements, if n is the number of elements in Q as a whole. Rewriting this recurrence as $T(n) = \frac{1}{2}T(n/2) + k'$ and expanding gives that $T(n) = O(1)$ (even replacing $n/2$ by $n-1$ in the RHS gives $T(n) = O(1)$).

This data structure is not suitable for use in a persistent setting as a single operation may still take $\Theta(\log n)$ time. For example, if $r(Q)$, $r(c(Q))$, $r(c(c(Q)))\ldots$ each contain two elements, then a single *inject* at the top level would cause changes at all $\Theta(\log n)$ levels of recursion. This is analogous to carry propagation in binary numbers—if we define a binary number where for $i = 0, 1, \ldots$, the ith digit is 0 if $c^i(Q)$ contains one element and 1 if it contains two (the 0th digit is considered to be the least significant) then each *inject* can be viewed as adding 1 to this binary number. In the worst case, adding 1 to a binary number can take time proportional to the number of digits.

A different number system can alleviate this problem. Consider a number system where the ith digit still has weight 2^i, as in the binary system, but where digits can take the value 0, 1 or 2 [19]. Further, we require that any pair of 2's be separated by at least one 0 and that the rightmost digit, which is not a 1 is a 0. This

number system is *redundant*, i.e., a number can be represented in more than one way (the decimal number 4, for example, can be represented as either 100 or 020). Using this number system, we can increment a value by one in constant time by the following rules: (i) add one by changing the rightmost 0 to a 1, or by changing x 1 to $(x+1)$ 0; then (ii) fixing the rightmost 2 by changing x 2 to $(x+1)$ 0. Now we increase the capacity of $r(Q)$ to 3 elements, and let a queue containing i elements represent the digit $i-1$. We then perform an *inject* in $O(1)$ worst-case time by simulating the algorithm above for incrementing a counter. Using a similar idea to make *tail* run in $O(1)$ time, we can make all operations run in $O(1)$ time.

In the version of their data structure which supports catenation, Kaplan and Tarjan again let a queue be represented by three queues $f(Q)$, $c(Q)$, and $r(Q)$, where $f(Q)$ and $r(Q)$ are of constant size as before. The center queue $c(Q)$ in this case holds either (i) a queue of constant size containing at least two elements or (ii) a pair whose first element is a queue as in (i) and whose second element is a catenable queue. To execute *catenate*(X, Y), the general aim is to first try and combine $r(X)$ and $f(Y)$ into a single queue. When this is possible, a pair consisting of the resulting queue and $c(Y)$ is *inject*ed into $c(X)$. Otherwise, $r(X)$ is *inject*ed into $c(X)$ and the pair $\langle f(X), c(X)\rangle$ is also *inject*ed into $c(X)$. Details can be found in [50].

Other Data Structures

A *deque* is a list which allows single elements to be added or removed from the front or the rear of the list. Efficient persistent deques implemented in functional languages were studied in [18, 35, 42], with some of these supporting additional operations. A *catenable deque* allows all the operations above defined for a catenable list, but also allows deletion of a single element from the end of the list. Kaplan and Tarjan [50] have stated that their technique extends to give purely functional catenable deques with constant worst-case time per operation. Other data structures which can be implemented in functional languages include finger search trees [51] and worst-case optimal priority queues [12]. (See [72, 73] for yet more examples.)

5.7 Research Issues and Summary

In this chapter we have described the most efficient known algorithms for set union and persistency.

Most of the set union algorithms we have described are optimal with respect to a certain model of computation (e.g., pointer machines with or without the separability assumption, random access machines). There are still several open problems in all the models of computation we have considered. First, there are no lower bounds for some of the set union problems on intervals: for instance, for nonseparable pointer algorithms we are only aware of the trivial lower bound for interval union–find. This problem requires $\Theta(1)$ amortized time on a random access machine as shown by Gabow and Tarjan [34]. Second, it is still open whether in the amortized and the single operation worst-case complexity of the set union problems with deunions or backtracking can be improved for nonseparable pointer algorithms or in the cell probe model of computation.

5.8 Defining Terms

Cell probe model: Model of computation where the cost of a computation is measured by the total number of memory accesses to a random access memory with $\lceil \log n \rceil$ bits cell size. All other computations are not accounted for and are considered to be free.

Persistent data structure: A data structure that preserves its old versions. Partially persistent data structures allow updates to their latest version only, while all versions of the data structure may be queried. Fully persistent data structures allow all their existing versions to be queried or updated.

Pointer machine: Model of computation whose storage consists of an unbounded collection of registers (or records) connected by pointers. Each register can contain an arbitrary amount of additional information, but no arithmetic is allowed to compute the address of a register. The only possibility to access a register is by following pointers.

Purely functional language: A language that does not allow any destructive operation—one which overwrites data—such as the assignment operation. Purely functional languages are side-effect-free, i.e., invoking a function has no effect other than computing the value returned by the function.

Random access machine: Model of computation whose memory consists of an unbounded sequence of registers, each of which is capable of holding an integer. In this model, arithmetic operations are allowed to compute the address of a memory register.

Separability: Assumption that defines two different classes of pointer-based algorithms for set union problems. An algorithm is separable if after each operation, its data structures can be partitioned into disjoint subgraphs so that each subgraph corresponds to exactly one current set, and no edge leads from one subgraph to another.

Further Information

Research on advanced algorithms and data structures is published in many computer science journals, including *Algorithmica, Journal of ACM, Journal of Algorithms,* and *SIAM Journal on Computing.* Work on data structures is published also in the proceedings of general theoretical computer science conferences, such as the "ACM Symposium on Theory of Computing (STOC)," and the "IEEE Symposium on Foundations of Computer Science (FOCS)." More specialized conferences devoted exclusively to algorithms are the "ACM–SIAM Symposium on Discrete Algorithms (SODA)" and the "European Symposium on Algorithms (ESA)." Online bibliographies for many of these conferences and journals can be found on the World Wide Web.

Galil and Italiano [37] provide useful summaries on the state of the art in set union data structures. A in-depth study of implementing data structures in functional languages is given in [72].

6.1 Introduction

Graphs provide a powerful tool to model objects and relationships between objects. The study of graphs dates back to the 18th century, when Euler defined the *Königsberg bridge* problem, and since then has been pursued by many researchers. Graphs can be used to model problems in many areas such as transportation, scheduling, networks, robotics, VLSI design, compilers, mathematical biology and software engineering. Many optimization problems from these and other diverse areas can be phrased in graph theoretic terms, leading to algorithmic questions about graphs.

Graphs are defined by a set of vertices and a set of edges, where each edge connects two vertices. Graphs are further classified into directed and undirected graphs, depending on whether their edges are directed

or not. An important subclass of directed graphs that arises in many applications, such as precedence constrained scheduling problems, are **directed acyclic graphs** (DAG). Interesting subclasses of undirected graphs include **trees, bipartite graphs,** and **planar graphs.**

In this chapter, we focus on a few basic problems and algorithms dealing with graphs. Other chapters in this handbook provide details on specific algorithmic techniques and problem areas dealing with graphs, e.g., randomized algorithms (Chapter 15), combinatorial algorithms (Chapter 7), dynamic graph algorithms (Chapter 8), graph drawing (Chapter 9), and approximation algorithms (Chapter 34). Pointers into the literature are provided for various algorithmic results about graphs that are not covered in depth in this chapter.

6.2 Preliminaries

An undirected *graph* $G = (V, E)$ is defined as a set V of *vertices* and a set E of *edges.* An edge $e = (u, v)$ is an unordered pair of vertices. A *directed graph* is defined similarly, except that its edges are ordered pairs of vertices, i.e., for a directed graph, $E \subseteq V \times V$. The terms *nodes* and vertices are used interchangeably. In this chapter, it is assumed that the graph has neither self loops — edges of the form (v, v) — nor multiple edges connecting two given vertices. The number of vertices of a graph, $|V|$, is often denoted by n. A graph is a **sparse graph** if $|E| \ll |V|^2$.

Bipartite graphs form a subclass of graphs and are defined as follows. A graph $G = (V, E)$ is bipartite if the vertex set V can be partitioned into two sets X and Y such that $E \subseteq X \times Y$. In other words, each edge of G connects a vertex in X with a vertex in Y. Such a graph is denoted by $G = (X, Y, E)$. Since bipartite graphs occur commonly in practice, often algorithms are designed specially for them. *Planar graphs* are graphs that can be drawn in the plane without any two edges crossing each other. Let K_n be the complete graph on n vertices, and $K_{x,y}$ be the complete bipartite graph with x and y vertices in either side of the bipartite graph respectively. A *homeomorph* of a graph is obtained by subdividing an edge by adding new vertices.

A vertex w is *adjacent* to another vertex v if $(v, w) \in E$. An edge (v, w) is said to be *incident* to vertices v and w. The *neighbors* of a vertex v are all vertices $w \in V$ such that $(v, w) \in E$. The number of edges incident to a vertex is called its **degree.** For a directed graph, if (v, w) is an edge, then we say that the edge goes from v to w. The *out-degree* of a vertex v is the number of edges from v to other vertices. The *in-degree* of v is the number of edges from other vertices to v.

A **path** $p = [v_0, v_1, \ldots, v_k]$ from v_0 to v_k is a sequence of vertices such that (v_i, v_{i+1}) is an edge in the graph for $0 \leq i < k$. Any edge may be used only once in a path. An *intermediate vertex* (or internal vertex) on a path $P[u, v]$, a path from u to v, is a vertex incident to the path, other than u and v. A path is *simple* if all of its internal vertices are distinct. A **cycle** is a path whose end vertices are the same, i.e., $v_0 = v_k$. A **walk** $w = [v_0, v_1, \ldots, v_k]$ from v_0 to v_k is a sequence of vertices such that (v_i, v_{i+1}) is an edge in the graph for $0 \leq i < k$. A *closed walk* is one in which $v_0 = v_k$. A graph is said to be *connected* if there is a path between every pair of vertices. A directed graph is said to be **strongly connected** if there is a path between every pair of vertices in each direction. An acyclic, undirected graph is a **forest,** and a *tree* is a connected forest. A *maximal forest* F of a graph G is a forest of G such that the addition of any other edge of G to F introduces a cycle. A directed graph that does not have any cycles is known as a *directed acyclic graph* (DAG). Consider a binary relation C between the vertices of an undirected graph G such that for any two vertices u and v, uCv if and only if there is a path in G between u and v. C is an equivalence relation, and it partitions the vertices of G into equivalence classes, known as the *connected components* of G.

Graphs may have weights associated with edges or vertices. In the case of edge-weighted graphs (edge weights denoting lengths), the *distance* between two vertices is the length of a shortest path between them, where the length of a path is defined as the sum of the weights of its edges. The *diameter* of a graph is the maximum of the distance between all pairs of vertices.

There are two convenient ways of representing graphs on computers. In the *adjacency list* representation, each vertex has a linked list; there is one entry in the list for each of its adjacent vertices. The graph is thus, represented as an array of linked lists, one list for each vertex. This representation uses $O(|V| + |E|)$ storage, which is good for sparse graphs. Such a storage scheme allows one to scan all vertices adjacent to a given vertex in time proportional to the degree of the vertex. In the *adjacency matrix* representation, an $n \times n$ array is used to represent the graph. The $[i, j]$ entry of this array is 1 if the graph has an edge between vertices i and j, and 0 otherwise. This representation permits one to test if there is an edge between any pair of vertices in constant time. Both these representation schemes extend naturally to represent directed graphs. For all algorithms in this chapter except the all-pairs shortest paths problem, it is assumed that the given graph is represented by an adjacency list.

Section 6.3 discusses various tree traversal algorithms. Sections 6.4 and 6.5 discuss depth-first and breadth-first search techniques. Section 6.6 discusses the single source shortest-path problem. Section 6.7 discusses **minimum spanning trees.** Section 6.8 discusses some traversal problems in graphs. Section 6.9 discusses various topics such as **planar graphs,** graph coloring, light approximate shortest path trees and network decomposition, and Section 6.10 concludes with some pointers to current research on graph algorithms.

6.3 Tree Traversals

A tree is *rooted* if one of its vertices is designated as the root vertex and all edges of the tree are oriented (directed) to point away from the root. In a rooted tree, there is a directed path from the root to any vertex in the tree. For any directed edge (u, v) in a rooted tree, u is v's *parent* and v is u's *child.* The *descendants* of a vertex w are all vertices in the tree (including w) that are reachable by directed paths starting at w. The *ancestors* of a vertex w are those vertices for which w is a descendant. Vertices that have no children are called **leaves.** A *binary tree* is a special case of a rooted tree in which each node has at most two children, namely the left child and the right child. The trees rooted at the two children of a node are called the *left subtree* and *right subtree.*

In this section we study techniques for processing the vertices of a given binary tree in various orders. It is assumed that each vertex of the binary tree is represented by a record that contains fields to hold attributes of that vertex and two special fields *left* and *right* that point to its left and right subtree respectively. Given a pointer to a record, the notation used for accessing its fields is similar to that used in the *C* programming language.

The three major tree traversal techniques are *preorder, inorder,* and *postorder.* These techniques are used as procedures in many tree algorithms where the vertices of the tree have to be processed in a specific order. In a preorder traversal, the root of any subtree has to be processed *before* any of its descendants. In a postorder traversal, the root of any subtree has to be processed *after* all of its descendants. In an inorder traversal, the root of a subtree is processed after all vertices in its left subtree have been processed, but before any of the vertices in its right subtree are processed. Preorder and postorder traversals generalize to arbitrary rooted trees. The algorithm below shows how postorder traversal of a binary tree can be used to count the number of descendants of each node and store the value in that node. The algorithm runs in linear time in the size of the tree.

```
PostOrder (T)
1  if T ≠ nil then
2     lc ← PostOrder(T → left).
3     rc ← PostOrder(T → right).
4     T → desc ← lc + rc + 1.
5     return (T → desc).
```

```
6   else
7       return 0.
8   end-if
end-proc
```

6.4 Depth-First Search

Depth-first search (DFS) is a fundamental graph searching technique developed by Hopcroft and Tarjan [16, 27]. Similar graph searching techniques were given earlier by Tremaux [8]. The structure of DFS enables efficient algorithms for many other graph problems such as biconnectivity, triconnectivity, and planarity [8].

The algorithm first initializes all vertices of the graph as being unvisited. Processing of the graph starts from an arbitrary vertex, known as the *root* vertex. Each vertex is processed when it is first discovered (also referred to as *visiting* a vertex). It is first marked as visited, and its adjacency list is then scanned for unvisited vertices. Each time an unvisited vertex is discovered, it is processed recursively by DFS. After a node's entire adjacency list has been explored, that instance of the DFS procedure returns. This procedure eventually visits all vertices that are in the same connected component of the root vertex. Once DFS terminates, if there are still any unvisited vertices left in the graph, one of them is chosen as the root and the same procedure is repeated.

The set of edges that led to the discovery of new vertices forms a maximal forest of the graph, known as the **DFS forest.** The algorithm keeps track of this forest using parent pointers; an array element $p[v]$ stores the parent of vertex v in the tree. In each connected component, only the root vertex has a *nil* parent in the DFS tree.

The DFS Algorithm

DFS is illustrated using an algorithm that assigns labels to vertices such that vertices in the same component receive the same label, a useful preprocessing step in many problems. Each time the algorithm processes a new component, it numbers its vertices with a new label.

```
DFS-Connected-Component (G)
1   c ← 0.
2   for all vertices v in G do
3       visited[v] ← false.
4       finished[v] ← false.
5       p[v] ← nil.
6   end-for
7   for all vertices v in G do
8       if not visited[v] then
9           c ← c + 1.
10          DFS (v, c).
11      end-if
12  end-for
end-proc
```

```
DFS (v, c)
1   visited[v] ← true.
2   component[v] ← c.
3   for all vertices w in adj[v] do
4      if not visited[w] then
5         p[w] ← v.
6         DFS (w, c).
7      end-if
8   end-for
9   finished[v] ← true.
end-proc
```

Sample Execution

Figure 6.1 shows a graph having two connected components. DFS started execution at vertex a, and the DFS forest is shown on the right. DFS visited the vertices b, d, c, e, and f, in that order. It then continued with vertices g, h, and i. In each case, the recursive call returned when the vertex has no more unvisited neighbors. Edges (d, a), (c, a), (f, d), and (i, g) are called *back edges,* and these edges do not belong to the DFS forest.

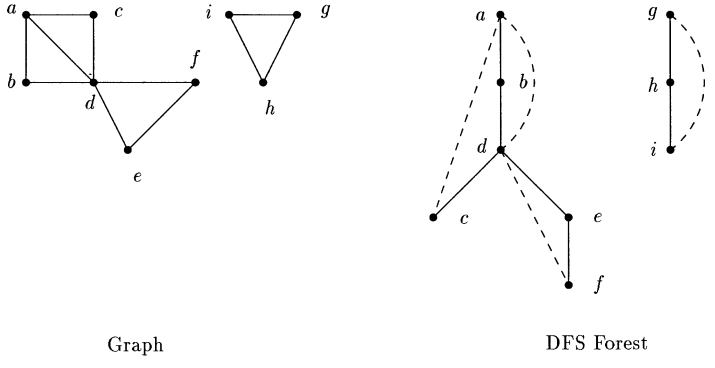

FIGURE 6.1 Sample execution of DFS on a graph having two connected components.

Analysis

A vertex v is processed as soon as it is encountered, and therefore at the start of DFS (v), *visited*$[v]$ is *false*. Since *visited*$[v]$ is set to *true* as soon as DFS starts execution, each vertex is visited exactly once. Depth-first search processes each edge of the graph exactly twice, once from each of its incident vertices. Since the algorithm spends constant time processing each edge of G, it runs in $O(|V| + |E|)$ time.

Classification of Edges

In the following discussion, there is no loss of generality in assuming that the input graph is connected. For a rooted DFS tree, vertices u and v are said to be *related,* if either u is an ancestor of v, or vice versa.

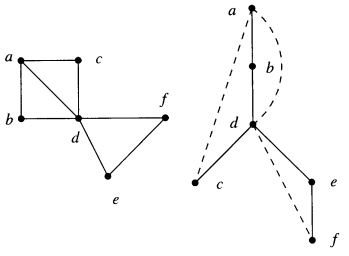
DFS is useful due to the special nature by which the edges of the graph may be classified with respect to a DFS tree. Note that the DFS tree is not unique, and which edges are added to the tree depends on

the order in which edges are explored while executing DFS. Edges of the DFS tree are known as *tree edges.* All other edges of the graph are known as *back edges,* and it can be shown that for any edge (u, v), u and v must be related. The graph does *not* have any *cross edges* — edges that connect two vertices that are unrelated.

Articulation Vertices and Biconnected Components

One of the many applications of depth-first search is to decompose a graph into its biconnected components. In this section, it is assumed that the graph is connected. An **articulation vertex** (also known as **cut vertex**) is a vertex whose deletion along with its incident edges breaks up the remaining graph into two or more disconnected pieces. A graph is called *biconnected* if it has no articulation vertices. A *biconnected component* of a **connected graph** is a maximal subset of edges such that the corresponding induced subgraph is biconnected. Each edge of the graph belongs to exactly one biconnected component. Biconnected components can have cut vertices in common.

The graph in Fig. 6.2 has two biconnected components, formed by the edge sets $\{(a, b), (a, c), (a, d), (b, d), (c, d)\}$ and $\{(d, e), (d, f), (e, f)\}$. There is a single cut vertex d and it is shared by both biconnected components.



Vertex	dis	fin	$low(v)$
a	1	12	1
b	2	11	1
c	4	5	1
d	3	10	1
e	6	9	3
f	7	8	3

FIGURE 6.2 Identifying cut vertices.

We now discuss a linear-time algorithm, developed by Hopcroft and Tarjan [16, 27], to identify the cut vertices and biconnected components of a connected graph. The algorithm uses the global variable *time* that is incremented every time a new vertex is visited or when DFS finishes visiting a vertex. Time is initially 0, and is $2|V|$ when the algorithm finally terminates. The algorithm records the value of *time* when a variable v is first visited in the array location *dis[v]* and the value of *time* when *DFS(v)* completes execution in *fin[v]*. We refer to *dis[v]* and *fin[v]* as the *discovery time* and *finish time* of vertex v, respectively.

Let T be a DFS tree of the given graph G. The notion of $low(v)$ of a vertex v with respect to T is defined as follows.

$$low(v) = \min(dis[v], dis[w] : (u, w) \text{ is a back edge for some descendant } u \text{ of } v)$$

$low(v)$ of a vertex is the discovery number of the vertex closest to the root that can be reached from v by following zero or more tree edges downward, and at most one back edge upward. It captures how far high the subtree of T rooted at v can reach by using at most one back edge. Figure 6.2 shows an example of a graph, a DFS tree of the graph and a table listing the values of *dis, fin,* and *low* of each vertex corresponding to that DFS tree.

Let T be the DFS tree generated by the algorithm, and let r be its root vertex. First, r is a cut vertex if and only if it has two or more children. This follows from the fact that there are no cross edges with respect to a DFS tree. Therefore the removal of r from G disconnects the remaining graph into as many

components as the number of children of r. The *low* values of vertices can be used to find cut vertices that are non-root vertices in the DFS tree. Let $v \neq r$ be a vertex in G. The following theorem characterizes precisely when v is a cut vertex in G.

THEOREM 6.1 *Let T be a DFS tree of a connected graph G, and let v be a non-root vertex of T. Vertex v is a cut vertex of G if and only if there is a child w of v in T with $low(w) \geq dis[v]$.*

Computing *low* values of a vertex and identifying all the biconnected components of a graph can be done efficiently with a single depth-first search scan. The algorithm uses a stack of edges. When an edge is encountered for the first time it is pushed into the stack irrespective of whether it is a tree edge or a back edge. Each time a cut vertex v is identified because $low(w) \geq dis[v]$ (as in Theorem 6.1), the stack contains the edges of the biconnected component as a contiguous block, with the edge (v, w) at the bottom of this block. The algorithm pops the edges of this biconnected component from the stack, and sets $cut[v]$ to *true* to indicate that v is a cut vertex.

```
BICONNECTED COMPONENTS (G)
1  time ← 0.
2  MAKEEMPTYSTACK (S).
3  for each u ∈ V do
4     visited[u] ← false.
5     cut[u] ← false.
6     p[u] ← nil.
7  end-for
8  Let v be an arbitrary vertex, DFS(v).
end-proc

DFS (v)
1  visited[v] ← true.
2  time ← time + 1.
3  dis[v] ← time.
4  low[v] ← dis[v].
5  for all vertices w in adj[v] do
6     if not visited[w] then
7        PUSH (S, (v, w)).
8        p[w] ← v.
9        DFS(w).
10       if (low[w] ≥ dis[v]) then
11          if (dis[v] ≠ 1) then cut[v] ← true.        (* v is not the root *)
12          else if (dis[w] > 2) then cut[v] ← true. (* v is root, and has at least 2 children *)
13          end-if
14          OUTPUTCOMP(v, w).
15       end-if
16       low[v] ← min(low[v], low[w]).
17    else if (p[v] ≠ w and dis[w] < dis[v]) then
18       PUSH (S, (v, w)).
19       low[v] ← min(low[v], dis[w]).
20    end-if
21 end-for
```

```
22  time ← time + 1.
23  fin[v] ← time.
end-proc
```

```
OUTPUTCOMP(v, w)
1   PRINT ("New Biconnected Component Found").
2   repeat
3      e ← POP (S).
4      PRINT (e).
5   until (e = (v, w)).
end-proc
```

In the example shown in Fig. 6.2 when DFS(e) finishes execution and returns control to DFS(d), the algorithm discovers that d is a cut vertex because $low(e) \geq dis[d]$. At this time, the stack contains the edges (d, f), (e, f), and (d, e) at the top of the stack, which are output as one biconnected component.

Remarks: The notion of biconnectivity can be generalized to higher connectivities. A graph is said to be k-connected, if there is no subset of $(k-1)$ vertices whose removal will disconnect the graph. For example, a graph is triconnected if it does not have any separating pairs of vertices — pairs of vertices whose removal disconnects the graph. A linear time algorithm for testing whether a given graph is triconnected was given by Hopcroft and Tarjan [15]. An $O(|V|^2)$ algorithm for testing if a graph is k-connected for any constant k was given by Nagamochi and Ibaraki [25]. One can also define a corresponding notion of edge-connectivity, where edges are deleted from a graph rather than vertices. Galil and Italiano [11] showed how to reduce edge connectivity to vertex connectivity.

Directed Depth-First Search

The DFS algorithm extends naturally to directed graphs. Each vertex stores an adjacency list of its outgoing edges. During the processing of a vertex, the algorithm first marks the vertex as visited, and then scans its adjacency list for unvisited neighbors. Each time an unvisited vertex is discovered, it is processed recursively. Apart from tree edges and back edges (from vertices to their ancestors in the tree), directed graphs may also have *forward edges* (from vertices to their descendants) and *cross edges* (between unrelated vertices). There may be a cross edge (u, v) in the graph only if u is visited after the procedure call "DFS (v)" has completed execution. The following algorithm implements DFS in a directed graph. For each vertex v, the algorithm computes the discovery time of v ($dis[v]$) and the time at which DFS(v) finishes execution ($fin[v]$). In addition, each edge of the graph is classified as either (i) tree edge, or (ii) back edge, or (iii) forward edge, or (iv) cross edge, with respect to the depth-first forest generated.

```
DIRECTED DFS (G)
1   for all vertices v in G do
2      visited[v] ← false.
3      finished[v] ← false.
4      p[v] ← nil.
5   end-for
6   time ← 0.
```

```
7   for all vertices v in G do
8       if not visited[v] then
9           DFS (v).
10      end-if
11      end-for
end-proc
```

```
DFS (v)
1   visited[v] ← true.
2   time ← time + 1.
3   dis[v] ← time.
4   for all vertices w in adj[j] do
5       if not visited[w] then
6           p[w] ← v.
7           PRINT ("Edge from" v "to" w "is a Tree edge").
8           DFS (w).
9       else if not finished[w] then
10          PRINT ("Edge from" v "to" w "is a Back edge").
11      else if dis[v] < dis[w] then
12          PRINT ("Edge from" v "to" w "is a Forward edge").
13      else
14          PRINT ("Edge from" v "to" w "is a Cross edge").
15      end-if
16  end-for
17  finished[v] ← true.
18  time ← time + 1.
19  fin[v] ← time.
end-proc
```

Sample Execution

A sample execution of the directed DFS algorithm is shown in Fig. 6.3. DFS was started at vertex a, and the DFS forest is shown on the right. DFS visits vertices b, d, f, and c, in that order. DFS then returns and continues with e, and then g. From g, vertices h and i are visited in that order. Observe that (d, a) and (i, g) are back-edges. Edges (c, d), (e, d), and (e, f) are cross edges. There is a single forward edge (g, i).

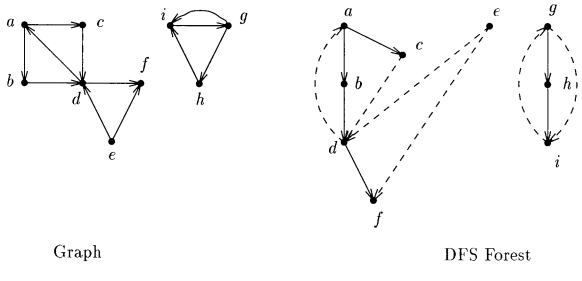


FIGURE 6.3 Sample execution of DFS on a directed graph.

Applications of DFS

Strong Connectivity: Directed DFS is used to design a linear-time algorithm that classifies the edges of a given directed graph into its **strongly-connected** components — maximal subgraphs that have directed paths connecting any pair of vertices in them. The algorithm itself involves running DFS twice, once on the original graph, and then a second time on G^R, which is the graph obtained by reversing the direction of all edges in G. During the second DFS, the algorithm identifies all the strongly connected components. The proof is somewhat subtle, and the reader is referred to [7] for details. Cormen et al. [7] credit Kosaraju and Sharir for this algorithm. The original algorithm due to Tarjan [27] is more complicated.

Directed Acyclic Graphs: Checking if a graph is acyclic can be done in linear time using DFS. A graph has a cycle if and only if there exists a back edge relative to its depth-first search forest. A directed graph that does not have any cycles is known as a **directed acyclic graph** (DAG). DAGs are useful in modeling precedence constraints in scheduling problems, where nodes denote jobs/tasks, and a directed edge from u to v denotes the constraint that job u must be completed before job v can begin execution. Many problems on DAGs can be solved efficiently using dynamic programming (see Chapter 1).

Topological Order: A useful concept in DAGs is that of a *topological order:* a linear ordering of the vertices that is consistent with the partial order defined by its edges. In other words, the vertices can be labeled with distinct integers in the range $[1 \ldots |V|]$ such that if there is a directed edge from a vertex labeled i to a vertex labeled j, then $i < j$. Topological sort has applications in diverse areas such as project management, scheduling and circuit evaluation.

The vertices of a given DAG can be ordered topologically in linear time by a suitable modification of the DFS algorithm. It can be shown that ordering vertices by decreasing finish times (as computed by DFS) is a valid topological order. The DFS algorithm is modified as follows. A counter is initialized to $|V|$. As each vertex is marked finished, the counter value is assigned as its topological number, and the counter is decremented. Since there are no back edges in a DAG, for all edges (u, v), v will be marked finished before u. Thus, the topological number of v will be higher than that of u.

The execution of the algorithm is illustrated with an example in Fig. 6.4. Along with each vertex, we show the discovery and finish times, respectively. Vertices are given decreasing topological numbers as they are marked finished. Vertex f finishes first and gets a topological number of 9 ($|V|$); d finishes next and gets numbered 8, and so on. The topological order found by the DFS is $g, h, i, a, b, e, c, d, f$, which is the reverse of the finishing order. Note that a given graph may have many valid topological ordering of the vertices.

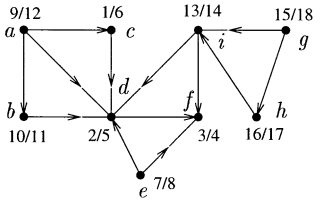

FIGURE 6.4 Example for topological sort. Order in which vertices finish: $f, d, c, e, b, a, i, h, g$.

Other topological ordering algorithms work by identifying and deleting vertices of in-degree zero (i.e., vertices with no incoming edges) recursively. With some care, this algorithm can be implemented in linear time as well.

Longest Path: In project scheduling, a DAG is used to model precedence constraints between tasks. A longest path in this graph is known as a *critical path* and its length is the least time that it takes to complete the project. The problem of computing the longest path in an arbitrary graph is NP-hard. However, longest paths in a DAG can be computed in linear time by using DFS. This method can be generalized to

the case when vertices have weights denoting duration of tasks.

The algorithm processes the vertices in reverse topological order. Let $P(v)$ denote the length of a longest path coming out of vertex v. When vertex v is processed, the algorithm computes the length of a longest path in the graph that starts at v.

$$P(v) = 1 + \max_{(v,w)\in E} P(w) .$$

Since we are processing vertices in reverse topological order, w is processed before v, if (v, w) is an edge, and thus, $P(w)$ is computed before $P(v)$.

6.5 Breadth-First Search

Breadth-first search is another natural way of searching a graph. The search starts at a *root* vertex r. Vertices are added to a queue as they are discovered, and processed in FIFO (first-in first-out) order.

Initially, all vertices are marked as unvisited, and the queue consists of only the root vertex. The algorithm repeatedly removes the vertex at the front of the queue, and scans its neighbors in the graph. Any neighbor that is unvisited is added to the end of the queue. This process is repeated until the queue is empty. All vertices in the same connected component as the root vertex are scanned and the algorithm outputs a spanning tree of this component. This tree, known as a breadth-first tree, is made up of the edges that led to the discovery of new vertices. The algorithm labels each vertex v by $d[v]$, the distance (length of a shortest path) from the root vertex to v, and stores the BFS tree in the array p, using parent-pointers. Vertices can be partitioned into levels based on their distance from the root. Observe that edges not in the BFS tree always go either between vertices in the same level, or between vertices in adjacent levels. This property is often useful.

The BFS Algorithm

```
BFS-DISTANCE (G, r)
1   MAKEEMPTYQUEUE (Q).
2   for all vertices v in G do
3      visited[v] ← false.
4      d[v] ← ∞.
5      p[v] ← nil.
6   end-for
7   visited[r] ← true.
8   d[r] ← 0.
9   ENQUEUE (Q, r).
10  while not EMPTY (Q) do
11     v ← DEQUEUE (Q).
12     for all vertices w in adj[v] do
13        if not visited[w] then
14           visited[w] ← true.
15           p[w] ← v.
16           d[w] ← d[v] + 1.
17           ENQUEUE (w, Q).
18        end-if
19     end-for
20  end-while
end-proc
```

Sample Execution

Figure 6.5 shows a connected graph on which BFS was run with vertex a as the root. When a is processed, vertices b, d, and c are added to the queue. When b is processed nothing is done since all its neighbors have been visited. When d is processed, e and f are added to the queue. Finally c, e, and f are processed.

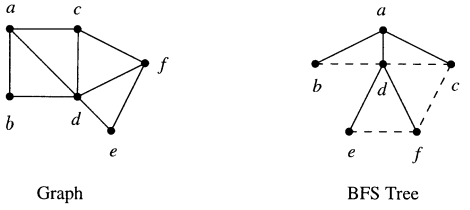

FIGURE 6.5 Sample execution of BFS on a graph.

Analysis

There is no loss of generality in assuming that the graph G is connected, since the algorithm can be repeated in each connected component, similar to the DFS algorithm. The algorithm processes each vertex exactly once, and each edge exactly twice. It spends a constant amount of time in processing each edge. Hence, the algorithm runs in $O(|V| + |E|)$ time.

Bipartite Graphs

A simple algorithm based on BFS can be designed to check if a given graph is bipartite: run BFS on each connected component of the graph, starting from an arbitrary vertex in each component as the root. The algorithm partitions the vertex set into the sets X and Y as follows. For a vertex v, if $d[v]$ is odd, then it inserts v into X. Otherwise $d[v]$ is even and it inserts v into Y. Now check to see if there is an edge in the graph that connects two vertices in the same set (X or Y). If the graph contains an edge between two vertices of the same set, say X, then we conclude that the graph is not bipartite, since the graph contains an odd-length cycle; otherwise the algorithm has partitioned the vertex set into X and Y and all edges of the graph connect a vertex in X with a vertex in Y, and therefore by definition, the graph is bipartite. (Note that it is known that a graph is bipartite if and only if it does not have a cycle of odd length.)

6.6 Single-Source Shortest Paths

A natural problem that often arises in practice is to compute the shortest paths from a specified node r to all other nodes in a graph. BFS solves this problem if all edges in the graph have the same length. Consider the more general case when each edge is given an arbitrary, nonnegative length. In this case, the length of a path is defined to be the sum of the lengths of its edges. The *distance* between two nodes is the length of a shortest path between them. The objective of the shortest path problem is to compute the distance from r to each vertex v in the graph, and a path of that length from r to v. The output is a tree, known as the *shortest path tree,* rooted at r. For any vertex v in the graph, the unique path from r to v in this tree is a shortest path from r to v in the input graph.

Dijkstra's Algorithm

Dijkstra's algorithm provides an efficient solution to the shortest path problem. For each vertex v, the algorithm maintains an upper bound of the distance from the root to vertex v in $d[v]$; initially $d[v]$ is set to infinity for all vertices except the root, which has d-value equal to zero. The algorithm maintains a set S of vertices with the property that for each vertex $v \in S$, $d[v]$ is the length of a shortest path from the root to v. For each vertex u in $V - S$, the algorithm maintains $d[u]$ to be the length of a shortest path from the root to u that goes entirely within S, except for the last edge. It selects a vertex u in $V - S$ with minimum $d[u]$ and adds it to S, and updates the distance estimates to the other vertices in $V - S$. In this update step it checks to see if there is a shorter path to any vertex in $V - S$ from the root that goes through u. Only the distance estimates of vertices that are adjacent to u need to be updated in this step. Since the primary operation is the selection of a vertex with minimum distance estimate, a priority queue is used to maintain the d-values of vertices (for more information about priority queues, see Chapter 4). The priority queue should be able to handle the DECREASEKEY operation to update the d-value in each iteration. The algorithm below implements Dijkstra's algorithm.

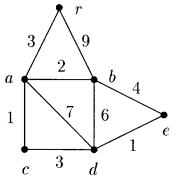
```
DIJKSTRA-SHORTEST PATHS (G, r)
1   for all vertices v in G do
2      visited[v] ← false.
3      d[v] ← ∞.
4      p[v] ← nil.
5   end-for
6   d[r] ← 0.
7   BUILDPQ (H, d).
8   while not EMPTY (H) do
9         u ← DELETEMIN (H).
10        visited[u] ← true.
11        for all vertices v in adj[u] do
12           RELAX (u, v).
13        end-for
14  end-while
end-proc
```

```
RELAX (u, v)
1   if not visited[v] and d[v] > d[u] + w(u, v) then
2      d[v] ← d[u] + w(u, v).
3      p[v] ← u.
4      DECREASEKEY (H, v, d[v]).
5   end-if
end-proc
```

Sample Execution

Figure 6.6 shows a sample execution of the algorithm. The column titled "Iter" specifies the number of iterations that the algorithm has executed through the while loop in Step 8. In iteration 0 the initial values of the distance estimates are ∞. In each subsequent line of the table, the column marked u shows the vertex that was chosen in Step 9 of the algorithm, and the other columns show the change to the distance estimates at the end of that iteration of the while loop. In the first iteration, vertex r was chosen, after

that a was chosen since it had the minimum distance label among the unvisited vertices, and so on. The distance labels of the unvisited neighbors of the visited vertex are updated in each iteration.



Iter	u	$d[a]$	$d[b]$	$d[c]$	$d[d]$	$d[e]$
0	-	∞	∞	∞	∞	∞
1	r	3	9	∞	∞	∞
2	a	3	5	4	10	∞
3	c	3	5	4	7	∞
4	b	3	5	4	7	9
5	d	3	5	4	7	8
6	e	3	5	4	7	8

FIGURE 6.6 Dijkstra's shortest path algorithm.

Analysis

The running time of the algorithm depends on the data structure that is used to implement the priority queue H. The algorithm performs $|V|$ DELETEMIN operations and at most $|E|$ DECREASEKEY operations. If a binary heap is used to find the records of any given vertex, each of these operations run in $O(\log |V|)$ time. There is no loss of generality in assuming that the graph is connected. Hence, the algorithm runs in $O(|E| \log |V|)$. If a Fibonacci heap [10] is used to implement the priority queue, the running time of the algorithm is $O(|E| + |V| \log |V|)$. Even though the Fibonacci heap gives the best asymptotic running time, the binary heap implementation is likely to give better running times for most practical instances.

Extensions

Dijkstra's algorithm can be generalized to solve several problems that are related to the shortest path problem. For example, in the bottleneck shortest path problem, the objective is to find, for each vertex v, a path from the root to v in which the length of the longest edge in that path is minimized. A small change to Dijkstra's algorithm (replacing the operation $+$ in RELAX by max) solves this problem. Other problems that can be solved by suitably modifying Dijkstra's algorithm include the following:

- Finding most reliable paths from the root to every vertex in a graph where each edge is given a probability of failure (independent of the other edges).
- Finding the fastest way to get from a given point in a city to a specified location using public transportation, given the train/bus schedules.

Bellman–Ford Algorithm

The shortest path algorithm described above directly generalizes to directed graphs, but it does not work if the graph has edges of negative length. For graphs that have edges of negative length, but no cycles of negative length, there is a different algorithm solves due to Bellman and Ford that solves the single source shortest paths problem in $O(|V||E|)$ time.

In a single scan of the edges, the RELAX operation is executed on each edge. The scan is then repeated $|V| - 1$ times. No special data structures are required to implement this algorithm, and the proof relies on the fact that a shortest path is simple and contains at most $|V| - 1$ edges.

This problem also finds applications in finding a feasible solution to a system of linear equations of a special form that arises in real-time applications: each equation specifies a bound on the difference between two variables. Each constraint is modeled by an edge in a suitably defined directed graph. Shortest paths

from the root of this graph capture feasible solutions to the system of equations (for more information, see [7, Chapter 25.5]).

The All-Pairs Shortest Paths Problem

Consider the problem of computing a shortest path between every pair of vertices in a directed graph with edge lengths. The problem can be solved in $O(|V|^3)$ time, even when some edges have negative lengths, as long as the graph has no negative length cycles. Let the lengths of the edges be stored in a matrix A; the array entry $A[i, j]$ stores the length of the edge from i to j. If there is no edge from i to j, then $A[i, j] = \infty$; also $A[i, i]$ is set to 0 for all i. A dynamic programming algorithm to solve the problem is discussed in this section. The algorithm is due to Floyd and builds on the work of Warshall.

Define $P_k[u, v]$ to be a shortest path from u to v that is restricted to using intermediate vertices only from the set $\{1, \ldots, k\}$. Let $D_k[u, v]$ be the length of $P_k[u, v]$. Note that $P_0[u, v] = (u, v)$ since the path is not allowed to use *any* intermediate vertices, and therefore $D_0[u, v] = A[u, v]$. Since there are no negative length cycles, there is no loss of generality in assuming that shortest paths are simple.

The structure of shortest paths leads to the following recursive formulation of P_k. Consider $P_k[i, j]$ for $k > 0$. Either vertex k is on this path or not. If $P_k[i, j]$ does not pass through k, then the path uses only vertices from the set $\{1, \ldots, k-1\}$ as intermediate vertices, and is therefore the same as $P_{k-1}[i, j]$. If k is a vertex on the path $P_k[i, j]$, then it passes through k exactly once because the path is simple. Moreover, the subpath from i to k in $P_k[i, j]$ is a shortest path from i to k that uses intermediate vertices from the set $\{1, \ldots, k-1\}$, as does the subpath from k to j in $P_k[i, j]$. Thus, the path $P_k[i, j]$ is the union of $P_{k-1}[i, k]$ and $P_{k-1}[k, j]$. The above discussion leads to the following recursive formulation of D_k:

$$D_k[i, j] = \begin{cases} \min\left(D_{k-1}[i, j], D_{k-1}[i, k] + D_{k-1}[k, j]\right) & \text{if } k > 0 \\ A[i, j] & \text{if } k = 0 \end{cases}$$

Finally, since $P_n[i, j]$ is allowed to go through any vertex in the graph, $D_n[i, j]$ is the length of a shortest path from i to j in the graph.

In the algorithm described below, a matrix D is used to store distances. It might appear at first glance that to compute the distance matrix D_k from D_{k-1}, different arrays must be used for them. However, it can be shown that in the kth iteration, the entries in the kth row and column do not change, and thus, the same space can be reused.

```
FLOYD-SHORTEST-PATH (G)
1   for i = 1 to |V| do
2      for j = 1 to |V| do
3         D[i, j] ← A[i, j]
4      end-for
5   end-for
6   for k = 1 to |V| do
7      for i = 1 to |V| do
8         for j = 1 to |V| do
9            D[i, j] ← min(D[i, j], D[i, k] + D[k, j]).
10        end-for
11     end-for
12  end for
end-proc
```

6.7 Minimum Spanning Trees

The following fundamental problem arises in network design. A set of sites need to be connected by a network. This problem has a natural formulation in graph-theoretic terms. Each site is represented by a vertex. Edges between vertices represent a potential link connecting the corresponding nodes. Each edge is given a non-negative cost corresponding to the cost of constructing that link. A tree is a minimal network that connects a set of nodes. The cost of a tree is the sum of the costs of its edges. A minimum-cost tree connecting the nodes of a given graph is called a minimum-cost spanning tree, or simply a **minimum spanning tree.**

The problem of computing a minimum spanning tree (MST) arises in many areas, and as a subproblem in combinatorial and geometric problems. MSTs can be computed efficiently using algorithms that are greedy in nature, and there are several different algorithms for finding an MST. One of the first algorithms was due to Boruvka. Two algorithms, popularly known as Prim's algorithm and Kruskal's algorithm, are described here.

We first describe some rules that characterize edges belonging to a minimum spanning tree. The various algorithms are based on applying these rules in different orders. Tarjan [28] uses colors to describe these rules. Initially, all edges are uncolored. When an edge is colored *blue* it is marked for inclusion in the MST. When an edge is colored *red* it is marked to be excluded from the MST. The algorithms maintain the property that there is an MST containing all the blue edges but none of the red edges.

A *cut* is a partitioning of the vertex set into two subsets S and $V - S$. An edge *crosses* the cut if it connects a vertex $x \in S$ to a vertex $y \in V - S$.

(**Blue rule**) Find a cut that is not crossed by any blue edge and color a minimum weight edge that crosses the cut to be blue.

(**Red rule**) Find a simple cycle containing no red edges and color a maximum weight edge on that cycle to be red.

The proofs that these rules work can be found in [28].

Prim's Algorithm

Prim's algorithm for finding an MST of a given graph is one of the oldest algorithms to solve the problem. The basic idea is to start from a single vertex and gradually "grow" a tree, which eventually spans the entire graph. At each step, the algorithm has a tree of blue edges that covers a set S of vertices. The blue rule is applied by picking the cut $S, V - S$. This may be used to extend the tree to include a vertex that is currently not in the tree. The algorithm selects a minimum-cost edge from the edges crossing the cut and adds it to the current tree (implicitly coloring the edge blue), thereby adding another vertex to S.

As in the case of Dijkstra's algorithm, each vertex $u \in V - S$ can attach itself to only one vertex in the tree so that the current solution maintained by the algorithm is always a tree. Since the algorithm always chooses a minimum-cost edge, it needs to maintain a minimum-cost edge that connects u to some vertex in S as the candidate edge for including u in the tree. A priority queue of vertices is used to select a vertex in $V - S$ that is incident to a minimum-cost candidate edge.

```
PRIM-MST (G, r)
1  for all vertices v in G do
2     visited[v] ← false.
3     d[v] ← ∞.
4     p[v] ← nil.
5  end-for
6  d[r] ← 0.
7  BUILDPQ (H, d).
```

```
8   while not Empty(H) do
9      u ← DeleteMin (H).
10     visited[u] ← true.
11     for all vertices v in adj[u] do
12        if not visited[v] and d[v] > w(u, v) then
13           d[v] ← w(u, v).
14           p[v] ← u.
15           DecreaseKey (H, v, d[v]).
16        end-if
17     end-for
18  end-while
end-proc
```

Analysis

First observe the similarity between Prim's and Dijkstra's algorithms. Both algorithms start building the tree from a single vertex and grow it by adding one vertex at a time. The only difference is the rule for deciding when the current label is updated for vertices outside the tree. Both algorithms have the same structure and therefore have similar running times. Prim's algorithm runs in $O(|E| \log |V|)$ time if the priority queue is implemented using binary heaps, and it runs in $O(|E| + |V| \log |V|)$ if the priority queue is implemented using Fibonacci heaps.

Kruskal's Algorithm

Kruskal's algorithm for finding an MST of a given graph is another classical algorithm for the problem, and is also greedy in nature. Unlike Prim's algorithm which grows a single tree, Kruskal's algorithm grows a forest. First the edges of the graph are sorted in nondecreasing order of their costs. The algorithm starts with an empty forest. The edges of the graph are scanned in sorted order, and if the addition of the current edge does not generate a cycle in the current forest, it is added to the forest. The main test at each step is: does the current edge connect two vertices in the same connected component of the current forest? Eventually the algorithm adds $n - 1$ edges to generate a spanning tree in the graph.

The following discussion explains the correctness of the algorithm based on the two rules described earlier. Suppose that as the algorithm progresses, the edges chosen by the algorithm are colored blue and the ones that it rejects are colored red. When an edge is considered and it forms a cycle with previously chosen edges, this is a cycle with no red edges. Since the algorithm considers the edges in nondecreasing order of weight, the last edge is the heaviest edge in the cycle and therefore it can be colored red by the red rule. If an edge connects two blue trees T_1 and T_2, then it is a lightest edge crossing the cut T_1 and $V - T_1$, because any other edge crossing the cut has not been considered yet and is therefore no lighter. Therefore it can be colored blue by the blue rule.

The main data structure needed to implement the algorithm is to maintain connected components. An abstract version of this problem is known as the union–find problem for collection of disjoint sets (Chapter 8). Efficient algorithms are known for this problem, where an arbitrary sequence of Union and Find operations can be implemented to run in almost linear time (for more information, see [7, 28]).

```
Kruskal-MST(G)
1   T ← φ.
2   for all vertices v in G do
3      p[v] ← v.
```

```
4   end-for
5   Sort the edges of G by nondecreasing order of costs.
6   for all edges e = (u, v) in G in sorted order do
7      if FIND (u) ≠ FIND (v) then
8         T ← T ∪ (u, v).
9         UNION (u, v).
10     end-if
11  end-for
end-proc
```

Analysis

The running time of the algorithm is dominated by Step 5 of the algorithm in which the edges of the graph are sorted by nondecreasing order of their costs. This takes $O(|E| \log |E|)$ (which is also $O(|E| \log |V|)$) time using an efficient sorting algorithm such as heap sort. Kruskal's algorithm runs faster in the following special cases: if the edges are presorted, if the edge costs are within a small range, or if the number of different edge costs is bounded. In all these cases, the edges can be sorted in linear time, and Kruskal's algorithm runs in the near-linear time of $O(|E|\alpha(|E|, |V|))$, where $\alpha(m, n)$ is the inverse Ackermann function [28].

Boruvka's Algorithm

Boruvka's algorithm also grows many trees simultaneously. Initially there are $|V|$ trees, where each vertex forms its own tree. At each stage the algorithm keeps a collection of blue trees (i.e., trees built using only blue edges). For convenience, assume that all edge weights are distinct. If two edges have the same weight, they may be ordered arbitrarily. Each tree selects a minimum cost edge that connects it to some other tree and colors it blue. At the end of this parallel coloring step, each tree merges with a collection of other trees. The number of trees decreases by at least a factor of 2 in each step, and therefore after $\log |V|$ iterations there is exactly one tree. In practice, many trees merge in a single step and the algorithm converges much faster. Each step can be implemented in $O(|E|)$ time, and hence, the algorithm runs in $O(|E| \log |V|)$. For the special case of planar graphs, the above algorithm actually runs in $O(|V|)$ time.

Almost linear-time deterministic algorithms for the MST problem in undirected graphs are known [5, 10]. Recently, Karger, Klein and Tarjan [18] showed that they can combine the approach of Boruvka's algorithm with a random sampling approach to obtain a randomized algorithm with an expected running time of $O(|E|)$. Their algorithm also needs to use as a subroutine a procedure to verify that a proposed tree is indeed an MST [20, 21]. The equivalent of minimum spanning trees in directed graphs are known as minimum **branchings** and are discussed in Chapter 7.

6.8 Tour and Traversal Problems

There are many applications for finding certain kinds of paths and tours in graphs. We briefly discuss some of the basic problems.

The **traveling salesman problem** (TSP) is that of finding a shortest tour that visits all the vertices of a given graph with weights on the edges. It has received considerable attention in the literature [22]. The problem is known to be computationally intractable (NP-hard). Several heuristics are known to solve practical instances. Considerable progress has also been made in finding optimal solutions for graphs with a few thousand vertices.

One of the first graph-theoretic problems to be studied, the **Euler tour problem** asks for the existence of a closed walk in a given connected graph that traverses each edge exactly once. Euler proved that such

a closed walk exists if and only if each vertex has even degree [12]. Such a graph is known as an **Eulerian graph.** Given an Eulerian graph, an Euler tour in it can be computed using an algorithm similar to DFS in linear time.

Given an edge-weighted graph, the **Chinese postman problem** is that of finding a shortest closed walk that traverses each edge at least once. Although the problem sounds very similar to the TSP problem, it can be solved optimally in polynomial time [1].

6.9 Assorted Topics

Planar Graphs

A graph is called *planar* if it can be drawn on the plane without any of its edges crossing each other. A *planar embedding* is a drawing of a planar graph on the plane with no crossing edges. An embedded planar graph is known as a *plane graph.* A *face* of a plane graph is a connected region of the plane surrounded by edges of the planar graph. The unbounded face is referred to as the *exterior face.* Euler's formula captures a fundamental property of planar graphs by relating the number of edges, the number of vertices and the number of faces of a plane graph: $|F| - |E| + |V| = 2$. One of the consequences of this formula is that a simple planar graph has at most $O(|V|)$ edges.

Extensive work has been done on the study of planar graphs and a recent book has been devoted to the subject [26]. A fundamental problem in this area is deciding whether a given graph is planar, and if so, finding a planar embedding for it. Kuratowski gave necessary and sufficient conditions for when a graph is planar, by showing that a graph is planar if and only if it has no subgraph that is a homeomorph of K_5 or $K_{3,3}$. Hopcroft and Tarjan [17] gave a linear time algorithm to test if a graph is planar, and if it is, to find a planar embedding for the graph.

A *balanced separator* is a subset of vertices that disconnects the graph in such a way, that the resulting components each have at most a constant fraction of the number of vertices of the original graph. Balanced separators are useful in designing "divide-and-conquer" algorithms for graph problems, such as graph layout problems (Chapter 23). Such algorithms are possible when one is guaranteed to find separators that have very few vertices relative to the graph. Lipton and Tarjan [24] proved that every planar graph on $|V|$ vertices has a separator of size at most $\sqrt{8|V|}$, whose deletion breaks the graph into two or more disconnected graphs, each of which has at most $\frac{2}{3}|V|$ vertices. Using the property that planar graphs have small separators, Frederickson [9] has given faster shortest path algorithms for planar graphs. Recently, this was improved to a linear time algorithm by Henzinger et al. [13].

Graph Coloring

A coloring of a graph is an assignment of colors to the vertices, so that any two adjacent vertices have distinct colors. Traditionally, the colors are not given names, but represented by positive integers. The *vertex coloring* problem is the following: given a graph, to color its vertices using the fewest number of colors (known as the *chromatic number* of the graph). This was one of the first problems that were shown to be intractable (NP-hard). Recently it has been shown that even the problem of approximating the chromatic number of the graph within any reasonable factor is intractable. But, the coloring problem needs to be solved in practice (such as in the channel assignment problem in cellular networks), and heuristics are used to generate solutions. We discuss a commonly used greedy heuristic below: the vertices of the graph are colored sequentially in an arbitrary order. When a vertex is being processed, the color assigned to it is the smallest positive number that is not used by any of its neighbors that have been processed earlier. This scheme guarantees that if the degree of a vertex is Δ, then its color is at most $\Delta + 1$. There are special classes of graphs, such as planar graphs, in which the vertices can be carefully ordered in such a way that the number of colors used is small. For example, the vertices of a planar graph can be ordered such that

every vertex has at most 5 neighbors that appear earlier in the list. By coloring its vertices in that order yields a 6-coloring. There is a different algorithm that colors any planar graph using only 4 colors.

Light Approximate Shortest Path Trees

To broadcast information from a specified vertex r to all vertices of G, one may wish to send the information along a shortest path tree in order to reduce the time taken by the message to reach the nodes (i.e., minimizing *delay*). Though the shortest path tree may minimize delays, it may be a much costlier network to construct and considerably heavier than a minimum spanning tree, which leads to the question of whether there are trees that are light (like an MST) and yet capture distances like a shortest path tree. In this section, we consider the problem of computing a light subgraph that approximates a shortest path tree rooted at r.

Let T_{min} be a minimum spanning tree of G. For any vertex v, let $d(r, v)$ be the length of a shortest path from r to v in G. Let $\alpha > 1$ and $\beta > 1$ be arbitrary constants. An (α, β)-*light approximate shortest path tree* $\Big((\alpha, \beta)\text{-LAST}\Big)$ of G is a spanning tree T of G with the property that the distance from the root to any vertex v in T is at most $\alpha \cdot d(r, v)$ and the weight of T is at most β times the weight of T_{min}.

Awerbuch, Baratz and Peleg [3], motivated by applications in broadcast-network design, made a fundamental contribution by showing that every graph has a *shallow-light* tree — a tree whose *diameter* is at most a constant times the diameter of G and whose total weight is at most a constant times the weight of a minimum spanning tree. Cong et al. [6] studied the same problem and showed that the problem has applications in VLSI-circuit design; they improved the approximation ratios obtained in [3] and also studied variations of the problem such as bounding the *radius* of the tree instead of the diameter.

Khuller, Raghavachari and Young [19] modified the shallow-light tree algorithm and showed that the distance from the root to each vertex can be approximated within a constant factor. Their algorithm also runs in linear time if a minimum spanning tree and a shortest path tree are provided. The algorithm computes an $(\alpha, 1 + \frac{2}{\alpha - 1})$-LAST.

The basic idea is as follows: initialize a subgraph H to be a minimum spanning tree T_{min}. The vertices are processed in a preorder traversal of T_{min}. When a vertex v is processed, its distance from r in H is compared to $\alpha \cdot d(r, v)$. If the distance exceeds the required threshold, then the algorithm adds to H a shortest path in G from r to v. When all the vertices have been processed, the distance in H from r to any vertex v meets its distance requirement. A shortest path tree in H is returned by the algorithm as the required LAST.

Network Decomposition

The problem of decomposing a graph into clusters, each of which has low diameter, has applications in distributed computing. Awerbuch [2] introduced an elegant algorithm for computing low diameter clusters, with the property that there are few inter-cluster edges (assuming that edges going between clusters are not counted multiply). This construction was further refined by Awerbuch and Peleg [4], and they showed that a graph can be decomposed into clusters of diameter $O(r \log |V|)$ with the property that each r neighborhood of a vertex belongs to some cluster. (An r neighborhood of a vertex is the set of nodes whose distance from the vertex is at most r.) In addition, each vertex belongs to at most $2 \log |V|$ clusters. Using a similar approach Linial and Saks [23] showed that a graph can be decomposed into $O(\log |V|)$ clusters, with the property that each connected component in a cluster has $O(\log |V|)$ diameter. These techniques have found several applications in the computation of approximate shortest paths, and in other distributed computing problems.

The basic idea behind these methods is to perform an "expanding BFS." The algorithm selects an arbitrary vertex, and executes BFS with that vertex as the root. The algorithm continues the search layer by layer, ensuring that the number of vertices in a layer is at least as large as the number of vertices currently

in that BFS tree. Since the tree expands rapidly, this procedure generates a low diameter BFS tree (cluster). If the algorithm comes across a layer in which the number of nodes is not big enough, it *rejects* that layer and stops growing that tree. The set of nodes in the layer that was not added to the BFS tree that was being grown is guaranteed to be small. The algorithm continues by selecting a new vertex that was not chosen in any cluster and repeats the above procedure.

6.10 Research Issues and Summary

We have illustrated some of the fundamental techniques that are useful for manipulating graphs. These basic algorithms are used as tools in the design of algorithms for graphs. The problems studied in this chapter included representation of graphs, tree traversal techniques, search techniques for graphs, shortest path problems, minimum spanning trees, and tour problems on graphs.

Current research on graph algorithms focuses on dynamic algorithms, graph layout and drawing, and approximation algorithms. More information about these areas can be found in Chapter 8, Chapter 9, and Chapter 34. The methods illustrated in our chapter find use in the solution of almost any graph problem.

The *graph isomorphism* problem is an old problem in this area. The input to this problem is two graphs and the problem is to decide whether the two graphs are isomorphic, i.e., whether the rows and columns of the adjacency matrix of one of the graphs can be permuted so that it is identical to the adjacency matrix of the other graph. This problem is neither known to be polynomial-time solvable nor known to be NP-hard. This is in contrast to the *subgraph isomorphism* problem in which the problem is to decide whether there is a subgraph of the first graph that is isomorphic to the second graph. The subgraph isomorphism is known to be NP-complete. Special instances of the **graph isomorphism problem** are known to be polynomially solvable, such as when the graphs are planar, or more generally of bounded genus. For more information on the isomorphism problem, see Hoffman [14].

Another open problem is whether there exists a *deterministic* linear time algorithm for computing a minimum spanning tree. Near-linear time deterministic algorithms using Fibonacci heaps have been known for finding an MST. The newly discovered probabilistic algorithm uses random sampling to find an MST in expected linear time. Much of the recent research in this area is focusing on the design of approximation algorithms for NP-hard problems.

6.11 Defining Terms

Articulation vertex/Cut vertex: A vertex whose deletion disconnects a graph into two or more connected components.

Biconnected graph: A graph that has no articulation/cut vertices.

Bipartite graph: A graph in which the vertex set can be partitioned into two sets X and Y, such that each edge connects a node in X with a node in Y.

Branching: A rooted spanning tree in a directed graph, such that the root has a path in the tree to each vertex.

Chinese postman problem: Find a minimum length tour that traverses each edge at least once.

Connected graph: A graph in which there is a path between each pair of vertices.

Cycle: A path in which the start and end vertices of the path are identical.

Degree: The number of edges incident to a vertex in a graph.

DFS forest: A rooted forest formed by depth-first search.

Directed acyclic graph: A directed graph with no cycles.

Euler tour problem: Asks for a traversal of the edges that visits each edge exactly once.

Eulerian graph: A graph that has an Euler tour.

Forest: An acyclic graph.

Graph isomorphism problem: Deciding if two given graphs are isomorphic to each other.

Leaves: Vertices of degree one in a tree.

Minimum spanning tree: A spanning tree of minimum total weight.

Path: An ordered list of distinct edges, $\{e_i = (u_i, v_i) | i = 1, \ldots, k\}$, such that for any two consecutive edges e_i and e_{i+1}, $v_i = u_{i+1}$.

Planar graph: A graph that can be drawn on the plane without any of its edges crossing each other.

Sparse graph: A graph in which $|E| \ll |V|^2$.

Strongly connected graph: A directed graph in which there is a directed path between each ordered pair of vertices.

Topological order: A numbering of the vertices of a DAG such that every edge in the graph that goes from a vertex numbered i to a vertex numbered j satisfies $i < j$.

Traveling salesman problem: Asks for a minimum length tour of a graph that visits all the vertices exactly once.

Tree: A connected forest.

Walk: A path in which edges may be repeated.

Further Information

The area of graph algorithms continues to be a very active field of research. There are several journals and conferences that discuss advances in the field. Here we name a partial list of some of the important meetings: "ACM Symposium on Theory of Computing (STOC)," "IEEE Conference on Foundations of Computer Science (FOCS)," "ACM-SIAM Symposium on Discrete Algorithms (SODA)," "International Colloquium on Automata, Languages and Programming (ICALP)," and "European Symposium on Algorithms (ESA)." There are many other regional algorithms/theory conferences that carry research papers on graph algorithms. The journals that carry articles on current research in graph algorithms are *Journal of the ACM, SIAM Journal on Computing, SIAM Journal on Discrete Mathematics, Journal of Algorithms, Algorithmica, Journal of Computer and System Sciences, Information and Computation, Information Processing Letters,* and *Theoretical Computer Science.* To find more details about some of the graph algorithms described in this chapter we refer the reader to the books by Cormen, Leiserson and Rivest [7], Even [8], Gibbons [12], and Tarjan [28].

7.1 Introduction

The optimization of a given objective, while working with limited resources is a fundamental problem that occurs in all walks of life, and is especially important in computer science and operations research. Problems in discrete optimization vary widely in their complexity, and efficient solutions are derived for many of these problems by studying their combinatorial structure and understanding their fundamental properties. In this chapter, we study several problems and advanced algorithmic techniques for solving them. One of the basic topics in this field is the study of **network flow** and related optimization problems; these problems occur in various disciplines, and provide a fundamental framework for solving problems. For example, the problem of efficiently moving entities, such as bits, people, or products, from one place

to another in an underlying network, can be modeled as a network flow problem. Network flow finds applications in many other areas such as **matching,** scheduling, and connectivity problems in networks. The problem plays a central role in the fields of operations research and computer science, and considerable emphasis has been placed on the design of efficient algorithms for solving it.

The network flow problem is usually formulated on directed graphs (which are also known as *networks*). A fundamental problem is the **maximum flow** problem, usually referred to as the *max-flow* problem. The input to this problem is a directed graph $G = (V, E)$, a nonnegative **capacity** function $u : E \mapsto \Re^+$ that specifies the *capacity* of each arc, a source vertex $s \in V$, and a sink vertex $t \in V$. The problem captures the situation when a commodity is being produced at node s, and needs to be shipped to node t, through the network. The objective is to send as many units of flow as possible from s to t, while satisfying flow conservation constraints at all intermediate nodes and capacity constraints on the edges. The problem will be defined formally later.

Many practical combinatorial problems such as the **assignment problem,** and the problem of finding the susceptibility of networks to failures due to faulty links or nodes, are special instances of the max-flow problem. There are several variations and generalizations of the max-flow problem including the vertex capacitated max-flow problem, the minimum-cost max-flow problem, the minimum-cost circulation problem, and the multicommodity flow problem.

Section 7.2 discusses the matching problem. The single commodity maximum flow problem is introduced in Section 7.3. The minimum-cut problem is discussed in Section 7.4. Section 7.5 discusses the min-cost flow problem. The multicommodity flow problem is discussed in Section 7.6. Section 7.7 introduces the problem of computing optimal **branchings.** Section 7.8 discusses the problem of coloring the edges and vertices of a graph. Section 7.9 discusses approximation algorithms for NP-hard problems. At the end, references to current research in graph algorithms are provided.

7.2 The Matching Problem

An entire book [23] has been devoted to the study of various aspects of the matching problem, ranging from necessary and sufficient conditions for the existence of perfect matchings to algorithms for solving the matching problem. Many of the basic algorithms studied in Chapter 6 play an important role in developing various implementations for network flow and matching algorithms.

First the *matching* problem, which is a special case of the max-flow problem is introduced. Then the *assignment problem,* a generalization of the matching problem, is studied.

The maximum matching problem is discussed in detail only for bipartite graphs. The same principles are used to design efficient algorithms to solve the matching problem in arbitrary graphs. The algorithms for general graphs are complex due to the presence of odd-length cycles called **blossoms,** and the reader is referred to [26, Chapter 10], or [29, Chapter 9] for a detailed treatment of how blossoms are handled.

Matching Problem Definitions

Given a graph $G = (V, E)$, a *matching* M is a subset of the edges such that no two edges in M share a common vertex. In other words, the problem is that of finding a set of independent edges, that have no incident vertices in common. The cardinality of M is usually referred to as its *size.*

The following terms are defined with respect to a matching M. The edges in M are called *matched edges* and edges not in M are called *free edges.* Likewise, a vertex is a *matched vertex* if it is incident to a matched edge. A *free vertex* is one that is not matched. The *mate* of a matched vertex v is its neighbor w that is at the other end of the matched edge incident to v. A matching is called *perfect* if all vertices of the graph are matched in it. (When the number of vertices is odd, we permit one vertex to remain unmatched.) The objective of the maximum matching problem is to maximize $|M|$, the size of the matching. If the edges of the graph have weights, then the *weight* of a matching is defined to be the sum of the weights of the

edges in the matching. A path $p = [v_1, v_2, \ldots, v_k]$ is called an *alternating path* if the edges (v_{2j-1}, v_{2j}), $j = 1, 2, \ldots$ are free, and the edges (v_{2j}, v_{2j+1}), $j = 1, 2, \ldots$ are matched. An **augmenting path** $p = [v_1, v_2, \ldots, v_k]$ is an alternating path in which both v_1 and v_k are free vertices. Observe that an augmenting path is defined with respect to a specific matching. The symmetric difference of a matching M and an augmenting path P, $M \oplus P$, is defined to be $(M - P) \cup (P - M)$. It can be shown that $M \oplus P$ is also a matching. Figure 7.1 shows an augmenting path $p = [a, b, c, d, g, h]$ with respect to the given matching. The symmetric difference operation can be also be used as above between two matchings. In this case, the resulting graph consists of a collection of paths and cycles with alternate edges from each matching.

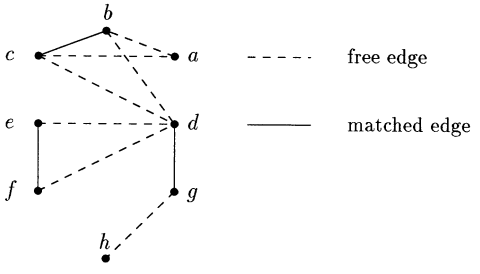

FIGURE 7.1 An augmenting path p with respect to a matching.

Applications of Matching

Matchings lie at the heart of many optimization problems and the problem has many applications: assigning workers to jobs, assigning a collection of jobs with precedence constraints to two processors such that the total execution time is minimized, determining the structure of chemical bonds in Chemistry, matching moving objects based on a sequence of snapshots, and localization of objects in space after obtaining information from multiple sensors (see [1]).

Matchings and Augmenting Paths

The following theorem gives necessary and sufficient conditions for the existence of a perfect matching in a bipartite graph.

THEOREM 7.1 **(Hall's Theorem)** *A bipartite graph $G = (X, Y, E)$ with $|X| = |Y|$ has a perfect matching if and only if $\forall S \subseteq X, |N(S)| \geq |S|$, where $N(S) \subseteq Y$ is the set of vertices that are neighbors of some vertex in S.*

Although the above theorem captures exactly the conditions under which a given bipartite graph has a perfect matching, it does not lead to an algorithm for finding perfect matchings directly. The following lemma shows how an augmenting path with respect to a given matching can be used to increase the size of a matching. An efficient algorithm will be described later that uses augmenting paths to construct a maximum matching incrementally.

LEMMA 7.1 Let P be the edges on an augmenting path $p = [v_1, \ldots, v_k]$ with respect to a matching M. Then $M' = M \oplus P$ is a matching of cardinality $|M| + 1$.

PROOF Since P is an augmenting path, both v_1 and v_k are free vertices in M. The number of free edges in P is one more than the number of matched edges in it. The symmetric difference operator replaces the matched edges of M in P by the free edges in P. Hence, the size of the resulting matching, $|M'|$, is one more than $|M|$.

The following theorem provides a necessary and sufficient condition for a given matching M to be a maximum matching.

THEOREM 7.2 *A matching M in a graph G is a maximum matching if and only if there is no augmenting path in G with respect to M.*

PROOF If there is an augmenting path with respect to M, then M cannot be a maximum matching, since by Lemma 7.1 there is a matching whose size is larger than that of M. To prove the converse we show that if there is no augmenting path with respect to M then M is a maximum matching. Suppose that there is a matching M' such that $|M'| > |M|$. Consider the subgraph of G induced by the edges $M \oplus M'$. Each vertex in this subgraph has degree at most two, since each node has at most one edge from each matching incident to it. Hence, each connected component of this subgraph is either a path or a simple cycle. For each cycle, the number of edges of M is the same as the number of edges of M'. Since $|M'| > |M|$, one of the paths must have more edges from M' than from M. This path is an augmenting path in G with respect to the matching M, contradicting the assumption that there were no augmenting paths with respect to M.

Bipartite Matching Algorithm

High-Level Description: The algorithm starts with the empty matching $M = \emptyset$, and augments the matching in phases. In each phase, an augmenting path with respect to the current matching M is found, and it is used to increase the size of the matching. An augmenting path, if one exists, can be found in $O(|E|)$ time, using a procedure similar to breadth-first search.

The search for an augmenting path proceeds from the free vertices. At each step when a vertex in X is processed, all its unvisited neighbors are also searched. When a matched vertex in Y is considered, only its matched neighbor is searched. This search proceeds along a subgraph referred to as the *Hungarian tree.*

The algorithm uses a queue Q to hold vertices that are yet to be processed. Initially, all free vertices in X are placed in the queue. The vertices are removed one by one from the queue and processed as follows. In turn, when vertex v is removed from the queue, the edges incident to it are scanned. If it has a neighbor in the vertex set Y that is free, then the search for an augmenting path is successful; procedure AUGMENT is called to update the matching, and the algorithm proceeds to its next phase. Otherwise, add the mates of all the matched neighbors of v to the queue if they have never been added to the queue, and continue the search for an augmenting path. If the algorithm empties the queue without finding an augmenting path, its current matching is a maximum matching and it terminates.

The main data structure that the algorithm uses are the arrays *mate* and *free.* The array *mate* is used to represent the current matching. For a matched vertex $v \in G$, $mate[v]$ denotes the matched neighbor of vertex v. For $v \in X$, $free[v]$ is a vertex in Y that is adjacent to v and is free. If no such vertex exists then $free[v] = 0$. The set A stores a set of directed edges (v, v') such that there is an alternating path of two edges from v to v'. This will be used in the search for augmenting paths from free vertices, while extending the alternating paths. When we add a vertex v' to the queue, we set $label[v']$ to v if we came to v' from v, since we need this information to augment on the alternating path we eventually find.

BIPARTITE MATCHING ($G = (X, Y, E)$)
1 **for** all vertices v in G **do**

9    end-if
end-proc
```

Sample Execution

Figure 7.2 shows a sample execution of the matching algorithm. We start with a partial matching and show the structure of the resulting Hungarian tree. In this example, the search starts from the free vertex b. We add c and e to Q. After we explore c, we add d to Q, and then f and a. Since $free[a] = u$, we stop since an augmenting path from vertex b to vertex u is found by the algorithm.

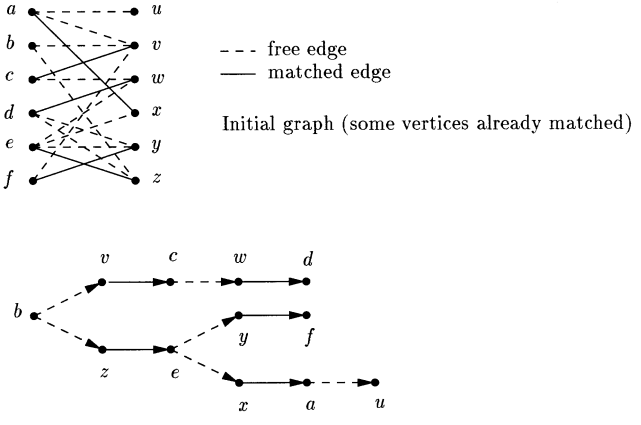

FIGURE 7.2 Sample execution of matching algorithm.

Analysis

If there are augmenting paths with respect to the current matching, the algorithm will find at least one of them. Hence, when the algorithm terminates, the graph has no augmenting paths with respect to the current matching and the current matching is optimal. Each iteration of the main while loop of the algorithm runs in $O(|E|)$ time. The construction of the auxiliary graph A and computation of the array $free$ also take $O(|E|)$ time. In each iteration, the size of the matching increases by one and thus, there are at most $\min(|X|, |Y|)$ iterations of the while loop. Therefore the algorithm solves the matching problem for bipartite graphs in time $O(\min(|X|, |Y|)|E|)$. Hopcroft and Karp (see [26]) showed how to improve the running time by finding a maximal set of disjoint augmenting paths in a single phase in $O(|E|)$ time. They also proved that the algorithm runs in only $O(\sqrt{|V|})$ phases, yielding a worst-case running time of $O(\sqrt{|V|}|E|)$.

The Matching Problem in General Graphs

The techniques used to solve the matching problem in bipartite graphs do not extend directly to non-bipartite graphs. The notion of augmenting paths and their relation to maximum matchings (Theorem 7.2) remain the same. Therefore the natural algorithm of starting with an empty matching and increasing its size repeatedly with an augmenting path until no augmenting paths exist in the graph still works. But the problem of finding augmenting paths in non-bipartite graphs is harder. The main trouble is due to odd length cycles known as *blossoms* that appear along alternating paths explored by the algorithm as it is looking for augmenting paths. We illustrate this difficulty with an example in Fig. 7.3. The search for an augmenting path from an unmatched vertex such as e, could go through the following sequence of vertices $[e, b, g, d, h, g, b, a]$. Even though the augmenting path satisfies the "local" conditions for being an augmenting path, it is not a valid augmenting path since it is not simple. The reason for this is that the odd length cycle (g, d, h, g) causes the path to "fold" on itself—a problem that does not arise in the bipartite case. In fact, the matching does contain a valid augmenting path $[e, f, c, d, h, g, b, a]$. In fact, not all odd cycles cause this problem, but odd cycles that are as dense in matched edges as possible, i.e., it depends on the current matching. By "shrinking" blossoms to single nodes, we can get rid of them [26]. Subsequent work focused on efficient implementation of this method.

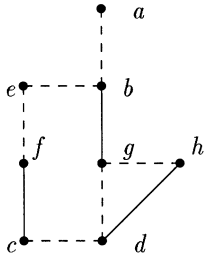

FIGURE 7.3 Difficulty in dealing with blossoms.

Edmonds (see [26]) gave the first polynomial-time algorithm for solving the maximum matching problem in general graphs. The current fastest algorithm for this problem is due to Micali and Vazirani [24] and their algorithm runs in $O(|E|\sqrt{|V|})$ steps, which is the same bound obtained by the Hopcroft–Karp algorithm for finding a maximum matching in bipartite graphs.

Assignment Problem

We now introduce the *assignment problem* — that of finding a maximum weight matching in a given bipartite graph in which edges are given nonnegative weights. There is no loss of generality in assuming that the graph is a complete bipartite graph, since zero-weight edges may be added between pairs of vertices that are nonadjacent in the original graph without affecting the weight of a maximum-weight matching. The minimization version of the weighted version is the problem of finding a *minimum-weight perfect matching* in a complete bipartite graph. Both versions of the weighted matching problem are equivalent and we sketch below how to reduce the minimum-weight perfect matching to maximum-weight matching. Choose a constant W that is larger than the weight of any edge, and assign each edge a new weight of $w'(e) = W - w(e)$. Observe that maximum-weight matchings with the new weight function are minimum-weight perfect matchings with the original weights.

In this section, we restrict our attention to the study of the maximum-weight matching problem for bipartite graphs. Similar techniques have been used to solve the maximum-weight matching problem in arbitrary graphs (see [22, 26]).

The input is a complete bipartite graph $G = (X, Y, X \times Y)$ and each edge e has a nonnegative weight of $w(e)$. The following algorithm is known as the *Hungarian method* (see [1, 23, 26]). The method can be viewed as a primal-dual algorithm in the framework of linear programming [26]. No knowledge of linear programming is assumed here.

A *feasible vertex-labeling* ℓ is defined to be a mapping from the set of vertices in G to the real numbers such that for each edge (x_i, y_j) the following condition holds:

$$\ell(x_i) + \ell(y_j) \geq w(x_i, y_j) .$$

The following can be verified to be a feasible vertex labeling. For each vertex $y_j \in Y$, set $\ell(y_j)$ to be 0, and for each vertex $x_i \in X$, set $\ell(x_i)$ to be the maximum weight of an edge incident to x_i:

$$\begin{aligned} \ell(y_j) &= 0 , \\ \ell(x_i) &= \max_j w(x_i, y_j) . \end{aligned}$$

The *equality subgraph*, G_ℓ, is defined to be the spanning subgraph of G which includes all vertices of G but only those edges (x_i, y_j) which have weights such that

$$\ell(x_i) + \ell(y_j) = w(x_i, y_j) .$$

The connection between equality subgraphs and maximum-weighted matchings is established by the following theorem.

THEOREM 7.3 *If the equality subgraph, G_ℓ, has a perfect matching, M^*, then M^* is a maximum weight matching in G.*

PROOF Let M^* be a perfect matching in G_ℓ. By definition,

$$w(M^*) = \sum_{e \in M^*} w(e) = \sum_{v \in X \cup Y} \ell(v) .$$

Let M be any perfect matching in G. Then

$$w(M) = \sum_{e \in M} w(e) \leq \sum_{v \in X \cup Y} \ell(v) = w(M^*) .$$

Hence, M^* is a maximum weight perfect matching.

High-Level Description: The above theorem is the basis of the following algorithm for finding a maximum weight matching in a complete bipartite graph. The algorithm starts with a feasible labeling, then computes the equality subgraph and a maximum cardinality matching in this subgraph. If the matching found is perfect, by Theorem 7.3, the matching must be a maximum weight matching and the algorithm returns it as its output. Otherwise the matching is not perfect, and more edges need to be added to the equality subgraph by *revising* the vertex labels. The revision should ensure that edges from the current matching do not leave the equality subgraph. After more edges are added to the equality subgraph, the algorithm grows the Hungarian trees further. Either the size of the matching increases because an augmenting path is found, or a new vertex is added to the Hungarian tree. In the former case, the current phase terminates and the algorithm starts a new phase since the matching size has increased. In the latter case, new nodes are added to the Hungarian tree. In $|X|$ phases, the tree includes all the nodes, and therefore there are at most $|X|$ phases before the size of the matching increases.

We now describe in more detail how the labels are updated and which edges are added to the equality subgraph. Suppose M is a maximum matching found by the algorithm. Hungarian trees are grown from all the free vertices in X. Vertices of X (including the free vertices) that are encountered in the search are added to a set S and vertices of Y that are encountered in the search are added to a set T. Let $\overline{S} = X - S$ and $\overline{T} = Y - T$. Figure 7.4 illustrates the structure of the sets S and T. Matched edges are shown in bold; the other edges are the edges in G_ℓ. Observe that there are no edges in the equality subgraph from S to $\overline{T}$, even though there may be edges from T to $\overline{S}$. The algorithm now revises the labels as follows. Decrease all the labels of vertices in S by a quantity δ (to be determined later) and increase the labels of the vertices in T by δ. This ensures that edges in the matching continue to stay in the equality subgraph. Edges in G (not in G_ℓ) that go from vertices in S to vertices in $\overline{T}$ are candidate edges to enter the equality subgraph, since one label is decreasing and the other is unchanged. The algorithm chooses δ to be the smallest value such that some edge of $G - G_\ell$ enters the equality subgraph. Suppose this edge goes from $x \in S$ to $y \in \overline{T}$. If y is free then an augmenting path has been found. On the other hand if y is matched, the Hungarian tree is grown by moving y to T and its matched neighbor to S and the process of revising labels is continued.

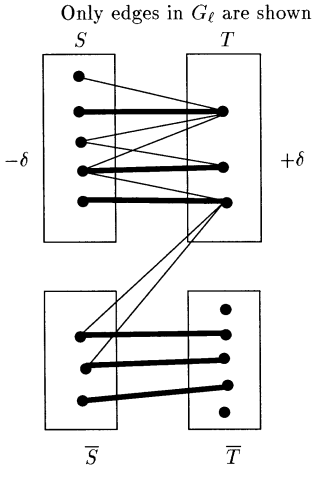

FIGURE 7.4 Sets S and T as maintained by the algorithm.

Weighted Edge-Cover Problem

There are many applications of weighted matchings. One useful application is the problem of finding a *minimum-weight edge cover* of a graph. Given a graph $G = (V, E)$ with weights on the edges, a set of edges $C \subseteq E$ forms an *edge cover* of G if every vertex in V is incident to at least one edge in C. The weight of the cover C is the sum of the weights of its edges. The objective is to find an edge cover C of minimum weight. The problem can be reduced to the minimum-weight perfect matching problem as follows: create an identical copy $G' = (V', E')$ of graph G, except the weights of edges in E' are all 0. Add an edge from each $v \in V$ to $v' \in V'$ with weight $w_{\min}(v) = \min_{x \in N(v)} w(v, x)$. The final graph H is the union of G and G', together with the edges connecting the two copies of each vertex; H contains $2|V|$ vertices and $2|E| + |V|$ edges. There exist other reductions from minimum-weight edge-cover to minimum-weight perfect matching; the reduction outlined above has the advantage that it creates a graph with $O(|V|)$ vertices and $O(|E|)$ edges. The minimum weight perfect matching problem may be solved using the techniques described earlier for the bipartite case, but the algorithm is more complex [22, 26].

THEOREM 7.4 *The weight of a minimum-weight perfect matching in H is equal to the weight of a minimum-weight edge cover in G.*

PROOF Consider a minimum-weight edge cover C in G. There is no loss of generality in assuming that a minimum-weight edge cover has no path of three edges, since the middle edge can be removed from the cover, thus, reducing its weight further. Hence, the edge cover C is a union of "stars" (trees of height 1). For each star that has a vertex of degree more than one, we can match one of the leaf nodes to its copy in G', with weight at most the weight of the edge incident on the leaf vertex, thus, reducing the degree of the star. We repeat this until each vertex has degree at most one in the edge cover, i.e., it is a matching. In H, select this matching, once in each copy of G. Observe that the cost of the matching within the second copy G' is 0. Thus, given C, we can find a perfect matching in H whose weight is no larger.

To argue the converse, we now show how to construct a cover C from a given perfect matching M in H. For each edge $(v, v') \in M$, add to C a least weight edge incident to v in G. Also include in C any edge of G that was matched in M. It can be verified that C is an edge cover whose weight equals the weight of M.

7.3 The Network Flow Problem

A number of polynomial time flow algorithms have been developed over the last two decades. The reader is referred to the books by Ahuja et al. [1] and Tarjan [29] for a detailed account of the historical development of the various flow methods. An excellent survey on network flow algorithms has been written by Goldberg et al. [13]. The book by Cormen et al. [5] describes the preflow push method, and to complement their coverage an implementation of the **blocking flow** technique of Malhotra et al. (see [26]) is discussed here.

Network Flow Problem Definitions

Flow network: A flow network $G = (V, E)$ is a directed graph with two specially marked nodes, namely, the source s, and the sink t. A *capacity* function $u : E \mapsto \Re^+$ maps edges to positive real numbers.
Max-flow problem: A flow function $f : E \mapsto \Re$ maps edges to real numbers. For an edge $e = (v, w)$, $f(v, w)$ refers to the flow on edge e, which is also called the net flow from vertex v to vertex w. This notation is extended to sets of vertices as follows: If X and Y are sets of vertices then $f(X, Y)$ is defined to be $\Sigma_{x \in X} \Sigma_{y \in Y} f(x, y)$. A flow function is required to satisfy the following constraints:

- (Capacity constraint) For all edges e, $f(e) \leq u(e)$.
- (Skew symmetry constraint) For an edge $e = (v, w)$, $f(v, w) = -f(w, v)$.
- (Flow conservation) For all vertices $v \in V - \{s, t\}$, $\Sigma_{w \in V} f(v, w) = 0$.

The capacity constraint states that the total flow on an edge does not exceed its capacity. The skew symmetry condition states that the flow on an edge is the negative of the flow in the reverse direction. The flow conservation constraint states that the total net flow out of any vertex other than the source and sink is zero.

The *value* of the flow is defined to be the net flow out of the source vertex:

$$|f| = \sum_{v \in V} f(s, v) \; .$$

In the *maximum flow problem* the objective is to find a flow function that satisfies the above three constraints, and also maximizes the total flow value $|f|$.

Remarks: This formulation of the network flow problem is powerful enough to capture generalizations where there are many sources and sinks (single commodity flow), and where both vertices and edges have

capacity constraints. To reduce multiple sources to a single source, we add a new source vertex with edges connecting it to the original source vertices. To reduce multiple sinks to a single sink, we add a new sink vertex with edges from the original sinks to the new sink. It is easy to reduce the vertex capacity problem to edge capacities by "splitting" a vertex into two vertices, and making all the incoming edges come into the first vertex and the outgoing edges come out of the second vertex. We then add an edge between them with the capacity of the corresponding vertex, so that the entire flow through the vertex is forced through this edge. The problem for undirected graphs can be solved by treating each undirected edge as two directed edges with the same capacity as the original undirected edge.

First the notion of cuts is defined, and then the max-flow min-cut theorem is introduced. We then introduce residual networks, layered networks and the concept of blocking flows. We then show how to reduce the max-flow problem to the computation of a sequence of blocking flows. Finally, an efficient algorithm for finding a blocking flow is described.

A *cut* is a partitioning of the vertex set into two subsets S and $V - S$. An edge *crosses* the cut if it connects a vertex $x \in S$ to a vertex $y \in V - S$. An s-t **cut** of the graph is a partitioning of the vertex set V into two sets S and $T = V - S$ such that $s \in S$ and $t \in T$. If f is a flow then the net flow across the cut is defined as $f(S, T)$. The capacity of the cut is defined as $u(S, T) = \Sigma_{x \in X} \Sigma_{y \in Y} u(x, y)$. The net flow across a cut may include negative net flows between vertices, but the capacity of the cut includes only non-negative values, i.e., only the capacities of edges from S to T. The net flow across a cut includes negative flows between vertices (flow from T to S), but the capacity of the cut includes only the capacities of edges from S to T.

Using the flow conservation principle, it can be shown that the net flow across an s-t cut is exactly the flow value $|f|$. By the capacity constraint, the flow across the cut cannot exceed the capacity of the cut. Thus, the value of the maximum flow is no greater than the capacity of a minimum s-t cut. The *max-flow min-cut theorem* states that the two quantities are actually equal. In other words, if f^* is a maximum flow, then there is some cut $(X, \overline{X})$ with $s \in X$ and $t \in \overline{X}$, such that $|f^*| = u(X, \overline{X})$. The reader is referred to [5, 29] for further details.

The *residual capacity* of an edge (v, w) with respect to a flow f is defined as follows:

$$u'(v, w) = u(v, w) - f(v, w) .$$

The quantity $u'(v, w)$ is the number of additional units of flow that can be pushed from v to w without violating the capacity constraints. An edge e is *saturated* if $u(e) = f(e)$, i.e., if its residual capacity $u'(e) = 0$. The residual graph, $G_R(f)$, for a flow f, is the graph with vertex set V, source and sink s and t, respectively, and those edges (v, w) for which $u'(v, w) > 0$. Figure 7.5 shows a network on the left with a given flow function. Each edge is labeled with two values: the flow through that edge and its capacity. The figure on the right depicts the residual network corresponding to this flow.

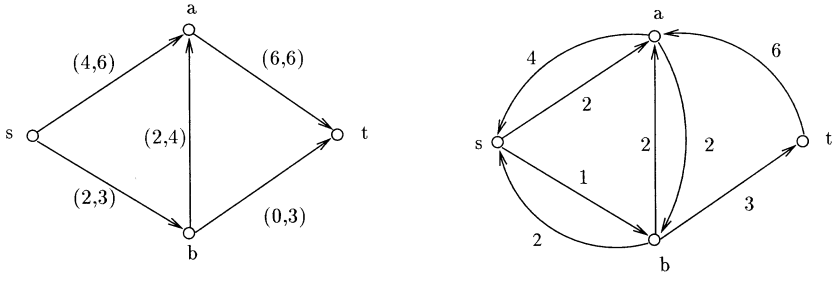

FIGURE 7.5 A network with a given flow function, and its residual network. A label of (f, c) for an edge indicates a flow of f and capacity of c.

An *augmenting path* for f is a path P from s to t in $G_R(f)$. The residual capacity of P, denoted by $u'(P)$, is the minimum value of $u'(v, w)$ over all edges (v, w) in the path P. The flow can be increased by $u'(P)$, by increasing the flow on each edge of P by this amount. Whenever $f(v, w)$ is changed, $f(w, v)$ is also correspondingly changed to maintain skew symmetry.

Most flow algorithms are based on the concept of augmenting paths pioneered by Ford and Fulkerson [8]. They start with an initial zero flow and augment the flow in stages. In each stage, a residual graph $G_R(f)$ with respect to the current flow function f is constructed, and an augmenting path in $G_R(f)$ is found, thus, increasing the value of the flow. Flow is increased along this path until an edge in this path is saturated. The algorithms iteratively keep increasing the flow until there are no more augmenting paths in $G_R(f)$, and return the final flow f as their output. Edmonds and Karp [6] suggested two possible improvements to this algorithm to make it run in polynomial time. The first was to choose shortest possible augmenting paths, where the length of the path is simply the number of edges on the path. This method can be improved using the approach due to Dinitz (see [29]) in which a sequence of blocking flows is found. The second strategy was to select a path which can be used to push the maximum amount of flow. The number of iterations of this method is bounded by $O(|E| \log C)$ where C is the largest edge capacity. In each iteration, we need to find a path on which we can push the maximum amount of flow. This can be done by suitably modifying Dijkstra's algorithm (Chapter 6).

The following lemma is fundamental in understanding the basic strategy behind these algorithms.

LEMMA 7.2 Let f be a flow and f^* be a maximum flow in G. The value of a maximum flow in the residual graph $G_R(f)$ is $|f^*| - |f|$.

PROOF Let f' be any flow in $G_R(f)$. Define $f + f'$ to be the flow $f(v, w) + f'(v, w)$ for each edge (v, w). Observe that $f + f'$ is a feasible flow in G of value $|f| + |f'|$. Since f^* is the maximum flow possible in G, $|f'| \leq |f^*| - |f|$. Similarly define $f^* - f$ to be a flow in $G_R(f)$ defined by $f^*(v, w) - f(v, w)$ in each edge (v, w), and this is a feasible flow in $G_R(f)$ of value $|f^*| - |f|$, and it is a maximum flow in $G_R(f)$.

Blocking Flow: A flow f is a *blocking flow* if every path from s to t in G contains a saturated edge. Blocking flows are also known as maximal flows. Figure 7.6 depicts a blocking flow. Any path from s to t contains at least one saturated edge. For example, in the path $[s, a, t]$, the edge (a, t) is saturated. It is important to note that a blocking flow is not necessarily a maximum flow. There may be augmenting paths that increase the flow on some edges and decrease the flow on other edges (by increasing the flow in the reverse direction). The example in Fig. 7.6 contains an augmenting path $[s, a, b, t]$, which can be used to increase the flow by 3 units.

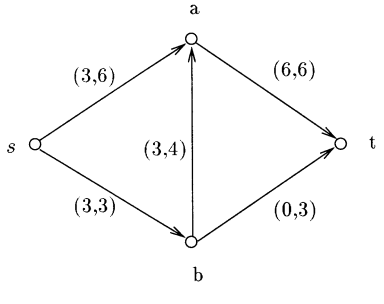

FIGURE 7.6 Example of blocking flow — all paths from s to t are saturated. A label of (f, c) for an edge indicates a flow of f and capacity of c.

Layered Networks: Let $G_R(f)$ be the residual graph with respect to a flow f. The level of a vertex v is the length of a shortest path from s to v in $G_R(f)$. The level graph L for f is the subgraph of $G_R(f)$ containing vertices reachable from s and only the edges (v, w) such that $level(w) = 1 + level(v)$. L contains all shortest length augmenting paths and can be constructed in $O(|E|)$ time.

The maximum flow algorithm proposed by Dinitz starts with the zero flow, and iteratively increases the flow by augmenting it with a blocking flow in $G_R(f)$ until t is not reachable from s in $G_R(f)$. At each step the current flow is replaced by the sum of the current flow and the blocking flow. This algorithm terminates in $|V| - 1$ iterations, since in each iteration the shortest distance from s to t in the residual graph increases. The shortest path from s to t is at most $|V| - 1$, and this gives an upper bound on the number of iterations of the algorithm.

An algorithm to find a blocking flow that runs in $O(|V|^2)$ time is described here (see [26] for details), and this yields an $O(|V|^3)$ max-flow algorithm. There are a number of $O(|V|^2)$ blocking flow algorithms available, some of which are described in [29].

Blocking Flows

Dinitz's algorithm finds a blocking flow as follows. The main step is to find paths from the source to the sink and push as much flow as possible on each path, and thus, saturate an edge in each path. It takes $O(|V|)$ time to compute the amount of flow that can be pushed on a path. Since there are $|E|$ edges, this yields an upper bound of $O(|V||E|)$ steps on the running time of the algorithm. The following algorithm shows how to find a blocking flow more efficiently.

Malhotra–Kumar–Maheshwari Blocking Flow Algorithm: The algorithm has a current flow function f and its corresponding residual graph $G_R(f)$. Define for each node $v \in G_R(f)$, a quantity $tp[v]$ that specifies its maximum throughput, i.e., either the sum of the capacities of the incoming arcs or the sum of the capacities of the outgoing arcs, whichever is smaller. The quantity $tp[v]$ represents the maximum flow that could pass through v in any feasible blocking flow in the residual graph. Vertices with zero throughput are deleted from $G_R(f)$.

The algorithm selects a vertex x with least throughput. It then greedily pushes a flow of $tp[x]$ from x toward t, level by level in the layered residual graph. This can be done by creating a queue which initially contains x, which is assigned the task of pushing $tp[x]$ out of it. In each step, the vertex v at the front of the queue is removed, and the arcs going out of v are scanned one at a time, and as much flow as possible is pushed out of them until v's allocated flow has been pushed out. For each arc (v, w) that the algorithm pushed flow through, it updates the residual capacity of the arc (v, w) and places w on a queue (if it is not already there) and increments the net incoming flow into w. Also $tp[v]$ is reduced by the amount of flow that was sent through it now. The flow finally reaches t, and the algorithm never comes across a vertex that has incoming flow that exceeds its outgoing capacity since x was chosen as a vertex with least throughput. The above idea is repeated to pull a flow of $tp[x]$ from the source s to x. Combining the two steps yields a flow of $tp[x]$ from s to t in the residual network that goes through x. The flow f is augmented by this amount. Vertex x is deleted from the residual graph, along with any other vertices that have zero throughput.

The above procedure is repeated until all vertices are deleted from the residual graph. The algorithm has a blocking flow at this stage since at least one vertex is saturated in every path from s to t. In the above algorithm, whenever an edge is saturated it may be deleted from the residual graph. Since the algorithm uses a greedy strategy to pump flows, at most $O(|E|)$ time is spent when an edge is saturated. When finding flow paths to push $tp[x]$, there are at most $|V|$ times (once for each vertex) when the algorithm pushes a flow that does not saturate the corresponding edge. After this step, x is deleted from the residual graph. Hence, the above algorithm to compute blocking flows terminates in $O(|E| + |V|^2) = O(|V|^2)$ steps.

Karzanov (see [29]) used the concept of preflows to develop an $O(|V|^2)$ time algorithm for developing blocking flows as well. This method was then adapted by Goldberg and Tarjan (see [5]), who proposed

a preflow-push method for computing a maximum flow in a network. A preflow is a flow that satisfies the capacity constraints, but not flow conservation. Any node in the network is allowed to have more flow coming into it than there is flowing out. The algorithm tries to move the excess flows towards the sinks without violating capacity constraints. The algorithm finally terminates with a feasible flow that is a max-flow. It finds a max-flow in $O(|V||E| \log \frac{|V|^2}{|E|})$ time.

7.4 The Min-Cut Problem

Two problems are studied in this section. The first is the s-t min-cut problem: given a directed graph with capacities on the edges and two special vertices s and t, the problem is to find a cut of minimum capacity that separates s from t. The value of a min-cut's capacity can be computed by finding the value of the maximum flow from s to t in the network. Recall that the max-flow min-cut theorem shows that the two quantities are equal. We now show how to find the sets S and T that provides an s-t min-cut from a given s-t max-flow.

The second problem is to find a smallest cut in a given graph G. In this problem on undirected graphs, the vertex set must be partitioned into two sets such that the total weight of the edges crossing the cut is minimized. This problem can be solved by enumerating over all $\{s, t\}$ pairs of vertices, and finding a s-t min-cut for each pair. This procedure is rather inefficient. However, Hao and Orlin [15] showed that this problem can be solved in the same order of running time as taken by a single max-flow computation. Stoer and Wagner [27] have given a simple and elegant algorithm for computing minimum cuts based on a technique due to Nagamochi and Ibaraki [25]. Recently, Karger [19] has given a randomized algorithm that runs in almost linear time for computing minimum cuts without using network-flow methods.

Finding an s-t Min-Cut

Let f^* be a maximum flow from s to t in the graph. Recall that $G_R(f^*)$ is the residual graph corresponding to f^*. Let S be the set of all vertices that are reachable from s in $G_R(f^*)$, i.e., vertices to which s has a directed path. Let T be all the remaining vertices of G. By definition $s \in S$. Since f^* is a max-flow from s to t, $t \in T$. Otherwise the flow can be increased by pushing flow along this path from s to t in $G_R(f^*)$. All the edges from vertices in S to vertices in T are saturated and form a minimum cut.

Finding All-Pair Min-Cuts

For an undirected graph G with $|V|$ vertices, Gomory and Hu (see [1]) showed that the flow values between each of the $|V|(|V|-1)/2$ pairs of vertices of G can be computed by solving only $|V|-1$ max-flow computations. Furthermore, they showed that the flow values can be represented by a weighted tree T on $|V|$ nodes. Each node in the tree represents one of the vertices of the given graph. For any pair of nodes (x, y), the maximum flow value from x to y (and hence, the x-y min-cut) in G is equal to the weight of the minimum-weight edge on the unique path in T between x and y.

Applications of Network Flows (and Min Cuts)

There are numerous applications of the maximum flow algorithm in scheduling problems of various kinds. It is used in open-pit mining, vehicle routing, etc. See [1] for further details.

Finding a minimum-weight vertex cover in bipartite graphs: A *vertex cover* of a graph is a set of vertices that is incident to all its edges. The weight of a vertex cover is the sum of the weights of its vertices. Finding a vertex cover of minimum weight is NP-hard for arbitrary graphs (see Section 7.9 for more details). For bipartite graphs, the problem is solvable efficiently using the maximum flow algorithm.

Given a bipartite graph $G = (X, Y, E)$ with weights on the vertices, we need to find a subset C of

vertices of minimum total weight, so that for each edge, at least one of its end vertices is in C. The weight of a vertex v is denoted by $w(v)$. Construct a flow network N from G as follows: add a new source vertex s, and for each $x \in X$, add a directed edge (s, x), with capacity $w(x)$. Add a new sink vertex t, and for each $y \in Y$, add a directed edge (y, t), with capacity $w(y)$. The edges in E are given infinite capacity and they are oriented from X to Y. Let C be a subset of vertices in G. We use the notation X_C to denote $X \cap C$ and Y_C to denote $Y \cap C$. Let $\overline{X_C} = X - X_C$ and $\overline{Y_C} = Y - Y_C$.

If C is a vertex cover of G, then there are no edges in G connecting $\overline{X_C}$ and $\overline{Y_C}$, since such edges would not be incident to C. A cut in the flow network N, whose capacity is the same as the weight of the vertex cover can be constructed as follows: $S = \{s\} \cup \overline{X_C} \cup Y_C$ and $T = \{t\} \cup X_C \cup \overline{Y_C}$. Each vertex cover of G gives rise to a cut of same weight. Similarly, any cut of finite capacity in N corresponds to a vertex cover of G of same weight. Hence, the minimum-weight s-t cut of N corresponds to a minimum-weight vertex cover of G.

Maximum-weight closed subset in a partial order: Consider a *directed acyclic graph* (DAG) $G = (V, E)$. Each vertex v of G is given a weight $w(v)$, that may be positive or negative. A subset of vertices $S \subseteq V$ is said to be *closed* in G if for every $s \in S$, the predecessors of s are also in S. The predecessors of a vertex s are vertices that have directed paths to s. We are interested in computing a closed subset S of maximum weight. This problem occurs for example in open-pit mining, and it can be solved efficiently by reducing it to computing the minimum cut in the following network N:

- The vertex set of $N = V \cup \{s, t\}$, where s and t are two new vertices.
- For each vertex v of negative weight, add the edge (s, v) with capacity $|w(v)|$ to N.
- For each vertex v of positive weight, add the edge (v, t) with capacity $w(v)$ to N.
- All edges of G are added to N, and each of these edges has infinite capacity.

Consider a minimum s-t cut in N. Let S be the positive weight vertices whose edges to the sink t are not in the min-cut. It can be shown that the union of the set S and its predecessors is a maximum-weight closed subset.

7.5 Minimum-Cost Flows

We now study one of the most important problems in combinatorial optimization, namely the minimum cost network flow problem.

We will outline some of the basic ideas behind the problem, and the reader can find a wealth of information in [1] about efficient algorithms for this problem.

The min-cost flow problem can be viewed as a generalization of the max-flow problem, the shortest path problem and the minimum weight perfect matching problem. To reduce the shortest path problem to the min-cost flow problem, notice that if we have to ship one unit of flow, we will ship it on the shortest path. We reduce the minimum weight perfect matching problem on a bipartite graph $G = (X, Y, X \times Y)$, to min-cost flow as follows. Introduce a special source s and sink t, and add unit capacity edges from s to vertices in X, and from vertices in Y to t. Compute a flow of value $|X|$ to obtain a minimum weight perfect matching.

Min-Cost Flow Problem Definitions

The flow network $G = (V, E)$ is a directed graph. There is a *capacity* function $u : E \mapsto \Re^+$ that maps edges to positive real numbers and a cost function $c : E \rightarrow R$. The cost function specifies the cost of shipping one unit of flow through the edge. Associated with each vertex v, there is a supply $b(v)$. If $b(v) > 0$ then v is a supply node, and if $b(v) < 0$ then it is a demand node. It is assumed that $\Sigma_{v \in V} b(v) = 0$; if the supply exceeds the demand we can add an artificial sink to absorb the excess flow.

A flow function is required to satisfy the following constraints:

- (Capacity Constraint) For all edges e, $f(e) \leq u(e)$.
- (Skew Symmetry Constraint) For an edge $e = (v, w)$, $f(v, w) = -f(w, v)$.
- (Flow Conservation) For all vertices $v \in V$, $\Sigma_{w \in V} f(v, w) = b(v)$.

We wish to find a flow function that minimizes the cost of the flow.

$$\min z(f) = \sum_{e \in E} c(e) \cdot f(e) .$$

Our algorithm again uses the concept of residual networks. As before, the residual network $G_R(f)$ is defined with respect to a specific flow function. The only difference is the following: if there is a flow $f(v, w)$ on edge $e = (v, w)$ then as before, its capacity in the residual network is $u(e) - f(e)$ and its residual cost is $c(e)$. The reverse edge (w, v) has residual capacity $f(e)$, but its residual cost is $-c(e)$. Note that sending a unit of flow on the reverse edge actually reduces the original amount of flow that was sent, and hence, the residual cost is negative. As before, only edges with strictly positive residual capacity are retained in the residual network.

Before studying any specific algorithm to solve the problem, we note that we can always find a feasible solution (not necessarily optimal), if one exists, by finding a max-flow, and ignoring costs. To see this, add two new vertices, a source vertex s and a sink vertex t. Add edges from s to all vertices v with $b(v) > 0$ of capacity $b(v)$, and edges from all vertices w with $b(w) < 0$ to t of capacity $|b(w)|$. Find a max-flow of value $\Sigma_{b(v)>0} b(v)$. If such flow does not exist then the flow problem is not feasible.

The following theorem characterizes optimal solutions.

THEOREM 7.5 *A feasible solution f is an optimal solution if and only if the residual network $G_R(f)$ has no directed cycles of negative cost.*

We use the above theorem to develop an algorithm for finding a min-cost flow. As indicated earlier, a feasible flow can be found by the techniques developed in the previous section. To improve the cost of the solution, we identify negative-cost cycles in the residual graph and push as much flow around them as possible and reduce the cost of the flow. We repeat this until there are no negative cycles left, and we have found a min-cost flow. A negative-cost cycle may be found by using an algorithm like the Bellman–Ford algorithm (Chapter 6), which takes $O(|E||V|)$ time.

An important issue that affects the running time of the algorithm is the choice of a negative cost cycle. For fast convergence, one should select a cycle that decreases the cost as much as possible, but finding such a cycle in NP-hard. Goldberg and Tarjan [12] showed that selecting a cycle with minimum mean-cost (the ratio of the cost of cycle to the number of arcs on the cycle) yields a polynomial time algorithm. There is a parametric search algorithm [1] to find a min-mean cycle that works as follows. Let μ^* be the average edge-weight of a min-mean cycle. Then μ^* is the largest value such that reducing the weight of every edge by μ^* does not introduce a negative-weight cycle into the graph. One can search for the value of μ^* using binary search: given a guess μ, decrease the weight of each edge by μ and test if the graph has no negative weight cycles. If the smallest cycle has zero weight, it is a min-mean cycle. If all cycles are positive, we have to increase our guess μ. If the graph has a negative weight cycle, we need to decrease our guess μ. Karp (see [1]) has given an algorithm based on dynamic programming for this problem that runs in $O(|E||V|)$ time.

The first polynomial-time algorithm for the min-cost flow problem was given by Edmonds and Karp [6]. Their idea is based on scaling capacities and the running time of their algorithm is $O(|E| \log U(|E| + |V| \log |V|))$, where U is the largest capacity. The first strongly polynomial algorithm (whose running time is only a function of $|E|$ and $|V|$) for the problem was given by Tardos [28].

7.6 The Multi-Commodity Flow Problem

A natural generalization of the max-flow problem is the **multi-commodity flow** problem. In this problem, there are a number of commodities $1, 2, \ldots, k$ that have to be shipped through a flow network from source vertices $s_1, s_2, \ldots, s_k$ to sink vertices $t_1, t_2, \ldots, t_k$, respectively. The amount of demand for commodity i is specified by d_i. Each edge and each vertex has a nonnegative capacity that specifies the total maximum flow of all commodities flowing through that edge or vertex. A flow is *feasible* if all the demands are routed from their respective sources to their respective sinks while satisfying flow conservation constraints at the nodes and capacity constraints on the edges and vertices. A flow is an ϵ*-feasible* flow for a positive real number ϵ if it satisfies $\frac{d_i}{1+\epsilon}$ of demand i. There are several variations of this problem as noted below:

In the simplest version of the *multi-commodity flow problem,* the goal is to decide if there exists a feasible flow that routes all the demands of the k commodities through the network. The flow corresponding to each commodity is allowed to be split arbitrarily (i.e., even fractionally) and routed through multiple paths. The **concurrent flow** problem is identical to the multi-commodity flow problem when the input instance has a feasible flow that satisfies all the demands. If the input instance is not feasible, then the objective is to find the smallest fraction ϵ for which there is an ϵ-feasible flow. In the *minimum-cost multi-commodity flow problem,* each edge has an associated cost for each unit of flow through it. The objective is to find a minimum-cost solution for routing all the demands through the network. All of the above problems can be formulated as linear programs, and therefore have polynomial-time algorithms using either the ellipsoid algorithm or the interior point method [20].

A lot of research has been done on finding approximately optimal multicommodity flows using more efficient algorithms. There are a number of papers that provide approximation algorithms for the multi-commodity flow problem. For a detailed survey of these results see [16, Chapter 5].

In this section, we will discuss a recent paper that introduced a new algorithm for solving multi-commodity flow problems. Awerbuch and Leighton [2] gave a simple and elegant algorithm for the concurrent flow problem. Their algorithm is based on the "liquid-flow paradigm." Flow is pushed from the sources on edges based on the "pressure difference" between the end vertices. The algorithm does not use any global properties of the graph (such as shortest paths) and uses only local changes based on the current flow. Due to its nature, the algorithm can be implemented to run in a distributed network since all decisions made by the algorithm are local in nature. They extended their algorithms to dynamic networks, where edge capacities are allowed to vary [3]. The best implementation of this algorithm runs in $O(k|V|^2|E|\epsilon^{-3}\ln^3(|E|/\epsilon))$ time.

In the *integer multi-commodity flow* problem, the capacities and flows are restricted to be integers. Unlike the single-commodity flow problem, for problems with integral capacities and demands, the existence of a feasible fractional solution to the multi-commodity flow problem does not guarantee a feasible integral solution. An extra constraint that may be imposed on this problem is to restrict each commodity to be sent along a single path. In other words, this constraint does not allow one to split the demand of a commodity into smaller parts and route them along independent paths (see the recent paper by Kleinberg [21] for approximation algorithms for this problem). Such constraints are common in problems that arise in telecommunication systems. All variations of the **integer multi-commodity flow** problem are NP-hard.

Local Control Algorithm

In this section, we describe Awerbuch and Leighton's local control algorithm that finds an approximate solution for the concurrent flow problem.

First, the problem is converted to the *continuous flow* problem. In this version of the problem, d_i units of commodity i is added to the source vertex s_i in each phase. Each vertex has queues to store the commodities that arrive at that node. The node tries to push the commodities stored in the queues towards the sink nodes. As the commodities arrive at the sinks, they are removed from the network. A continuous flow problem is *stable* if the total amount of all the commodities in the network at any point in time is

bounded (i.e., independent of the number of phases completed). The following theorem establishes a tight relationship between the multi-commodity flow problem (also known as the *static* problem) and its continuous version.

THEOREM 7.6 *A stable algorithm for the continuous flow problem can be used to generate an ϵ-feasible solution for the static concurrent flow problem.*

PROOF Let R be the number of phases of the stable algorithm for the continuous flow problem at which $\frac{1}{1+\epsilon}$ fraction of each of the commodities that have been injected into the network have been routed to their sinks. We know that R exists since the algorithm is stable. The average behavior of the continuous flow problem in these R phases generates an ϵ-feasible flow for the static problem. In other words, the flow of a commodity through a given edge is the average flow of that commodity through that edge over R iterations, and this flow is ϵ-feasible.

In order to get an approximation algorithm using the fluid-flow paradigm, there are two important challenges. First, it must be shown that the algorithm is stable, i.e., that the queue sizes are bounded. Second, the number of phases that it takes the algorithm to reach "steady state" (specified by R in the above theorem) must be minimized. Note that the running time of the approximation algorithm is R times the time it takes to run one phase of the continuous flow algorithm.

Each vertex v maintains one queue per commodity for each edge to which it is incident. Initially all the queues are empty. In each phase of the algorithm, commodities are added at the source nodes. The algorithm works in four steps:

1. Add $(1+\epsilon)d_i$ units of commodity i at s_i. The commodity is spread equally to all the queues at that vertex.
2. Push the flow across each edge so as to balance the queues as much as possible. If Δ_i is the discrepancy of commodity i in the queues at either end of edge e, then the flow f_i crossing the edge in that step is chosen so as to maximize $\Sigma_i f_i(\Delta_i - f_i)/d_i^2$ without exceeding the capacity constraints.
3. Remove the commodities that have reached their sinks.
4. Balance the amount of each commodity in each of the queues at each vertex.

The above 4 steps are repeated until $\frac{1}{1+\epsilon}$ fraction of the commodities that have been injected into the system have reached their destination.

It can be shown that the algorithm is stable and the number of phases is $O(|E|^2 k^{1.5} L\epsilon^{-3})$, where $|E|$ is the number of edges, k is the number of commodities, and $L \leq |V|$ is the maximum path length of any flow. The proof of stability and the bound on the number of rounds are not included here. The actual algorithm has a few other technical details that are not mentioned here, and the reader is referred to the original paper for further details [2].

7.7 Minimum Weight Branchings

A natural analog of a spanning tree in a directed graph is a *branching* (also called an *arborescence*). For a directed graph G and a vertex r, a branching rooted at r is an acyclic subgraph of G in which each vertex but r has exactly one outgoing edge, and there is a directed path from any vertex to r. This is also sometimes called an *in-branching*. By replacing "outgoing" in the above definition of a branching to "incoming," we get an *out-branching*. An *optimal branching* of an edge-weighted graph is a branching of minimum total weight. Unlike the minimum spanning tree problem, an optimal branching cannot be

computed using a greedy algorithm. Edmonds gave the first polynomial time algorithm to find optimal branchings (see [11]).

Let $G = (V, E)$ be an arbitrary graph, let r be the root of G, and let $w(e)$ be the weight of edge e. Consider the problem of computing an optimal branching rooted at r. In the following discussion, assume that all edges of the graph have a nonnegative weight.

Two key ideas are discussed below that can be converted into a polynomial time algorithm for computing optimal branchings. First, for any vertex $v \neq r$ in G, suppose that all outgoing edges of v are of positive weight. Let $\epsilon > 0$ be a number that is less than or equal to the weight of any outgoing edge from v. Suppose the weight of every outgoing edge from v is decreased by ϵ. Observe that since any branching has exactly one edge out of v, its weight decreases by exactly ϵ. Therefore an optimal branching of G with the original weights is also an optimal branching of G with the new weights. In other words, decreasing the weight of the outgoing edges of a vertex uniformly, leaves optimal branchings invariant. Second, suppose there is a cycle C in G consisting only of edges of zero weight. Suppose the vertices of C are combined into a single vertex, and the resulting multigraph is made into a simple graph by replacing each multiple edge by a single edge whose weight is the smallest among them, and discarding self loops. Let G_C be the resulting graph. It can be shown that the weights of optimal branchings of G and G_C are the same. An optimal branching of G_C can also be converted into an optimal branching of G by adding sufficiently many edges from C without introducing cycles. The above two ideas can be used to design a recursive algorithm for finding an optimal branching. The fastest implementation of a branching algorithm is due to Gabow et al. [9].

7.8 Coloring Problems

Vertex Coloring

A **vertex coloring** of a graph G is a coloring of the vertices of G such that no two adjacent vertices of G receive the same color. The objective of the problem is to find a coloring that uses as few colors as possible. The minimum number of colors needed to color the vertices of a graph is known as its **chromatic number.** The register allocation problem in compiler design and the map coloring problem are instances of the vertex coloring problem.

The problem of deciding if the chromatic number of a given graph is at most a given integer k is NP-complete. The problem is NP-complete even for fixed $k \geq 3$. For $k = 2$, the problem is to decide if the given graph is bipartite, and this can be solved in linear time using depth-first or breadth-first search. The vertex coloring problem in general graphs is a notoriously hard problem and it has been shown to be intractable even for approximating within a factor of n^{ϵ} for some constant $\epsilon > 0$ [16, Chapter 10]. A greedy coloring of a graph yields a coloring that uses at most $\Delta + 1$ colors, where Δ is the maximal degree of the graph. Unless the graph is an odd cycle or the complete graph, it can be colored with Δ colors (known as Brooks theorem) [11]. A celebrated result on graph coloring is that every planar graph is 4-colorable. However, checking if a planar graph is 3-colorable is NP-complete [10]. For more information on recent results on approximating the chromatic number, see [18].

Edge Coloring

The **edge coloring** problem is similar to the vertex coloring problem. In this problem, the goal is to color the edges of a given graph using the fewest colors such that no two edges incident to a common vertex are assigned the same color. The problem finds applications in assigning classroom to courses and in scheduling problems. The minimum number of colors needed to color a graph is known as its **chromatic index.** Since any two incident edges must receive distinct colors, the chromatic index of a graph with maximal degree Δ is at least Δ. In a remarkable theorem, Vizing (see [11]) has shown that every graph can be edge-colored using at most $\Delta + 1$ colors. Deciding whether the edges of a given graph can be colored

using Δ colors is NP-complete (see [16]). Special classes of graphs such as bipartite graphs and planar graphs of large maximal degree are known to be Δ-edge-colorable.

7.9 Approximation Algorithms for Hard Problems

Many graph problems are known to be NP-complete (see Sections A.1 and A.2 of [10]). The area of approximation algorithms explores intractable (NP-hard) optimization problems and tries to obtain polynomial-time algorithms that generate feasible solutions that are close to optimal. In this section, a few fundamental NP-hard optimization problems in graphs that can be approximated well are discussed. For more information about approximating these and other problems, see the chapter on approximation algorithms (Chapter 34) and a book on approximation algorithms edited by Hochbaum [16].

In the following discussion $G = (V, E)$ is an arbitrary undirected graph and k is a positive integer.

Vertex cover: a set of vertices $S \subset V$ such that every edge in E is incident to at least one vertex of S. The minimum vertex cover problem is that of computing a vertex cover of minimum cardinality. If the vertices of G have weights associated with them, a minimum-weight vertex cover is a vertex cover of minimum total weight. Using the primal-dual method of linear programming, one can obtain a 2-approximation.

Dominating set: a set of vertices $S \subset V$ such that every vertex in the graph is either in S or adjacent to some vertex in S. There are several versions of this problem such as the total dominating set (every vertex in G must have a neighbor in S, irrespective of whether it is in S or not), the connected dominating set (induced graph of S must be connected) and the independent dominating set (induced graph of S must be empty). The minimum dominating set problem is to compute a minimum cardinality dominating set. The problems can be generalized to the weighted case suitably. All but the independent dominating set problem can be approximated within a factor of $O(\log n)$.

Steiner tree problem: a tree of minimum total weight that connects a set of terminal vertices S in a graph $G = (V, E)$. There is a 2-approximation algorithm for the general problem. There are better algorithms when the graph is defined in Euclidean space. For more information, see [16, 17].

Minimum k-connected graph: a graph G is k-vertex-connected, or simply *k-connected,* if the removal of up to $k - 1$ vertices, along with their incident edges leaves the remaining graph connected. It is *k-edge-connected* if the removal of up to $k - 1$ edges does not disconnect the graph. In the minimum k-connected graph problem, we need to compute a k-connected spanning subgraph of G of minimum cardinality. The problem can be posed in the context of vertex or edge connectivities, and with edge weights. The edge-connectivity problems can be approximated within a factor of 2 from optimal, and a factor smaller than 2 when the edges do not have weights. The unweighted k-vertex-connected subgraph problem can be approximated within a factor of $1 + 2/k$, and the corresponding weighted problem can be approximated within a factor of $O(\log k)$. When the edges satisfy the triangle inequality, the vertex connectivity problem can be approximated within a factor of about $2 + 2/k$. These problems find applications in fault-tolerant network-design. For more information on approximation algorithms for connectivity problems, see [16, Chapter 6].

Degree constrained spanning tree: a spanning tree of maximal degree k. This problem is a generalization of the traveling salesman path problem. There is a polynomial time approximation algorithm that returns a spanning tree of maximal degree at most $k + 1$ if G has a spanning tree of degree k.

Max-cut: a partition of the vertex set into (V_1, V_2) such that the number of edges in $E \cap (V_1 \times V_2)$ (edges between a vertex in V_1 and a vertex in V_2) is maximized. It is easy to compute a partition in which at least half the edges of the graph cross the cut. This is a 2-approximation. Semi-definite programming techniques can be used to derive an approximation algorithm with a performance guarantee of about 1.15.

7.10 Research Issues and Summary

Some of the recent research efforts in graph algorithms have been in the areas of dynamic algorithms, graph layout and drawing, and approximation algorithms. Detailed references about these areas may be found in Chapter 8, Chapter 9, and Chapter 34, respectively. Many of the methods illustrated in our chapter find use in the solution of almost any optimization problem. For approximation algorithms see the edited book by Hochbaum [16], and more information in the area of graph layout and drawing can be found in an annotated bibliography by Di Battista et al. [4].

A recent exciting result of Karger's [19] is a randomized near-linear time algorithm for computing minimum cuts. Finding a deterministic algorithm with similar bounds is a major open problem.

Computing a maximum flow in $O(|E||V|)$ time in general graphs is still open. Several recent algorithms achieve these bounds for certain graph densities. A recent result by Goldberg and Rao [14] breaks this barrier, by paying an extra $\log U$ factor in the running time, when the edge capacities are in the range $[1 \ldots U]$. Finding a maximum matching in time better than $O(|E|\sqrt{|V|})$ or obtaining non trivial lower bounds are open problems.

7.11 Defining Terms

Assignment problem: The problem of finding a matching of maximum (or minimum) weight in an edge-weighted graph.

Augmenting path: A path used to augment (increase) the size of a matching or a flow.

Blocking flow: A flow function in which any directed path from s to t contains a saturated edge.

Blossoms: Odd length cycles that appear during the course of the matching algorithm on general graphs.

Branching: A spanning tree in a rooted graph, such that each vertex has a path to the root (also known as in-branching). An out-branching is a rooted spanning tree in which the root has a path to every vertex in the graph.

Capacity: The maximum amount of flow that is allowed to be sent through an edge or a vertex.

Chromatic index: The minimum number of colors with which the edges of a graph can be colored.

Chromatic number: The minimum number of colors needed to color the vertices of a graph.

Concurrent flow: A multi-commodity flow in which the same fraction of the demand of each commodity is satisfied.

Edge coloring: An assignment of colors to the edges of a graph such that no two edges incident to a common vertex receive the same color.

Integer multi-commodity flow: A multi-commodity flow in which the flow through each edge of each commodity is an integral value. The term is also used to capture the multi-commodity flow problem in which each demand is routed along a single path.

Matching: A subgraph in which every vertex has degree at most one.

Maximum flow: The maximum amount of feasible flow that can be sent from a source vertex to a sink vertex in a given network.

Multi-commodity flow: A network flow problem involving multiple commodities, in which each commodity has an associated demand and source-sink pairs.

Network flow: An assignment of flow values to the edges of a graph that satisfies flow conservation, skew symmetry and capacity constraints.

***s*-*t* cut:** A partitioning of the vertex set into S and T such that $s \in S$ and $t \in T$.

Vertex coloring: An assignment of colors to the vertices of a graph such that no two adjacent vertices receive the same color.

Further Information

The area of graph algorithms continues to be a very active field of research. There are several journals and conferences that discuss advances in the field. Here we name a partial list of some of the important meetings: "ACM Symposium on Theory of Computing (STOC)," "IEEE Conference on Foundations of Computer Science (FOCS)," "ACM-SIAM Symposium on Discrete Algorithms (SODA)," "International Colloquium on Automata, Languages and Programming (ICALP)," and the "European Symposium on Algorithms (ESA)." There are many other regional algorithms/theory conferences that carry research papers on graph algorithms. The journals that carry articles on current research in graph algorithms are *Journal of the ACM, SIAM Journal on Computing, SIAM Journal on Discrete Mathematics, Journal of Algorithms, Algorithmica, Journal of Computer and System Sciences, Information and Computation, Information Processing Letters,* and *Theoretical Computer Science.*

To find more details about some of the graph algorithms described in this chapter we refer the reader to the books by Cormen, Leiserson and Rivest [5], Even [7], Gibbons [11], and Tarjan [29]. Ahuja et al. [1] have provided a comprehensive book on the network flow problem. The survey chapter by Goldberg et al. [13] provides an excellent survey of various min-cost flow and generalized flow algorithms. A detailed survey describing various approaches for solving the matching and flow problems can be found in Tarjan's book [29]. Papadimitriou and Steiglitz [26] discuss the solution of many combinatorial optimization problems using a primal-dual framework.

8.1 Introduction

In many applications of graph algorithms, including communication networks, graphics, assembly planning, and VLSI design, graphs are subject to discrete changes, such as additions or deletions of edges or vertices. In the last decade there has been a growing interest in such dynamically changing graphs, and a whole body of algorithms and data structures for dynamic graphs has been discovered. This chapter is intended as an overview of this field.

In a typical dynamic graph problem one would like to answer queries on graphs that are undergoing a sequence of updates, for instance, insertions and deletions of edges and vertices. The goal of a dynamic graph algorithm is to update efficiently the solution of a problem after dynamic changes, rather than having to recompute it from scratch each time. Given their powerful versatility, it is not surprising that dynamic algorithms and dynamic data structures are often more difficult to design and analyze than their static counterparts.

We can classify dynamic graph problems according to the types of updates allowed. A problem is said to be *fully dynamic* if the update operations include unrestricted insertions and deletions of edges. A problem is called *partially dynamic* if only one type of update, either insertions or deletions, is allowed. If only insertions are allowed, the problem is called *incremental*; if only deletions are allowed it is called *decremental*.

In this chapter, we focus our attention to dynamic algorithms for undirected graphs, which were studied more extensively than dynamic algorithms for directed graphs. Indeed, designing efficient fully dynamic data structures for directed graphs has turned out to be an extremely difficult task. Most of the efficient data structures available for directed graphs are partially dynamic [3, 27, 28, 33, 45], and only preliminary results are available for fully dynamic problems [22]. For this reason, an alternative viewpoint that has been

proposed is to measure the complexity of a dynamic algorithm as a function of the *output change* [15, 36]. The main dynamic problems considered on directed graphs include shortest paths and transitive closure. For lack of space, we do not include in this chapter dynamic algorithms for planar graphs, which have received considerable attention in recent years [4, 5, 9, 10, 11, 18, 19, 26, 30, 38, 40, 41, 42], and focus our attention to general undirected graphs only.

The remainder of the chapter is organized as follows. In Section 8.2 we give some preliminary definitions and a little terminology. Dynamic tree problems are considered in Section 8.3, while in Section 8.4 we describe partially dynamic algorithms for undirected graphs. Fully dynamic algorithms for undirected graphs are described in Section 8.5. Finally, in Section 8.6 we describe some open problems.

8.2 Preliminary Definitions

In this section, we recall some basic graph-theoretic terminology from Chapter 6. Given an undirected graph G, the *minimum spanning forest of G* is the subgraph of minimum total weight that has the same connected components as the original graph. Whenever G is connected, this forest consists of a unique tree, and we refer to this tree as a minimum spanning tree of G. Note that a minimum spanning forest, or a minimum spanning tree is not necessarily unique. It is well known that a minimum spanning forest can be computed by either of two dual greedy algorithms, based on the following properties:

> *Cut Property:* Add edges one at a time to the spanning forest until it spans the graph. At each step, find a cut in the graph that contains no edges of the current forest, and add the edge with lowest weight crossing the cut.
>
> *Cycle Property:* Remove edges one at a time from the graph until only a forest is left. At each step, find a cycle in the remaining graph and remove the edge with the highest weight in the cycle.

Given an undirected graph $G = (V, E)$, and an integer $k \geq 2$, a pair of vertices $\langle u, v \rangle$ is said to be *k-edge-connected* if the removal of any $(k-1)$ edges in G leaves u and v connected. This is an equivalence relationship, and we denote it by $\equiv_k$, i.e., if a pair of vertices $\langle x, y \rangle$ is k-edge-connected we write $x \equiv_k y$. The vertices of a graph G are partitioned by this relationship into equivalence classes called *k-edge-connected components.* G is said to be *k-edge-connected* if the removal of any $(k-1)$ edges leaves G connected. As a result of these definitions, G is k-edge-connected if and only any two vertices of G are k-edge-connected. An edge set $E' \subseteq E$ is an *edge-cut for vertices x and y* if the removal of all the edges in E' disconnects G into two graphs, one containing x and the other containing y. An edge set $E' \subseteq E$ is an *edge-cut for G* if the removal of all the edges in E' disconnects G into two graphs. An edge-cut E' for G [for x and y, respectively] is *minimal* if removing any edge from E' reconnects G [x and y, respectively]. The cardinality of an edge-cut E', denoted by $|E'|$, is given by the number of edges in E'. An edge-cut E' for G [for x and y, respectively] is said to be a *minimum cardinality edge-cut* or in short a *connectivity edge-cut* if there is no other edge-cut E'' for G [for x and y, respectively] such that $|E''| < |E'|$. Connectivity edge-cuts are of course minimal edge-cuts. Note that G is k-edge-connected if and only if a connectivity edge-cut for G contains at least k edges, and $x \equiv_k y$ if and only if a connectivity edge-cut for x and y contains at least k edges. A connectivity edge-cut of cardinality 1 is called a *bridge.*

8.3 Dynamic Problems on Trees

This section presents data structures that maintain properties of a dynamically changing forest of trees. The basic operations that we will consider are edge insertions and edge deletions. Many properties of dynamically changing trees have been considered in the literature. The basic property is tree membership: namely, while the forest of trees is dynamically changing, we would like to know at any time which tree

contains a given vertex, or whether two vertices are in the same tree. Dynamic tree membership is a special case of dynamic connectivity in undirected graphs, and indeed we will later use some of the data structures developed here for trees to solve the more general problem on graphs. The partially dynamic tree membership problem can be solved by means of the set union data structures described in Chapter 5. We will thus, focus on the fully dynamic tree membership problem. Other properties that have been considered are finding the parent of a vertex, or finding the least common ancestor of two vertices [39]. When costs are associated either to vertices or to edges, one could also ask what is the minimum (or maximum) cost in a given path.

The fully dynamic tree membership problem consists of maintaining a forest of unrooted trees under insertion of edges (which merge two trees into one), deletion of edges (which split one tree into two), and membership queries. Typical queries return the name of the tree containing a given vertex, or ask whether two vertices are in a same tree. Most of the solutions presented here will root each tree arbitrarily at one of its vertices; by keeping extra information at the root (such as the name of the tree), membership queries are equivalent to finding the root of the tree containing the given vertex.

There are two fully dynamic data structures for this problem: the dynamic trees of Sleator and Tarjan [39], and the **topology trees** of Frederickson [12]. Both data structures follow the common idea of partitioning a tree into a set of vertex-disjoint paths. However, they are very different in how this partition is chosen, and in the data structures they use to represent the paths inside the partition. Indeed, Sleator and Tarjan [39] use a simple partition of the trees based upon a careful choice of sophisticated data structures to represent paths. On the contrary, Frederickson [12] uses a more sophisticated partition that is based upon the topology of the tree; this implies more complicated algorithms but simpler data structures for representing paths.

The dynamic trees of Sleator and Tarjan [39] are able to maintain a collection of rooted trees, each of whose vertices has a real-valued cost, under an arbitrary sequence of the following operations:

maketree(v)*:* initialize a new tree consisting of single vertex v with cost zero.

findroot(v)*:* return the root of the tree containing vertex v.

findcost(v)*:* return a vertex of minimum cost in the path from v to findroot(v).

addcost(v, δ)*:* add the real number δ to the cost of every vertex in the path from v to findroot(v).

link(v, w)*:* Merge the trees containing vertices v and w by inserting edge (v, w). This operation assumes that v and w are in different trees and that v is a tree root.

cut(v)*:* Delete the edge leaving v, thus, splitting into two the tree containing vertex v. This operation assumes that v is not a tree root.

evert(v)*:* Make v the root of its tree.

THEOREM 8.1 **[39]** *Each of the above operations can be supported in* $O(\log n)$ *worst-case time.*

We do not give the details of the method here, and refer the interested reader to reference [39]. Rather than the dynamic trees of Sleator and Tarjan, we describe in more detail the topology trees of Frederickson. The reason for this choice is that the topology trees are often used as building blocks by many dynamic graph algorithms.

Topology Trees

In this section we consider trees with maximum vertex degree 3. This is without loss of generality, as we can convert any tree T to a tree T' with maximum vertex degree 3 by means of a standard transformation [20], which will be defined in a more general sense for graphs in "Clustering and Topology Trees." Let T be a tree of maximum degree 3 to be maintained dynamically. Before defining formally a topology tree, we need a little terminology. A *vertex cluster* with respect to T is a set of vertices that induces a connected

subgraph on T. The *cardinality* of a cluster is the number of vertices in it. An edge is *incident* to a cluster if exactly one of its endpoints is inside the cluster. Two clusters are *adjacent* if there is a tree edge that is incident to both. A *boundary vertex* of a cluster is a vertex that is adjacent in T to some vertex not in the cluster. The *external degree* of a cluster is the number of tree edges incident to it. A *restricted partition* of T is a partition of its vertex set V into vertex clusters such that

(1) Each cluster of external degree 3 is of cardinality 1.

(2) Each cluster of external degree less than 3 is of cardinality at most 2.

(3) No two adjacent clusters can be combined and still satisfy the above.

There can be several restricted partitions for a given tree T, based upon different choices of the vertices to be unioned. Because of (3), the restricted partition implements a cluster-forming scheme according to a locally greedy heuristic, which does not always obtain the minimum number of clusters. However, this greedy method has the advantage of requiring only local adjustments during updates. Thus, although not optimal from the viewpoint of number of clusters generated, this partition is well suited for dynamic operations. To illustrate this point clearly, we sketch how to update the clusters of a restricted partition when the underlying tree is subject to updates.

Assume we want to delete an edge e from T. First, removing e splits T into two trees, say T_1 and T_2. T_1 and T_2 inherit all of the clusters of T, possibly with the following exceptions. If e is entirely contained in a cluster, this cluster is no longer connected and therefore must be split. After the split, we must check whether each of the two resulting clusters is adjacent to a cluster of tree degree at most 2, and if these two adjacent clusters together have at most 2 vertices. If so, we combine these two clusters in order to maintain condition (3) above. If e is between two clusters, then no split is needed. However, since the tree degree of the clusters containing the endpoints of e has been decreased, we must check if each cluster should be combined with an adjacent cluster, again because of condition (3). This completes the updates needed for the deletion of e.

Next, we show how to combine two trees T_1 and T_2 into one tree T by adding an edge f. Again, T inherits the clusters of T_1 and T_2 with the only following exceptions. If f increases the tree degree of a cluster from 1 to 2, in order to preserve condition (3) we must again check whether this cluster must be combined with the cluster newly adjacent to it. If f increases the tree degree of a cluster containing more than one vertex from 2 to 3, condition (1) is violated and we have to split the cluster. For each cluster formed after the split, we check whether it must be combined with an adjacent cluster.

A *restricted multilevel partition* consists of a collection of restricted partitions of V satisfying the following:

(1) The clusters at level 0 (known as *basic clusters*) contain one vertex each.

(2) The clusters at level $\ell \geq 1$ form a restricted partition with respect to the tree obtained after shrinking all the clusters at level $\ell - 1$.

(3) There is exactly one vertex cluster at the topmost level.

From this definition, it follows that any cluster at level $\ell \geq 1$ is either (a) the union of two adjacent clusters of level $(\ell - 1)$ such that the external degree of one cluster is 1 or the external degree of both is 2, or (b) one cluster of level $(\ell - 1)$, if rule (a) does not apply. Thus, any cluster obtained by unioning two clusters at a lower level, has always tree degree at most 2. This implies that at any level a cluster of tree degree 3 consists always of a single vertex. Once again, several multilevel partitions are possible. But each restricted multilevel partition has the nice property of having only logarithmic depth, as implied by the following lemma of Frederickson [13].

LEMMA 8.1 **[13]** For any $\ell \geq 0$, the number of clusters at level $\ell + 1$ is at most 5/6 times the number of clusters at level ℓ.

The *topology tree* is a hierarchical representation of T. Each level of the topology tree partitions the vertices of T into connected subsets called *clusters*. More precisely, given a restricted multilevel partition for T, a *topology tree* for T is a tree satisfying the following:

(1) A topology tree node at level ℓ represents a vertex cluster at level ℓ in the restricted multilevel partition.
(2) A node at level $\ell \geq 1$ has at most two children, representing the vertex clusters at level $\ell - 1$ whose union gives the vertex cluster the node represents.

Since by Lemma 8.1 a restricted multilevel partition reduces the number of clusters at each level by a constant fraction, the height of the topology tree is $O(\log n)$. We now sketch how to update a topology tree during edge insertions or deletions. If there are updates in the spanning tree T, the restricted multilevel partition of T may be required to change. The changes in the topology tree are caused by the changes in the restricted multilevel partition it represents: at each level of the topology tree, we apply few locally greedy adjustments similar to the ones described before for one-level restricted partitions. As shown in [13], the topology tree update actually consists of two subtasks. First, a constant number of basic clusters (corresponding to leaves in the topology tree) have to be examined and possibly updated. Second, the changes in these basic clusters percolate up in the topology tree, possibly causing vertex clusters in the multilevel partition to be regrouped in different ways. This is handled by rebuilding portions of the topology tree in a bottom-up fashion, and involves a constant amount of work to be done on at most $O(\log n)$ topology tree nodes.

LEMMA 8.2 **[12]** The update of a topology tree because of an edge insertion or deletion can be supported in time $O(\log n)$.

8.4 Partially Dynamic Problems on Undirected Graphs

For undirected graphs, most of the **partially dynamic problems** considered are incremental, namely they support edge insertions only. We first show how to maintain a minimum spanning forest when the underlying graph G is subject to insertions of edges. We represent each tree in the minimum spanning forest as a dynamic tree (as defined in Section 8.3). Let $e = (x, y)$ be the edge to be inserted, and let F be a minimum spanning forest of G before inserting e. If the endpoints of e are in two different connected components of G, then the new forest F' will be $F \cup \{e\}$. Note that all this can be done in $O(\log n)$ worst-case time with the dynamic trees: we find the root of x, the root of y, and then link the two trees. Otherwise, x and y are in the same tree of the forest F, and inserting e in F introduces one cycle λ. To compute the new spanning forest F' we apply the cycle property in λ as follows. Let T be the tree of F containing both x and y: perform an evert on T and root it at x. Next, find the maximum cost edge f in the path from y to the root. If the cost of e is greater than the cost of f, then $F' = F$. Otherwise, swap e and f. Note that again this implies a constant number of operations to be executed on a forest of dynamic trees and therefore can be accomplished in $O(\log n)$ worst-case time.

THEOREM 8.2 *A minimum spanning forest of a graph G subject to edge insertions only can be maintained in $O(\log n)$ worst-case time per operation, where n is the number of vertices in G.*

The previous theorem gives implicitly an incremental algorithm for maintaining the connected components of a graph, since a minimum spanning forest of G is trivially a spanning forest of G (we assume that each edge has cost 1). A query on whether two vertices x and y are in a same connected component can be answered in $O(\log n)$ time by finding and comparing the roots of x and y. A better bound can

be achieved by representing the trees in the forest using the set union data structures of Chapter 5. A query on whether two vertices x and y are connected can be answered by checking whether *find*(x) equals *find*(y). When inserting edge $e = (x, y)$, we first perform $A \leftarrow$ *find*(x) and $B \leftarrow$ *find*(y). If $A = B$, x and y were already connected and the insertion of e does not change the connected components of G. If $A \neq B$ then A and B have to be merged into a new connected component: we do this by executing a *union*(A, B). Since each operation can be implemented by a constant number of set union operations, we have the following theorem.

THEOREM 8.3 *The connected components a graph G subject to edge insertions only can be maintained in $O(\alpha(q, n))$ amortized time per query or update operation, where q is the total number of queries and n is the number of vertices in G.*

Set union data structures can be used for the partially dynamic maintenance of other graph properties, such as bipartiteness, and edge and vertex connectivity. For lack of space, we describe here only how to solve the partially dynamic 2-edge connectivity problem. This problem consists of maintaining a graph G under an intermixed sequence of operations of the following kinds.

> *Same2EdgeBlock*(u, v)*:* Return *true* if vertices u and v are in the same 2-edge-connected component. Return *false* otherwise.
>
> *InsertEdge*(x, y)*:* Insert a new edge between the two vertices x and y.

Westbrook and Tarjan [44] presented one algorithm that runs in a total of $O(q\alpha(q, n))$ time, where q is the total number of *Same2EdgeBlock* and *InsertEdge* operations, and n is the number of vertices. For sake of simplicity, we describe in details only the algorithm that operates on connected graphs, and refer the interested reader to [44] for the full details of the method on general unconnected graphs.

For any vertex x in G denote by $C_{2E}(x)$ the 2-edge-connected component of G containing x. The main data structure maintained by the algorithm is the bridge-block tree of G, which is defined as follows. Nodes in this tree correspond to 2-edge-connected components of G, and any two nodes are connected by an edge if and only if there is a bridge connecting the corresponding 2-edge-connected components. We assume that the bridge-block tree is rooted arbitrarily at one node, and we denote by *parent*(σ) the parent of a tree node σ in the bridge-block tree.

Besides maintaining the bridge-block tree of G, we maintain the actual 2-edge-connected components of G as disjoint sets, subject to *union* and *find* operations. For this, we use any of the fast set-union data structures described in Chapter 5, which are able to process any sequence of q *union* and *find* operations on a collection of n elements in $O(q\alpha(q, n))$ worst-case time.

We define the name of each disjoint set in the set-union data structure as a pointer to the tree node associated to the corresponding 2-edge-connected component. Thus, we can assume that for each vertex x in G, *find*$(x) = C_{2E}(x)$. With this data structure, a *Same2EdgeBlock*(x, y) can be simply performed by checking whether *find*(x)=*find*(y). The *union* operations will be used to update efficiently the 2-edge-connected components during *InsertEdge* operations. The effect of an *InsertEdge*(u, v) on the bridge-block tree depends on whether u and v are in the same 2-edge-connected component or in different 2-edge-connected components. Let $C_{2E}(u)$ and $C_{2E}(v)$ be the 2-edge-connected components containing u and v, respectively, before inserting the edge (u, v).

We now describe the changes caused in the bridge-block tree by the insertion of edge (u, v). If $C_{2E}(u) = C_{2E}(v)$, the bridge-block tree is unaffected by the new edge and hence, no change is needed in the data structure. If $C_{2E}(u) \neq C_{2E}(v)$, the inserted edge creates a new cycle that reduces the number of 2-edge-connected components and bridges of G. This cycle consists of (u, v) plus all the edges in the tree path between node $C_{2E}(u)$ and node $C_{2E}(v)$. All the nodes in this tree path must be replaced by a single node, and every node previously adjacent to one of the nodes in the tree path becomes adjacent to the new single node. This process is called *path condensation.*

To implement *InsertEdge* operations, the bridge-block tree is maintained as a data structure that supports the following primitives:

> *FindPath*(σ_1, σ_2)*:* Given two tree nodes σ_1 and σ_2, return the tree path between σ_1 and σ_2. If $\sigma_1 = \sigma_2 = \sigma$, return σ.
>
> *CondensePath*(π)*:* Perform path condensation on the tree path π, unioning the corresponding disjoint sets associated with the encountered tree nodes. Return the modified bridge-block tree. Note that a *CondensePath* does nothing if π is an empty path consisting of a single node.

A *FindPath*(σ_1, σ_2) can be implemented as follows: we proceed from u and from v toward the tree root, alternating one step at the time, until the paths traced from u and from v intersect at their nearest common ancestor. Note that this returns the nearest common ancestor of u and v, and the tree path π between u and v. The number of steps required to return π is at most $2|\pi|$. Since they are performed by following parent pointers, we call these *parent steps.* The path π is returned as a list of nodes (not in order along the path), with the nearest common ancestor at the end. Let $\widetilde{\sigma}$ be the parent of the nearest common ancestor. To perform a *CondensePath*(π), π is condensed into a single node σ, which is made child of $\widetilde{\sigma}$. All the disjoint sets associated with nodes in π are unioned. Since we perform a union at each step, we call these *union steps.*

LEMMA 8.3 In any sequence of operations, there are at most $O(n)$ parent and union steps.

PROOF Suppose a path π is being condensed. To generate π, $O(|\pi|)$ parent steps are required, and $|\pi| - 1$ nodes are condensed. Since after $(n-1)$ condensations the graph becomes 2-edge-connected, there can be at most $O(n)$ parent steps and $(n-1)$ union steps.

With the help of these primitives, we support an *InsertEdge*(u, v) as follows:

```
InsertEdge(u, v) begin
    return CondensePath(FindPath(find(u), find(v)));
end
```

THEOREM 8.4 **[44]** *Given an initially connected graph $G_0 = (V_0, E_0)$ and $O(|E_0|)$ preprocessing time, a sequence of q* InsertEdge *and* Same2EdgeBlock *operations can be processed in $O(q\alpha(q, n))$ time.*

PROOF The 2-edge-connected components and the bridge-block tree of G_0 can be found in $O(|E_0|)$ using the algorithm of Tarjan [43]. By Lemma 8.3, the total number of parent and union steps is $O(n)$, giving a total of $O(q)$ finds and $O(n)$ unions in the set union data structure.

To complete this section, we mention that most of the incremental algorithms proposed in the literature for edge and vertex connectivity (see, e.g.,[5, 6, 17, 29, 31, 32, 44]) follow the approach outlined here for 2-edge connectivity. Namely, connectivity queries are answered by maintaining a tree that reflects the structure of the connectivity cuts of the graph. When a new edge (u, v) is added to the graph, some connectivity cuts may be invalidated; these connectivity cuts can be easily found since they all lie in a tree path, whose endpoints correspond to u and v. After locating the path, some form of path condensation takes place. To support efficiently path condensation, set-union based data structures are used. The tree structure of the $(k-1)$-cuts is fairly complicated, however, as k increases, and it requires sophisticated data structures and a quite delicate analysis.

8.5 Fully Dynamic Problems on Undirected Graphs

This section describes fully dynamic algorithms for undirected graphs. These algorithms maintain efficiently some property of a graph that is undergoing structural changes defined by insertion and deletion of edges, and/or edge cost updates. For instance, the fully dynamic minimum spanning tree problem consists of maintaining a minimum spanning forest of a graph during the above operations. The typical updates for a fully dynamic problem will therefore be inserting a new edge, and deleting an existing edge. To check the graph property throughout a sequence of these updates, the algorithms must prepared to answer queries on the graph property. Thus, a fully dynamic connectivity algorithm must be able to insert edges, delete edges, and answer a query on whether the graph is connected, or whether two vertices are connected. Similarly, a fully dynamic k-edge connectivity algorithm must be able to insert edges, delete edges, and answer a query on whether the graph is k-edge-connected, or whether two vertices are k-edge-connected. The goal of a dynamic algorithm is to minimize the amount of recomputation required after each update. All of the fully dynamic algorithms that we describe in this section are able to dynamically maintain the graph property at a cost (per update operation) that is significantly smaller than the cost of recomputing the graph property from scratch. Many of the algorithms proposed in the literature use the same general techniques, and so we begin by describing these techniques. All of these techniques use some form of graph decomposition, and partition either the vertices or the edges of the graph to be maintained.

The first technique we present is the *clustering* technique of Frederickson [12], which is based upon partitioning the graph into a suitable collection of connected subgraphs called *clusters,* such that each update involves only a small number of such clusters. The dynamic trees of Sleator and Tarjan [39] can be used to maintain information about the edges of a tree; clusters dually keep track of the edges that are not part of some given spanning tree, by grouping them according to which clusters they connect. Typically, this decomposition is applied recursively and the information about the subgraphs is combined with the topology trees described in Section 8.3. A refinement of the clustering technique appears in the idea of *ambivalent data structures* [13], in which edges can belong to multiple groups, only one of which is actually selected depending on the topology of the given spanning tree.

Another technique we describe is **sparsification** by Eppstein et al. [8]. This is a divide-and-conquer technique that can be used to reduce the dependence on the number of edges in a graph, so that the time bounds for maintaining some property of the graph match the times for computing in sparse graphs. Roughly speaking, sparsification works as follows. Let $\mathcal{A}$ be an algorithm that maintains some property of a dynamic graph G with m edges and n vertices in time $T(n, m)$. Sparsification maintains a proper decomposition of G into small subgraphs, with $O(n)$ edges each. In this decomposition, each update involves applying algorithm $\mathcal{A}$ to few small subgraphs of G, resulting into an improved $T(n, n)$ time bound per update. Thus, throughout a sequence of operations, sparsification makes a graph looks sparse (i.e., with only $O(n)$ edges): hence, the reason for its name. Sparsification works on top of a given algorithm, and need not to know the internal details of this algorithm. Consequently, it can be applied orthogonally to other data structuring techniques; we will actually see a number of situations in which both clustering and sparsification can be combined to produce an efficient dynamic graph algorithm.

The previous two techniques allows one to design efficient deterministic algorithms. The last technique we present in this section is due to Henzinger and King [21], and it is a combination of a suitable graph decomposition and randomization. We now sketch how this decomposition is defined. Let G be a graph whose spanning forest has to be maintained dynamically. The edges of G are partitioned into $O(\log n)$ levels: the lower levels contain tightly-connected portions of G (i.e., dense edge cuts), while the higher levels contain loosely-connected portions of G (i.e., sparse cuts). For each level i, a spanning forest for the graph defined by all the edges in levels i or below is maintained. If a spanning forest edge e is deleted at some level i, random sampling is used to quickly find a replacement for e at that level. If random sampling succeeds, the forest is reconnected at level i. If random sampling fails, the edges that can replace e in level i form with high probability a sparse cut. These edges are moved to level $(i + 1)$ and the same procedure is applied recursively on level $(i + 1)$.

One particular dynamic graph problem that has been thoroughly investigated is the maintenance of a minimum spanning forest. This is an important problem on its own, but it has also impact on other problems as well. Indeed the data structures and techniques developed for dynamic minimum spanning forests have found applications also in other areas, such as dynamic edge and vertex connectivity [8, 13, 16, 24, 37, 38]. Thus, we will focus our attention to the fully dynamic maintenance of minimum spanning trees.

Clustering and Topology Trees

Let $G = (V, E)$ be a graph, with a designated spanning tree S. *Clustering* is a method of partitioning the vertex set V, into connected subtrees in S, so that each subtree is only adjacent to a few other subtrees. *Topology trees* are a representation of the tree S using a different tree with logarithmic height, formed by recursive clustering, and are a generalization of the topology trees described in Section 8.3. *2-dimensional topology trees* are formed from pairs of nodes in a topology tree, and allow us to maintain information about the edges in $E - S$. Fully dynamic algorithms based only on a single level of clustering obtain typically time bounds of $O(m^{2/3})$ (see for instance [16, 37]). When the partition can be applied recursively, better $O(m^{1/2})$ time bounds can be achieved with the help of topology trees (see for instance [12, 13]). Along with their applications to dynamic graph algorithms, topology trees can be used in situations in which a dynamic tree is part of a static graph; for instance, topology trees can be used to speed up the execution of pivots in the network simplex algorithm for minimum cost circulations [7].

Before defining clustering and topology trees, we describe a standard graph transformation that we use throughout. We convert the graph G into a graph with maximum vertex degree 3 [20]: Suppose $v \in V$ has degree $d(v) > 3$, and is adjacent to vertices $u_1, u_2, \ldots, u_d$. In the transformed graph, v is replaced by a cycle of d *dashed* edges: namely, we substitute v by d vertices $v_1, v_2, \ldots, v_d$. For each edge (v, u) of the original graph, in position i among the list of edges adjacent to v and position j among the edges adjacent to u, we create an *actual* edge (v_i, u_j). We also create *dashed* edges (v_i, v_{i+1}) for $1 \leq i \leq d - 1$, and a *dashed* edge (v_d, v_1) to close the loop. We call these the *dashed edges of* v. As a result of this transformation, the graph keeps its actual edges, and has an additional $O(m)$ dashed edges. Note that this transformation affects the problems we would like to solve. However for most of the problems to which this technique is applied (such as minimum spanning forests, connectivity and 2-edge connectivity), either the two solutions are identical (such as in the case of connectivity and 2-edge connectivity), or we can easily compute the solution in the original graph once we know the solution in the transformed graph (such as in the case of minimum spanning forests). In other cases, although this computation is not easy (such in the case of biconnectivity), it can be handled with some little extra effort.

Throughout the sequence of updates, any cluster-based dynamic graph algorithm maintains a spanning tree T of G. For each vertex v, T contains all of the dashed edges of v except one. The only one dashed edge of v that does not belong to T can be arbitrarily chosen. We now generalize the notion of restricted partition given in Section 8.3. Let $z > 0$ be an integer, to be fixed later on. A *restricted partition of order* z of G is a partition of its vertex set V into $O(m/z)$ vertex clusters such that:

(1) Each set in the partition yields a vertex cluster of external degree at most 3.

(2) Each cluster of external degree 3 is of cardinality 1.

(3) Each cluster of external degree less than 3 is of cardinality less than or equal to z.

(4) No two adjacent clusters can be combined and still satisfy the above.

Note that since any cluster has maximum external degree 3, it can have at most three boundary vertices. A restricted partition of order z can be found in linear time as shown in [13]. We now discuss how to update the clusters of a restricted partition of order z when the underlying graph is subject to updates. The basic update we will consider is a *swap*: a *swap* (e, f) in a spanning tree T replaces a tree edge e by a non-tree edge f, yielding a new spanning tree. This is a basic update operation, since each edge insertion,

edge deletion, or edge cost change causes at most one swap in a spanning tree: at most one edge is added to the tree and one edge removed. When a swap (e, f) is performed, we do the following. First, removing e splits T into two trees, say T_1 and T_2. T_1 and T_2 inherit all of the clusters of T, possibly with the following exceptions. If e is entirely contained in a cluster, this cluster is no longer connected and therefore must be split. After the split, we must check whether each of the two resulting clusters can be merged with neighboring clusters in order to maintain condition (4) above. If e is between two clusters, then no split is needed. However, since the tree degree of the clusters containing the endpoints of e has been decreased, we must check if each cluster should be combined with an adjacent cluster, again because of condition (4). This completes the updates needed for the deletion of e.

Next, we show how to combine T_1 and T_2 into one tree T by adding edge f. Again, T inherits the clusters of T_1 and T_2 with the only following exceptions. If f increases the tree degree of a cluster from 1 to 2, in order to preserve condition (4) we must again check whether this cluster must be combined with the cluster newly adjacent to it. If f increases the tree degree of a cluster containing more than one vertex from 2 to 3, condition (2) is violated and we do the following. Let w', w'', and w''' be the endpoints of the three tree edges incident on this cluster. Let x be the common vertex on tree paths between w', w'', and w'''. Make x into a cluster (of tree degree 3) by itself, and take the remaining parts of the old cluster as new clusters. For each cluster so formed, we check whether it must be combined with an adjacent cluster.

LEMMA 8.4 The time required to update a restricted partition of order z because of a swap is $O(z)$.

PROOF As described before, at most a constant number of vertex clusters is changed, deleted or created during a swap. Each cluster that is modified in some way, has at most z vertices and edges, and therefore can be handled in time $O(z)$.

The notion of *restricted multilevel partition* of "Topology Trees" can be generalized as follows:

(1) The clusters at level 0 (known as *basic clusters*) form a restricted partition of order z.
(2) The clusters at level $\ell \geq 1$ form a restricted partition of order 2 with respect to the tree obtained after shrinking all the clusters at level $\ell - 1$.
(3) There is exactly one vertex cluster at the topmost level.

We now list some properties of a multilevel restricted partition. First, any basic vertex cluster of tree degree 3 consists of a single vertex. Second, any cluster obtained by unioning two clusters at a lower level, has always tree degree at most 2. These two properties imply that any nonbasic cluster of tree degree 3 also consists of a single vertex, and all of its incident edges will be tree edges. Furthermore, there are no non-tree edges having an endpoint in a cluster of tree degree 3. Finally, the restricted multilevel partition has the nice property of having only logarithmic depth. Indeed Frederickson [13] shows that each level of the topology tree has a number of nodes which is a constant fraction of the previous level, from which the following lemma follows.

LEMMA 8.5 **[12, 13]** The number of levels in a restricted multilevel partition is $\Theta(\log n)$.

The *topology tree* is a hierarchical representation of G based on T. Each level of the topology tree partitions the vertices of G into connected subsets called *clusters.* More precisely, given a restricted multilevel partition for T, a *topology tree* for T is a tree satisfying the following:

(1) A topology tree node at level ℓ represents a vertex cluster at level ℓ in the restricted multilevel partition.

(2) A node at level $\ell \geq 1$ has at most two children, representing the vertex clusters at level $\ell - 1$ whose union gives the vertex cluster the node represents.

As shown in [13], the update of a topology tree because of an edge swap in T consists of two subtasks. First, a constant number of basic clusters (corresponding to leaves in the topology tree) have to be examined and possibly updated. As shown in Lemma 8.4, this can be supported in $O(z)$ time. Second, the changes in these basic clusters percolate up in the topology tree, possibly causing vertex clusters in the multilevel partition to be regrouped in different ways. This is handled by rebuilding portions of the topology tree in a bottom-up fashion, and involves a constant amount of work to be done on at most $O(\log n)$ topology tree nodes. This yields the following lemma.

LEMMA 8.6 **[12, 13]** The update of a topology tree because of an edge swap can be supported in time $O(z + \log n)$.

We now give the definition of *2-dimensional topology tree.* This is somehow involved, and we only sketch it here, referring the reader to [12, 13] for the full details. For every pair of nodes V_α and V_β at the same level in the topology tree there is a node labeled $V_\alpha \times V_\beta$ in the 2-dimensional topology tree. Let E_T be the tree edges of G (i.e., the edges in the spanning tree T): node $V_\alpha \times V_\beta$ represents all the non-tree edges of G (i.e., the edges of $E - E_T$) having one endpoint in V_α and the other in V_β. The root of the 2-dimensional topology tree is labeled $V \times V$ and represents all the non-tree edges of G. If a node is labeled $V_\alpha \times V_\beta$, and V_α has children V_{α_i}, $1 \leq i \leq p$, and V_β has children V_{β_j}, $1 \leq j \leq q$, in the topology tree, then $V_\alpha \times V_\beta$ has children $V_{\alpha_i} \times V_{\beta_j}$, $1 \leq i \leq p$, $1 \leq j \leq q$, in the 2-dimensional topology tree.

Note that a 2-dimensional topology tree corresponds roughly to having $O(m/z)$ topology trees, one for each basic cluster in the restricted multilevel partition. As previously described, updating the basic clusters because of an edge swap would require a total of $O(z)$ time, and then updating these $O(m/z)$ topology trees would require a total of $O((m/z)\log n)$ time. This yields a total of $O(z + (m/z)\log n)$ time. The computational saving of a 2-dimensional topology tree is that it can be updated during a swap in its corresponding topology tree in $O(m/z)$ time only [13]. The crucial point of this analysis is that only $O(m/z)$ nodes in the 2-dimensional topology tree need to be looked at and eventually updated during a swap, and this can be done in constant time per node.

LEMMA 8.7 **[12, 13]** The update of a 2-dimensional topology tree because of an edge swap in the corresponding topology tree can be supported in time $O(m/z)$.

Note that the bound in Lemma 8.7 does not take into account the time needed to update the topology tree upon which the 2-dimensional topology tree is based. If this is taken into account, the total time required to perform a swap becomes $O(z + (m/z))$. Typical algorithms will balance this bound by choosing $z = \Theta(m^{1/2})$ to get an $O(m^{1/2})$ total time bound, as shown in the following theorem.

THEOREM 8.5 **[12]** *The minimum spanning forest of an undirected graph can be maintained in time $O(m^{1/2})$ per update, where m is the current number of edges in the graph.*

PROOF We maintain a restricted multilevel partition of order z, and the corresponding topology tree and 2-dimensional topology tree as described before. We augment the 2-dimensional topology tree as follows. Each leaf $V_i \times V_j$ of the 2-dimensional topology tree stores the set $E_{i,j}$ of edges having one endpoint in V_i and the other in V_j, as well as the minimum cost edge in this set. This information is stored in a heap-like fashion: internal nodes of the 2-dimensional topology tree have the minimum of the values of their children. This additional information required constant time per node to be maintained.

Consequently, as in Lemma 8.7 the update of this augmented 2-dimensional topology tree because of a swap can be done in $O(m/z)$ time.

Whenever a new edge is inserted or a non-tree edge has its cost decreased, we can find a replacement edge in time $O(\log n)$ with the dynamic trees of Sleator on Tarjan, as described in Section 8.4. Whenever an edge is deleted, or a tree edge has its cost increased, we can find a replacement edge as follows. Let e be the edge that has been deleted or increased. We first split the 2-dimensional topology tree at e in $O(z+m/z)$ time by Lemma 8.7. Suppose this splits the corresponding topology tree into two trees, whose roots are the clusters V_α and V_β, with V_β having no fewer levels than V_α. To find a possible replacement edge for e, we examine the values at the nodes $V_\alpha \times V_\gamma$ for all possible V_γ in the 2-dimensional topology tree, and take the minimum. It takes $O(m/z)$ time to find and examine these nodes.

This yields a total of $O(z+(m/z))$ time for each update. Choosing $z = \lceil m^{1/2} \rceil$ gives an $O(m^{1/2})$ bound. However, m is changing because of insertions and deletions. When the value of z changes because of m, there will be at least $m^{1/2}$ update before z advances to the next value up or down in the same directions. Since there are at most $O(m/z)$ basic clusters that need to be adjusted, we can adjust a constant number of clusters during each update.

Sparsification

The techniques described in the previous section allow us to obtain an $O(m^{1/2})$ time bound for the fully dynamic maintenance of a minimum spanning forest, connectivity and 2-edge connectivity [12, 13]. The type of clustering used is very problem-dependent, however, and makes these techniques unsuitable to be used as a black box. Namely, whenever we want to apply such techniques to solve a certain problem, we must devise a proper partition of the graph into clusters. Furthermore, we must get into the low-level details of the data structures employed. For instance, we have to make sure that the problem can be represented as a small set of alternatives at each node of the 2-dimensional topology tree, and show how we can select efficiently among those alternatives, or select the information we are interested more directly from the topology tree.

In this section we describe a general technique for designing dynamic graph algorithms, due to Eppstein et al. [8], which is called *sparsification.* This technique can be used to speed up many fully dynamic graph algorithms. Roughly speaking, when the technique is applicable it speeds up a $T(n, m)$ time bound for a graph with n vertices and m edges to $T(n, O(n))$; i.e., to the time needed if the graph were sparse. For instance if $T(n, m) = O(m^{1/2})$, we get a better bound of $O(n^{1/2})$. Sparsification applies to a wide variety of dynamic graph problems, including minimum spanning forests, edge and vertex connectivity. Moreover, it is a general technique and can be used as a black box (without having to know the internal details) in order to dynamize graph algorithms.

The technique itself is quite simple. Let G be a graph with m edges and n vertices. We partition the edges of G into a collection of $O(m/n)$ sparse subgraphs, i.e., subgraphs with n vertices and $O(n)$ edges. The information relevant for each subgraph can be summarized in an even sparser subgraph, which is called a *sparse certificate.* We merge **certificates** in pairs, producing larger subgraphs that are made sparse by again computing their certificate. The result is a balanced binary tree in which each node is represented by a sparse certificate. Each update involves $\log(m/n)$[1] graphs with $O(n)$ edges each, instead of one graph with m edges. With some extra care, the $O(\log(m/n))$ overhead term can be eliminated.

We describe two variants of the sparsification technique. We use the first variant in situations where no previous fully dynamic algorithm was known. We use a static algorithm to recompute a sparse certificate in each tree node affected by an edge update. If the certificates can be found in time $O(m+n)$, this variant gives time bounds of $O(n)$ per update. In the second variant, we maintain certificates using a dynamic

[1] Throughout $\log x$ stands for $\max(1, \log_2 x)$, so $\log(m/n)$ is never smaller than 1 even if $m < 2n$.

data structure. For this to work, we need a *stability* property of our certificates to ensure that a small change in the input graph does not lead to a large change in the certificates. This variant transforms time bounds of the form $O(m^p)$ into $O(n^p)$. We start by describing an abstract version of sparsification. The technique is based on the concept of a *certificate*:

DEFINITION 8.1 For any graph property $\mathcal{P}$, and graph G, a *certificate* for G is a graph G' such that G has property $\mathcal{P}$ if and only if G' has the property.

Nagamochi and Ibaraki [35] use a similar concept, however they require G' to be a subgraph of G. We do not need this restriction. However, this allows trivial certificates: G' could be chosen from two graphs of constant complexity, one with property $\mathcal{P}$ and one without it.

DEFINITION 8.2 For any graph property $\mathcal{P}$, and graph G, a *strong certificate* for G is a graph G' on the same vertex set such that, for any H, $G \cup H$ has property $\mathcal{P}$ if and only if $G' \cup H$ has the property.

In all our uses of this definition, G and H will have the same vertex set and disjoint edge sets. A strong certificate need not be a subgraph of G, but it must have a structure closely related to that of G. The following facts follow immediately from Definition 8.2.

FACT 8.1 *Let G' be a strong certificate of property $\mathcal{P}$ for graph G, and let G'' be a strong certificate for G'. Then G'' is a strong certificate for G.*

FACT 8.2 *Let G' and H' be strong certificates of $\mathcal{P}$ for G and H. Then $G' \cup H'$ is a strong certificate for $G \cup H$.*

A property is said to have *sparse certificates* if there is some constant c such that for every graph G on an n-vertex set, we can find a strong certificate for G with at most cn edges.

The other key ingredient is a *sparsification tree.* We start with a partition of the vertices of the graph, as follows: we split the vertices evenly in two halves, and recursively partition each half. Thus, we end up with a complete binary tree in which nodes at distance i from the root have $n/2^i$ vertices. We then use the structure of this tree to partition the edges of the graph. For any two nodes α and β of the vertex partition tree at the same level i, containing vertex sets V_α and V_β, we create a node $E_{\alpha\beta}$ in the edge partition tree, containing all edges in $V_\alpha \times V_\beta$. The parent of $E_{\alpha\beta}$ is $E_{\gamma\delta}$, where γ and δ are the parents of α and β, respectively, in the vertex partition tree. Each node $E_{\alpha\beta}$ in the edge partition tree has either three or four children (three if $\alpha = \beta$, four otherwise). We use a slightly modified version of this edge partition tree as our sparsification tree. The modification is that we only construct those nodes $E_{\alpha\beta}$ for which there is at least one edge in $V_\alpha \times V_\beta$. If a new edge is inserted new nodes are created as necessary, and if an edge is deleted those nodes for which it was the only edge are deleted.

LEMMA 8.8 In the sparsification tree described above, each node $E_{\alpha\beta}$ at level i contains edges inducing a graph with at most $n/2^{i-1}$ vertices.

PROOF There can be at most $n/2^i$ vertices in each of V_α and V_β.

We say a time bound $T(n)$ is *well behaved* if for some $c < 1$, $T(n/2) < cT(n)$. We assume well-behavedness to eliminate strange situations in which a time bound fluctuates wildly with n. All polynomials are well behaved. Polylogarithms and other slowly growing functions are not well behaved, but since

sparsification typically causes little improvement for such functions we will in general assume all time bounds to be well behaved.

THEOREM 8.6 **[8]** *Let $\mathcal{P}$ be a property for which we can find sparse certificates in time $f(n, m)$ for some well-behaved f, and such that we can construct a data structure for testing property $\mathcal{P}$ in time $g(n, m)$ which can answer queries in time $q(n, m)$. Then there is a fully dynamic data structure for testing whether a graph has property $\mathcal{P}$, for which edge insertions and deletions can be performed in time $O(f(n, O(n))) + g(n, O(n))$, and for which the query time is $q(n, O(n))$.*

PROOF We maintain a sparse certificate for the graph corresponding to each node of the sparsification tree. The certificate at a given node is found by forming the union of the certificates at the three or four child nodes, and running the sparse certificate algorithm on this union. As shown in Lemmas 8.1 and 8.2, the certificate of a union of certificates is itself a certificate of the union, so this gives a sparse certificate for the subgraph at the node. Each certificate at level i can be computed in time $f(n/2^{i-1}, O(n/2^i))$. Each update will change the certificates of at most one node at each level of the tree. The time to recompute certificates at each such node adds in a geometric series to $f(n, O(n))$. This process results in a sparse certificate for the whole graph at the root of the tree. We update the data structure for property $\mathcal{P}$, on the graph formed by the sparse certificate at the root of the tree, in time $g(n, O(n))$. The total time per update is thus $O(f(n, O(n))) + g(n, cn)$.

This technique is very effective at producing dynamic graph data structures for a multitude of problems, in which the update time is $O(n \log^{O(1)} n)$ instead of the static time bounds of $O(m + n \log^{O(1)} n)$. To achieve sublinear update times, we further refine our sparsification idea.

DEFINITION 8.3 Let A be a function mapping graphs to strong certificates. Then A is *stable* if it has the following two properties:

(1) For any graphs G and H, $A(G \cup H) = A(A(G) \cup H)$.
(2) For any graph G and edge e in G, $A(G - e)$ differs from $A(G)$ by $O(1)$ edges.

Informally, we refer to a certificate as stable if it is the certificate produced by a stable mapping. The certificate consisting of the whole graph is stable, but not sparse.

THEOREM 8.7 **[8]** *Let $\mathcal{P}$ be a property for which stable sparse certificates can be maintained in time $f(n, m)$ per update, where f is well behaved, and for which there is a data structure for property $\mathcal{P}$ with update time $g(n, m)$ and query time $q(n, m)$. Then $\mathcal{P}$ can be maintained in time $O(f(n, O(n))) + g(n, O(n))$ per update, with query time $q(n, O(n))$.*

PROOF As before, we use the sparsification tree described above. After each update, we propagate the changes up the sparsification tree, using the data structure for maintaining certificates. We then update the data structure for property $\mathcal{P}$, which is defined on the graph formed by the sparse certificate at the tree root.

At each node of the tree, we maintain a stable certificate on the graph formed as the union of the certificates in the three or four child nodes. The first part of the definition of stability implies that this certificate will also be a stable certificate that could have been selected by the mapping A starting on the subgraph of all edges in groups descending from the node. The second part of the definition of stability

then bounds the number of changes in the certificate by some constant s, since the subgraph is changing only by a single edge. Thus, at each level of the sparsification tree there is a constant amount of change.

When we perform an update, we find these s changes at each successive level of the sparsification tree, using the data structure for stable certificates. We perform at most s data structure operations, one for each change in the certificate at the next lower level. Each operation produces at most s changes to be made to the certificate at the present level, so we would expect a total of s^2 changes. However, we can cancel many of these changes since as described above the net effect of the update will be at most s changes in the certificate.

In order to prevent the number of data structure operations from becoming larger and larger at higher levels of the sparsification tree, we perform this cancellation before passing the changes in the certificate up to the next level of the tree. Cancellation can be detected by leaving a marker on each edge, to keep track of whether it is in or out of the certificate. Only after all s^2 changes have been processed do we pass the at most s uncancelled changes up to the next level.

Each change takes time $f(n, O(n))$, and the times to change each certificate then add in a geometric series to give the stated bound.

Theorem 8.6 can be used to dynamize static algorithms, while Theorem 8.7 can be used to speed up existing fully dynamic algorithms. In order to apply effectively Theorem 8.6 we only need to *compute* efficiently *sparse* certificates, while for Theorem 8.7 we need to *maintain* efficiently *stable sparse* certificates. Indeed stability plays an important role in the proof of Theorem 8.7. In each level of the update path in the sparsification tree we compute s^2 changes resulting from the s changes in the previous level, and then by stability obtain only s changes after eliminating repetitions and canceling changes that require no update. Although in most of the applications we consider stability can be used directly in a much simpler way, we describe it in this way here for sake of generality.

We next describe the $O(n^{1/2})$ algorithm for the fully dynamic maintenance of a minimum spanning forest given by Eppstein et al. [8] based on sparsification. A minimum spanning forest is not a graph property, since it is a subgraph rather than a Boolean function. However sparsification still applies to this problem. Alternately, sparsification maintains any property defined on the minimum spanning trees of graphs. The data structure introduced in this section will also be an important subroutine in some results described later. We need the following analogue of strong certificates for minimum spanning trees:

LEMMA 8.9 Let T be a minimum spanning forest of graph G. Then for any H there is some minimum spanning forest of $G \cup H$ which does not use any edges in $G - T$.

PROOF If we use the cycle property on graph $G \cup H$, we can eliminate first any cycle in G (removing all edges in $G - T$) before dealing with cycles involving edges in H.

Thus, we can take the strong certificate of any minimum spanning forest property to be the minimum spanning forest itself. Minimum spanning forests also have a well-known property which, together with Lemma 8.9, proves that they satisfy the definition of stability:

LEMMA 8.10 Let T be a minimum spanning forest of graph G, and let e be an edge of T. Then either $T - e$ is a minimum spanning forest of $G - e$, or there is a minimum spanning forest of the form $T - e + f$ for some edge f.

If we modify the weights of the edges so that no two are equal, we can guarantee that there will be exactly one minimum spanning forest. For each vertex v in the graph let $i(v)$ be an identifying number chosen as an integer between 0 and $n - 1$. Let ϵ be the minimum difference between any two distinct weights of the

graph. Then for any edge $e = (u, v)$ with $i(u) < i(v)$ we replace $w(e)$ by $w(e) + \epsilon i(u)/n + \epsilon i(v)/n^2$. The resulting MSF will also be a minimum spanning forest for the unmodified weights, since for any two edges originally having distinct weights the ordering between those weights will be unchanged. This modification need not be performed explicitly—the only operations our algorithm performs on edge weights are comparisons of pairs of weights, and this can be done by combining the original weights with the numbers of the vertices involved taken in lexicographic order. The mapping from graphs to unique minimum spanning forests is stable, since part (1) of the definition of stability follows from Lemma 8.9, and part (2) follows from Lemma 8.10.

We use Frederickson's algorithm of Theorem 8.5 that states that minimum spanning trees can be maintained in time $O(m^{1/2})$. We improve this bound by combining Frederickson's algorithm with sparsification: we apply the stable sparsification technique of Theorem 8.7, with $f(n, m) = g(n, m) = O(m^{1/2})$ by Theorem 8.5.

THEOREM 8.8 **[8]** *The minimum spanning forest of an undirected graph can be maintained in time* $O(n^{1/2})$ *per update.*

The dynamic spanning tree algorithms described so far produce fully dynamic connectivity algorithms with the same time bounds. Indeed, the basic question of connectivity can be quickly determined from a minimum spanning forest. However, higher forms of connectivity are not so easy. For edge connectivity, sparsification can be applied using a dynamic minimum spanning forest algorithm, and provides efficient algorithms: 2-edge connectivity can be solved in $O(n^{1/2})$ time per update, 3-edge connectivity can be solved in $O(n^{2/3})$ time per update, and for any higher k, k-edge connectivity can be solved in $O(n \log n)$ time per update [8]. Vertex connectivity is not so easy: for $2 \leq k \leq 4$, there are algorithms with times ranging from $O(n^{1/2} \log^2 n)$ to $O(n\alpha(n))$ per update [8, 24, 38].

We end this section by mentioning that Henzinger and King have recently improved the update bound of Theorem 8.8 from $O(n^{1/2})$ to $O(n^{1/3} \log n)$. We refer the interested reader to [23] for the details.

Randomized Algorithms

All the previous techniques yield efficient deterministic algorithms for fully dynamic problems. Recently, Henzinger and King [21] proposed a new approach that, exploiting the power of randomization, is able to achieve faster update times for some problems. For the fully dynamic connectivity problem, the randomized technique of Henzinger and King yields an expected amortized update time of $O(\log^3 n)$ for a sequence of at least m_0 updates, where m_0 is the number of edges in the initial graph, and a query time of $O(\log n)$. It needs $\Theta(m + n \log n)$ space. We now sketch the main ideas behind this technique. The interested reader is referred to Chapter 15 for basic definitions on randomized algorithms.

Let $G = (V, E)$ be a graph to be maintained dynamically, and let F be a spanning forest of G. We call edges in F *tree edges,* and edges in $E \setminus F$ *non-tree edges.* First, we describe a data structure which stores all trees in the spanning forest F. This data structure is based on Euler tours, and allows one to obtain logarithmic updates and queries within the forest. Next, we show how to keep the forest F spanning throughout a sequence of updates. The Euler tour data structure for a tree T is simple, and consists of storing the tree vertices according to an Euler tour of T.

Each time a vertex v is visited in the Euler tour, we call this an *occurrence* of v and we denote it by $o(v)$. A vertex of degree Δ has exactly Δ occurrences, except for the root which has $(\Delta + 1)$ occurrences. Furthermore, each edge is visited exactly twice. Given an n-nodes tree T, we encode it with the sequence of $2n - 1$ symbols produced by procedure ET. This encoding is referred to as $ET(T)$. We now analyze how to update $ET(T)$ when T is subject to dynamic edge operations.

If an edge $e = (u, v)$ is deleted from T, denote by T_u and T_v the two trees obtained after the deletion, with $u \in T_u$ and $v \in T_v$. Let $o(u_1)$, $o(v_1)$, $o(u_2)$ and $o(v_2)$ be the occurrences of u and v encountered

during the visit of (u, v). Without loss of generality assume that $o(u_1) < o(v_1) < o(v_2) < o(u_2)$ so that $ET(T) = \alpha o(u_1)\beta o(v_1)\gamma o(v_2)\delta o(u_2)\epsilon$. $ET(T_u)$ and $ET(T_v)$ can be easily computed from $ET(T)$, as $ET(T_v) = o(v_1)\gamma o(v_2)$, and $ET(T_v) = \alpha o(u_1)\beta\delta o(u_2)\epsilon$. To change the root of T from r to another vertex s, we do the following. Let $ET(T) = o(r)\alpha o(s_1)\beta$, where $o(s_1)$ is any occurrence of s. Then, the new encoding will be $o(s_1)\beta\alpha o(s)$, where $o(s)$ is a newly created occurrence of s that is added at the end of the new sequence. If two trees T_1 and T_2 are joined in a new tree T because of a new edge $e = (u, v)$, with $u \in T_1$ and $v \in T_2$, we first reroot T_2 at v. Now, given $ET(T_1) = \alpha o(u_1)\beta$ and the computed encoding $ET(T_2) = o(v_1)\gamma o(v_2)$, we compute $ET(T) = \alpha o(u_1)o(v_1)\gamma o(v_2)o(u)\beta$, where $o(u)$ is a newly created occurrence of vertex u.

Note that all the above primitives require the following operations: (i) splicing out an interval from a sequence, (ii) inserting an interval into a sequence, (iii) inserting or (iv) deleting a single occurrence from a sequence. If the sequence $ET(T)$ is stored in a balanced search tree of degree d (i.e., a balanced d-ary search tree), then one may insert or splice an interval, or insert or delete an occurrence in time $O(d \log n / \log d)$, while maintaining the balance of the tree. It can be checked in $O(\log n/d)$ whether two elements are in the same tree, or whether one element precedes the other in the ordering. The balanced d-ary search tree that stores $ET(T)$ is referred to as the *ET(T)-tree.*

We augment ET-trees to store non-tree edges as follows. For each occurrence of vertex $v \in T$, we arbitrarily select one occurrence to be the *active occurrence* of v. The list of non-tree edges incident to v is stored in the active occurrence of v: each node in the $ET(T)$-tree contains the number of non-tree edges and active occurrences stored in its subtree; thus, the root of the $ET(T)$-tree contains the weight and size of T.

Using these data structures, we can implement the following operations on a collection of trees:

tree(x): return a pointer to $ET(T)$, where T is the tree containing vertex x.

non_tree_edges(T): return the list of non-tree edges incident to T.

sample_n_test(T): select one non-tree edge incident to T at random, where an edge with both endpoints in T is picked with probability $2/w(T)$, and an edge with only endpoint in T is picked with probability $1/w(T)$. Test whether the edge has exactly one endpoint in T, and if so return this edge.

insert_tree(e): join by edge e the two trees containing its endpoints. This operation assumes that the two endpoints of e are in two different trees of the forest.

delete_tree(e): remove e from the tree that contains it. This operation assumes that e is a tree edge.

insert_non_tree(e): insert a non-tree edge e. This operation assumes that the two endpoints of e are in a same tree.

delete_non_tree(e): remove the edge e. This operation assumes that e is a non-tree edge.

Using a balanced binary search tree for representing $ET(T)$, yields the following running times for the above operations: *sample_n_test(T), insert_tree(e), delete_tree(e), insert_non_tree(e),* and *delete_non_tree(e)* in $O(\log n)$ time, and *non_tree_edges(T)* in $O(w(T) \log n)$ time.

We now turn to the problem of keeping the forest of G spanning throughout a sequence of updates. Note that the hard operation is a deletion of a tree edge: indeed, as shown in Section 8.4 a spanning forest is easily maintained throughout edge insertions, and deleting a non-tree edge does not change the forest. Let $e = (u, v)$ be a tree edge of the forest F, and let T_e be the tree of F containing edge e. Let T_u and T_v the two trees obtained from T after the deletion of e, such that T_u contains u and T_v contains v. When e is deleted, T_u and T_v can be reconnected if and only if there is a non-tree edge in G with one endpoint in T_u and one endpoint in T_v. We call such an edge a *replacement edge for e*. In other words, if there is a replacement edge for e, T is reconnected via this replacement edge; otherwise, the deletion of e disconnects T into T_u and T_v. The set of all the replacement edges for e (i.e., all the possible edges reconnecting T_u and T_v), is called the *candidate set of e*.

One main idea behind the technique of Henzinger and King is the following: when e is deleted, use random sampling among the non-tree edges incident to T_e in order to find quickly whether there exists a replacement edge for e. Using the Euler tour data structure, a single random edge adjacent to T_e can be selected and tested whether it reconnects T_e in logarithmic time. The goal is an update time of $O(\log^3 n)$, so we can afford a number of sampled edges of $O(\log^2 n)$. However, the candidate set of e might only be a small fraction of all non-tree edges which are adjacent to T. In this case it is unlikely to find a replacement edge for e among the sampled edges. If we found no candidate among the sampled edges, we check explicitly all the non-tree edges adjacent to T. After random sampling has failed to produce a replacement edge, we need to perform this check explicitly, otherwise we would not be guaranteed to provide correct answers to the queries. Since there might be a lot of edges which are adjacent to T, this explicit check could be an expensive operation, so it should be made a low probability event for the randomized algorithm. This is not yet true, however, since deleting all edges in a relatively small candidate set, reinserting them, deleting them again, and so on will almost surely produce many of those unfortunate events.

The second main idea prevents this undesirable behavior: we maintain an edge decomposition of the current graph G into $O(\log n)$ edge disjoint subgraphs $G_i = (V, E_i)$. These subgraphs are hierarchically ordered. Each i corresponds to a *level*. For each level i, there is a forest F_i such that the union $\cup_{i \leq k} F_i$ is a spanning forest of $\cup_{i \leq k} G_i$; in particular the union F of all F_i is a spanning forest of G. A *spanning forest at level i* is a tree in $\cup_{j \leq i} F_j$. The *weight* $w(T)$ of a spanning tree T at level i is the number of pairs (e', v) such that e' is a non-tree edge in G_i adjacent to the node v in T. If T_1 and T_2 are the two trees resulting from the deletion of e, we sample edges adjacent to the tree with the smaller weight. If sampling is unsuccessful due to a candidate set which is non-empty but relatively small, then the two pieces of the tree which was split are reconnected on the next higher level using one candidate, and all other candidate edges are copied to that level. The idea is to have sparse cuts on high levels and dense cuts on low levels. Non-tree edges always belong to the lowest level where their endpoints are connected or a higher level, and we always start sampling at the level of the deleted tree edge. After moving the candidates one level up, they are normally no longer a small fraction of all adjacent non-tree edges at the new level. If the candidate set on one level is empty, we try to sample on the next higher level. There is one more case to mention: if sampling was unsuccessful despite the fact that the candidate set was big enough, which means that we had bad luck in the sampling, we do not move the candidates to the next level, since this event has a small probability and does not happen very frequently. We present the pseudocode for *replace(u,v,i),* which is called after the deletion of the forest edge $e = (u, v)$ on level i:
replace(u,v,i)

1. **Let** T_u and T_v be the spanning trees at level i containing u and v, respectively. **Let** T be the tree with smaller weight among T_u and T_v. Ties are broken arbitrarily.
2. **If** $w(T) > \log^2 n$ **then**
   (a) **Repeat** sample_n_test(T) for at most $16 \log^2 n$ times. Stop if a replacement edge e is found.
   (b) **If** a replacement edge e is found **then do** delete_non_tree(e), insert_tree(e), and **return.**
3. (a) **Let** S be the set of edges with exactly one endpoint in T.
   (b) **If** $|S| \geq w(T)/(8 \log n)$ **then**
   Select one $e \in S$, delete_non_tree(e), and insert_tree(e).
   (c) **Else if** $0 < |S| < w(T)/(8 \log n)$ **then**
   Delete one edge e from S, delete_non_tree(e), and insert_tree(e) in level $(i + 1)$.
   Forall $e' \in S$ **do** delete_non_tree(e') and insert_non_tree(e') in level $(i + 1)$.
   (d) **Else if** $i < l$ **then** replace$(u, v, i + 1)$.

Note that edges may migrate from level 1 to level l, one level at the time. However, an upper bound of $O(\log n)$ for the number of levels is guaranteed, if there are only deletions of edges. This can be proved as follows. For any i, let m_i be the number of edges ever in level i.

LEMMA 8.11 For any level i, and for all smaller trees T_1 on level i, $\Sigma w(T_1) \leq 2m_i \log n$.

PROOF Let T be a tree which is split into two trees: if an endpoint of an edge is contained in the smaller split tree, the weight of the tree containing the endpoint is at least halved. Thus, each endpoint of a non-tree edge is incident to a small tree at most $\log n$ times in a given level i and the lemma follows.

LEMMA 8.12 For any level i, $m_i \leq m/4^{i-1}$.

PROOF We proceed by induction on i. The lemma trivially holds for $i = 1$. Assume it holds for $(i-1)$. When summed over all small trees T_1 on level $(i-1)$, at most $\Sigma w(T_1)/(8 \log n)$ edges are added to level i. By Lemma 8.11, $\Sigma w(T_1) \leq 2m_{i-1} \log n$, where m_{i-1} is the number of edges ever in level $(i-1)$. The lemma now follows from the induction step.

The following is an easy corollary of Lemma 8.12:

COROLLARY 8.1 The sum over all levels of the total number of edges is $\Sigma_i m_i = O(m)$.

Lemma 8.12 gives immediately a bound on the number of levels:

LEMMA 8.13 The number of levels is at most $l = \lceil \log m - \log \log n \rceil + 1$.

PROOF Since edges are never moved to a higher level from a level with less than $2 \log n$ edges, Lemma 8.12 implies that all edges of G are contained in some E_i, $i \leq \lceil \log m - \log \log n \rceil + 1$.

We are now ready to describe an algorithm for maintaining a spanning forest of a graph G subject to edge deletions. Initially, we compute a spanning forest F of G, compute $ET(T)$ for each tree in the forest, and select active occurrences for each vertex. For each i, the spanning forest at level i is initialized to F. Then, we insert all the non-tree edges with the proper active occurrences into level 1, and compute the number of non-tree edges in the subtree of each node of the binary search tree. This requires $O(m+n)$ times to find the spanning forest and initialize level 1, plus $O(n)$ for each subsequent level to initialize the spanning forest at that level. To check whether two vertices x and y are connected, we test if *tree(x)=tree(y)* on the last level. This can be done in time $O(\log n)$. To update the data structure after the deletion of an edge $e = (u, v)$, we do the following. If e is a non-tree edge, it is enough to perform a *delete_non_tree(e)* in the level where e appears. If e is a tree edge, let i be the level where e first appears. We do a *delete_tree(e)* at level j, for $j \geq i$, and then call *replace(u, v, i)*. This yields the following bounds.

THEOREM 8.9 **[21]** *Let G be a graph with m_0 edges and n vertices subject to edge deletions only. A spanning forest of G can be maintained in $O(\log^3 n)$ expected amortized time per deletion, if there are at least $\Omega(m_0)$ deletions. The time per query is $O(\log n)$.*

PROOF The bound for queries follows from the above argument. Let e be an edge to be deleted. If e

is a non-tree edge, its deletion can be taken care of in $O(\log n)$ time via a *delete_non_tree* primitive.

If e is a tree edge, let T_1 and T_2 the two trees created by the deletion of e, $w(T_1) \leq w(T_2)$. During the sampling phase we spend exactly $O(\log^3 n)$ time, as the cost of *sample_n_test* is $O(\log n)$ and we repeat this for at most $16 \log^2 n$ times.

If the sampling is not successful, collecting and testing all the non-tree edges incident to T_1 implies a total cost of $O(w(T_1) \log n)$. We now distinguish two cases. If we are unlucky in the sampling, $|S| \geq w(T_1)/(8 \log n)$: this happens with probability at most $(1 - 1/(8 \log n))^{16 \log^2 n} = O(1/n^2)$ and thus, contributes an expected cost of $O(\log n)$ per operation. If the cut S is sparse, $|S| < w(T_1)/(8 \log n)$, and we move the candidate set for e one level higher. Throughout the sequence of deletions, the cost incurred at level i for this case is $\Sigma w(T_1) \log n$, where the sum is taken over the small trees T_1 on level i. By Lemma 8.13 and Corollary 8.1 this gives a total cost of $O(m_0 \log^2 n)$.

In all cases where a replacement edge is found, $O(\log n)$ tree operations are performed in the different levels, contributing a cost of $O(\log^2 n)$. Hence, each tree edge deletion contributes a total of $O(\log^3 n)$ expected amortized cost towards the sequence of updates.

If there are also insertions, however, the analysis in Theorem 8.9 does not carry through, as the upper bound on the number of levels in the graph decomposition is no longer guaranteed. To achieve the same bound, there have to be periodical rebuilds of parts of the data structure. This is done as follows. We let the maximum number of levels to be $l = \lceil 2 \log n \rceil$. When an edge $e = (u, v)$ is inserted into G, we add it to the last level l. If u and v were not previously connected, then we do this via a *tree_insert,* otherwise we perform a *non_tree_insert.* In order to prevent the number of levels to grow behind their upper bound, a rebuild of the data structure is executed periodically. A *rebuild at level* i, $i \geq 1$, is carried out by moving all the tree and non-tree edges in level j, $j > i$, back to level i. Also, for each $j > i$ all the tree edges in level i are inserted into level j. Note that after a rebuild at level i, $E_j = \emptyset$ and $F_j = F_i$ for all $j > i$, i.e., there are no non-tree edges above level i, and the spanning trees on level $j \geq i$ span G.

The crucial point of this method is deciding when to apply a rebuild at level i. This is done as follows. We keep a counter K that counts the number of edge insertions modulo $2^{\lceil 2 \log n \rceil}$ since the start of the algorithm. Let $K_1, K_2, \ldots, K_l$ be the binary representation of K, with K_1 being the most significant bit: we perform a rebuild at level i each time the bit K_i flips to 1. This implies that the last level is rebuilt every other insertion, level $(l - 1)$ every four insertions. In general, a rebuild at level i occurs every 2^{l-i+1} insertions. We now show that the rebuilds contribute a total cost of $O(\log^3 n)$ toward a sequence of insertions and deletions of edges.

For the sake of completeness, assume that at the beginning the initialization of the data structures is considered a rebuild at level 1. Given a level i, we define an *epoch for* i to be any period of time starting right after a rebuild at level j, $j \leq i$, and ending right after the next rebuild at level j', $j' \leq i$. Namely, an epoch for i is the period between two consecutive rebuilds below or at level i: an epoch for i starts either at the start of the algorithm or right after some bit K_j, $j \leq i$, flips to 1, and ends with the next such flip. It can be easily seen that each epoch for i occurs every 2^{l-i} insertions, for any $1 \leq i \leq l$. There are two types of epochs for i, depending on whether it is bit K_i or a bit K_j, $j > i$, that flips to 1: an *empty* epoch for i starts right after a rebuild at j, $j < i$, and a *full* epoch for i starts right after a rebuild at i. At the time of the initialization, a *full* epoch for 1 starts, while for $i \geq 2$, *empty* epochs for i starts. The difference between these two types of epochs is the following. When an *empty* epoch for i starts, all the edges at level i have been moved to some level j, $j < i$, and consequently E_i is empty. On the contrary, when a *full* epoch for i starts, all the edges at level k, $k > i$, have been moved to level i, and thus, $E_i \neq \emptyset$.

An important point in the analysis is that for any $i \geq 2$, any epoch for $(i - 1)$ consists of two parts, one corresponding to an *empty* epoch for i followed by another corresponding to a *full* epoch for i. This happens because a flip to 1 of a bit K_j, $j \leq 2$, must be followed by a flip to 1 of K_i before another bit $K_{j'}$, $j' \leq i$ flips again to 1. Thus, when each epoch for $(i - 1)$ starts, E_i is empty. Define m'_i to be the number of edges ever in level i during an epoch for i. The following lemma is the analogous of Lemma 8.11.

LEMMA 8.14 For any level i, and for all smaller trees T_1 on level i searched during an epoch for i, $\Sigma w(T_1) \leq 2m'_i \log n$.

LEMMA 8.15 $m'_i < n^2/2^{i-1}$.

PROOF To prove the lemma, it is enough to bound the number of edges that are moved to level i during any one epoch for $(i-1)$, as $E_i = \emptyset$ at the start of each epoch for $(i-1)$ and each epoch for i is contained in one epoch for $(i-1)$. Consider an edge e that is in level i during one epoch for $(i-1)$. There are only two possibilities: either e was passed up from level $(i-1)$ because of an edge deletion, or e was moved down during a rebuild at i. Assume that e was moved down during a rebuild at i: since right after the rebuild at i the second part of the epoch for $(i-1)$ (i.e., the *full* epoch for i) starts, e was moved back to level i still during the *empty* epoch for i. Note that E_k, for $k \geq i$, was empty at the beginning of the epoch for $(i-1)$; consequently, either e was passed up from E_{i-1} to E_i or e was inserted into G during the *empty* epoch for i. In summary, denoting by a_{i-1} the maximum number of edges passed up from E_{i-1} to E_i during one epoch for $(i-1)$, and by b_i the number of edges inserted into G during one epoch for i, we have that $m'_i \leq a_{i-1} + b_i$. By definition of epoch, the number of edges inserted during an epoch for i is $b_i = 2^{l-i}$. It remains for us to bound a_{i-1}. Applying the same argument as in the proof of Lemma 8.12, using this time Lemma 8.14, yields that $a_{i-1} \leq m'_{i-1}/4$. Substituting for a_{i-1} and b_i yields $m'_i \leq m'_{i-1}/4 + 2^{l-i}$, with $m'_1 \leq n^2$. Since $l = \lceil 2 \log n \rceil$, $m'_i < n^2/2^{i-1}$.

Lemma 8.15 implies that $m'_l \leq 2$, and thus, edges never need to be passed to a level higher than l.

COROLLARY 8.2 All edges of G are contained in some level E_i, $i \leq \lceil 2 \log n \rceil$.

We are now ready to analyze the running time of the entire algorithm.

THEOREM 8.10 **[21]** *Let G be a graph with m_0 edges and n vertices subject to edge insertions and deletions. A spanning forest of G can be maintained in $O(\log^3 n)$ expected amortized time per update, if there are at least $\Omega(m_0)$ updates. The time per query is $O(\log n)$.*

PROOF There are two main differences with the algorithm for deletions only described in Theorem 8.9. The first is that now the actual cost of an insertion has to be taken into account (i.e., the cost of operation *move_edges*). The second difference is that the argument that a total of $O(m_i \log n)$ edges are examined throughout the course of the algorithm when sparse cuts are moved one level higher must be modified to take into account epochs.

The cost of executing *move_edges(i)* is the cost of moving each non-tree and tree edge from E_j to E_i, for all $j > i$, plus the cost of updating all the forests F_k, $i \leq k < j$. The number of edges moved into level i by a *move_edges(i)* is $\Sigma_{j>i} m'_j$, which by Lemma 8.15, is never greater than $n^2/2^{i-1}$. Since moving one edge costs $O(\log n)$, the total cost incurred by a *move_edges(i)* operation is $O(n^2 \log n/2^i)$. Note that during an epoch for i, at most one *move_edges(i)* can be performed, since that will end the current epoch and start a new one.

Inserting a tree edge into a given level costs $O(\log n)$. Since a tree edge is never passed up during edge deletions, it can be added only once to a given level. This yields a total of $O(\log^2 n)$ per tree edge.

We now analyze the cost of collecting and testing the edges from all smaller trees T_1 on level i during an epoch for i (when sparse cuts for level i are moved to level $(i+1)$). Fix a level $i \leq l$. If $i = l$, since there are $O(1)$ edges in E_l at any given time, the total cost for collecting and testing on level l will be

$O(\log n)$. If $i < l$, the cost of collecting and testing edges on all small trees on level i during an epoch for i is $O(2m'_i \log n \times \log n)$ because of Lemma 8.14. By Lemma 8.15, this is $O(n^2 \log^2 n/2^i)$.

In summary, each update contributes $O(\log^3 n)$ per operation plus $O(n^2 \log^2 n/2^i)$ per each epoch for i, $1 \leq i \leq l$. To amortized the latter bound against insertions, during each insertion we distribute $\Theta(\log^2 n)$ credits per level. This sums up to $\Theta(\log^3 n)$ credits per insertion. An epoch for i occurs every $2^{l-i} = \Theta(n^2/2^i)$ insertions, at which time level i has accumulated $\Theta(n^2 \log^2 n/2^i)$ credits to pay for the cost of *move_edges(i)* and the cost of collecting and testing edges on all small trees.

We end this section by mentioning that Henzinger and Thorup have recently improved the update bound of Theorem 8.10 from $O(\log^3 n)$ to $O(\log^2 n)$. We refer the interested reader to [25] for the details.

8.6 Research Issues and Summary

In this chapter we have described the most efficient known algorithms for maintaining dynamic graphs. Experimental comparison of some of the dynamic connectivity algorithms has recently been performed by Alberts et al. [1], who showed that in the average case for sufficiently random inputs, a simple sparsification tree based on edge subdivision performs as well as the vertex subdivision method we described in Theorem 8.6. Furthermore, they compared this simplified sparsification algorithm (having a worst-case update bound of $O(n \log(m/n))$) with the randomized method of Henzinger and King (having an expected amortized bound of $O(\log^3 n)$). The sparsification method worked well for small update sequences, but the other method was faster on longer sequences. In subsequent work, Amato et al. [2] conducted an empirical study of some dynamic minimum spanning trees algorithms. In particular, they showed that a variant of the algorithm of Frederickson (based on one-level clustering) performs well both for random and nonrandom inputs. Sparsification on top of this variant of Frederickson yields better algorithms for nonrandom inputs.

There are still several open questions. For some of the fully dynamic problems described in this chapter, such as connectivity and 2-connectivity, polylogarithmic randomized algorithms are available. However, the deterministic bounds for the same problems have higher running times. Are there any faster deterministic algorithms for these problems? Furthermore, no randomized algorithm is known for the fully dynamic maintenance of a minimum spanning tree, and the fastest algorithm requires $O(n^{1/2})$ time per update. Is there any faster randomized algorithm for this? Very little is known about lower bounds for **fully dynamic graph problems.** The only nontrivial lower bounds known are the $\Omega(\log n/\log\log n)$ lower bounds of Fredman and Henzinger [14] for the cell-probe model of computation. While the randomized algorithms described in this chapter are close to these lower bounds, there is still a big gap for the deterministic algorithms. Can the gap between upper and lower bounds be tightened in this case? Furthermore, can we prove nontrivial lower bounds for other fully dynamic problems as well? Can we allow other update operations besides edge insertion and deletion? Usually, isolated vertices can be inserted and deleted in the same times as edge insertion and deletion. Is there some way of allowing rapid deletion of vertices that may still be connected to many edges?

8.7 Defining Terms

Certificate: For any graph property $\mathcal{P}$, and graph G, a certificate for G is a graph G' such that G has property $\mathcal{P}$ if and only if G' has the property.

Fully dynamic graph problem: Problem where the update operations include unrestricted insertions and deletions of edges.

Partially dynamic graph problem: Problem where the update operations include either edge insertions (*incremental*) or edge deletions (*decremental*).

Sparsification: Technique for designing dynamic graph algorithms, which when applicable transform a time bound of $T(n, m)$ into $O(T(n, n))$, where m is the number of edges, and n is the number of vertices of the given graph.

Topology tree: Tree that describes a balanced decomposition of another tree, according to its topology.

9.1 Introduction

Graphs are commonly used in Computer Science to model relational structures such as programs, databases, and data structures. For example:

- Petri nets are used extensively to model communications protocols.
- Call graphs of programs are often used in CASE tools; an example is Fig. 9.1(a).
- Object-oriented design techniques use a variety of graphs; one such example is the class diagram in Fig. 9.1(b).
- Data flow graphs are used widely in software engineering.

One of the critical problems in using such models is that the graph must be drawn in a way that illuminates the information in the application. A good **graph drawing** gives a clear understanding of a structural model; a bad drawing is simply misleading. For example, a graph of a computer network is pictured in Fig. 9.2(a); this drawing is easy to follow. A different drawing of the same graph in Fig. 9.2(b); this is much more difficult to follow.

A *graph drawing algorithm* takes a graph and produces a drawing of it. The *graph drawing problem* is to find graph drawing algorithms that produce good drawings. To make the problem more precise, we define a *graph* $G = (V, E)$ to consist of a set V of *vertices* and a set E of *edges,* that is, unordered pairs of vertices. A *drawing* of G assigns a location (in two or three dimensions) to every vertex of G and a simple curve c_{uv} to every edge (u, v) of G such that the endpoints of c_{uv} are the locations of u and v. Notation and terminology of graph theory is given in [4].

The remainder of this chapter gives an overview of graph drawing (Section 9.2) and details some methods for straight-line ("Straight Line Drawings" and "Straight-Line Drawings in Three Dimensions") and orthogonal ("Orthogonal Drawings" and "Three Dimensional Orthogonal Grid

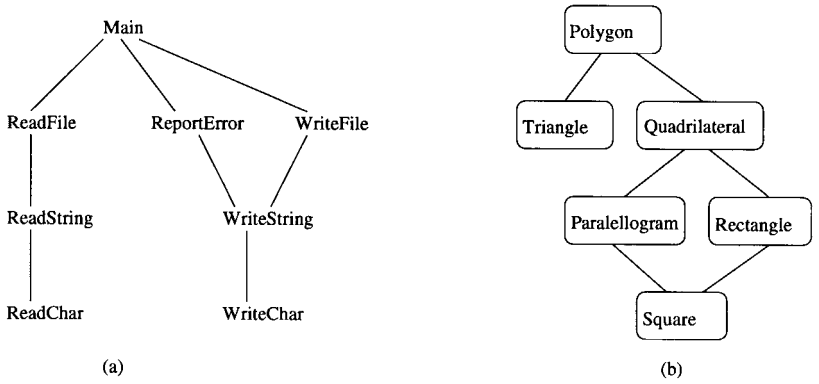

Figure 9.1 Two graphs.

Drawings") drawings in two (Section 9.3) and three (Section 9.4) dimensions. A list of research problems is given in Section 9.5, and a review of the defining terms is given in Section 9.6.

9.2 Overview

In this section we provide a brief overview of the graph drawing problem. "Drawing Conventions" outlines the main conventions for drawing graphs, and "Aesthetic Criteria" lists the most common "aesthetic criteria," or optimization goals, of graph drawing. A brief survey of some significant graph drawing algorithms is given in "Drawing Methods."

Drawing Conventions

Drawing conventions for graphs differ from one application area to another. Some of the common conventions are listed below.

- Many graph drawing methods output a *grid* drawing: the location of each vertex has integer coordinates. Some **grid drawings** appear in Fig. 9.3. The algorithms in Sections 9.3 and 9.4 produce grid drawings.
- In a *polyline* drawing, the curve representing each edge is a polyline, that is, a chain of line segments. Polyline drawings are in Fig. 9.3(b), (c), and (d). If each polyline is just a line segment, then the drawing is a *straight-line* drawing, as in Fig. 9.3(c). Algorithms for creating **straight-line drawings** are given in "Straight Line Drawings" and "Straight-Line Drawings in Three Dimensions."
- In an *orthogonal* drawing, each edge is a polyline composed of straight line segments parallel to one of the coordinate axes. **Orthogonal drawings** are used in many application areas because horizontal and vertical line segments are easy to follow.

Figures 9.3(b) and (d) are orthogonal drawings. Orthogonal drawing algorithms are described in "Orthogonal Drawings" and "Three Dimensional Orthogonal Grid Drawings."

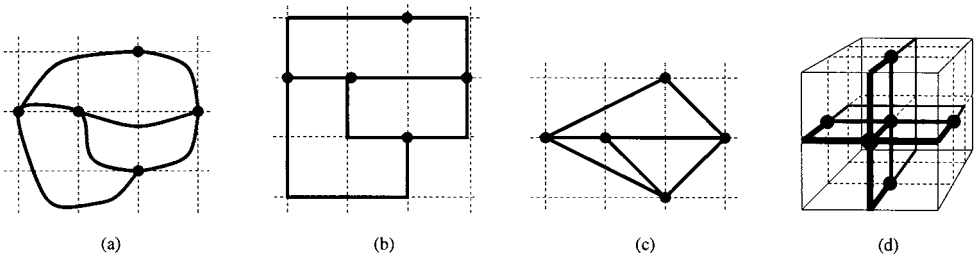

Figure 9.3 Examples of drawing conventions: (a) grid drawing (b) orthogonal grid drawing (c) straight-line drawing (d) three-dimensional orthogonal drawing.

Aesthetic Criteria

The main requirement of a graph drawing method is that the output should be *readable*; that is, it should be easy to understand, easy to remember, and it should illuminate rather than obscure the application. Of course it is difficult to model readability precisely, since it varies from one application to another, and from one human to another; these variations mean that there are many graph drawing problems. The problems can be classified roughly according to the specific optimization goals which they try to achieve. These goals are called *aesthetic criteria*; a list of some such criteria is below.

- Minimization of the number of **edge crossings** is an aesthetic that is important in many application areas. The drawing in Fig. 9.2(a) has no edge crossings, and Fig. 9.2(b) has ten.
  A graph that can be drawn in the plane with no edge crossings is called a **planar graph.** Methods for drawing planar graphs are described in Section 9.3.
  In general, visualization systems must deal with graphs which are not planar. To exploit the theory of planar graphs and methods for drawing planar graphs, it is necessary to *planarize* nonplanar graphs, that is, to transform them to planar graphs. A **planarization** technique is described in "Planarization."
- The *vertex resolution* of a drawing is the minimum distance between a pair of vertices. For a given screen size, we would like to have a drawing with maximum resolution.
  In most cases, the drawing is a grid drawing; this guarantees that the drawing has vertex resolution at least one. To ensure adequate vertex resolution, we try to keep the *size* of the grid drawing bounded. If a two-dimensional grid drawing lies within an isothetic rectangle of width w and height h, then the vertex resolution for a unit square screen is at least $\max(1/w, 1/h)$. All the methods described in Sections 9.3 and 9.4 give grid drawings with polynomially bounded size.
- *Bends*: In polyline drawings it is easier to follow edges with fewer bends. Thus, many graph drawing methods aim to minimize, or at least bound, the number of edge bends. In the drawing in Fig. 9.3(b), there are 6 edge bends; the maximum number of bends on an edge is two. Algorithms for straight-line drawings (no bends at all) are given in "Straight Line Drawings" and "Straight-Line Drawings in Three Dimensions."

Very few graphs have an orthogonal drawing with no bends, but there are a number of methods which aim to keep the number of bends in orthogonal drawings small. A method for creating 2-dimensional planar orthogonal drawings of a planar graph (with a fixed embedding) with a minimum number of bends is described in "Orthogonal Drawings." A method for creating orthogonal drawings in 3 dimensions with a bound on the number of bends in each edge is described in "Three Dimensional Orthogonal Grid Drawings."

Drawing Methods

In Sections 9.3 and 9.4, we describe some two- and three-dimensional graph drawing methods in detail. However, there are many different approaches to the graph drawing problem besides those described in Sections 9.3 and 9.4. Here we briefly overview some of the more significant methods.

Force-Directed Methods

Force-directed methods draw a physical analogy between the layout problem and a system of forces defined on drawings of graphs. For example, vertices may be replaced with bodies that repel each other, and edges have been replaced with Hooke's law springs. In general, these methods have two parts:

The *model*: this is a "force system" defined by the vertices and edges of the graph. It is a physical model for a graph. The model may be defined in terms of "energy" rather than a system of forces; the force system is just the derivative of the energy system.

The *algorithm*: this is a technique for finding an equilibrium state of the force system, that is, a position for each vertex such that the total force on every vertex is zero. This state defines a drawing of the graph. If the model is stated as an energy system then the algorithm is usually stated as a technique for finding a configuration with locally minimal energy.

Force-directed algorithms are easy to understand and easy to implement, and thus, they have become quite popular. They are fairly successful with "tree-like" graphs [see Fig. 9.4(a)]. They work in both two and three dimensions. A comparison of the many variations of the basic idea appears in [6].

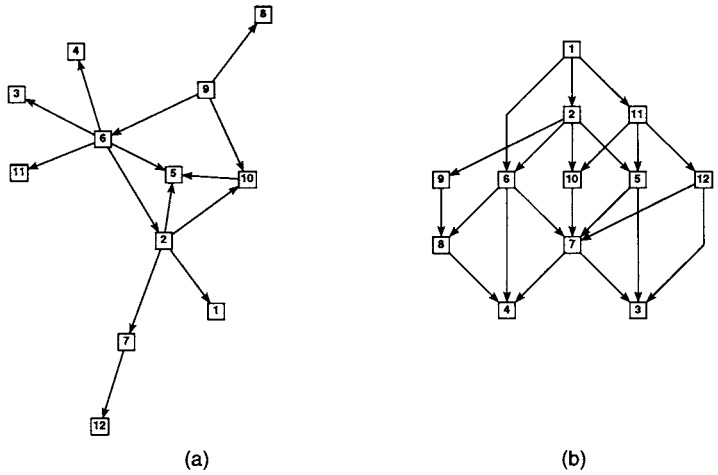

Figure 9.4 (a) A force-directed drawing and (b) a hierarchical drawing.

Hierarchical Methods

Hierarchical methods are suitable for directed graphs, especially where the graph has very few directed cycles.

Suppose that $G = (V, E)$ is an acyclic directed graph. A *layering* of G is a partition of V into subsets $L_1, L_2, \ldots, L_h$, such that if $(u, v) \in E$ where $u \in L_i$ and $v \in L_j$ then $i > j$. An acyclic directed graph with a layering is a *hierarchical graph.*

Hierarchical methods convert a directed graph into a hierarchical graph, and draw the hierarchical graph such that layer L_i lies on the horizontal line $y = i$. A sample drawing is in Fig. 9.4(b). The layers in this graph are $L_1 = \{3, 4\}$, $L_2 = \{7, 8\}$, $L_3 = \{5, 6, 9, 10, 12\}$, $L_4 = \{2, 11\}$, and $L_5 = \{1\}$. The aims of these methods include the following.

(a) Represent the "flow" of the graph from top to bottom of the page. This implies that most arcs should point downward.

(b) Ensure that the graph drawing fits the page; that is, it is not too high (not too many layers) and not too wide (not too many vertices in each layer).

(c) Ensure that arcs are not too long. This implies that the y extent $|i - j|$ of an arc (u, v) with $u \in L_i$ and $v \in L_j$ should be minimized.

(d) Reduce the number of edge crossings.

(e) Ensure that arcs are as straight as possible.

There are many hierarchical methods, but the following four steps are common to most.

1. Directed cycles are removed by temporarily reversing some of the arcs. The arcs that are reversed will appear pointing upward in the final drawing and thus, the number of arcs reversed should be small to achieve (a) above.
2. The set of vertices is partitioned into layers. The partition aims to achieve (b) and (c) above.
3. Vertices within each layer are permuted so that the overall number of crossings is small.
4. Vertices are positioned in each layer so that edges which span more than one layer are as straight as possible.

Each step involves heuristics for NP-hard optimization problems. A detailed description of hierarchical methods appears in [20]. An empirical comparison of various hierarchical drawing methods appears in [15].

Tree Drawing Methods

Rooted trees are special hierarchical graphs, and hierarchical methods apply. We can assign vertices at depth k in the tree to layer $h - k$, where h is the maximum depth. The convention that layer i is drawn on the horizontal line $y = i$ helps the viewer to see the hierarchy represented by the tree. However, for trees there are some simpler approaches; here we outline one such method.

Note that the edge crossing problem is trivial for trees. The main challenge is to create a drawing with width small enough to fit the page. The *Reingold–Tilford algorithm* [37] is a simple heuristic method designed to reduce width. Suppose that T is an oriented binary rooted tree. We denote the left subtree by T_L and the right subtree by T_R. Draw subtrees T_L and T_R recursively on separate sheets of paper. Move the drawings of T_L and T_R toward each other as far as possible without the two drawings touching. Now center the root of T between its children. A drawing computed with the Reingold–Tilford algorithm is shown in Fig. 9.5(a).

The Reingold–Tilford method can be extended to nonbinary trees. However, for trees with many children per vertex it is difficult to reduce width while retaining the layering convention (that is, placing vertices of depth k in the tree at a vertical distance of k below the root). The *tip-over* convention reduces width by "tipping over" some of the subtree drawings, and is effective

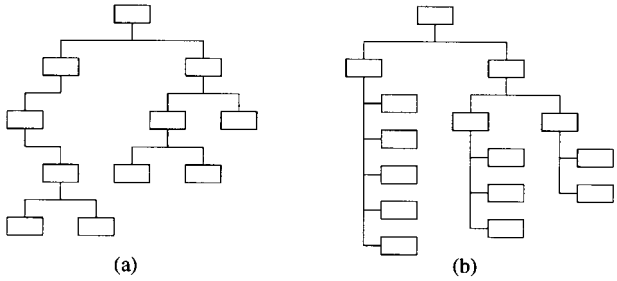

Figure 9.5 (a) Tree drawn with the Reingold–Tilford algorithm and (b) tip-over drawing of a tree.

for trees with large degrees. A sample tip-over drawing is shown in Fig. 9.5(b); algorithms for producing tip-over drawings are given in [19].

9.3 Graph Drawing in Two Dimensions

A great deal of the long history of graph theory has been devoted to the study of representations of graphs in the plane. The concepts and results developed over centuries by graph theorists have proved very useful in recent visualization and VLSI layout applications. This section describes some techniques used in finding good drawings in two dimensions.

A representation of a planar graph without edge crossings in the plane is called a *plane representation* or a *planar embedding.* The graph is then called a *plane* graph. A planar embedding divides the plane into regions, which we call *faces.* The unbounded face is called the *outer face.* A *planar embedding* can be represented by a *planar map,* that is a cyclic ordered list of the edges bounding each face.

Many graphs are not planar, and the first subsection of this section describes methods for transforming a nonplanar graph into a planar graph. The following subsections give two approaches to drawing the planar graph so obtained.

Planarization

Given a nonplanar graph, we want to find a drawing with a minimum number of edge crossings. This problem is NP-hard [24]. A natural approach to the problem is to first determine a maximum planar subgraph, and then insert the remaining edges, while trying to keep a minimal number of crossings.

The first step, finding a maximum planar subgraph, also involves an NP-hard problem [33]. We can find acceptable solutions using a *branch and cut* method, described in this section.

The second step, inserting the "nonplanar" edges, can be done by the following algorithm. We construct a plane representation G_P of the maximum planar subgraph output from the first step; see [34]. Next we construct the geometric dual graph $G_P^* = (V^*, E^*)$ of G_P. For each face f in G_P we introduce a vertex $v_f^* \in V^*$, and for each edge $e \in E$ we introduce an edge $e^* \in E^*$ between the vertices v_f^* and $v_{f'}^*$, where f and f' denote the two faces adjacent to e in G_P [see Fig. 9.6(a)].

Suppose that we already added a new edge $e = (v, w)$ to G_P. The edge e introduces a crossing to G_P, whenever it crosses a border edge between two faces in G_P. Hence, the number of crossings is exactly the number of border edges we cross. Thus, minimizing the number of crossings is equivalent to minimize the corresponding number of edges in the geometric dual on a path from a face in G_P adjacent to v to a face in G_P adjacent to w. We have to solve $|\delta(v)||\delta(w)|$ shortest path problems from vertices $v^* \in A^*(v)$, $w^* \in A^*(w)$ in G_P^*, where $A^*(v)$ and $A^*(w)$ contain all vertices corresponding to all the faces f_v and f_w that are adjacent to v or w in G_P. By adding two super-vertices v_0^* and w_0^* to G^* and edges to all vertices in $A^*(v)$ and $A^*(w)$, the number of shortest path problems can be reduced to one.

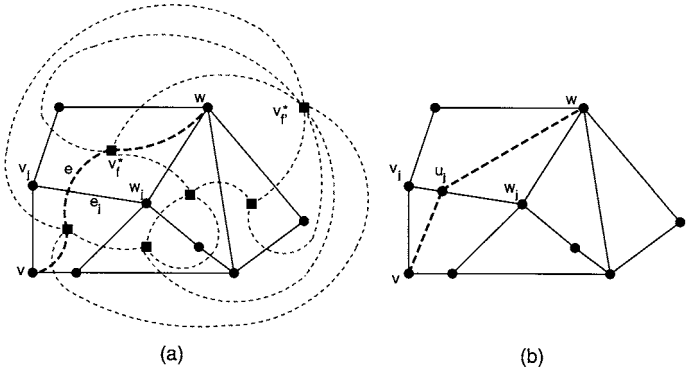

Figure 9.6 Introducing a new edge e to a plane graph G_P: (a) the geometric dual graph G_P^* with the edge e, (b) substituting the new crossing.

If the maximum planar subgraph contains all edges but one, we get the minimal number of crossings with respect to the plane representation G_P. In order to be able to add further edges, we substitute all the new crossings between each pair of edges, say $e = (v, w)$, and $e_j = (v_j, w_j)$, by a new vertex u_j adjacent to the end vertices v, w, v_j, and w_j [see Fig. 9.6(b)]. Again, we have a planar graph and can repeat the above process. Note that this approach is not an exact algorithm for crossing minimization, but experience has shown that it is a good heuristic in the case that the number of inserted edges is small. When all the edges are reinserted, we can use planar graph drawing algorithms as described in the following sections.

Next we consider the problem of determining the maximum planar subgraph. Given a (nonplanar) weighted graph with edge weights c_e for $e \in E$, the *maximum (weight) planar subgraph problem* is to delete a set of edges F to obtain a planar subgraph $G' = (V, E \setminus F)$ such that the sum of all edge weights $\Sigma_{e \in E \setminus F} c_e$ of G' is maximum. In the unweighted case, where $c_e = 1$ for all edges $e \in E$, the problem consists of finding the minimum number of edges whose deletion from a nonplanar graph gives a planar subgraph.

An efficient way to solve a given maximum planar subgraph problem in practice is to use polyhedral combinatorics, a subfield of combinatorial optimization that aims at describing relaxations of combinatorial optimization problems as linear programs and solving these with special purpose methods. In the following we describe this technique and the corresponding algorithm, which leads to quite good and in many cases provably optimal solutions for moderately sized sparse graphs (i.e., up to 100 edges) and very dense graphs.

Integer Programming Formulation

Suppose that a graph $G = (V, E)$ with edge weights c_e for all $e \in E$ is given. Let $\mathcal{P}_\mathcal{G}$ be the set of all planar subgraphs of G. For each planar subgraph $G[P] = (V', P) \in \mathcal{P}_\mathcal{G}$ induced by the edge set $P \subseteq E$, we define its *characteristic vector* $\chi^P \in \mathrm{R}^E$ by setting $\chi_e^P = 1$ if $e \in P$ and $\chi_e^P = 0$ if $e \notin P$. This yields a 1–1-correspondence between the planar subgraphs and certain $\{0, 1\}$-vectors in R^E. The *planar subgraph polytope* $\mathcal{PLS}(G)$ of G is defined as the convex hull over all characteristic vectors of planar subgraphs of G:

$$\mathcal{PLS}(G) := \mathrm{conv}\left\{\chi^P \in \mathrm{R}^E \mid G[P] \in \mathcal{P}_G\right\} \ .$$

The problem of finding a planar subgraph $G[P]$ of G with weight $c(P)$ as large as possible can be written as the linear program

$$\max\left\{c^T x \mid x \in \mathcal{PLS}(G)\right\} \ ,$$

since the vertices of the polytope $\mathcal{PLS}(G)$ are exactly the characteristic vectors of the planar subgraphs of G. In order to apply linear programming techniques to solve this linear program one

has to represent $\mathcal{PLS}(G)$ as the solution of an inequality system. Due to the NP-hardness of our problem, we cannot expect to be able to find a full description of $\mathcal{PLS}(G)$ by linear inequalities. Nevertheless, a partial description of the facial structure of $\mathcal{PLS}(G)$ by linear inequalities is useful in practice, because such a description defines a relaxation of the original problem. Such relaxations can be solved within a branch and bound framework via cutting plane techniques and linear programming in order to produce tight bounds.

In an irredundant description of $\mathcal{PLS}(G)$ by linear inequalities only facet-defining inequalities are present. An inequality $c^T x \leq c_0$ is *facet-defining* for a polytope $\mathcal{P}$ if it is *valid* for $\mathcal{P}$, i.e., $\mathcal{P} \subseteq \{x \in \mathrm{R}^{|E|} \mid c^T x \leq c_0\}$, and there exist $\dim(P)$ affinely independent points in $\mathcal{P}$ satisfying the inequality with equality. Geometrically, a facet-defining inequality corresponds to a face of maximal dimension of $\mathcal{P}$. For efficiency, also in a partial description by inequalities, we concentrate on those valid inequalities for $\mathcal{PLS}(G)$ which are facet-defining.

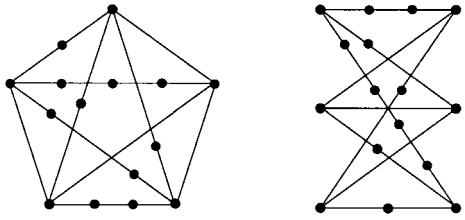

Figure 9.7 Subdivisions of K_5 and $K_{3,3}$.

By Kuratowski's Theorem every nonplanar graph contains a subdivision of K_5 or $K_{3,3}$, (see Fig. 9.7) and it follows that the minimal nonplanar graphs are exactly K_5, $K_{3,3}$, and their subdivisions. Let us call the minimal nonplanar subgraphs Kuratowski subgraphs. A Kuratowski subgraph gives rise to a Kuratowski inequality which requires that at least one edge has to be removed from it. We use the notation $x(K) = \Sigma_{e \in K} x_e$ for $K \subseteq E$. We have the following integer programming formulation for the maximum planar subgraph problem for a graph $G = (V, E)$ with weights c_e associated with every edge:

$$
\begin{array}{lll}
\text{maximize} & c^T x & \\
\text{subject to} & x(K) \leq |K| - 1 & \text{for all } K \subseteq E, K \text{ induces a Kuratowski subgraph} \\
& 0 \leq x_e \leq 1 & \text{for all } e \in E \\
& x_e \text{ integral} & \text{for all } e \in E\ .
\end{array}
$$

The following theorem states that all the above inequalities are necessary in the minimal description of $\mathcal{PLS}(G)$.

THEOREM 9.1 *[30] The dimension of the $\mathcal{PLS}$-polytope of $G = (V, E)$ is $|E|$, so it is full-dimensional. For all edges $e \in E$, the inequalities $x_e \geq 0$ and $x_e \leq 1$ define facets of $\mathcal{PLS}(G)$. Moreover, for all minimal nonplanar subgraphs $G' = (V', F)$ of $G = (V, E)$ the Kuratowski inequality $x(F) \leq |F| - 1$ defines a facet of $\mathcal{PLS}(G)$.*

Another class of inequalities plays an important role in the theory of planar graphs. These can be obtained from Euler's formula for the relationships of vertices, edges and faces in a plane connected graph, as in the following lemma.

LEMMA 9.1 (Euler inequalities) Suppose that $G = (V, E)$ and $G' = (V', E')$ is the subgraph of G induced by $V' \subseteq V$. Then $x(E') \leq 3|V'| - 6$ is valid for $\mathcal{PLS}(G)$. If G' contains no triangles, then the inequality intensifies to $x(E') \leq 2|V'| - 4$.

If the graph $G = (V, E)$ is dense then the Euler inequality may yield a facet; this is the case for $G = K_n$, resp. $G = K_{m,n}$. Further facet-defining inequalities for $\mathcal{PLS}(G)$ that generalize the Kuratowski inequalities are known (see [30]).

The Branch and Cut Algorithm

In the following we outline a cutting plane algorithm using facet-defining inequalities for $\mathcal{PLS}(G)$. The method uses a sequence of "relaxations" of the maximum planar subgraph problem, each solved by linear programming. A relaxation of a combinatorial maximization problem P is another maximization problem P_0, whose set of feasible solutions properly contains all feasible solutions of the original problem. The objective function of P_0 is an extension of the objective function of P. Hence, the value of the optimum solution of the relaxation of our maximum planar subgraph problem is at least as high as the optimum value of the original problem. Consequently, a solution of a relaxation of the maximum planar subgraph problem yields an upper bound.

A possible relaxation is obtained by dropping the integrality constraints in the integer programming formulation for the maximum planar subgraph problem. In general the number of Kuratowski subgraphs in a given graph is too big to be able to enumerate them all. But we do not have to add all of them. In every iteration of our cutting plane algorithm, we only add a few inequalities. We start with an initial linear program containing as constraints only the trivial inequalities and the Euler inequality for G. Hence, we optimize over a polytope containing the planar subgraph polytope $\mathcal{PLS}(G)$.

If the solution vector $\bar{x}$ of this linear program is integral, and it is a characteristic vector of a planar graph, then we know that we have found the optimum solution to our original maximum planar subgraph problem. This is true since we have solved a relaxation of the original problem P, for which we know that a solution of P cannot be better. If either integrality or planarity conditions are not satisfied, then we try to find inequalities which are violated by our current solution vector $\bar{x}$ and which are valid for all planar subgraphs of G. Geometrically speaking, we try to find an inequality defining a hyperplane that cuts off $\bar{x}$; this is the reason why these hyperplanes are called "cutting planes."

The cutting planes can be of type Kuratowski, Euler, or any other facet-defining or valid inequalities [30]. We add the inequality corresponding to such cutting planes to our current linear program. We solve the linear program and proceed in the same way, until we either find an optimum solution or we do not find any violated inequalities for $\bar{x}$. In the latter case, a solution value $z = c^T\bar{x}$ is obtained from the solution vector $\bar{x}$, which is not an incidence vector of a planar graph. A flow diagram of a cutting plane algorithm is shown in Fig. 9.8.

If we fail to solve the maximum planar subgraph problem to optimality, we can switch to branch and bound. That is, we branch by setting a variable to zero or one, and create two new subproblems. In each branching node, exactly the same procedure can be used. Note that all valid inequalities for $\mathcal{PLS}(G)$ are globally valid in the whole branch and bound tree.

The main question arising within every cutting plane method, namely, how to find those cutting planes, is called the *separation problem with respect to* $\mathcal{D}$:

> Given a class of inequalities $\mathcal{D}$, and a vector $\bar{x}$, either find an inequality in this class that is violated by $\bar{x}$, or prove that no such inequality exists.

Unfortunately, the separation problem for the Kuratowski inequalities is still unsolved. A heuristic separation procedure based on finding Kuratowski subgraphs may be used (see [30]). This may find violated inequalities, but in the case that it cannot find any, it is unable to prove that no violated inequality exists.

After a linear program has been solved, we try to exploit the solution to produce a feasible solution. This can be done by a simple greedy heuristic in which the edges are subsequently added, in increasing LP-value order, while they do not destroy planarity.

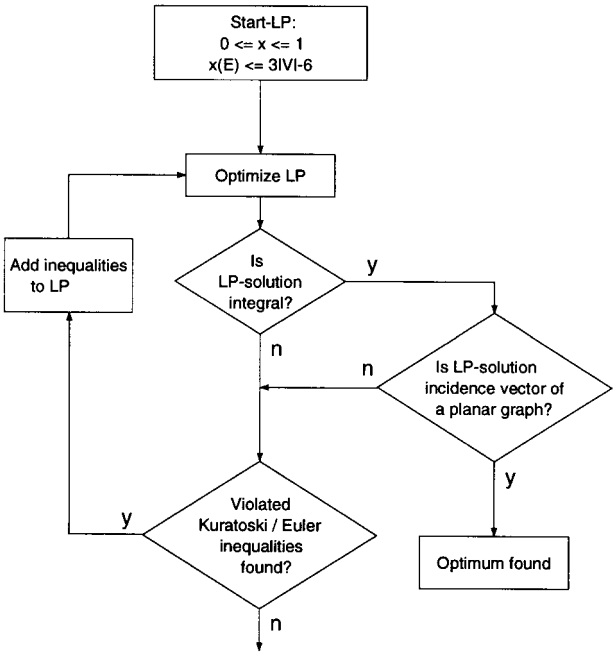

Figure 9.8 Flow diagram of a cutting plane algorithm.

Since during the computation of the branch and cut algorithm a sequence of increasing lower bounds l and decreasing upper bounds u is produced, we can stop the computation at any time with a quality guaranteed solution that deviates by at most a factor of $\frac{u-l}{u}$ from the optimum. Alternatively, we can run the branch and cut algorithm with a prespecified time limit.

Remarks

Computational results for the branch and cut approach are encouraging. For the graph shown in Fig. 9.9, the method took less than one second to find the maximum planar subgraph. In most graphs with up to 70 edges, the branch and cut algorithm provides the optimum solution within a few seconds.

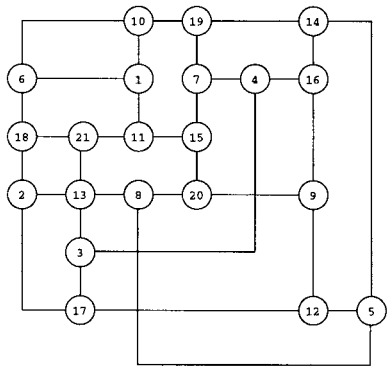

Figure 9.9 Orthogonal layout based on a maximum planar subgraph.

There are many other approaches to the maximum planar subgraph problem; see, for example, [7, 26].

Straight Line Drawings

In this section we consider the problem of constructing straight-line planar drawings of planar graphs. This problem predates the applications in information visualization and was considered by a number of mathematicians [22, 40, 42]. The problem with these early approaches was that they offered poor resolution; that is, they placed vertices exponentially close together. The breakthrough came with the following theorem from [13].

THEOREM 9.2 *Every n-vertex planar graph has a straight-line planar grid drawing which is contained within a rectangle of dimensions $O(n) \times O(n)$.*

The purpose of this section is to outline a constructive proof of Theorem 9.2. Roughly speaking, it proceeds as follows.

1. Dummy edges are added to the graph to ensure that it is a triangulated planar graph, that is, each face is a triangle.
2. The vertices are ordered in a certain way defined below.
3. The vertices are placed one at a time on the grid in the order defined at step 2.

The first step is not difficult. First we find a planar embedding, and then add edges to every face until it becomes a triangle. We present steps 2 and 3 in the following two subsections.

Computing the Ordering

Let $G = (V, E)$ be a triangulated plane graph with $n > 3$ vertices, with vertices u, v, and w on the outer face. Suppose that the vertices of V are ordered $v_1, v_2, \ldots, v_n$. Denote the subgraph induced by $v_1, v_2, \ldots, v_\ell$ by G_ℓ, and the outer face of G_ℓ by C_ℓ. The ordering $v_1 = u, v_2 = v, \ldots, v_n = w$ is a *canonical ordering* if for $3 \leq \ell \leq n-1$, G_ℓ is 2-connected, C_ℓ is a cycle containing the edge (v_1, v_2), $v_{\ell+1}$ is in outer face of G_ℓ, and $v_{\ell+1}$ has the least two neighbors in G_ℓ, and the neighbors are consecutive on the path $C_\ell - (v_1, v_2)$.

LEMMA 9.2 Every triangulated plane graph has a canonical ordering.

PROOF The proof proceeds by reverse induction. The outer face of G is the triangle v_1, v_2, v_n. Since G is triangulated, the neighbors of v_n form a cycle which is the boundary of the outer face of $G - \{v_n\} = G_{n-1}$. Thus, the lemma holds for $\ell = n - 1$.

Suppose that $i \leq n - 2$, and assume that $v_n, v_{n-1}, \ldots v_{i+2}$ have been chosen so that G_{i+1} and C_{i+1} satisfy the requirements of the lemma. We need to choose a vertex w as v_{i+1} on C_{i+1} so that w is not incident with a chord of C_{i+1}. It is not difficult to show that such a vertex exists.

The Drawing Algorithm

The algorithm for drawing the graph begins by drawing vertices v_1, v_2, and v_3 at locations $(0, 0)$, $(2, 0)$, and $(1, 1)$, respectively. Then the vertices $v_4, \ldots v_n$ are placed one at a time, increasing in y coordinate. After v_k has been placed, we have a drawing of the subgraph G_k. Suppose that the outer face C_k of the drawing of G_k consists of the edge (v_1, v_2), and a path $P_k = (v_1 = w_1, w_2, \ldots, w_m = v_2)$; then the drawing is constructed to satisfy the following three properties:

1. The vertices v_1 and v_2 are located at $(0, 0)$ and $(2k - 4, 0)$, respectively.
2. The path P_k is monotonically increasing in the x direction; that is, $x(w_1) < x(w_2) < \cdots < x(w_m)$.

3. For each $i \in \{1, 2, \ldots, m-1\}$, the edge (w_i, w_{i+1}) has slope either $+1$ or -1.

Such a drawing is illustrated in Fig. 9.10.

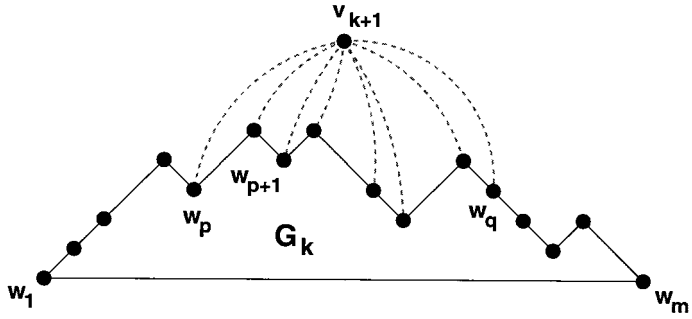

Figure 9.10 The subgraph G_k with v_{k+1} placed at $\mu(p, q)$.

We proceed by induction to show how a drawing with the properties may be computed. The drawing of G_3 satisfies the three properties. Now suppose that $k \geq 3$, and we have a drawing of G_k which satisfies the three properties. The canonical ordering of the vertices implies that the neighbors of v_{k+1} in G_k occur consecutively on the path P_k; suppose that they are $w_p, w_{p+1}, \ldots, w_q$. Note that the intersection of the line of slope $+1$ through w_p with the line of slope -1 through w_q is at a grid point $\mu(p, q)$ (since the Manhattan distance between two vertices is even). If we placed v_{k+1} at $\mu(p, q)$, then the resulting drawing would have no edge crossings, but perhaps the edge (w_p, v_{k+1}) overlaps with the edge (w_p, w_{p+1}), as in Fig. 9.10. This can be repaired by moving all $w_{p+1}, w_{p+2}, \ldots, w_m$ one unit to the right. It is also possible that the edge (v_{k+1}, w_q) overlaps the edge (w_{q-1}, w_q), so we move all the vertices $w_q, w_{q+1}, \ldots w_m$ a further unit to the right. This ensures that the newly added edges do not overlap with the edges of G_k. Now, we can place v_{k+1} safely at $\mu(p, q)$ as shown in Fig. 9.11 (note that $\mu(p, q)$ is still a grid point). The three required properties clearly hold.

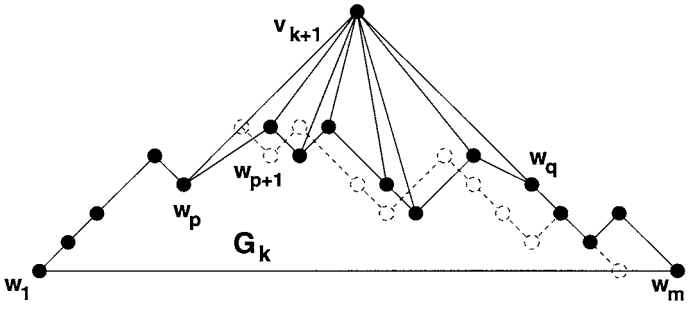

Figure 9.11 The subgraph G_k with v_{k+1} placed at $\mu(p, q)$ after moving the vertices $w_{p+1}, \ldots, w_{q-1}$ one unit and the vertices $w_q, \ldots, w_m$ two units to the right.

But there is a problem with merely moving the vertices on P_k: after the vertices $w_p, w_{p+1}, \ldots, w_m$ are moved to the right, the drawing of G_k may have edge crossings. We must use a more comprehensive strategy to repair the drawing of G_k; we must move even more vertices. Roughly speaking, when moving vertex w_i to the right, we will also move the vertices to the right below w_i. To this end we define a sequence of sets $M_k(w_1), M_k(w_2), \ldots, M_k(w_m)$ below. For a given sequence $\alpha(w_1), \alpha(w_2), \ldots, \alpha(w_m)$ of nonnegative integers, the vertices of G_k are moved succes-

sively as follows: first, all vertices of $M_k(w_1)$ are moved by $\alpha(w_1)$, then all vertices of $M_k(w_2)$ are moved by $\alpha(w_2)$, and so on.

The sets M_k are defined recursively as follows: $M_3(v_1) = \{v_1, v_2, v_3\}$, $M_3(v_2) = \{v_2, v_3\}$, $M_3(v_3) = \{v_3\}$. To compute M_{k+1} from M_k, note that if v_{k+1} is adjacent to $w_p, w_{p+1}, \ldots, w_q$, then P_{k+1} is $(w_1, w_2, \ldots, w_p, v_{k+1}, w_q, \ldots, w_m)$. For each vertex u on this path we must define $M_{k+1}(u)$. Roughly speaking, we add v_k to $M_k(w_i)$ if w_i is left of v_{k+1}, and do not alter $M_k(w_i)$ otherwise. More precisely, for $1 \leq i \leq p$, we define $M_{k+1}(w_i)$ to be $M_k(w_i) \cup \{v_{k+1}\}$, and $M_{k+1}(v_{k+1})$ is $M_k(w_{p+1}) \cup \{v_{k+1}\}$. For $q \leq j \leq M$, we define $M_{k+1}(w_j)$ to be $M_k(w_j)$. It is not difficult to show that the sets satisfy the following three properties.

(a) $w_j \in M_k(w_i)$ if and only if $i \leq j$.
(b) $M_k(w_m) \subset M_k(w_{m-1}) \subset \cdots \subset M_k(w_1)$.
(c) Suppose that $\alpha(w_1), \alpha(w_2), \ldots, \alpha(w_m)$ is a sequence of nonnegative integers and we apply algorithm *Move* to G_k; then the drawing of G_k remains planar.

These properties guarantee planarity.

Remarks

The proof of Theorem 9.2 constitutes an algorithm that can be implemented in linear time [10]. The area of the drawing that is produced is $2n - 4 \times n - 2$; this is asymptotically optimal [41], but the constants can be reduced to $n - 2 \times n - 2$ [8]. A sample drawing appears in Fig. 9.12.

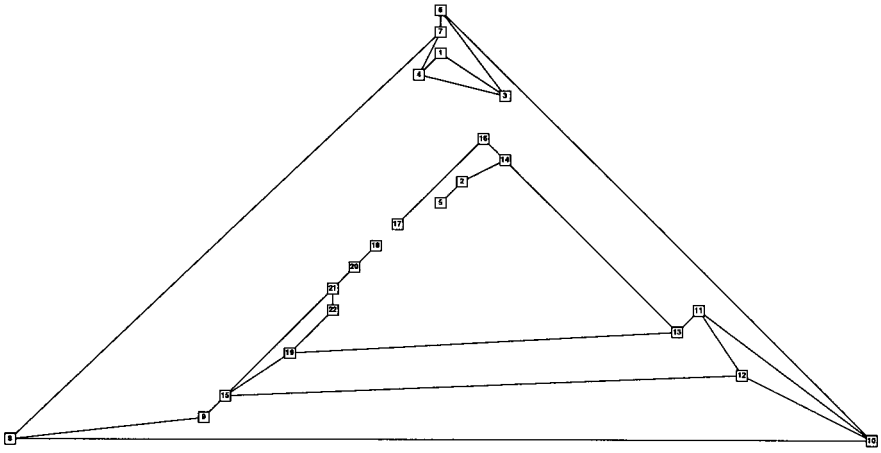

Figure 9.12 Sparse graph drawn with straight line edges.

There are some problems with the method. If the input graph is relatively sparse, then the number of "dummy" edges that must be added can be significant. These dummy edges have considerable influence over the final shape of the drawing but do not occur in the final drawing; the result may appear strange (see Fig. 9.12). Using a different ordering, the algorithm also works for 3-connected and even for biconnected planar graphs [27, 31]. This reduces the number of dummy edges considerably.

Although the drawings produced have relatively good vertex resolution, they are not very readable, because of two reasons: the angles between incident edges can get quite small, and the area is still too big in practice. These two significant problems can be overcome by allowing bends in the edges. Kant [31] modifies the algorithm described above to obtain a "mixed model algorithm;" this algorithm constructs a polyline drawing of a 3-connected planar graph such that the size of the minimal angle is at least $\frac{1}{d}\pi$, where d is the maximal degree of a vertex. Figure 9.13

shows the same graph as in Fig. 9.12 drawn with a modification of the mixed model algorithm for biconnected planar graphs by [27]. The grid size of the drawing in Fig. 9.12 is 38×19, whereas the size for the mixed model drawing is 10×8.

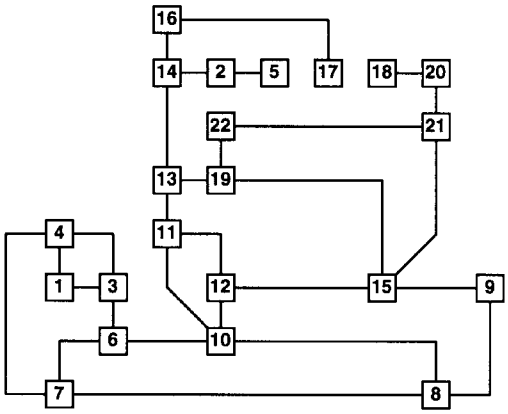

Figure 9.13 Sparse graph drawn with the mixed model algorithm.

Orthogonal Drawings

In polyline drawing, one aesthetic is to minimize the total number of bends. Generating an orthogonal drawing of a planar graph with the minimum number of bends is a NP-hard problem [25]. However, for the restricted problem where a fixed planar embedding is part of the input, there is a polynomial time algorithm [39]. In this subsection we will describe the transformation of this restricted bend minimization problem into a network flow problem.

Mathematical Preliminaries

Intuitively, the *orthogonal representation* of an orthogonal planar drawing of a graph describes its "shape;" it does not specify the length of the line-segments but determines the number of bends of each edge. The algorithm described in this section takes as input a planar embedding, represented as a planar map (that is a cyclic ordered list of the edges bounding each face). It produces as output an orthogonal representation with the minimum number of bends. From this, an actual drawing can be constructed via well-known compaction algorithms (see, e.g.,[29] or Chapter 23).

Formally, an orthogonal representation is a function H which assigns an ordered list $H(f)$ to each face f. Each element of $H(f)$ has the form (e, s, a), where e is an edge adjacent to f, s is a binary string, and $a \in \{90, 180, 270, 360\}$. If r is an element in $H(f)$ then $e[r]$, $s[r]$, and $a[r]$ denote the corresponding entries, that is, $r = (e[r], s[r], a[r])$. The list is ordered so that the edges $e[r]$ appear in clockwise order around the face f; thus, H consists of a planar map of the graph extended by the s- and a-arrays. The binary string $s[r]$ describes the shape of the edge $e[r]$, in the following way. The k-th bit in $s[r]$ represents the k-th bend while traversing the edge in face f in clockwise order: the entry is 0 if the bend produces a 90 degree angle (on the right hand side) and 1 otherwise. An edge without bend is represented by the zero-string ϵ. The number $a[r]$ represents the angle between the last line segment of edge $e[r]$ and the first line segment of edge $e[r']$, where r' follows r in the clockwise order around f. An orthogonal representation of

Fig. 9.14 is:

$$\begin{aligned} H(f_1) &= ((e_1, \varepsilon, 270), (e_5, 11, 90), (e_4, \varepsilon, 270), (e_2, 1011, 90)) \\ H(f_2) &= ((e_1, \varepsilon, 90), (e_6, \varepsilon, 180), (e_5, 00, 90)) \\ H(f_3) &= ((e_2, 0010, 90), (e_4, \varepsilon, 90), (e_6, \varepsilon, 90), (e_3, 0, 360), (e_3, 1, 90)) \ . \end{aligned}$$

The number of bends $B(H)$ of an orthogonal representation is

$$B(H) = \frac{1}{2} \sum_{f} \sum_{r \in H(f)} |s[r]| \ ,$$

where $|s|$ is the length of string s. Geometrical observations lead to the following lemma.

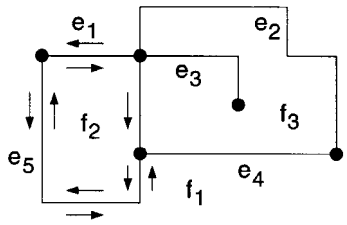

Figure 9.14 A graph and its orthogonal representation.

LEMMA 9.3 The function H is an orthogonal representation of an orthogonal planar drawing of a graph if and only if the properties (P1) to (P4) below are satisfied.

(P1) There is a plane graph with maximal degree four, whose planar map corresponds to the e-arrays in $H(f)$.

(P2) Suppose that r and r' are two elements in the orthogonal representation representing the same edge, that is, $e[r] = e[r']$. Then reversing the ordering of the elements in the string $s[r]$ and complementing each bit gives the string $s[r']$.

(P3) Suppose that ZEROS(s) denotes the number of 0's in string s, ONES(s) the number of 1's in string s, and

$$ROT(r) = \text{ZEROS}(s[r]) - \text{ONES}(s[r]) + (2 - a[r]/90) \ .$$

Then the faces described by H build rectilinear polygons, that is, polygons in which the lines are horizontal and vertical, if and only if

$$\sum_{r \in H(f)} ROT(r) = \begin{cases} -4 & \text{if } f \text{ is the outer face} \\ +4 & \text{otherwise} \end{cases} \ .$$

(P4) For all vertices v in the plane graph represented by H the following holds: the sum of the angles between adjacent edges to v given in the a-arrays of the corresponding elements in the lists $H(f)$ is 360.

The Transformation into a Network Flow Problem

Suppose that $G = (V, E)$ is a plane graph and P is a planar map, that is, for each face f of the embedding, $P(f)$ is a list of the edges on f in clockwise order. Denote the set of faces of G

defined by P by F. Let $\hat{V}$ denote the set of vertices of G with degree at most three. We define a network $N(P) = (S, A, u, c, b)$ with vertex set S, arc set A, capacity u, cost c and demand/supply b, as follows. The vertex set S consists of the vertices in $\hat{V}$ and the set F of faces. The arc set A is made up of two sets A_V and A_F, as follows:

- A_V contains the arcs (v, f), $v \in \hat{V}$, $f \in F$, for all vertices v that are endpoints of edges in $P(f)$. Each arc in A_V has infinite capacity and zero cost.
- A_F contains two arcs (f, g) and (g, f) for each pair $\{f, g\}$ of faces for which $P(f)$ and $P(g)$ share an arc. Moreover, A_F contains a self-loop (f, f) for each face f containing a bridge. Arcs in A_F have infinite capacity and unit cost.

The vertices $v \in \hat{V}$ supply $b(v) = 4 - \deg(v) > 0$ units of flow. The vertices $f \in F$ of the inner faces of size at most three ($|P(f)| \leq 3$), are supply vertices of value $b(f) = 4 - |P(f)| > 0$. The inner faces of size at least five and the outer face are demand vertices of value

$$b(f) = \begin{cases} -(|P(f)| + 4) & \text{if f is outer face} \\ -(|P(f)| - 4) & \text{otherwise .} \end{cases}$$

A graph and its network is shown in Fig. 9.15.

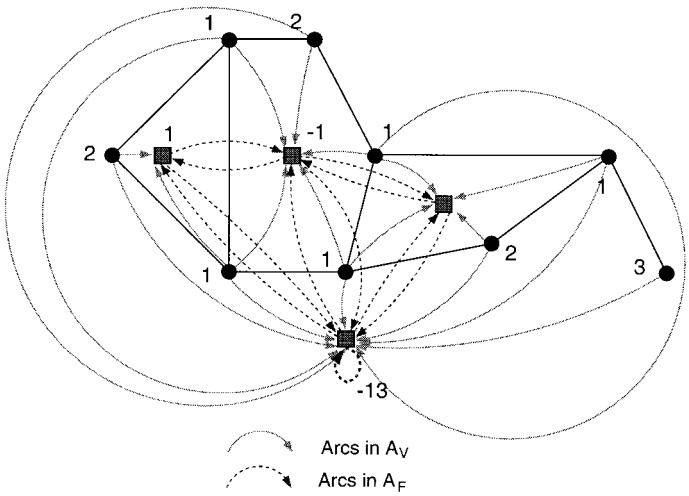

Figure 9.15 A graph and its network. Nodes are labeled with their supply and demand.

The value of the flow through the network is $z(P) = \Sigma_{s:b(s)>0} b(s) = -\Sigma_{t:b(t)<0} b(t)$.

The transformation defined above seems to be quite complex, but it can be intuitively interpreted as follows. Each unit of flow represents an angle of 90 degrees. For arcs in A_V the flow $x(v, f) + 1$ represents the sum of the angles between elements r in face f whose edges $e[r]$ are incident to v. The flow $x(f, g)$ in the arcs A_F represents the number of bends along those edges that separate the faces f and g and that create 90 degree angles in face f. The flow conservation rule on vertices $\hat{V}$ forces the sum of the angles around the vertices to be 360 degrees (see property (P4)). The conservation rule for vertices F arising from faces in P forces the created faces to be rectilinear polygons (see (P3)). Most importantly, the cost of a given flow in $N(P)$ is equal to the number of bends in the constructed orthogonal representation.

LEMMA 9.4 For any orthogonal planar drawing Π of a planar graph with given planar map P there exists an integer flow x in $N(P)$ with value $z(P)$ with cost equal to the number of bends in Π.

PROOF Let H be an orthogonal representation of G. The flow x in $N(P)$ can be constructed in the following way: for every arc (v, f) in A_v, the flow $x(v, f)$ arises from the a-entries in the elements in $H(f)$:

$$x(v,f) = \sum_{r \in R(v,f)} (a[r]/90 - 1), \text{ where}$$

$R(v, f) = \{r \in H(f) \mid e[r]$ and $e[r']$ are adjacent to vertex v and r precedes edge r' in $H(f)\}$.

For every arc (f, g) in A_F the flow is defined by the s-arrays of the elements in $H(f)$ associated with (f, g):

$$x(f,g) = \sum_{r \in R(f,g)} \text{ZEROS}(s[r]) \ ,$$

where $R(f, g) = \{r \in H(f) \mid e[r] \in P(f) \cap P(g)\}$. The flow $x(f, g)$ represents the angles of 90 degrees within region f along those edges separating f and g. In the case that $f = g$, we can see that $x(f, f)$ is equal to the number of bends along the bridges of f.

We have to show that the function f is, indeed, a flow with cost equal to the number of bends in H. Let us show that the conservation rule is satisfied at f. For vertices $v \in \hat{V}$ [using (P4)] we have

$$\sum_f x(v,f) - b(v) = \sum_f \sum_{r \in R(v,f)} (a[r]/90 - 1) - (4 - \deg(v)) = 0 \ .$$

For vertices $f \in F$ [using (P2) and (P3)] we have

$$\begin{aligned} \sum_g x(f,g) - \sum_s x(s,f) - b(f) &= \sum_g x(f,g) - \sum_g x(g,f) - \sum_v x(v,f) + |P(f)| \pm 4 \\ &= \sum_{r \in H(f)} (\text{ZEROS}(s[r]) - \text{ONES}(s[r]) - a[r]/90 + 1) \\ &\quad + |P(f)| \pm 4 \\ &= 0 \ . \end{aligned}$$

The costs of the flow are

$$\text{COST}(x) = \sum_{a \in A} c_a x_a = \sum_{(f,g) \in A_F} x(f,g) = \frac{1}{2} \sum_f \sum_{r \in H(f)} |s[r]| = B(H) \ ,$$

which is the number of bends in H.

LEMMA 9.5 For any integer flow x in $N(P)$ there exists an orthogonal planar drawing of a planar graph G with planar map P and with number of bends is equal to the cost of the flow x. The corresponding orthogonal representation can be constructed from x.

PROOF We construct the orthogonal representation as follows: the edge lists $H(f)$ are given by the planar map. For every arc (v, f) in A_V, let $r_1, \ldots, r_n$ be the elements in $R(v, f)$. We set $a[r_1] = 90(x(v, f) + 1)$, and $a[r_i] = 90$ for $2 \leq i \leq n$. For every pair (f, g) and (g, f) in A_F, let $r_1, \ldots, r_n$ be the elements in $R(f, g)$ and let $r'_1, \ldots, r'_n$ be the corresponding elements in $R(g, f)$. If $f = g$, then r_i and r'_i are the pairs of elements in $H(f)$ associated with both sides of the same bridge. We set

$$\begin{aligned} s[r_1] &= \begin{cases} 0^{x(f,g)} & \text{if } f = g \\ 0^{x(f,g)} 1^{x(g,f)} & \text{otherwise} \end{cases} \ , \\ s[r'_1] &= \begin{cases} 1^{x(g,f)} & \text{if } f = g \\ 0^{x(g,f)} 1^{x(f,g)} & \text{otherwise} \end{cases} \ , \end{aligned}$$

and $s[r_i] = s[r'_i] = \epsilon$ for $2 \leq i \leq n$.

The properties (P1) to (P4) are satisfied by our defined e, s- and a-arrays. The number of bends in the orthogonal representation is given by

$$\begin{aligned} B(H) &= \frac{1}{2}\sum_{f}\sum_{r\in H(f)} |s[r]| \\ &= \frac{1}{2}\sum_{(f,g)\in A_F} (x(f,g) + x(g,f)) \\ &= \sum_{a\in A} c(a)x(a) \\ &= \text{COST}(x) \ . \end{aligned}$$

In a network with integral costs and capacities there always exists a min-cost flow with integer flow values. Hence, we have the following theorem.

THEOREM 9.3 *Let P be a planar map of a planar graph G with maximal degree 4. The minimal number of bends in an orthogonal planar drawing with planar map P is equal to the cost of a min-cost flow in $N(P)$ with value $z(P)$. The orthogonal representation H of any orthogonal planar drawing of G can be constructed from the integer-valued min-cost flow in $N(P)$.*

The algorithm for constructing an orthogonal drawing is as follows. First construct the network $N(P)$ in time $O(|S|+|A|)$. A min-cost flow can be computed in time $O(n^2 \log n)$ (see Chapter 7 for the theory of network algorithms). The orthogonal representation can be constructed easily from the given flow. The length of the line segments can be generated by any compaction algorithm (see [29] or Chapter 23).

Remarks

The drawings produced by the algorithm described above look very pleasant (see Fig. 9.9). One drawback of the algorithm is that it is restricted to planar graphs with maximal degree four. In fact the methods described in this section can be extended to planar graphs of high degree ([2, 23, 32]). Figure 9.16 shows a drawing of a graph of maximum degree 6; this was obtained using the planarization above as well as the method of [32].

There are also orthogonal drawing methods for graphs which are not planar. These methods take no account of the number of crossings but try to keep the number of bends and the drawing area small [3, 36]. An experimental comparison of various orthogonal graph drawing algorithms is given in [18].

9.4 Graph Drawing in Three Dimensions

Three dimensional scientific visualization is now commonplace. Research into three-dimensional graph drawing has begun [38]. Most of this work has proceeded in an *ad hoc* manner; here we describe two fundamental algorithms. Both produce grid drawings with no edge crossings. The first, from [11], simply produces a straight-line drawing of an n vertex graph in a box of dimensions $O(n) \times O(n) \times O(n)$. The second, from [21], takes a graph of maximum degree at most 6 as input and produces an orthogonal grid drawing with at most 3 bends per edge.

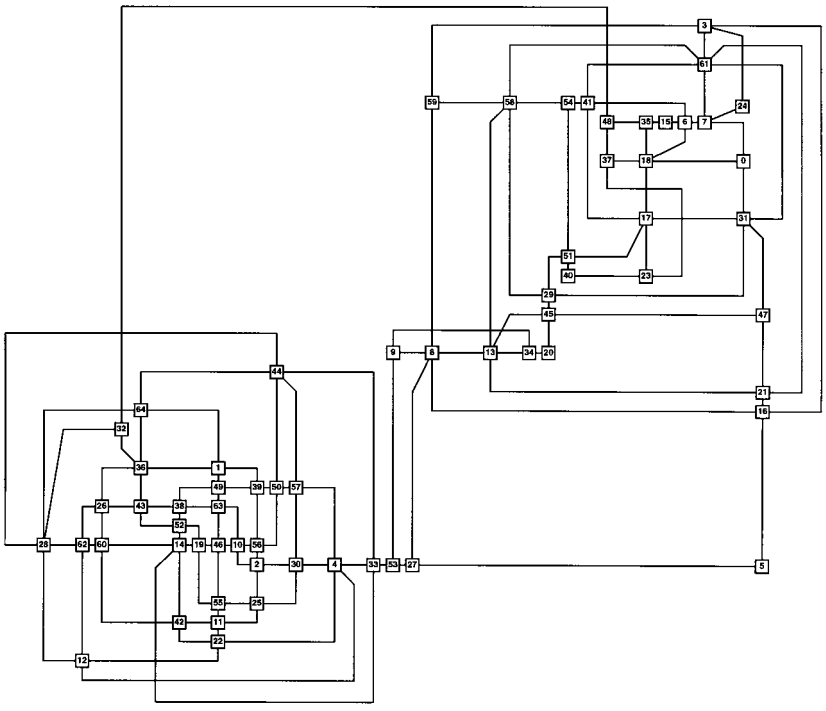

Figure 9.16 A graph drawn using network flow techniques.

Straight-Line Drawings in Three Dimensions

In this section we show that every graph with n vertices admits a straight-line crossing-free drawing with dimensions $n \times 2n \times 2n$.

Firstly note that a larger straight-line crossing-free drawing can be obtained using the *moment curve* $M(t) = (t, t^2, t^3)$. This curve has the well known property that no four points on the curve are coplanar. If the vertices of G are $v_1, v_2, \ldots, v_n$ and we place vertex v_t at $M(t)$, then no two edges of G are coplanar and thus, cannot cross. This drawing uses a large volume $(n \times n^2 \times n^3)$; next we show how to reduce this volume.

The method uses a prime number p with $n \leq p < 2n$. The existence of such a prime is guaranteed by Bertram's Theorem, and one can be found with a simple prime number sieve. The main observation is that we can use the *modulo p moment curve*

$$M_p(t) = \big(t \bmod p, t^2 \bmod p, t^3 \bmod p\big)$$

instead of the usual moment curve. We place vertex v_t at $M_p(t)$. For $t = 1, 2, \ldots, n$, $0 < t^k \bmod p < p < 2n$; thus, the volume of this drawing is bounded by $n \times 2n \times 2n$. It is a simple exercise to show that four distinct vertices cannot share a plane. Thus, we have the following theorem.

THEOREM 9.4 *Every graph with n vertices has a three-dimensional straight-line crossing-free grid drawing graph with volume $n \times 2n \times 2n$.*

Note that the volume bound of Theorem 9.4 is asymptotically optimal. Suppose that a drawing of the complete graph on n vertices lies strictly between the planes $x = 0$ and $x = \frac{n}{4}$. Then for some integer m, the plane $x = m$ contains at least 5 vertices. The straight-line edges between these 5 vertices must also lie in the plane $x = m$. But the subgraph induced by the 5 vertices is complete and thus, nonplanar. We can deduce the following theorem.

THEOREM 9.5 *Suppose that D is a three-dimensional straight-line crossing-free grid drawing of the complete graph G on n vertices, and D uses volume $X \times Y \times Z$. Then each of X, Y, Z is $\Omega(n)$.*

Three-Dimensional Orthogonal Grid Drawings

A graph that has a three-dimensional orthogonal drawing with no edge crossings clearly has maximum degree 6. The edge set of such a graph has a useful decomposition into three sets of cycles, as described by the following lemma.

LEMMA 9.6 Suppose that $G = (V, E)$ is a graph of maximum degree at most 6. Then there is an orientation $G' = (V, E')$ of G with subgraphs $C_{red} = (V_{red}, E_{red})$, $C_{blue} = (V_{blue}, E_{blue})$, and $C_{green} = (V_{green}, E_{green})$, such that

- $E' = E_{red} \cup E_{blue} \cup E_{green}$, and
- $E_\alpha \cap E_\beta = \emptyset$ for $\alpha, \beta \in \{red, blue, green\}$.
- Each vertex of C_α has in-degree one and out-degree one in C_α, for $\alpha \in \{red, blue, green\}$.

The decomposition can be obtained in $O(n^{1.5})$ time.

PROOF The existence of the orientation and the coloring follows from the fact that every regular graph of even degree is *2-factorable* [28]. The coloring can be found in time $O(n^{1.5})$ by using a matching algorithm for bipartite graphs.

Each of the subgraphs C_{red}, C_{blue}, and C_{green} in Lemma 9.6 consists of a set of disjoint directed cycles; we call these the *red cycles, blue cycles,* and *green cycles,* respectively. These cycles are used in the proof of the following theorem.

THEOREM 9.6 *Suppose that G is a graph of maximum degree at most 6. Then there is an orthogonal grid drawing of G with at most 3 bends per edge. The drawing can be computed in time $O(n^{1.5})$.*

The remainder of this section describes the proof of Theorem 9.6. The construction uses the preprocessing of the input graph $G = (V, E)$ as described in Lemma 9.6. Thus, we assume that G is a directed graph and the subgraphs C_{red}, C_{blue}, and C_{green} have been computed.

The vertices are listed in an arbitrary order $v_1, v_2, \ldots, v_n$ and v_i is placed at the location $p_i = (3i, 3i, 3i)$. If $1 \le i < j \le n$ then the isothetic cube with p_i and p_j at opposite corners is denoted by $C(i, j)$. The cube is illustrated in Fig. 9.17(a).

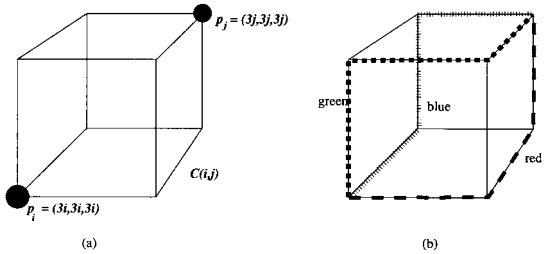

Figure 9.17 The cube $C(i, j)$.

Three disjoint routes can be defined along the edges of the cube $C(i,j)$ as illustrated in Fig. 9.17(b); these can be colored in three colors corresponding to the three colors on the arcs of G, as follows.

- *Red*: $p_i = (3i, 3i, 3i) \rightarrow (3j, 3i, 3i) \rightarrow (3j, 3j, 3i) \rightarrow (3j, 3j, 3j) = p_j$
- *Blue*: $p_i = (3i, 3i, 3i) \rightarrow (3i, 3j, 3i) \rightarrow (3i, 3j, 3j) \rightarrow (3j, 3j, 3j) = p_j$
- *Green*: $p_i = (3i, 3i, 3i) \rightarrow (3i, 3i, 3j) \rightarrow (3j, 3i, 3j) \rightarrow (3j, 3j, 3j) = p_j$

Note that each of these routes has only two bends. This coloring scheme for routes of edges of the cubes will be used to define routes for the edges of the graph. If the arc (v_i, v_j) of the graph has color $\alpha \in \{red,\ blue,\ green\}$, then it will approximately follow the route of $C(i,j)$ of color α.

Before defining the precise routes for the arcs, some intuitive feel for the reasons that they do not cross may be helpful. The way in which edges of different cubes intersect with each other is significant. The following lemma is easy to prove.

LEMMA 9.7 Suppose that $i < j$ and $k < \ell$, $i < k$, and $j \neq \ell$. Let s be a point on an edge of $C(i,j)$, and let t be a point on an edge of $C(k,\ell)$. Then the Euclidean distance between s and t is at least 3.

Lemma 9.7 implies that if the edges of two cubes $C(i,j)$ and $C(k,\ell)$ intersect then either $j = k$, $i = k$, or $j = \ell$. Intuitively, this means that if $(v_i, v_j) \in A$ is routed along edges of $C(i,j)$ and $(v_k, v_\ell) \in A$ is routed along edges of $C(k,\ell)$, and these routes intersect, then the edge (v_i, v_j) shares an endpoint with the edge (v_k, v_ℓ). Further, note from Lemma 9.7 that even if the route of $(v_i, v_j) \in A$ is "offset a little" from the edges of $C(i,j)$ and the route of $(v_k, v_\ell) \in A$ is "offset a little" from the edges of $C(k,\ell)$, and these routes intersect, then they are incident to a common vertex.

Next we define the precise routes for the red edges of G; the routes for other colors are similar. Basically, if (v_i, v_j) is a red edge then it follows the red route around the cube $C(i,j)$. In most cases it follows this route exactly. However, in some cases it must follow a path that is close to the red route on $C(i,j)$, but offset a little to avoid crossing another red edge.

The red edges form a set of disjoint cycles, and we shall route each cycle separately. Suppose that $(w_0, w_1, \ldots, w_{k-1})$ is a red cycle. For each vertex w_c on this cycle, there is an integer $f(w_c)$ such that $w_c = v_{f(w_c)}$, that is, w_c has been placed at $(3f(w_c), 3f(w_c), 3f(w_c))$. The function f orders the vertices of the cycle by their distance from the origin. An arc (w_c, w_{c+1}) on the cycle falls into one of four categories, defined by the order imposed by f (here the subscript addition is modulo k):

- *Normal increasing arcs*: $f(w_c) < f(w_{c+1})$ and $f(w_{c+1}) < f(w_{c+2})$.
- *Normal decreasing arcs*: $f(w_c) > f(w_{c+1})$ and $f(w_{c+1}) > f(w_{c+2})$.
- *Special arcs entering a local minimum*: $f(w_c) > f(w_{c+1})$ and $f(w_{c+1}) < f(w_{c+2})$.
- *Special arcs entering a local maximum*: $f(w_c) < f(w_{c+1})$ and $f(w_{c+1}) > f(w_{c+2})$.

A normal red arc (w_c, w_{c+1}) (increasing or decreasing) is routed exactly along the red path of edges of the cube $C(f(w_c), f(w_{c+1}))$. Note that each normal arc has two bends. The special arcs are routed near the red path; for two of the cube edges, they are offset by a distance of one. Each has three bends. If $a = 3f(w_c)$ and $b = 3f(w_{c+1})$, then the routes for special red arcs are:

- *Special arcs entering a local minimum* [Fig. 9.18(a)]: $(a,a,a) \rightarrow (a,a,b-1) \rightarrow (a,b,b-1) \rightarrow (b,b,b-1) \rightarrow (b,b,b)$.
- *Special arcs entering a local maximum* [Fig. 9.18(b)]: $(a,a,a) \rightarrow (b+1,a,a) \rightarrow (b+1,b,a) \rightarrow (b+1,b,b) \rightarrow (b,b,b)$.

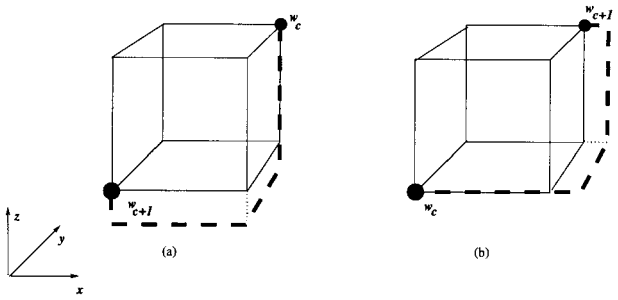

Figure 9.18 (a) Local minimum route, (b) local maximum route.

Now suppose that two arcs of different colors cross. Using Lemma 9.7 one can see that the crossing is between arcs which share a vertex, and it must be inside a $2 \times 2 \times 2$ box centered the shared vertex. Note a red arc always enters or leaves a vertex in a plane parallel to the xz plane, while a blue arc always enters or leaves a vertex in a plane parallel to the xy plane; thus, a red–blue crossing is impossible. Continuing this argument, we can deduce that two arcs of different colors cannot cross.

Next suppose that two arcs of the same color cross. We can assume that these arcs do not share both endpoints, since we will only draw one of a pair of multiple edges in the final drawing. Thus, by Lemma 9.7, the arcs share precisely one vertex. Lemma 9.6 ensures that one arc is entering a shared vertex, and one is leaving the shared vertex; suppose that the arcs are (v_i, v_j) and (v_j, v_k). There are essentially two cases to consider: $i < j < k$, and $j < i < k$. In the first case, the cubes $C(i, j)$ and $C(j, k)$ intersect only at the location of v_j, as in Fig. 9.19(a). Here (v_i, v_j) is a normal increasing arc, and (v_j, v_k) is either a normal increasing arc or special arc entering a local maximum. It is easy to see that no crossing is possible. In the second case, $C(j, i)$ and $C(j, k)$ overlap as in Fig. 9.19(b); (v_i, v_j) is a special arc entering a local minimum and (v_j, v_k) is either a normal increasing arc or a special arc entering a local maximum. Again, it is easy to observe that their routes are disjoint.

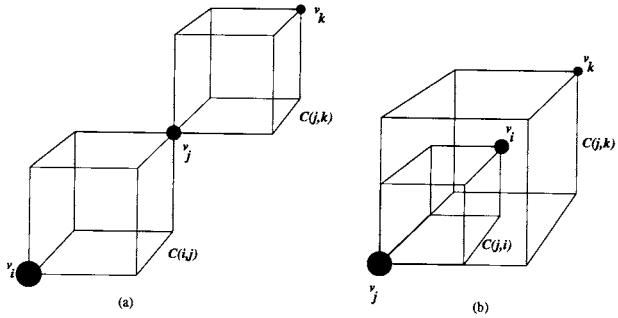

Figure 9.19 (a) Cubes intersect only at a vertex. (b) Cubes overlap.

9.5 Research Issues and Summary

The field of graph drawing is still developing and there are many fundamental questions to be resolved. Here we list a few.

- In the exact planarization algorithm, it is essential to solve the separation problem for the Kuratowski inequalities for nonintegral vectors $\bar{x}$ (see "Planarization"). It is not known whether this problem is NP-hard or not.

- The grid size for planar straight-line drawings is bounded below; there is an n-vertex plane graph G such that, for any straight-line grid drawing of G, each dimension of the grid is at least $\lfloor \frac{2(n-1)}{3} \rfloor$ even if the other dimension is allowed to be unbounded [9, 13]. It is conjectured that this lower bound is almost achievable; more precisely, that every planar graph with n vertices has a 2-dimensional straight-line drawing on a grid of size $\lceil \frac{2n}{3} \rceil \times \lceil \frac{2n}{3} \rceil$.
- There are many algorithms for creating planar orthogonal grid drawings in 2 dimensions using area $O(n^2)$ and a constant number of bends per edge. For binary trees, this result can be improved: $O(n \log(n))$ area with no bends at all [12]. However, it is not known whether every binary tree has an orthogonal planar drawing using linear area and no bends. This question is open even for three dimensions.
- The trade-off between volume and numbers of bends in three dimensions needs further exploration. Does every graph of maximum degree 6 admit an orthogonal drawing with at most 2 bends per edge? Does every graph of maximum degree 6 admit an orthogonal drawing with less than 7 bends per edge and volume $O(\sqrt{n}) \times O(\sqrt{n}) \times O(\sqrt{n})$?

9.6 Defining Terms

Edge crossing: Two nonincident edges *cross* in a graph drawing if their geometric representations intersect. The number of crossings in a graph drawing is the number of pairs of edges which cross.

Graph drawing: A geometric representation of a graph is a *graph drawing.* Usually, the representation is in either 2- or 3-dimensional Euclidean space, where a vertex v is represented by a point $p(v)$ and an edge (u, v) is represented by a simple curve whose endpoints are $p(u)$ and $p(v)$.

Grid drawing: A *grid drawing* is a graph drawing in which each vertex is represented by a point with integer coordinates.

Orthogonal drawing: An *orthogonal drawing* is a graph drawing in which each edge is represented by a polyline, each segment of which is parallel to a coordinate axis.

Planar graph: A graph drawing is *planar* if it has no edge crossings. A graph is *planar* if it has a planar drawing.

Planarization: Informally, *planarization* is the process of transforming a graph into a planar graph. More precisely, the transformation involves either removing edges (*planarization by edge removal*), or replacing pairs of nonincident edges by 4-stars, as in Fig. 9.20 (*planarization by adding crossing vertices*). In both cases, the aim of planarization is to make the number of operations (either removing edges or replacing pairs of nonincident edges by 4-stars) as few as possible.

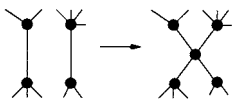

Figure 9.20 Planarization by crossing vertices.

Straight-line drawing: A *straight-line drawing* is a graph drawing in which each edge is represented by a straight line segment.

On-line Algorithms: Competitive Analysis and Beyond

Steven Phillips
AT&T Labs – Research

Jeffery Westbrook
AT&T Labs – Research

10.1 Introduction

The field of **on-line algorithms** addresses problems in which an algorithm is handicapped by lack of knowledge of the future. An on-line algorithm receives a sequence of inputs, and must process each input in turn, without detailed knowledge of later inputs. Typically the on-line algorithm is managing a system with persistent state, and the changes made to the state affect the cost of processing future inputs.

An example is the following idealization of load balancing on a multiprocessor computer. A sequence of jobs appear on-line, each having a known size. Each job must be irrevocably assigned on arrival to one of n machines. The load on a machine is the sum of the sizes of jobs assigned to it. We would prefer the assignments to balance the load on the machines, and in particular to minimize the maximum machine load. Graham showed that the algorithm that assigns each job to the machine that is currently least loaded achieves a maximum load that is never more than $2 - 1/n$ times greater than the best possible assignment of the jobs [38]. This is an example of what is now called **competitive analysis**. In competitive analysis, an on-line algorithm is evaluated by comparing its performance to the best that could have been achieved if all the inputs had been known in advance.

On-line algorithms have become an active topic of research. Competitive analysis has been applied to

a multitude of **on-line problems,** and the notion of competitive analysis has been refined in a number of ways. This chapter gives an overview of the scope of research in on-line algorithms. The reader will be introduced to the major topics and problems that have been studied to date, as well as a variety of methods and models that can be used to analyze and solve on-line problems.

We start with a study of the ski rental problem in Section 10.2. This simple problem arises in a number of contexts, and it provides a natural setting in which to start exploring the design and analysis of on-line algorithms. The basic models and methods of Section 10.2 are formalized in Section 10.3, and a review of some more advanced models is given in Section 10.4, using paging, an archetypal on-line problem, as the backdrop. Section 10.5 describes some general purpose algorithms that are applicable to large classes of on-line problems. Lastly, Section 10.6 is a selective compendium of topics in on-line algorithms that is intended to serve as a starting point for the investigation of old or new on-line problems.

10.2 The Ski Rental Problem

We begin with a classic example of an on-line problem, "ski rental," first posed in this form by Larry Rudolph. Suppose you decide to learn to ski. After each trip, you will make an irrevocable decision whether to stop skiing or continue learning, and you have no idea in advance what your decision will be. Skiing is an equipment-intensive sport, of course, and before each trip you have two options: rent the equipment at x dollars per day, or buy the equipment for a grand total of y dollars. For convenience we assume that $y = cx$ for some integer $c > 1$. Before each trip to the mountain you have to decide whether to rent or buy. You would like to spend as little money on equipment as possible. Buying equipment before even taking one lesson could be a terrible waste, if you decide to stop after the first trip. On the other hand, if you take many trips then at some point it will have been cheaper to buy than rent. At what point should you stop renting and buy?

The ski rental problem is relevant not only to the management of sporting equipment. It is applicable in a wide variety of resource allocation problems. For example, consider power management in a laptop computer. A typical laptop powers down the hard drive when it is not in use, because a running hard drive consumes battery power. It takes a significant amount of power and time, however, to start the hard drive running again once it has been powered down. If the user of the laptop doesn't use the hard drive for a while, how long should the laptop wait before powering it down? This is just the ski rental problem—running the drive is renting and powering down is buying (since a one-time cost is incurred when the drive is restarted).

A second application is spinning vs. blocking at a lock in a parallel program [45]. If a thread blocks at the lock, it does not consume valuable computing cycles while waiting for some other thread to free the lock. However, a context switch is needed to restart the thread when the lock is freed, costing some cycles. If instead the thread spins, waiting for the lock to be freed, then it can resume running as soon as the lock is freed, but it consumes cycles while it waits. The problem of deciding how long to spin before blocking is just ski rental — spinning is renting and blocking is buying. Other applications include snoopy caching [46] and IP-over-ATM networks [55].

Let's head back to the slopes. There is some number t of ski trips that you will take before stopping (or moving on to that great powder basin in the sky). Suppose you are told t in advance. Then it is easy to decide whether to rent or buy. If $tx \leq y$, you should rent, and otherwise you should buy right at the start. This is the **off-line** ski rental problem. The solution to the off-line problem is called the **optimal solution** and the cost of the optimal solution is called the **optimal cost.** The optimal cost is tx for $t \leq c$ and y for $t > c$.

In the *on-line* problem, the rent-or-buy decision must be made prior to each trip, without knowledge of t. All that can be determined after i trips is that $t \geq i$. Consider the following strategy: rent until $c = y/x$ trips have occurred, and then buy if a $(c + 1)$st trip happens. How well does this strategy do? If $t \leq c$, then it is optimal— the minimum possible amount is spent. Suppose $t > c$. Then the cost is exactly twice

the optimal cost. Therefore, although this strategy can be optimal in some situations, in the worst case it incurs a cost twice the optimal. This worst-case ratio between the cost incurred by the on-line strategy and the optimal cost is called the **competitive ratio**.

One may ask, is there a better strategy given the rules of the game? A strategy is simply a value k: the number of times to rent before buying. The on-line cost using such a strategy is tx for $t \leq k$ and $kx + y$ for $t > k$. Clearly, there is no value of k that is guaranteed to achieve the optimal cost in all cases. Indeed, any k is nonoptimal for the case $t = k + 1$, since $kx + y \geq (k + 2)x > (k + 1)x = tx$. This is typical of on-line problems. Without knowledge of the future, there is no on-line algorithm that is always optimal.

Furthermore, it is not hard to see that no strategy can have a competitive ratio that is lower than 2. The worst-case ratio between the on-line cost and the optimal cost is

$$\max\left\{\frac{kx+y}{tx}, \frac{kx+y}{y}\right\}.$$

If $k = 0$, then for $t = 1$ the first ratio is y/x, which is at least 2 by assumption. Otherwise, if $kx \leq y$, then the ratio is at least 2 when $t = k$ (the first ratio in the max), and if $kx > y$ the ratio is at least 2 when $t > k$ (the second ratio in the max).

A skier who abides by the rules of the game might be termed a cautious skier. She can be sure that she never pays more than twice what she had to. However, skiing is hardly a sport that attracts cautious people, so we'll change the rules to add an element of daring. (First we had the "green circle" model, next comes the "blue square" model.)

You are now allowed a **randomized** purchasing strategy. Your decision of whether to buy or rent might be made by a coin flip, or based on your horoscope. Your goal is now to minimize the *expected* ratio to the off-line cost, rather than the worst-case ratio.

Let strategy A_i be to rent $i - 1$ times, then buy on the ith ski trip. A randomized strategy can be summarized by a probability distribution π, where π_i is the probability you use algorithm A_i. Now assume we want the expected ratio to be at most α. Then if we ski exactly t times, as we noted earlier the optimal cost is tx for $t \leq c$ and y for $t > c$. We must therefore choose π to satisfy

$$\begin{aligned}
\mathbf{E}[\text{on-line cost}] &\leq \alpha t x \quad t \leq c\,, \\
\mathbf{E}[\text{on-line cost}] &\leq \alpha y \quad t > c\,.
\end{aligned}$$

If we make these inequalities equalities and solve the resulting equations, we get

$$\pi_i = \begin{cases} \frac{\alpha-1}{c}\left(\frac{c}{c-1}\right)^i & i = 1 \ldots c \\ 0 & \text{otherwise}\,. \end{cases} \tag{10.1}$$

Finally to solve for α we use $\sum \pi_i = 1$, giving

$$\alpha = \frac{1}{\left(1 + \frac{1}{c-1}\right)^c - 1} + 1\,. \tag{10.2}$$

It isn't hard to show that no better competitive ratio is achievable. While this no longer seems like simple financial advice to give to a first-time skier, the solution starts to make sense in a situation of hyperinflation in ski prices. As $c \to \infty$, so renting becomes infinitesimally cheap compared to buying, the competitive ratio tends to

$$\frac{e}{e-1} \approx 1.58\,.$$

This limit is best thought of in terms of *continuous ski rental.* You embark on a ski trip of unknown duration. You may rent skis, but rather than renting in discrete increments, you are charged for the exact

length of time you keep the skis. An any point, if you are still skiing you can choose to buy, incurring a large cost but ending the rental charges. For some applications of ski rental this continuous model is more suitable, for example in the laptop power-management application, where the power consumed by running the disk during one system clock tick is far less than by powering down and restarting the disk.

That completes the "blue square" model, and we are now ready for the "black diamond" model, namely *repeated ski rental.* Say you first learn to ski. Then you decide to try snowboarding. Then in the summer you take up waterskiing. Each time you have a new rental problem, but you have new information. For example, if you quickly tired of snowboarding, the same may be true for water skiing, so you would do better renting. The same issue arises in various applications. In laptop power-management, the system needs to decide over and over when to shut down the disk, and it can observe the user's disk-access behavior to achieve better performance. In a parallel program, a thread might encounter very similar behavior each time it reaches a particular lock, and that behavior can be used to make a more well-informed decision of how long to spin before blocking [45]. In particular, the thread's behavior might be modeled by a probability distribution for the time the thread must wait for the lock. If the thread chooses the amount of time it spins before blocking, the probability distribution can be used to derive the thread's expected cost (in wasted cycles). The best option for the thread is to choose the amount of time it spins so as to minimize this expected cost. Repeated ski rental has also been applied to IP-over-ATM networks [49]. In addition to having good theoretical properties, the algorithms in [45, 49] are shown empirically to have better performance than previous algorithms.

10.3 On-Line Adversaries and the Competitive Ratio

As suggested in the previous section, many algorithms for on-line problems can be studied by *competitive analysis.* Competitive analysis determines for an on-line algorithm the maximum over all possible inputs of the ratio of the cost incurred by the algorithm on that input to the minimum cost possible on that input. Sleator and Tarjan popularized the use of this performance measure in their seminal paper on sequential search and paging [66]. Their use of the performance ratio, though not new (having appeared in earlier bin-packing and scheduling work, for example [38]), triggered the proverbial avalanche, and competitive analysis has since been applied to an immense range of on-line problems.

In general, let F denote a family $\{I_1, I_2, \ldots\}$ of instances of an on-line problem. We require that an instance be finite, containing a bounded number of requests. Let $A(I)$ denote the cost of algorithm A on instance $I \in F$, and let $\mathrm{OPT}(I)$ denote the optimum cost to solve instance I. Then A is c_F*-competitive* if, for all $I \in F$,

$$A(I) \leq c_F \mathrm{OPT}(I) + b_F \ , \tag{10.3}$$

where c_F and b_F are constant with respect to I. They are in general functions of the family, F.

For example, in the ski rental problem, an instance is simply the number t, and the family of instances is the natural numbers. The competitive ratio of the green circle strategy is 2, because Eq. (10.3) holds with $c_F = 2$ and $b_F = 0$.

As an example of a more complicated situation, consider the *on-line Steiner tree problem,* defined as follows. An instance consists of a connected, weighted graph $G = (V, E)$ of n vertices and m edges, and a set $R \subseteq V$ of *required* vertices. A Steiner tree on R is a minimum-weight subtree of G that contains all the vertices in R. In the on-line problem, the set R is revealed on-line. Initially the subtree is empty. As each node is revealed, enough additional edges must be added to the tree so that the new node is connected to all previously revealed nodes. Once an edge has been added, it cannot be removed. The on-line Steiner tree problem arises in several settings, including facility location, planning of telecommunication networks, and as a subproblem of file allocation and load-balancing problems in networks.

Let $F(n, m)$ denote the family of instances of the on-line Steiner tree problem on n-node, m-edge weighted graphs, where the edge weights can be arbitrary. The "greedy algorithm," which always connects a new node to the previous tree in the cheapest possible way, is $O(\log n)$-competitive with $b_F = 0$ [41].

Furthermore, if b_F is required to be 0, then every on-line algorithm for the Steiner problem has a competitive ratio that is $\Omega(\log n)$ [41]. Here the competitive ratio is a function of the family of graphs, but independent of the weights. On the other hand, if we define $F(n, m, B)$ to be the family of n-node, m-edge graphs with all edge weights positive and total edge weight bounded by B, then the greedy algorithm is 0-competitive with $b_F = B$, since the weight of any solution is no more than the total edge weight.

The point of this discussion is that when we talk about the competitive ratio of a given algorithm, we will have Eq. (10.3) in mind, but the precise details of the model (the definition of the family) and the restrictions we place on the additive constant b_F may have a rather profound effect on the competitive ratio that we end up with for the algorithm.

Randomized Algorithms

A **randomized algorithm** is an algorithm that has access to an oracle that generates random bits when requested. It can use these random bits to "flip coins" and make different decisions based on the random bits. The competitive ratio is defined with respect to expected cost. Randomized algorithm A is c_F-*competitive* if, for all $I \in F$,

$$\mathbf{E}[A(I)] \leq c_F \mathrm{OPT}(I) + b_F \ . \tag{10.4}$$

The expectation is with respect to the sequence of random choices that A makes.

Adversaries

It is often useful to think of an on-line problem as a game between two players. One player, the **adversary,** generates requests on-line according to some specified mechanism and is charged a cost for its selections according to some specified rule. For example, it can be charged the optimum cost to satisfy the complete sequence of requests. The other player is the algorithm, which responds to requests by making a decision, and incurs some total cost over the course of the game. The adversary's goal is to maximize the ratio of the algorithm's cost to the adversary's cost, while the on-line algorithm's goal is to minimize it.

The basic definition of competitiveness for nonrandomized (deterministic) algorithms, given at the start of Section 10.3, corresponds to an adversary that has complete knowledge of the algorithm, that is allowed to generate any request sequence, and that is charged the minimum (off-line) cost to perform any request sequence it generates. Such an adversary can first decide how many requests it wants to generate, and then internally simulate the algorithm on each possible sequence of that length to find the sequence that maximizes the ratio between the on-line algorithm's cost and the adversary's cost. This kind of adversary is called a *deterministic off-line* adversary.

The definition of competitiveness for randomized algorithms given in "Randomized Algorithms" corresponds to an adversary that has complete knowledge of the algorithm but does not know what random bits the algorithm will have. It can generate any request sequence, and is charged the off-line cost. The adversary can internally simulate the algorithm with all possible strings of random bits to find a sequence that maximizes the expected ratio of costs. Such an adversary is called a *randomized oblivious* adversary (because it is oblivious to the actual random choice made by the on-line algorithm). Rather more subtle analyses of randomized algorithms are possible with when the adversary is allowed to know the random bits. We will return to this in a later section.

Extending the Notion of Competitiveness

Our plan is to measure the quality of an on-line algorithm by its competitive ratio. But is this always the best measure? For example, a person who was really considering learning to ski might not be convinced that the deterministic (green circle) and randomized (blue square) algorithms for ski rental are truly the best ones, despite our argument that they are optimal according to the measure of competitive ratio. Such

a person might complain that the competitive ratio is not always the right way to measure quality. For example, one might rather want to minimize the maximum cost incurred (in which case you should always buy right away). A number of other approaches to measuring the quality of an on-line strategy can be found in [53]. The competitive ratio is the only one used in computer science, however, and it seems to be flexible and useful, so we shall limit our attention to this measure.

Another possible complaint about competitive analysis is that the assumption of no knowledge about the future is overly pessimistic. For example, it may be unreasonable to assume that the fact that one has already made i ski trips gives no information about whether or not one will make the $(i+1)$st trip. In real life, people are not truly arbitrary. For some people, the more one has gone, the more likely one is to go again. Other people will try anything once but nothing twice, and so on. An on-line algorithm might be able to take advantage of these characteristics to reduce the overall cost. But the basic definition of competitive analysis does not take this into account. It presupposes a worst-case adversary, which is allowed to generate request in a completely capricious fashion. Such an analysis provides no way to differentiate a ski-rental strategy that tries to take advantage of observed characteristics of the request sequence, and one that always does the same thing (such as buying after y/x trips). In the worst case, both will have a competitive ratio no better than 2. In fact, an algorithm that does well for "reasonable" people might have a competitive ratio higher than 2.

We can account for this kind of situation within the basic framework of competitive analysis, however, by limiting the way that the adversary chooses request sequences. For example, in the "blue square" version of ski rental, the adversary might choose t according to some probability distribution D. Instance I occurs with probability p specified by D.

The definition of competitive ratio is extended to include probability distributions over the family of instances in the following way. An algorithm is c_F competitive on distribution D over a family of instances F if

$$\mathbf{E}[A(I) - c_F \cdot \mathrm{OPT}(I)] \leq b_F \,. \tag{10.5}$$

Here the expectation is over the distribution D on instances in F. By the linearity of expectations, this is equivalent to

$$\mathbf{E}[A(I)] \leq c_F \cdot \mathbf{E}[\mathrm{OPT}(I)] + b_F \,. \tag{10.6}$$

As an example, consider a version of ski rental in which the probability that t trips are taken is $e^{-t} \cdot \frac{e-1}{e}$ (the quantity $\frac{e-1}{e}$ is a normalizing constant). This models the case where one is likely to get bored with skiing (or become irreparably injured) as time goes on. The expected number of trips in this situation is $\frac{1}{e-1}$. One on-line strategy in this situation is to always rent, leading to an expected cost of $\frac{x}{e-1}$. This strategy turns out to be optimal, although we do not prove it here. The optimum off-line strategy for a given t is as in Section 10.2, and the exact closed-form expression for the expected off-line cost can be computed fairly easily. The adversary can maximize the ratio of the on-line to off-line cost by setting $y = x$. In this case the competitive ratio is $\frac{e}{e-1}$.

The reader may recall from Section 10.2 that the value $\frac{e}{e-1}$ is also the optimal competitive ratio that can be achieved by a randomized algorithm against a worst-case adversary. This is neither a coincidence nor a simple trick perpetrated by the authors of this article, but rather a deep principle of on-line analysis known as *Yao's minimax theorem* [73]. This theorem is actually an adaptation of the famous minimax theorem of game theory [71]. It states that the best ratio achievable by a deterministic algorithm against any distribution is exactly the same as the best ratio achievable by a randomized algorithm against a worst-case adversary.

More formally, for a given on-line problem let F_n denote the family of input instances of size at most n. Let $\mathcal{D}_n$ denote the set of all probability distributions over the instances in F_n. Let $\mathcal{A}_n$ denote the set of deterministic on-line algorithms for instances of size n. We think of a deterministic on-line algorithm as being a decision tree; a node at depth i in the tree represents a decision about how to respond to the ith request. Finally, let $\mathcal{R}_n$ denote the set of probability distributions on the algorithms in $\mathcal{A}_n$. A randomized

on-line algorithm is a simply a particular probability distribution $R \in \mathcal{R}_n$ on the deterministic algorithms in $\mathcal{A}$. Yao's minimax principle says

$$\lim_{n\to\infty} \left\{ \max_{D\in\mathcal{D}_n} \min_{A\in\mathcal{A}_n} \frac{\mathbf{E}_{I:D}[A(I)]}{\mathbf{E}_{I:D}[\mathrm{OPT}(I)]} \right\} = \lim_{n\to\infty} \left\{ \min_{R\in\mathcal{R}_n} \max_{I\in F_n} \frac{\mathbf{E}_{A:R}[A(I)]}{\mathbf{E}_{A:R}[\mathrm{OPT}(I)]} \right\} . \tag{10.7}$$

The notation $\mathbf{E}_{I:D}$ indicates that the expectation is over instances $I \in F_n$ according to the probability distribution D. Similarly, $\mathbf{E}_{A:R}$ indicates the expectation over algorithms $A \in \mathcal{A}_n$ according to the probability distribution R. Several variants of this minimax principle have been used in the analysis of on-line algorithms; see for example [20].

10.4 Paging: A Classic On-Line Problem

Paging is the archetypal problem in on-line algorithms, the problem that has been the testing ground for most new methods of analysis of on-line algorithms.

Consider a hierarchical storage system consisting of a small, fast memory, that can store k memory pages, and a large slow device with room for n pages, with $n \gg k$. The classic instantiation is a virtual memory system, with the fast memory constructed of RAM and the slow device being a hard disk. (There are other instantiations, see for example [49, 55].) When a program references a memory location in a page that isn't in memory, a *page fault* occurs, and the program is blocked and must wait while the page is loaded into memory. Some page must be evicted from memory to make room for the page being loaded, and a *paging algorithm* chooses which page to evict. The aim of the paging algorithm is to minimize the number of page faults caused by the sequence of memory references.

The first application of competitive analysis to paging occurred in the seminal CACM paper of Sleator and Tarjan [66]. They analyzed the performance of the least recently used (LRU) rule, an algorithm widely regarded as very effective in practice. They proved (generalizations of) the following two theorems, whose proofs we provide as examples of the genre.

THEOREM 10.1 *LRU has competitive ratio k.*

PROOF Partition the page reference sequence σ into $\sigma_0, \sigma_1, \ldots, \sigma_i$, such that LRU faults exactly k times in $\sigma_1, \ldots, \sigma_i$ and at most k times in σ_0. For $1 \le j \le i$, let p_j be the last page referenced in σ_{j-1}. During σ_j, LRU cannot fault twice on any page, and it cannot fault on p_j. Therefore σ_j contains references to k different pages, all different from p_j, so the optimal algorithm must fault at least once in σ_j. This suffices to prove the theorem.

THEOREM 10.2 *No deterministic on-line algorithm has a competitive ratio less than k.*

PROOF Let $\mathcal{A}$ be a deterministic algorithm, and consider the case $n = k + 1$. Let σ be the sequence constructed by always referencing the page that is *not* in $\mathcal{A}$'s fast memory. $\mathcal{A}$ faults on each reference, whereas the optimum algorithm, which always evicts the page whose next reference is furthest in the future [14], faults at most once every k references.

A better competitive ratio is achievable through the use of randomization. Fiat et al. [30] give a simple randomized algorithm that has competitive ratio $2\mathcal{H}_k$, where $\mathcal{H}_k = \sum_{1\le i\le k} 1/k$ is the k harmonic number, and is $\Theta(\log k)$. A more complex algorithm has competitive ratio $\mathcal{H}_k$ [58], matching a lower bound proved by Fiat et al.

These tight bounds for deterministic and randomized competitive ratios are pleasing, particularly in the case of an empirically good algorithm such as LRU. There are, however, some limitations with these results. First, other nonrandomized algorithms that behave worse than LRU in practice, such as first-in first-out (FIFO), also have a competitive ratio of k. Second, on traces taken from program executions, the performance ratio of LRU is much less than k, or even $\log k$, typically close to 2 [74].

Borodin et al. added some realism by modeling *locality of reference,* the property of page reference sequences that makes hierarchical storage useful at all. They modeled locality using an access graph, where the reference sequence is restricted to be a walk through the graph. In addition to analyzing LRU in this model, they considered how to use advance knowledge of the access graph, an approach continued by Irani et al. [43] and Fiat and Karlin [29]. Fiat and Mendel [31] show how to optimally use the access graph, even when it is not known in advance but must be learnt as the requests arrive. In addition, they need only store the most recently seen part of the access graph, rather than the entirety.

As discussed in "Extending the Notion of Competitiveness," an access graph is a way to limit the power of the adversary, restricting the possible reference sequences so that the results obtained have more bearing on paging in practice. A alternative approach was taken in the earliest theoretical treatments of paging in which reference sequences were assumed to be generated by various probability distributions. In one study, each page reference was chosen according to a fixed probability distribution over the set of pages [33], while others did probabilistic analyses of LRU in which page references were chosen according to LRU stack-depth (where the ith most recently accessed page has stack-depth i) [52, 64]. Results in these papers are specific to the particular probabilistic model of reference sequences, however, and we'd like more general-purpose results.

A step in this direction was the Markov paging model of Karlin et al. [47], in which the locality of reference inherent in a program is modeled by a Markov chain. Each node in the chain corresponds to a page and each transition into a state generates a reference to that page. Hence, a reference sequence is generated by the probabilistic transitions of the chain. Karlin et al. found an algorithm whose expected page fault rate on any Markov chain is within a constant factor of the best possible for that chain. This approach was extended by Lund et al. [55], who show that for *any* distribution over page reference sequences, there is a natural algorithm that gets within a constant factor of the best possible expected fault rate for the distribution, which needs only to know, for pages i and j in the fast memory, the probability that i will be referenced before j.

Koutsoupias and Papadimitriou [51] introduced two other alternative analysis techniques: the diffuse adversary model and comparative analysis. In the first technique, reference sequences are generated by some distribution $\mathcal{D}$ from a set Δ. The on-line algorithm can take advantage of knowing Δ, but doesn't know which $\mathcal{D}$ will be used, and its expected fault rate is compared to the expected optimal fault rate on sequences from $\mathcal{D}$. In comparative analysis, rather than comparing on-line algorithms to the optimal algorithm, we compare two arbitrary classes of algorithms. Koutsoupias and Papadimitriou use the diffuse adversary mode to exhibit a simple family Δ for which LRU is the best on-line algorithm, and comparative analysis to investigate the value of lookahead in paging, comparing algorithms with lookahead to those without.

Torng [70] includes the time to access fast memory, in addition to the time incurred during a page fault, in the cost of servicing a page reference sequence. This has a number of attractive consequences: lookahead provably helps, and on reference sequences exhibiting a natural notion of locality of reference, some algorithms (including LRU) achieve a *constant* competitive ratio. Another model for analyzing on-line algorithms, and algorithms for paging in particular, is Young's loose competitiveness [75].

10.5 General Models for On-line Problems

In this section we review some of the general models and tools that have been developed for on-line problems. If a given on-line problem can be phrased in terms of one of these models, standard algorithms

are available to solve the problem. In this section the adversaries are assumed to be worst-case.

Most of the models we discuss are defined over *metric spaces.* A metric space, M, is a pair (P, δ) where P is a set (finite or infinite) and δ is a distance function from $P \times P$ to $\mathcal{R}$. A typical example of a metric space is the plane with Euclidean distance. The function δ must satisfy several conditions:

1. $\delta(a, a) = 0 \; \forall \, a \in P$.
2. $\delta(a, b) \geq 0 \; \forall \, a, b \in P$.
3. $\delta(a, b) = \delta(b, a) \; \forall \, a, b \in P$.
4. $\delta(a, b) + \delta(b, c) \geq \delta(a, c) \; \forall \, a, b, c \in P$.

The k-Server Model

The k-server model, defined in [57], had its genesis in paging problems. Let M be a metric space and let S be a set of k *servers.* The servers are always located on k not necessarily distinct points $s_1, \ldots, s_k$ in M. An instance of the k-server problem consists of a metric space M, the initial positions of the servers, and a sequence σ of requests, which are revealed one-at-a-time. A request is simply a point r in M. The servers must satisfy the following condition.

> Let r be the most recently revealed request point. There must be at least one server, i, such that $s_i \equiv r$.

After request r is revealed, the set of servers are moved as necessary so that at least one server is located at the request point. Let s_i' denotes the position of server i after being moved. The cost of moving the servers is $\sum_i \delta(s_i, s_i')$. The total cost of servicing σ is the sum over requests of the movement costs.

Example: Paging. The paging problem is modeled as a k-server problem in the following way. There is one point in P for each unique page of memory. There is one server for each cache location. Define $\delta(a, b) = 1$ for any pair $a, b \in P$. If server i is located at point p, then page p is in cache location i. If no server is located at point p then the corresponding page is out of cache. Moving server i from a to b corresponds to ejecting page a and loading b into slot i.

When Manasse et al. [57] first proposed the k-server model, they conjectured that there exists a deterministic algorithm that has competitive ratio of k on any instance of the k-server problem (not just a paging instance). This became the rather famous "k-server conjecture." For deterministic algorithms, k is the best possible ratio. This follows from the lower bound on the competitive ratio of paging algorithms.

So far, the truth of the k-server conjecture has not been resolved, but a good candidate for a deterministic algorithm with ratio k is the *work-function algorithm,* developed independently by several researchers [21, 24, 57]. The work-function algorithm keeps track of the optimal off-line costs and tries to make moves that keep its cost close to the optimal cost. Given a sequence of m tasks, the optimal off-line cost can be computed with a simple dynamic programming algorithm. Let $g_i(X)$ denote the minimum cost to perform tasks 1 to i and end in configuration X, where $X = (s_1, \ldots, x_k)$. Then $g_0(X) = \delta(X_0, X)$, where X_0 is the start configuration, and

$$g_i(X) = \min_{X'} \left\{ g_{i-1}\left(X'\right) + \delta\left(X, X'\right) \right\} . \tag{10.8}$$

The optimal cost to process the sequence is $\min_X g_m(X)$.

The function $g_i(\cdot)$ is an example of a *work function.* A work function is a function mapping the configuration space to the positive reals, with the property that the value of the work function at point X lower-bounds the optimal cost to process requests 1 through i and end at position X.

Work Function Algorithm. Let r be the tth request, and let X_{t-1} be the configuration of the on-line servers when r arrives. Let X_t be the configuration X, $r \in X$, that minimizes $g_t(X) + \delta(X_{t-1}, X)$.

Koutsopias and Papadimtriou [50] showed that the work-function algorithm is $2k - 1$ competitive, but the proof is beyond the scope of this survey. Note that the work-function algorithm requires space $\Theta(n^k)$ space, which is quite prohibitive for large k.

Sometimes it is useful to compute the optimal off-line strategy. For example, it is useful in the design of a prefetching strategy for a data-independent computation flow, as might occur in a large matrix application such as Gaussian elimination or an eigenvalue calculation. Chrobak et al. [23] showed how to reduce finite instances of the off-line k-server problem to an instance of the network flow problem. If there are n points in the metric space, and there are m requests, the flow instance consists of a network of size $O(k(m + n))$. Using a standard network flow algorithm [68] a solution to the **off-line problem** can be found in time $O(k^2(m + n)^2 \log(k(m + n)))$.

Metrical Task Systems

Borodin et al. [21] proposed a more general model of on-line computation called *metrical task systems.* A metrical task system consists of a set of n states S and a distance function δ so that (S, δ) is a metric space. At any time, the system must be in exactly one of the n states. A sequence σ of *tasks* is revealed, one task at a time. Task t_i is an arbitrary cost vector, $(c_{i1}, \ldots c_{in})$, that maps states to costs. Value c_{ij} is a nonnegative real number. If the system is in state j at the time task i is processed, the cost of the task is then c_{ij}. The cost vectors can be entirely arbitrary and need have no relation to each other or the state transition function. If the function δ is not symmetric but still obeys the triangle inequality then (S, δ) is just called a *task system.*

The notion of *lookahead* arises in metrical task systems. Informally, an on-line problem has *lookahead* k if an on-line algorithm is allowed to know the next k requests when making decisions about how to change state. More formally, an on-line problem modeled as a metrical task system proceeds in a series of rounds. At the start of a round, the on-line algorithm is shown the next k tasks. The on-line algorithm can then change the state of the system at cost $\delta(s, s')$, where s and s' are the old and new states, respectively. Finally, the on-line algorithm "accepts" the next task t, at cost $c_{ts'}$. This ends the round. The value of k may be a function of the number of states n, but it cannot be a function of the number of tasks. An off-line algorithm, which can see the entire sequence of tasks, is said to have *unbounded* lookahead.

Example: sequential search. This problem models searching for an item in a linked list containing n items. After each search, the list can be rearranged to move more commonly accessed items forward. The subsection "Data Structure Problems" gives more details. The metrical task system (S, δ) has one state for each of the $n!$ permutations of the list. The cost of moving between two states is given by the number of inversions between the two lists: it is not hard to show that one list can be rearranged to any other with a number of exchanges equal to the number of inversions between source and target list. An access to element x is modeled by a task t such that c_{ts} is the position of item x in permutation s. This model has lookahead 0.

Example: paging. There are $\binom{m}{k}$ states, one for each possible subset of k pages in cache out of m total pages. The cost of moving between states is equal to the number of pages they differ in. An access to page x is modeled by a task t such that c_{ts} is 0 if s contains x in cache and $+\infty$ otherwise. The paging problem has lookahead 1. This reduction can be extended to model the k-server problem as a metrical task system by letting the cost to change state be the minimum distance servers must move to make the change.

It is evident that the task system model is very general and encompasses a large range of on-line problems. Borodin, Linial and Saks gave a general-purpose algorithm for the model.

The Borodin–Linial–Saks algorithm. This algorithm for task systems is a straightforward extension of the work function algorithm of "The k Server Model," although in fact the BLS algorithm

appeared first. As before, we keep track of the optimal off-line cost with a function $g_i(s)$, which denotes the minimum cost to perform tasks 1 to i and end in state s. This function can be computed as in the section on k-servers. Let r be the tth request, and let s_{t-1} be the current state when r arrives. Move to the state s_t that minimizes $g_t(s_t) + \delta(s_t, s_{t-1}) + c_{ts_t}$.

When δ is not symmetric, it is important that $\delta(s_t, s_{t-1})$ be used in the minimization, rather than $\delta(s_{t-1}, s_t)$. The formulation given above is different from that in [21] but the two are essentially equivalent.

Borodin, Linial, and Saks prove that this algorithm is $2n-1$-competitive on any metrical task system and $O(n^2)$-competitive on any task system that is not metrical. Furthermore, they show that no deterministic algorithm is better than $2n-1$-competitive. This result is rather depressing, since the number of states could be very large, as in the sequential search example above. There the number of states is $k!$, where k is length of the list. On the other hand, there are practical problems such as multiprocessor page migration (see "Data Management in Networks") in which the number of states is much smaller and plenty of processing time is available, and the BLS algorithm is certainly applicable in these situations.

Like the work function algorithm, the BLS algorithm requires lookahead 1. The paging example shows that there cannot be a general algorithm with lookahead 0 that has bounded competitiveness. Let $\delta(a, b) = 0$ for all states a, b. If the on-line algorithm is in state i, an adversary simply creates a task that has cost 1 in state i and cost 0 in all other states. The off-line cost is always 0 while the cost to the on-line algorithm can be made arbitrarily high by creating a sufficiently long sequence.

Recently Bartal et al. [11] found a randomized algorithm for metrical task systems that achieves a competitive ratio that is polylogarithmic in n. The algorithm is rather complicated, however, and lies beyond the scope of this section.

Request-Answer Games

The most general model of on-line problems that appears in the literature is *request-answer* games [15]. This model exploits the relationship between on-line algorithms and game theory hinted at in "Adversaries." An on-line problem can be regarded as a game between two players, the algorithm and the adversary. At each round of the game, the adversary makes a move, which is a request plus a list of legal responses (answers) and associated costs. The algorithm then selects one of the answers to respond with. Two types of adversaries have been considered: oblivious adversaries, which do not know what responses the algorithm gives and must decide on the next move in the dark, an adaptive adversaries, which are given complete information about the algorithm's responses. The distinction is only relevant when the algorithm is randomized. If the algorithm is deterministic, an adversary can simulate the algorithm and so know exactly what moves are made.

The adversary is charged a cost for the sequence of requests it generates. The cost can be assessed in two ways. The adversary may be charged the minimum cost to answer the requests using the given answers. This is the off-line adversary. Alternatively, the adversary may have an associated on-line algorithm that it must choose in advance. The cost incurred by this associated on-line algorithm is the cost charged to the adversary. This is the on-line adversary. Again, the distinction is moot if the algorithm is deterministic, because the adversary can simulate the algorithm, choose a sequence of requests, and then select an "on-line" algorithm that just happens to exactly minimize the cost on that particular sequence.

The algorithm wins against a particular adversary if the cost incurred by the algorithm is no more than a constant c times the cost incurred by the adversary. In this case we say the algorithm is c-competitive against the adversary. Because the request-answer model is so general, there cannot be an algorithm that is always competitive against all adversaries.

10.6 The Trail Map: A Selective Guide to On-line Problems

In recent years there has been a flurry of work on on-line problems. Competitive analysis has been applied to a mountain of old and new problems. This section contains a guide to some of the major areas that have received attention.

Data Structure Problems

Most dynamic data structures can be studied as on-line decision problems. So far, however, only two have received much attention.

In the *sequential search* or *list-update* problem, a dictionary of keys is stored in a linked-list data structure. The list may be searched for a particular key by scanning the list in order from front to back, stopping the scan as soon as the item is found. After each search, the list can be reordered by swapping adjacent pairs of elements. By moving items that are frequently searched for to the front of the list, the overall search time can be decreased, but the total cost of a request sequence is the sum of the search time for elements plus the cost of the swaps. Swaps that move the searched-for item forward are free. A popular optimization is the "move-to-front" rule: after a search succeeds, the found element is moved to the front of the list.

Early work on sequential search (see for example [63]) studied the performance of the move-to-front heuristic against an adversary that generates requests using a fixed probability distribution on the list elements. The adversary is charged the cost incurred by a static list that is optimally sorted for the given distribution (i.e., the item with highest probability of access is at the front, then the second highest probability, and so on). Chung et al. [25] showed that move-to-front never incurs a cost greater than $\pi/2$ times the cost incurred by the optimal static list, and Gonnet et al. [37] showed a distribution on which move-to-front did this badly.

A sea-change occurred in 1985, starting with Bentley and McGeoch [16] and followed shortly by Sleator and Tarjan's seminal paper on competitive analysis [66], which gave the first analysis of an on-line algorithm against the optimal off-line adversary. Sleator and Tarjan showed that move-to-front is 2-competitive. It is not hard to see that this is the best possible competitive ratio for a deterministic algorithm by considering a sequence in which the adversary always accesses the last element in the on-line algorithm's list. Since the early 1990s research has concentrated on randomized algorithms. The best known algorithm is 1.6-competitive against an oblivious adversary [3], and a lower bound of 1.5 is known for all randomized algorithms [69].

Another important data structure for storing and searching is the dynamic binary tree. An item is searched for using the standard binary tree search algorithm. After each search, the tree may be reorganized by doing a series of *rotations.* Let (u, v) be a tree edge such that v is the right child u. A rotation of edge (u, v) makes u the new left child of v, the old left child of v becomes the new right child of u, and v replaces u as the left or right child of the old parent of u. Rotations are a fundamental method of reorganizing binary trees, and more information can be found in a standard introductory algorithms textbook such as Cormen et al. [26]. The goal of the rotation is to reduce the search time, by moving frequently accessed items nearer to the root of the search tree.

Any standard balanced search tree such as AVL-trees or red/black trees (see [26]) ensures that the cost of an individual search is $O(\log n)$ and that $O(\log n)$ rotations are done per search. Since the optimal cost is at least 1 per search, balanced trees are trivially $O(\log n)$-competitive. Although there has been considerable work on the problem, no one has yet produced a reorganization algorithm that is provably better than $O(\log n)$-competitive. Conversely, no lower bound greater than 1 is known. It is known, however, that of all dynamic binary search tree algorithms that have so far been proposed, only one can be better than $O(\log n)$ competitive. That candidate is the splay tree data structure of Sleator and Tarjan [67]. Sleator and Tarjan showed that splay trees are $O(\log n)$-competitive, and conjectured that they are in fact $O(1)$-competitive. This conjecture has been shown true or nearly true in certain special cases but the competitiveness of splay trees remains open in the general case, and is one of the most interesting open problems in the theory of

data structures and on-line algorithms. See the survey on on-line data structure problems by Albers and Westbrook in [32] (also available at http://www.research.att.com/~jeffw/data-survey.ps)

Network Admission Control

The explosive growth of the Internet and World Wide Web, and the promise of revolutionary services combining voice, video, and data communications in asynchronous transfer mode (ATM) networks provide a fertile source of on-line problems. The main focus has been on admission control and routing problems in ATM networks, starting with Garay and Gopal [34] and Garay et al. [35], who studied preemptive call control on a single link or a line network. Awerbuch et al. [9] applied approximation techniques for multicommodity flow problems to give an elegant analysis of the following problem: calls are offered to a network on-line, each call having a bandwidth requirement, source and destination nodes and duration. The goal is to accept or reject calls, routing accepted calls subject to edge capacity constraints, so as to maximize the *throughput,* defined as the average over time of the aggregate bandwidth of accepted calls. Subject to a restriction that no call bandwidth is more than $1/\log \rho$ times the minimum edge capacity, they give an algorithm that is $\log \rho$-competitive, which is best possible, within constant factors, for deterministic algorithms. Here ρ is the product of the number of nodes in the network and the ratio of the maximum to minimum job duration. The algorithm essentially uses shortest-path routing with a load-dependent cost metric. More specifically, the cost of an edge is exponential in the load (fraction of capacity used), the cost of a path is the sum of its edge costs, and a call, if admitted, is routed on a least cost path. Load-dependent routing has been used in practice as an important component of established networks; Gawlick et al. [36] show that the exponential cost model gives good results in a practical setting.

A number of variants of competitive routing and admission control have been developed, for example where tight bounds are achieved for tree networks, arrays and hypercubes, where the objective is to minimize congestion rather than throughput. A good survey of these results is given by Plotkin [61].

Data Management in Networks

The problem of managing data in a network of computers can be abstracted as follows. A collection of n computers is connected by some kind of connection network. The network is modeled as an undirected graph whose nodes are computers and whose edges correspond to direct connects between computers. Each edge has a weight, which is a measure of the cost to send a message across the corresponding connection. (The cost may model delay, dollar cost per message, or any other actual cost measure.) The cost to send a message of size q bytes, $q \geq 1$, from machine i to machine j is modeled as $q \cdot \delta(i, j)$, where $\delta(i, j)$ is the total weight of the shortest path connecting i and j.

Each computer has some amount of local storage and supports a collection of local processes (users, or programs). A large collection of data, which we call the "file," is to be read or written concurrently by the processes. The file is partitioned into D records; a *request* at machine i is either a read or a write of an individual record. There may be one or more complete copies of the file stored in the network, each stored at a single machine. If machine i generates a read request, that request is satisfied at zero cost if the machine is storing a copy of the file. Otherwise, a message must be sent through the network to the nearest machine j storing a copy of the file. The requested record is then sent back, at cost $q\delta(i, j)$ for some constant q. For convenience, we assume $q = 1$. A write request is slightly more complicated. If there is a single copy in the network, then the write request is handled the same way as a read request. If there are multiple copies, all copies must be kept consistent. Hence, if a machine generates a write request, all machines containing a copy of the file must be notified. The message cost is lower-bounded by the weight of a minimum Steiner tree containing the requesting machine and all machines with a copy. This can be achieved (within constant factors) if the machines can store and forward messages intelligently (i.e., each machine transmits messages only to its adjacent neighbors in the Steiner tree. (Computing a Steiner tree is NP-hard, of course, but although we use a Steiner tree to model costs, in practice a Steiner tree can be

approximated within a factor of 2 by a minimum spanning tree, which is fast to compute.)

The overall goal is to minimize total message cost. As the request patterns change, it may be advantageous to make new copies of the data file. For example, a machine that is generating many reads can benefit from keeping a copy locally, although the addition of a new copy will increase the message cost of subsequent writes. Similarly, if there are many write requests compared to reads, it may be useful to decrease the number of copies. A copy of the file can be placed at machine i by transmitting the D records to i from the nearest machine j with a copy. The cost is $D \cdot \delta(i, j)$. A copy can be discarded from a machine at no cost. Of course, there must always be one copy of the file in the network.

Although this model is idealized it captures much of the main difficulties in handling files in networks. The static problem of assigning a fixed set of copies has been extensively studied. For the static problem a probabilistic distribution is typically assumed and then the expected cost per unit time is calculated for various cost models. Dowdy and Foster give a survey of these results [27].

The on-line problem has been studied in various settings. Two interesting restrictions are *replication,* in which there are only read requests, and *migration,* in which the file can be moved but there is never more than one copy. Migration and replication were the earliest of this class of problem to be studied in an on-line setting [18]. The general problem, which allows for reads, writes, and multiple copies, is called *file allocation.*

Consider replication in a network of two machines connected by an edge. Initially there is one copy, at machine a. Now suppose b begins to generate read requests. When should a copy be placed at b? A little reflection reveals that this is exactly the ski rental problem, with the rent cost 1 and the buy cost D. Hence, there is a two-competitive deterministic algorithm and an $e/(e-1)$-competitive randomized algorithm. For general networks, however, the problem becomes much harder. The off-line adversary, having decided what machines will need copies in the end, will achieve minimum cost by replicating all copies at the start along a minimum Steiner tree connecting the machines. The on-line algorithm must essentially generate on-line an approximation to this minimum Steiner tree. The competitive ratio for this problem is $\Theta(\log n)$ [41].

On-line migration has the advantage of avoiding the problem of maintaining consistency and is popular in designs of virtual shared memory. There are several deterministic and randomized algorithms, all with low constant competitive ratios, in the range 2–5. See Bartal et al. [12] for further details.

For file allocation, deterministic and randomized algorithms are known that are $O(\log n)$-competitive (the best possible up to constant factors). If the network is a bus or a tree, small constant competitive ratios can be achieved, in the range 2–3. In general networks, there is also a problem with simply keeping track of the nearest copy of the file. If the cost of this data tracking problem is included, the best-known competitive ratio increases to $O(\log^2 n)$. See Lund et al. [56] for more information.

There are various related problems, such as providing fault tolerance [72] or handling bounded storage at each machine [13]. A completely unexplored problem is when there is a cost per unit storage.

Robot Searching and Navigation

In this class of problems, an automaton is placed in an unknown environment, and asked to find its way to a certain location, or to find an object hidden in the environment. It discovers the nature of the environment only by exploring. In general, the goal is to limit the amount of time-consuming exploration required to reach the goal.

In the most abstract setting, the environment consists of a directed graph. The robot is started at some node in the graph, and asked to reach a particular other node. Each node can be uniquely identified by the robot, and when at a node, the robot can see and identify the set of incident edges. But it does not know where an edge leads until it has crossed the edge.

As an example, we can state the following problem, due in its original form to Chrobak and Larmore. A downhill skier, having inadvertently missed his turn and plunged off a cliff, finds himself in the afterlife, still wearing his skis. The afterlife consists of a completely flat, foggy, snowy 1-dimensional space, in which

the skier is standing at Cartesian coordinate zero. A supernatural being appears, states that a door into Heaven is located somewhere in the one-dimensional space, and then disappears again. What strategy should the skier adopt to find the doorway with the minimum amount of tedious cross-country poling? (Because of the fog, the skier has to actually ski right up to the doorway to find it.) The optimal strategy is to head right to the doorway, but the skier does not know in which of the two directions the doorway is located. But, if the skier adopts the strategy of moving in one direction for 1 time unit, then returning to the start, then going in the other direction for two time units, then returning, then going in the first direction for four time units, and so forth, the skier will eventually find the doorway having traveled no more than 9 times the optimal distance. Hence, this strategy is 9-competitive.

More geometrical papers concern a robot traveling in a two-dimensional plane that contains obstacles. An obstacle is a closed two-dimensional curve (i.e., a square or circle). The robot must find a path to the target (the location searched for) that avoids all the obstacles. Generally it is assumed that the robot knows its initial position and the location of the target, in Cartesian coordinates. An obstacle is discovered only when the robot runs into it.

In the model introduced by Blum et al. [19] it is assumed that the robot is told the dimensions of an obstacle once it encounters the obstacle, and that the robot has perfect position information. A navigation algorithm is called $c(n)$-competitive if the length of the path traveled by the robot is no more than $c(n)$ times the length of the shortest obstacle-avoiding path. In brief, it is known that if the obstacles are axis-parallel simple rectangles then there are $O(\sqrt{n})$-competitive navigation algorithms (and slightly better randomized algorithms [17]). If the obstacles can be concave, however, then even if the sides of obstacles are axis-parallel, no algorithm is better than $\Omega(n)$-competitive.

A somewhat different model and complexity measure has been adopted by the theoretical robotics community [54]. Here the obstacles can be bounded by arbitrary curves, and the shape of the obstacle must be discovered by traversing its boundary. The distance traveled by the robot is compared against the sum, P, of the perimeters of the obstacles. It is shown that in the worst-case any algorithm must travel distance at least P. How close the robot can come to that bound depends on how much knowledge the robot has about its position. With complete, exact knowledge of Cartesian coordinates there is an algorithm that never travels more than $2P$ [54]. With only partial position information (perhaps more interesting in practice) the robot multiplicative factor varies from 3 to $O(\log n / \log \log n)$. For references to more recent work see Angluin et al. [4].

Graph Theory

One can create an on-line version of almost any graph-theoretic problem by requiring that the graph be revealed in an on-line fashion. This can mean that the vertex set is known initially and edges of the graph are added one-at-a-time, or that nothing is known initially, and at each step a vertex plus all edges to already revealed nodes are given. In addition, one can allow node or vertex deletions in an on-line fashion. On-line algorithms for graph problems can often serve as simple approximation algorithms for problems that are hard to solve optimally, such as the Steiner tree problem in networks.

In the on-line matching problem, at each step a vertex is revealed, along with all its edges to previously revealed vertices. The new vertex can be matched to some previously revealed vertex, or it can be left unmatched in the expectation that some vertex to be revealed subsequently can be matched to the current vertex. Once the choice has been made, however, it cannot be unmade. Node and edges are never deleted. The matching constructed on-line is compared to the maximum matching in the full graph. No constant is allowed in the competitive ratio. One can also ask to construct a matching of maximum weight, when each edge has a weight. For unweighted matching [48], low constant competitive ratios are achievable. For example, the simple greedy strategy, which matches each vertex as it arrives, if possible, is 2-competitive. Weighted matching [44] is harder.

A generalized version of the on-line Steiner tree problem (see Section 10.3) in which nodes must be connected with multiple paths, is examined in [7]. The on-line traveling salesman problem is examined in [6].

Substantial research has been done on coloring a graph on-line (see for example [40]). The nodes and incident edges are revealed one at a time, and as each node is revealed it must be colored so that no adjacent vertex has the same color. The goal is to minimize the number of colors.

Scheduling and Load Balancing

Many scheduling and load-balancing problems are essentially on-line in nature. Scheduling problems arise, for example, in a computer operating system when users present tasks to be run on the system, and the tasks must be scheduled without knowledge of future task arrivals. An example of a load balancing problem is when a program running on a parallel machine spawns processes in an unpredictable way, and to optimize the program's performance, the processes must be partitioned on-line among the machine's processors.

On-line scheduling and load balancing is an active field of study. Representative topics are on-line scheduling of sequential jobs on parallel machines to minimize the makespan (maximum completion time) [65], scheduling parallel jobs on parallel machines [28], load balancing when each job can be handled only by a subset of the machines and we wish to minimize the maximum load [10] or the L_p norm of the machines [8], preemptively scheduling jobs in a single processor to minimize the flow time, or average waiting time of jobs [59], scheduling to minimize the average waiting time of precedence-constrained jobs [39]. Work in this area has had an impact on virtual-circuit routing (e.g., [5]) and algorithms for maximum-flow [60].

To give a sense of the typical approach to on-line scheduling and load balancing problems, we present a single problem in some detail. Consider a system consisting of m identical machines. A set of jobs is presented to the system, and a scheduler must assign each job to a machine, so as to minimize the maximum load. Here the load of a machine is the sum of the weights of jobs assigned to it. In perhaps the first on-line treatment of a scheduling problem, Graham observed that the *list processing* algorithm, which assigns each job in turn to the machine whose current load is smallest, has a competitive ratio of $2 - 1/m$.

The argument is follows. Suppose a collection of jobs has been assigned to the machines using Graham's algorithm. Let i be the most loaded machine, j be the job that was last assigned to machine i, let s be its size, and let w be the load on machine i just before job j was assigned. The algorithm's maximum load is $s + w$. Let Opt be the maximum load of the optimal algorithm. Clearly,

$$\text{Opt} \geq s \; . \tag{10.9}$$

In addition, the total weight of all jobs must be at least $mw + s$, because at the time job j was assigned to machine i, all other machines must have had load at least w.

Therefore

$$\text{Opt} \geq w + s/m \; . \tag{10.10}$$

Combining these inequalities gives

$$(2 - 1/m)\text{Opt} \geq w + s \; , \tag{10.11}$$

which proves that list processing is $2 - 1/m$ competitive. This bound is shown to be tight by the job sequence consisting of $m(m - 1)$ jobs of size 1 followed by a single job of size m.

Recently attention has been focused on the problem of determine the best-possible competitive ratio for this problem (see [2], and the references therein). Currently the best known bounds are due to Albers, who demonstrates an algorithm with competitive ratio at most 1.923, and proves that no algorithm can be better than 1.852-competitive.

Finance

A natural application area for on-line methods is finance. The worst-case nature of competitive analysis offers an appealing alternative to methods of mathematical finance which are based on detailed probabilistic models approximating the behavior of economic variables. On the other hand, the worst-case nature of competitive analysis is also problematic: if the markets are truly adversarial, the best investment strategy might be never to invest (and instead spend it all skiing). Therefore research in this area has focused on creating on-line models that, while remaining worst-case, allow some realistic constraints to be included. Raghavan's statistical adversary model [22, 62] allows an adversary to pick any input sequence (for example a sequence of daily share prices) as long as the sequence exhibits a particular statistical property (for example, a mean value within some range). Al-Binali [1] introduces a competitive risk-reward framework, in which an algorithm uses a particular forecast (for example, that interest rates will rise 1% within 6 months). This framework distinguishes between the restricted competitive ratio, which is the competitive ratio on inputs for which the forecast is correct, and the unrestricted competitive ratio. Let OC be the best possible unrestricted competitive ratio. The reward of the algorithm is the ratio of its restricted competitive ratio to OC, while the risk is the ratio of the algorithm's unrestricted competitive ratio to OC. The risk measures how badly the algorithm does when the forecast is wrong, the reward quantifies the benefit when the forecast is right.

10.7 Research Issues and Summary

As we have suggested in our Trail Map, on-line problems are ubiquitous in computer science. There is much research into on-line algorithms that is called by other names, and an important research goal is to further integrate competitive analysis into these areas.

The foundational questions in the study of on-line algorithms concern the right model and right measure of goodness. Designing algorithms to have good competitive ratios is a useful exercise that brings additional insight into the problem at hand. Since the standard competitive ratio is a worst-case measure, however, it may sometimes be too pessimistic, and variants of the standard competitive analysis have been proposed to address this issue. An important avenue of research is to provide a unifying framework for these variants, and to better understand when each variant it is likely to be a good predictor of actual performance.

Such research is both empirical and theoretical. As described in Section 10.4, the paging problem has become a proving ground both for empirical studies and for attempts to refine competitive analysis to provide a measure that better distinguishes between algorithms that have substantially different behavior in practice, and to capture situations in which worst-case adversaries are very unlikely. A skier doesn't have to use that same pair of skis on all terrain; she can buy different equipment for powder, moguls, ice, or slush.

The classic open problem in competitive analysis is resolving the "k-server conjecture" (see Section 10.5). Although substantial progress has been made on this problem, a tantalizing gap still remains.

10.8 Defining Terms

Adversary: The input sequence can be thought of as being generated by an adversary that uses information about the past moves of the on-line algorithm to choose inputs that maximize the ratio between the cost to the algorithm and the optimal cost.

Competitive analysis: A performance analysis in which an on-line algorithm is evaluated by comparing its performance to the best that could have been achieved if all the inputs had been known in advance.

Competitive ratio: The worst-case ratio between the cost incurred by an on-line algorithm and the optimal cost.

Off-line problem: A decision problem in which an algorithm is given the entire sequence of inputs in advance.

On-line algorithm: An algorithm that solves an on-line problem.

On-line problem: A problem in which an algorithm receives a sequence of inputs, and must process each input in turn, without detailed knowledge of future inputs.

Optimal cost: The minimum cost to process an input sequence.

Randomized algorithm: An algorithm that uses random bits to make decisions.

Further Information

Irani and Karlin [42] provide a short survey of the field from a more theoretical viewpoint, while the book of Borodin and El-Yaniv [20] is an extensive treatment of on-line algorithms. A collection of surveys of various subfields has been edited by Fiat and Woeginger [32]. Marek Chrobak and John Noga have collected a bibliography of papers on on-line problems, available at

http://www.cs.ucr.edu/~marek/pubs/online.bi

We have extended that bibliography with recent papers and our revised version is available at

http://www.research.att.com/~jeffw/online.bib

Current research into on-line problems and algorithms is published in a number of conferences and journals. Currently there is a lag time of several years between journal submission and final publication, so conferences provide the forum for fast dissemination of cutting-edge research. A partial list of larger conferences includes the ACM Symposium on Theory of Computing (STOC), the IEEE Conference on Foundations of Computer Science (FOCS), the ACM-SIAM Symposium on Discrete Algorithms (SODA), the International Colloquium on Automata, Languages, and Programming (ICALP), and the European

Symposium on Algorithms (ESA). There are also numerous regional conferences. Announcements about conferences can generally be found in the *Communications of the ACM* or *IEEE Spectrum.*

A partial list of journals includes *Journal of the ACM, SIAM Journal on Computing, Journal of Algorithms, Algorithmica, Information Processing Letters,* and *Theoretical Computer Science.*

Pattern Matching in Strings

11.1 Introduction

The present chapter describes a few standard algorithms used for processing **texts.** They apply, for example, to the manipulation of texts (text editors), to the storage of textual data (text compression), and to data retrieval systems. The algorithms of the chapter are interesting in different respects. First, they are basic components used in the implementations of practical software. Second, they introduce programming methods that serve as paradigms in other fields of computer science (system or software design). Third, they play an important role in theoretical computer science by providing challenging problems.

Although data are stored variously, text remains the main form of exchanging information. This is particularly evident in literature or linguistics where data are composed of huge corpora and dictionaries. This applies as well to computer science where a large amount of data are stored in linear files. And this is also the case in molecular biology where biological molecules can often be approximated as sequences of nucleotides or aminoacids. Moreover, the quantity of available data in these fields tends to double every 18 months. This is the reason why algorithms should be efficient even if the speed of computers increases regularly.

The manipulation of texts involves several problems among which are **pattern** matching, approximate pattern matching, comparing strings, and text compression. The first problem is partially treated in the present chapter, in that we consider only one-dimensional objects. Extensions of the methods to higher dimensional objects and solutions to the second problem appear in Chapter 13. The third problem includes the comparison of molecular sequences, and is developed in the corresponding chapter. Finally, Chapter 12 is devoted to text compression.

Pattern matching is the problem of locating a collection of objects (the pattern) inside raw text. This is the opposite of the data base approach in which texts are structured in fields which themselves are searched by keywords. In this chapter, texts and elements of patterns are strings, which are finite sequences

of symbols over a finite alphabet. Methods for searching patterns described by general regular expressions derive from standard parsing techniques (see the chapter on formal grammars and languages). We focus our attention to the case where the pattern represents a finite set of strings. Although the latter case is a specialization of the former case, it can be solved with more efficient algorithms.

Solutions to pattern matching in strings divide in two families. In the first one, the pattern is fixed. This situation occurs for example in text editors for the "search" and "substitute" commands, and in telecommunications for checking tokens. In the second family of solutions, the text is considered as fixed while the pattern is variable. This applies to dictionaries and to data bases of molecular sequences, for example, and to full-text data bases in general.

The efficiency of algorithms is evaluated by their worst-case running times and the amount of memory space they require. In almost all cases, these are the most objective and consistent criteria to appreciate the efficiency of algorithms. A more realistic measure is to consider the expected running time of programs. But such a computation is machine dependent and, moreover, it is based on an average analysis that is often unreachable. This is partly due to the fact that texts are hard to modelize in a probabilistic framework and that computations are impracticable in pertinent models. So, most average-case analyses are on random texts.

The alphabet, the finite set of symbols, is denoted by Σ, and the whole set of strings over Σ by Σ^*. The length of a string u is denoted by $|u|$; it is the length of the underlying finite sequence of symbols. The concatenation of two strings u and v is denoted by uv. A string v is said to be a **factor** (also called segment, substring, etc.) of a string u if u can be written in the form $u'vu''$ where $u', u'' \in \Sigma^*$; if $i = |u'|$ and $j = |u'v| - 1$, we say that the factor v starts at position i and ends at position j in u; the factor v is also denoted by $u[i\,..\,j]$. The symbol at position i in a string u, that is the $i+1$-th symbol of u, is denoted by $u[i]$; we consider implicitly that $u = u[0\,..\,|u| - 1]$.

11.2 Matching Fixed Patterns

We consider in this section the two cases where the pattern represents a fixed string or a fixed dictionary (a finite set of strings). Algorithms search for and locate all the **occurrences** of the pattern in any text.

In the string-matching problem, the first case, it is convenient to consider that the text is examined through a **window.** The window delimits a factor of the text and has usually the length of the pattern. It slides along the text from left to right. During the search, it is periodically shifted according to rules that are specific to each algorithm. When the window is at a certain position on the text, the algorithm checks whether the pattern occurs there or not by comparing some symbols in the window with the corresponding aligned symbols of the pattern; if there is a whole match, the position is reported. During this scan operation, the algorithm acquires from the text information that is often used to determine the length of the next shift of the window. Some part of the gathered information can also be memorized in order to save time during the next scan operation.

In the dictionary-matching problem, the second case, methods are based on the use of automata, or related data structures.

The Brute Force Algorithm

The simplest implementation of the sliding window mechanism is the brute force algorithm. The strategy consists here in uniformly sliding the window one position to the right after each scan operation. As far as scans are correctly implemented, this obviously leads to a correct algorithm.

We give below the pseudocode of the corresponding procedure. The inputs are a nonempty string x, its length m (thus $m \geq 1$), a string y, and its length n. The variable p in the procedure corresponds to the current left position of the window on the text. It is understood that the string-to-string comparison in line 2 has to be processed symbol per symbol according to a given order.

```
BRUTE-FORCE-MATCHER(x, m, y, n)
1  for p from 0 up to n − m
2      loop if y[p .. p + m − 1] = x
3                then report p
```

The time complexity of the brute force algorithm is $O(m \times n)$ in the worst case (for instance when $a^{m-1}b$ is searched in a^n for any two symbol $a, b \in \Sigma$ satisfying $a \neq b$ if we assume that the rightmost symbol in the window is compared last). But its behavior is linear in n when searching in random texts.

The Karp–Rabin Algorithm

Hashing provides a simple method for avoiding a quadratic number of symbol comparisons in most practical situations. Instead of checking at each position p of the window on the text whether the pattern occurs here or not, it seems to be more efficient to check only if the factor of the text delimited by the window, namely $y[p \,..\, p + m - 1]$, "looks like" x. In order to check the resemblance between the two strings, a hash function is used. But, to be helpful for the string-matching problem, the hash function should be highly discriminating for strings. According to the running times of the algorithms, the function should also have the following properties:

- To be efficiently computable;
- To provide an easy computation of the value associated with the next factor from the value associated with the current factor.

The last point is met when symbols of alphabet Σ are assimilated with integers and when the hash function, say h, is defined for each string $u \in \Sigma^*$ by

$$h(u) = \left(\sum_{i=0}^{|u|-1} u[i] \times d^{|u|-1-i} \right) \bmod q \ ,$$

where q and d are two constants. Then, for each string $v \in \Sigma^*$, for each symbols $a', a'' \in \Sigma$, $h(va'')$ is computed from $h(a'v)$ by the formula

$$h\left(va''\right) = \left(\left(h\left(a'v\right) - a' \times d^{|v|} \right) \times d + a'' \right) \bmod q \ .$$

During the search for pattern x, it is enough to compare the value $h(x)$ with the hash value associated with each factor of length m of text y. If the two values are equal, that is, in case of collision, it is still necessary to check whether the factor is equal to x or not by symbol comparisons.

The underlying string-matching algorithm, which is denoted as the Karp–Rabin algorithm, is implemented below as the procedure KARP-RABIN-MATCHER. In the procedure, the values $d^{m-1} \bmod q$, $h(x)$, and $h(y[0 \,..\, m-2])$ are first precomputed, and stored respectively in the variables r, s, and t (lines 1–7). The value of t is then recomputed at each step of the search phase (lines 8–12). It is assumed that the value of symbols ranges from 0 to $c - 1$; the quantity $(c - 1) \times q$ is added in line 8 to provide correct computations on positive integers.

KARP-RABIN-MATCHER(x, m, y, n)
1 $r \leftarrow 1$
2 $s \leftarrow x[0] \bmod q$
3 $t \leftarrow 0$
4 **for** i from 1 up to $m-1$
5 **loop** $r \leftarrow (r \times d) \bmod q$
6 $s \leftarrow (s \times d + x[i]) \bmod q$
7 $t \leftarrow (t \times d + y[i-1]) \bmod q$
8 **for** p from 0 up to $n-m$
9 **loop** $t \leftarrow (t \times d + y[p+m-1]) \bmod q$
10 **if** $t = s$ and $y[p\,..\,p+m-1] = x$
11 **then** report p
12 $t \leftarrow ((c-1) \times q + t - y[p] \times r) \bmod q$

Convenient values for d are powers of 2; in this case, all the products by d can be computed as shifts on integers. The value of q is generally a large prime (such that the quantities $(q-1) \times d + c - 1$ and $c \times q - 1$ do not cause overflows), but it can also be the value of the implicit modulus supported by integer operations. An illustration of the behavior of the algorithm is given in Fig. 11.1.

p	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
$y[p]$	n	o	␣	d	e	f	e	n	s	e	␣	f	o	r	␣	s	e	n	s	e
$h(y[p\,..\,p+4])$	8	8	6	28	9	18	28	26	22	12	17	24	16	0	1	9	—	—	—	—

FIGURE 11.1 An illustration of the behavior of the Karp–Rabin algorithm when searching for the pattern $x =$ `sense` in the text $y =$ `no␣defense␣for␣sense`. Here, symbols are assimilated with their ASCII codes (hence $c = 256$), and the values of q and d are set, respectively, to 31 and 2. This is valid for example when the maximal integer is $2^{16} - 1$. The value of $h(x)$ is $(115 \times 16 + 101 \times 8 + 110 \times 4 + 115 \times 2 + 101) \bmod 31 = 9$. Since only $h(y[4\,..\,8])$ and $h(y[15\,..\,19])$ among the defined values of $h(y[p\,..\,p+4])$ are equal to $h(x)$, two string-to-string comparisons against x are performed.

The worst case complexity of the above string-matching algorithm is quadratic, as it is for the brute force algorithm, but its expected running time is $O(m+n)$ if parameters q and d are adequate.

The Knuth–Morris–Pratt Algorithm

This section presents the first discovered linear-time string-matching algorithm. Its design follows a tight analysis of a version of the brute force algorithm in which the string-to-string comparison proceeds from left to right. The brute force algorithm wastes the information gathered during the scan of the text. On the contrary, the Knuth–Morris–Pratt algorithm stores the information with two purposes. First, it is used to improve the length of shifts. Second, there is no backward scan of the text.

Consider a given position p of the window on the text. Assume that a mismatch occurs between symbols $y[p+i]$ and $x[i]$ for some i, $0 \le i < m$ (an illustration is given in Fig. 11.2). Thus, we have $y[p\,..\,p+i-1] = x[0\,..\,i-1]$ and $y[p+i] \neq x[i]$. With regard to the information given by $x[0\,..\,i-1]$, interesting shifts are necessarily connected with the **borders** of $x[0\,..\,i-1]$. (A border of a string u is a factor of u that is both a **prefix** and a **suffix** of u). Among the borders of $x[0\,..\,i-1]$, the longest proper border followed by a symbol different from $x[i]$ is the best possible candidate, subject to the existence of such of a border. (A factor v of a string u is said to be a **proper** factor of u if u and v are not identical, that

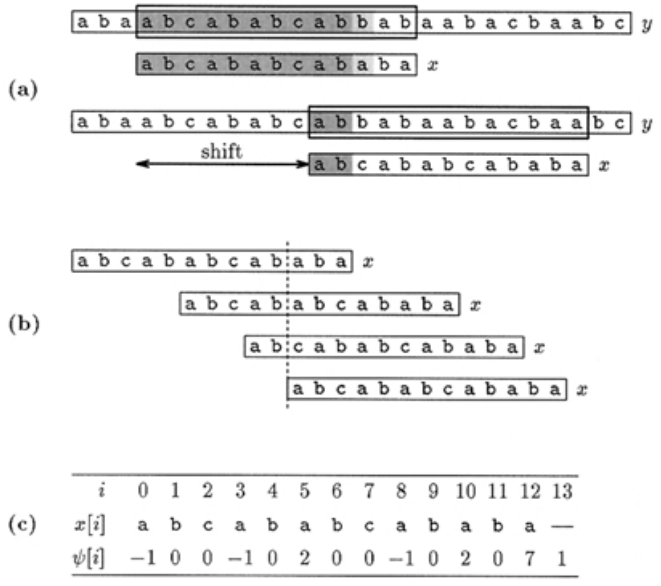

FIGURE 11.2 An illustration of the shift in the Knuth–Morris–Pratt algorithm when searching for the pattern $x = \texttt{abcababcababa}$. **(a)** The window on the text y is at position 3. A mismatch occurs at position 10 on x. The matching symbols are shown darkly shaded, and the current analyzed symbols lightly shaded. Avoiding both a backtrack on the text and an immediate mismatch leads to shift the window 8 positions to the right. The string-to-string comparison resumes at position 2 on the pattern. **(b)** The current shift is the consequence of an analysis of the list of the proper borders of $x[0\,..\,9]$ and of the symbol which follow them in x. The prefixes of x that are borders of $x[0\,..\,9] = \texttt{abcabacbab}$ are right-aligned along the discontinuous vertical line. String $x[0\,..\,4] = \texttt{abcab}$ is a border of $x[0\,..\,9]$, but is followed by symbol $\texttt{a}$ which is identical to $x[10]$. String $x[0\,..\,1]$ is the expected border, since it is followed by symbol $\texttt{c}$. **(c)** The values of the function ψ for pattern x.

is, if $|v| < |u|$.) This introduces the function ψ defined for each $i \in \{0, 1, \ldots, m-1\}$ by

$$\psi[i] = \max\{k \mid (0 \le k < i,\ x[i-k\,..\,i-1] = x[0\,..\,k-1],\ x[k] \ne x[i]) \text{ or } (k = -1)\}\ .$$

Then, after a shift of length $i - \psi[i]$, the symbol comparisons can resume with $y[p+i]$ against $x[\psi[i]]$ in the case where $\psi[i] \ge 0$, and $y[p+i+1]$ against $x[0]$ otherwise. Doing so, we miss no occurrence of x in y, and avoid a backtrack on the text. The previous statement is still valid when no mismatch occurs, that is when $i = m$, if we consider for a moment the string $x\$$ instead of x, where $\$$ is a symbol of alphabet Σ occurring nowhere in x. This amounts to completing the definition of function ψ by setting

$$\psi[m] = \max\{k \mid 0 \le k < m,\ x[m-k\,..\,m-1] = x[0\,..\,k-1]\}\ .$$

The Knuth–Morris–Pratt string-matching algorithm is given in pseudocode below as the procedure KNUTH-MORRIS-PRATT-MATCHER. The values of function ψ are first computed by the function BETTER-PREFIX-FUNCTION given after. The value of the variable j is equal to $p+i$ in the remainder of the code (the search phase of the algorithm strictly speaking); this simplifies the code, and points out the sequential processing of the text. Observe that the preprocessing phase applies a similar method to the pattern itself, as if $y = x[1\,..\,m-1]$.

```
KNUTH-MORRIS-PRATT-MATCHER(x, m, y, n)
1  ψ ← BETTER-PREFIX-FUNCTION (x, m)
2  i ← 0
3  for j from 0 up to n − 1
4     loop while i ≥ 0 and y[j] ≠ x[i]
5              loop i ← ψ[i]
6        i ← i + 1
7        i i = m
8              then report j + 1 − m
9                   i ← ψ[m]
```

```
BETTER-PREFIX-FUNCTION(x, m)
1  ψ[0] ← −1
2  i ← 0
3  for j from 1 up to m − 1
4     loop if x[j] = x[i]
5              then ψ[j] ← ψ[i]
6              else ψ[j] ← i
7                   loop i ← ψ[i]
8                      while i ≥ 0 and x[j] ≠ x[i]
9           i ← ψ + 1
10 ψ[m] ← i
11 return ψ
```

The algorithm has a worst-case running time in $O(m + n)$, and requires $O(m)$ extra-space to store function ψ. The linear running time results from the fact that the number of symbol comparisons performed during the preprocessing phase and the search phase is less than $2m$ and $2n$, respectively. All the previous bounds are independent of the size of the alphabet.

The Boyer–Moore Algorithm

The Boyer–Moore algorithm is considered as the most efficient string-matching algorithm in usual applications. A simplified version of it, or the entire algorithm, is often implemented in text editors for the "search" and "substitute" commands.

The scan operation proceeds from right to left in the window on the text, instead of left to right as in the Knuth–Morris–Pratt algorithm. In case of a mismatch, the algorithm uses two functions to shift the window. These two shift functions are called the better-factor shift function and the bad-symbol shift function. In the two next paragraphs, we explain the goal of the two functions and we give procedures to precompute their values.

We first explain the aim of the better-factor shift function. Let p be the current (left) position of the window on the text. Assume that a mismatch occurs between symbols $y[p + i]$ and $x[i]$ for some i, $0 \leq i < m$ (an illustration is given in Fig. 11.3). Then, we have $y[p + i] \neq x[i]$ and $y[p + i + 1 \,..\, p + m - 1] = x[i + 1 \,..\, m - 1]$. The better-factor shift consists in aligning the factor $y[p + i + 1 \,..\, p + m - 1]$ with its rightmost occurrence $x[k + 1 \,..\, m - 1 - i + k]$ in x preceded by a symbol $x[k]$ different from $x[i]$ to avoid an immediate mismatch. If no such factor exists, the shift consists in aligning the longest suffix of $y[p + i + 1 \,..\, p + m - 1]$ with a matching prefix of x. The better-factor shift function β is defined by

$$\begin{aligned} \beta[i] \quad = \quad & \min\{i - k \mid (0 \leq k < i,\ x[k + 1 \,..\, m - 1 - i + k] = x[i + 1 \cdot\cdot m - 1],\ x[k] \neq x[i]) \\ & \text{or } (i - m \leq k < 0,\ x = x[i - k \,..\, m - 1]x[m - i + k \,..\, m - 1])\} \end{aligned}$$

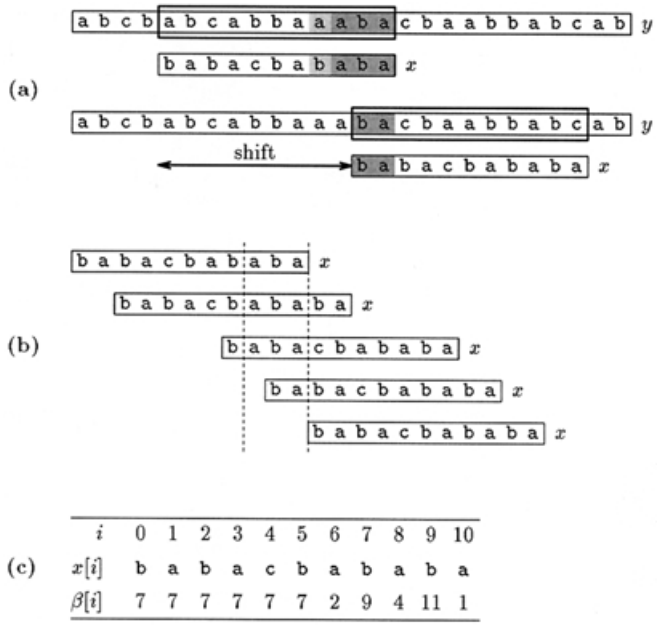

FIGURE 11.3 An illustration of the better-factor shift in the Boyer–Moore algorithm when searching for the pattern $x = \texttt{babacbababa}$. **(a)** The window on the text is at position 4. The string-to-string comparison, which proceeds from right to left, stops with a mismatch at position 7 on x. The window is shifted 9 positions to the right to avoid an immediate mismatch. **(b)** Indeed, the string $x[8\,..\,10] = \texttt{aba}$ is repeated three times in x, but is preceded each time by symbol $x[7] = \texttt{b}$. The expected matching factor in x is then the prefix $\texttt{ba}$ of x. The factors of x identical with $\texttt{aba}$ and the prefixes of x ending with a suffix of $\texttt{aba}$ are right-aligned along the rightmost discontinuous vertical line. **(c)** The values of the shift function β for pattern x.

for each $i \in \{0, 1, \ldots, m-1\}$. The value $\beta[i]$ is then exactly the length of the shift induced by the better-factor shift. The values of function β are computed by the function given below as the function BETTER-FACTOR-FUNCTION. An auxiliary table, namely f, is used; it is an analogue of the function ψ used in the Knuth–Morris–Pratt algorithm, but defined this time for the reverse pattern; it is indexed from 0 to $m-1$. The running time of the function BETTER-FACTOR-FUNCTION is $O(m)$.

```
BETTER-FACTOR-FUNCTION(x, m)
1   for j from 0 up to m − 1
2       loop β[j] ← 0
3   i ← m
4   for j from m − 1 down to 0
5       loop f[j] ← i + 1
6           while i < m and x[j] ≠ x[i]
7               loop if β[i] = 0
8                       then β[i] ← i − j
9                    i ← f[i] − 1
10          i ← i − 1
11  for j from 0 up to m − 1
12      loop if β[j] = 0
13              then β[j] ← i + 1
14          if j = i
15              then i ← f[i] − 1
16  return β
```

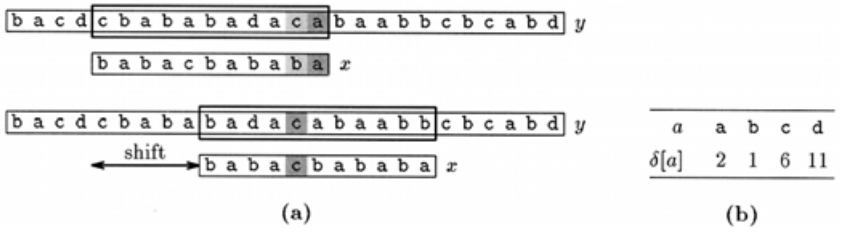

FIGURE 11.4 An illustration of the bad-symbol shift in the Boyer–Moore algorithm when searching for the pattern $x = \texttt{babacbababa}$. **(a)** The window on the text is at position 4. The string-to-string comparison stops with a mismatch at position 9 on x. Considering only this position and the unexpected symbol occurring at this position, namely symbol $y[13] = \texttt{c}$, leads to shift the window 5 positions to the right. Notice that if the unexpected symbol were `a` or `d`, the applied shift would have been 1 and 10, respectively. **(b)** The values of the table δ for pattern x when alphabet Σ is reduced to { `a`, `b`, `c`, `d` }.

We now come to the aim of the bad-symbol shift function (Fig. 11.4 shows an illustration). Consider again the text symbol $y[p+i]$ that causes a mismatch. Assume first that this symbol occurs in $x[0\,..\,m-2]$. Then, let k be the position of the rightmost occurrence of $y[p+i]$ in $x[0\,..\,m-2]$. The window can be shifted $i-k$ positions to the right if $k < i$, and only one position otherwise, without missing an occurrence of x in y. Assume now that symbol $y[p+i]$ does not occur in x. Then, no occurrence of x in y can overlap the position $p+i$ on the text, and thus, the window can be shifted $i+1$ positions to the right. Let δ be the table indexed on alphabet Σ, and defined for each symbol $a \in \Sigma$ by

$$\delta[a] = \min\{m\} \cup \{m-1-j \mid 0 \le j < m-1,\ x[j] = a\}\,.$$

According to the above discussion, the bad-symbol shift for the unexpected text symbol a aligned with the symbol at position i on the pattern is the value

$$\gamma[a, i] = \max\{\delta[a] + i - m + 1,\ 1\}\,,$$

which defines the bad-symbol shift function γ on $\Sigma \times \{0, 1, \ldots, m-1\}$. We give now the code of the function LAST-OCCURRENCE-FUNCTION that computes table δ. Its running time is $O(m + \text{card}\Sigma)$.

```
LAST-OCCURRENCE-FUNCTION(x, m)
1  for each a ∈ Σ
2     loop δ[a] ← m
3  for j from 0 up to m − 2
4     loop δ[x[j]] ← m − 1 − j
5  return δ
```

The shift applied in the Boyer–Moore algorithm in case of a mismatch is the maximum between the better-factor shift and the bad-symbol shift. In case of a whole match, the shift applied to the window is m minus the length of the longest proper border of x, that is also the value $\beta[0]$ (this value is indeed what is called "the period" of the pattern). The code of the entire algorithm is given below.

```
BOYER-MOORE-MATCHER(x, m, y, n)
1  β ← BETTER-FACTOR-FUNCTION(x, m)
2  δ ← LAST-OCCURRENCE-FUNCTION(x, m)
3  p ← 0
4  while p ≤ n − m
5     loop i ← m − 1
6          while i ≥ 0 and y[p + i] = x[i]
7             loop i ← i − 1
8          if i ≥ 0
9             then p ← p + max{β[i], δ[y[p + i]] + i − m + 1}
10            else report p
11                 p ← pβ[0]
```

The worst-case running time of the algorithm is quadratic. It is surprising however that, when used to search only for the first occurrence of the pattern, the algorithm runs in linear time. Slight modifications of the strategy yield linear-time algorithms. When searching for $a^{m-1}b$ in a^n with $a, b \in \Sigma$ and $a \neq b$, the algorithm considers only $\lfloor n/m \rfloor$ symbols of the text. This bound is the absolute minimum for any string-matching algorithm in the model where only the pattern is preprocessed. Indeed, the algorithm is expected to be extremely fast on large alphabets (relative to the length of the pattern).

Practical String-Matching Algorithms

The bad-symbol shift function introduced in the Boyer–Moore algorithm is not very efficient for small alphabets, but when the alphabet is large compared with the length of the pattern (as it is often the case with the ASCII table and ordinary searches made under a text editor), it becomes very useful. Using only the corresponding table produces some efficient algorithms for practical searches. We describe one of these algorithms below.

Consider a position p of the window on the text, and assume that the symbols $y[p+m-1]$ and $x[m-1]$ are identical. If $x[m-1]$ does not occur in the prefix $x[0\,..\,m-2]$ of x, the window can be shifted m positions to the right after the string-to-string comparison between $y[p\,..\,p+m-2]$ and $x[0\,..\,m-2]$ is performed. Otherwise, let k be the position of the rightmost occurrence of $x[m-1]$ in $x[0\,..\,m-2]$; the window can be shifted $m-1-k$ positions to the right. This shows that $\delta[y[p+m-1]]$ is also a valid shift in the case where $y[p+m-1] = x[m-1]$. The underlying algorithm is the Horspool algorithm.

The pseudocode of the Horspool algorithm is given below. To prevent two references to the rightmost symbol in the window at each scan and shift operation, table δ is slightly modified: $\delta[x[m-1]]$ contains the sentinel value 0, after its previous value is saved in variable t. The value of the variable j is the value of the expression $p+m-1$ in the discussion above.

```
HORSPOOL-MATCHER(x, m, y, n)
1  δ ← LAST-OCCURRENCE-FUNCTION(x, m)
2  t ← δ[x[m − 1]]
3  δ[x[m − 1]] ← 0
4  j ← m − 1
5  while j < n
6     loop s ← δ[y[j]]
7          if s ≠ 0
8             then j ← j + s
9             else if y[j − m + 1 .. j − 1] = x[0 .. m − 2]
10                    then report j − m + 1
11                 j ← j + t
```

Just like the brute force algorithm, the Horspool algorithm has a quadratic worst-case time complexity. But its behavior may be at least as good as the behavior of the Boyer–Moore algorithm in practice because the Horspool algorithm is simpler. An example showing the behavior of both algorithms is given in Fig. 11.5.

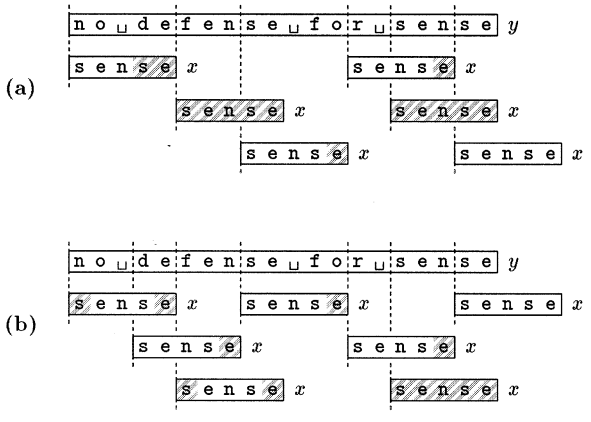

FIGURE 11.5 An illustration of the behavior of two fast string-matching algorithms when searching for the pattern $x = \texttt{sense}$ in the text $y = \texttt{no␣defense␣for␣sense}$. The successive positions of the window on the text are suggested by the alignments of x with the corresponding factors of y. The symbols of x considered during each scan operation are shown hachured. **(a)** Behavior of the Boyer–Moore algorithm. The first and second shifts result from the better-shift function, the third and fourth from the bad-symbol function, and the fifth from a shift of the length of x minus the length of its longest proper border (the period of x). **(b)** Behavior of the Horspool algorithm. We assume here that the four leftmost symbols in the window are compared with the symbols of $x[0\,..\,3]$ from left to right.

The Aho–Corasick Algorithm

The UNIX operating system provides standard text-file facilities. Among them is the series of `grep` commands that locate patterns in files. We describe in this section the Aho–Corasick algorithm underlying an implementation of the `fgrep` command of UNIX. It searches files for a finite and fixed set of strings (the dictionary), and can for instance output lines containing at least one of the strings.

If we are interested in searching for all occurrences of all strings of a dictionary, a first solution consists in repeating some string-matching algorithm for each string. Considering a dictionary X containing k strings and a text y, the search runs in that case in time $O(m + n \times k)$, where m is the sum of the length of the strings in X, and n the length of y. But this solution is not efficient, since text y has to be read k times. The solution described in this section provides both a sequential read of the text and a total running time which is $O(m + n)$ on a fixed alphabet. The algorithm can be viewed as a direct extension of a weaker version of the Knuth–Morris–Pratt algorithm.

The search is done with the help of an automaton that stores the situations encountered during the process. At a given position on the text, the current state is identified with the set of pattern prefixes ending here. The state represents all the factors of the pattern that can possibly lead to occurrences. Among the factors, the longest contains all the information necessary to continue the search. So, the search is realized with an automaton, denoted by $\mathcal{D}(X)$, of which states are in one-to-one correspondence with the prefixes of X. Implementing completely the transition function of $\mathcal{D}(X)$ would required a size $O(m \times \text{card}\Sigma)$. Instead of that, the Aho–Corasick algorithm requires only $O(m)$ space. To get this space complexity, a part of the transition function is made explicit in the data, and the other part is computed with the help of a

failure function. For the first part, we assume that for any input (p, a), the function denoted by TARGET returns some state q if the triple (p, a, q) is an edge in the data, and the value NIL otherwise. The second part uses the failure function *fail,* which is an analogue of the function ψ used in the Knuth–Morris–Pratt algorithm. But this time, the function is defined on the set of states, and for each state p different from the initial state,

$$fail[p] \quad = \quad \text{the state identified with the longest proper suffix of the prefix identified with } p \text{ that is also a prefix of a string of } X .$$

The aim the failure function is to defer the computation of a transition from the current state, say p, to the computation of the transition from the state $fail[p]$ with the same input symbol, say a, when no edge from p labeled by symbol a is in the data; the initial state, which is identified with the empty string, is the default state for the statement. We give below the pseudocode of the function NEXT-STATE that computes the transitions in the representation. The initial state is denoted by i.

```
NEXT-STATE(p, a, i)
1  while p ≠ NIL and TARGET(p, a)= NIL
2     loop p ← fail[p]
3  if p ≠ NIL
4     then q ← TARGET(p, a)
5     else  q ← i
6  return q
```

The preprocessing phase of the Aho–Corasick algorithm builds the explicit part of $\mathcal{D}(X)$ including function *fail.* It is divided itself into two phases.

The first phase of the preprocessing phase consists in building a sub-automaton of $\mathcal{D}(X)$. It is the **trie** of X (the digital tree in which branches spell the strings of X and edges are labeled by symbols) having as initial state the root of the trie and as terminal states the nodes corresponding to strings of X (an example is given in Fig. 11.6). It differs from $\mathcal{D}(X)$ in two points:

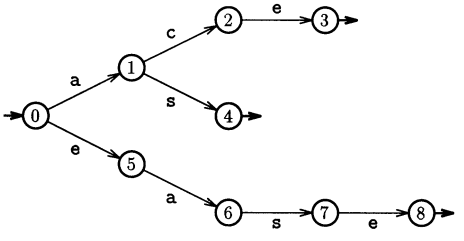

FIGURE 11.6 The trie-like automaton of the pattern $X = \{\texttt{ace}, \texttt{as}, \texttt{ease}\}$. The initial state is distinguished by a thick ingoing arrow, each terminal state by a thick outgoing arrow. The states are numbered from 0 to 8, according to the order in which they are created by the construction statement described in the present section. State 0 is identified with the empty string, state 1 with `a`, state 2 with `ac`, state 3 with `ace`, and so on. The automaton accepts the language X.

- It contains only the forward edges;
- It accepts only the set X.

(An edge (p, a, q) in the automaton is said to be forward if the prefix identified with q is in the form ua where u is the prefix corresponding to p.) The function given below as the function TRIE-LIKE-AUTOMATON computes the automaton corresponding to the trie of X by returning its initial state. The terminal mark of each state r is managed through the attribute $terminal[r]$; the mark is either TRUE or FALSE depending on whether state r is terminal or not. We assume that the function NEW-STATE creates and returns a new state, and that the procedure MAKE-EDGE adds a given new edge to the data.

```
TRIE-LIKE-AUTOMATON(X)
1  i ← NEW-STATE
2  terminal[i] ← FALSE
3  for string x from first to last string of X
4     loop p ← i
5          for symbol a from first to last symbol of x
6             loop q ← TARGET(p, a)
7                  if q = NIL
8                     then q ← NEW-STATE
9                          terminal[q] ← FALSE
10                         MAKE-EDGE(p, a, q)
11                 p ← q
12       terminal[p] ← TRUE
13 return i
```

The second step of the preprocessing phase consists mainly in precomputing the failure function. This is done by a breadth-first traversal of the trie-like automaton. The corresponding pseudocode is given below as the procedure MAKE-FAILURE-FUNCTION.

```
MAKE-FAILURE-FUNCTION(i)
1  fail[i] ← NIL
2  θ ← EMPTY-QUEUE
3  ENQUEUE(θ, i)
4  while not QUEUE-IS-EMPTY(θ)
5     loop p ← DEQUEUE(θ)
6          for each symbol a such that TARGET(p, a) ≠ NIL
7             loop q ← TARGET(p, a)
8                  fail[q] ← NEXT-STATE(fail[p], a, i)
9                  if terminal[fail[q]]
10                    then terminal[q] ← TRUE
11                 ENQUEUE (θ, q)
```

During the computation, some states can be made terminal. This occurs when the state is identified with a prefix that ends with a string of X (an illustration is given in Fig. 11.7).

The complete dictionary-matching algorithm, implemented in the pseudocode below as the procedure AHO-CORASICK-MATCHER, starts with the two steps of the preprocessing; the search follows, which simulates automaton $\mathcal{D}(X)$. It is understood that the empty string does not belong to X.

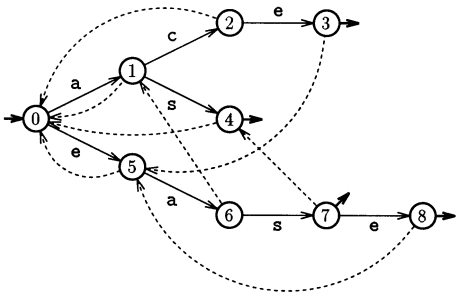

FIGURE 11.7 The explicit part of the automaton $\mathcal{D}(X)$ of the pattern $X = \{\texttt{ace}, \texttt{as}, \texttt{ease}\}$. Compared to the trie-like automaton of X displayed in Fig. 11.6, state 7 has been made terminal; this is because the corresponding prefix, namely `eas`, ends with the string `as` that is in X. The failure function *fail* is depicted with discontinuous non-labeled directed edges.

```
AHO-CORASICK-MATCHER(X, y)
1  i ← TRIE-LIKE-AUTOMATON(X)
2  MAKE-FAILURE-FUNCTION(i)
3  p ← i
4  for symbol a from first to last symbol of y
5     loop p ← NEXT-STATE(p, a, i)
6          if terminal[p]
7             then report an occurrence
```

The total number of tests "TARGET$(p, a) =$ NIL" performed by function NEXT-STATE during its calls by procedure MAKE-FAILURE-FUNCTION and during its calls by the search phase of the algorithm are bounded by $2m$ and $2n$, respectively, similarly as the bounds of comparisons in the Knuth–Morris–Pratt algorithm. Using a total order on the alphabet, the running time of function TARGET is both $O(\log k)$ and $O(\log \text{card}\Sigma)$, since the maximum number of edges outgoing a state in the data representing automaton $\mathcal{D}(X)$ is bounded both by k and by $\text{card}\Sigma$. Thus, the entire algorithm runs in time $O(m+n)$ on a fixed alphabet, and in time $O((m+n) \times \log \min\{k, \text{card}\Sigma\})$ in the general case. The algorithm requires $O(m)$ extra space to store the data and to implement the queue used during the breadth-first traversal executed in procedure MAKE-FAILURE-FUNCTION.

Let us discuss the question of reporting occurrences of pattern X (line 7 of procedure AHO-CORASICK-MATCHER). The simplest way of doing it is to report the ending positions of occurrences. This remains to output the value of the position of the current symbol in the text. A second possibility is to report the whole set of strings in X ending at the current position. To do so, the attribute *terminal* has to be transformed. First, for a state r, *terminal*$[r]$ is the set of the string of X that are suffixes of the string corresponding to r. Second, to avoid a quadratic behavior, sets are manipulated by their identifiers only.

Small Patterns

For most text-searching problems, the length of the pattern is small, and is no more than the word size. Representing the state of the search as an integer, and using binary operations to compute the transitions from state to state give some efficient algorithms easy to implement. We present below one algorithm of this class.

Let X be a dictionary of k strings, and m be the sum of the length of the strings in X. Now, consider the automaton $\mathcal{N}(X)$ obtained from the k straightforward deterministic automata accepting the k strings by

- Merging the k initial states into one initial state, say i,

- Adding the edges in the form (i, a, i), for each symbol $a \in \Sigma$.

The automaton $\mathcal{N}(X)$ is nondeterministic, and it accepts the language $\Sigma^* X$ (an example is given in Fig. 11.8).

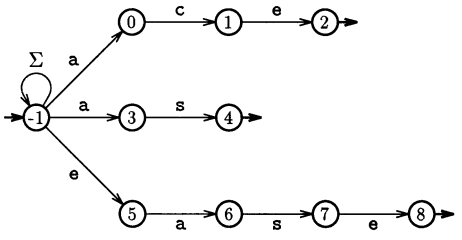

FIGURE 11.8 A straightforward nondeterministic automaton with only one initial state that accepts the language $\Sigma^* X$ for pattern $X = \{\texttt{ace}, \texttt{as}, \texttt{ease}\}$. The edge labeled by Σ denotes the cardΣ edges labeled by the cardΣ distinct symbols in Σ.

The search for occurrences of strings in X is performed with a simulation of the deterministic automaton recognizing $\Sigma^* X$. Indeed, the determinization of $\mathcal{N}(X)$ is not performed, but is just simulated via the subset construction: at a given time, the automaton is not in a given state, but in a set of states. This subset is recomputed whenever necessary in the execution of the search.

Let us number the states of $\mathcal{N}(X)$ from -1 to $m-1$ using a preorder tree walk (this is the case for the example given in Fig. 11.8). Let us code the subsets of the set of states of $\mathcal{N}(X)$ minus the initial state by an integer using the following convention: state number j is in the subset if and only if the bit at position j of the binary code (starting at position 0) of the integer is 1. Now, let v be the binary value corresponding to the current subset, let a be the current input symbol, and let v' be the binary value corresponding to the next subset. It is then easy to verify that v' is computed from v from following rule: the jth bit in v' is 1 if and only if

- Either there is an edge labeled by a from the initial state to state number j,
- Either there is an edge from state number $j-1$ to state number j and the bit at position $j-1$ in v is 1.

Consider now a binary value f defined for each $j, 0 \leq j \leq m-1$, by:

$$\text{the } j\text{th bit of } f \text{ is 1 if and only if}$$
$$\text{there exists an edge labeled by } a \text{ from initial state to state number } j \ ,$$

and the binary value table σ indexed on alphabet Σ, and defined for each symbol $a \in \Sigma$ and each bit-position $j, 0 \leq j \leq m-1$, by:

$$\text{the } j\text{th bit of } \sigma[a] \text{ is 1 if and only if}$$
$$\text{number } j \text{ corresponds to a target state of some edge labeled by } a \ .$$

Then, v, v' and a satisfy the relation

$$v' = (2v \vee f) \wedge \sigma[a] \ ,$$

denoting respectively by $\vee$ and $\wedge$ the binary operations "or" and "and." It only remains to be able to test whether one of the states represented by v' is a terminal state or not. Let t be a binary value such that, for each $j, 0 \leq j \leq m-1$,

$$\text{the } j\text{th bit of } t \text{ is 1 if and only if state number } j \text{ is a terminal state.}$$

The corresponding test is then

$$v' \wedge t \neq 0 \,.$$

An example is given in Fig. 11.9.

		a	a	c	e	s	x
1	0		1	0	0	0	0
0	0		0	1	0	0	0

(a) **(b)** **(c)** **(d)**

FIGURE 11.9 An illustration of the behavior of the TINY-MATCHER algorithm when searching for the pattern $X = \{\texttt{ace}, \texttt{as}, \texttt{ease}\}$ in the text $y = \texttt{teases}$. **(a)** The binary value f, which codes potential transitions from the initial state. Bits of a given binary value are written downward, bit at position 0 right at the top. **(b)** The binary value t, which codes terminal states. **(c)** The values of the table σ for pattern X. Symbol x means a symbol that does not appear in the strings in X. **(d)** The successive binary values of the integer r corresponding to the subset of states reached during the search. Asterisked bits indicate that a terminal state is reached, which means that a string in X ends at the current position on the text.

We give now the code of the function TINY-AUTOMATON that computes binary values f and t, and table σ. Its running time is $O(m + \text{card}\Sigma)$.

```
TINY-AUTOMATON(X)
1   f ← 0
2   t ← 0
3   for each a ∈ Σ
4       loop σ[a]0
5   r ← 1
6   for string x from first to last string of X
7       loop f ← f ∨ r
8           for symbol a from first to last symbol of x
9               loop σ[a] ← σ[a] ∨ r
10                  r′ ← r
11                  r ← 2r
12          t ← t ∨ r′
13  return (f, t, σ)
```

The code of the entire algorithm is given below.

```
TINY-MATCHER(X, y)
1  (f, t, σ) ← TINY-AUTOMATON(X)
2  r ← f
3  for symbol a from first to last symbol of y
4     loop r ← (2r ∨ f) ∧ σ[a]
5          if r ∧ t ≠ 0
6             then report an occurrence
```

The total-running time of the algorithm is $O(m + n + \mathrm{card}\Sigma)$, where n is the length of y. It requires $O(\mathrm{card}\Sigma)$ extra space to store table σ.

The technique developed in the current section can easily be generalized, for example in allowing do not care symbols.

11.3 Indexing Texts

This section deals with the pattern-matching problem applied to fixed texts. Solutions consist in building an index on the text that speeds up further searches. The indexes that we consider here are data structures that contain all the suffixes and therefore all the factors of the text. Two types of structures are presented: **suffix trees** and suffix automata. They are both compact representations of suffixes in the sense that their sizes are linear in the length of the text, although the sum of lengths of suffixes of a string is quadratic. Moreover, their constructions take linear time on fixed alphabets. On an arbitrary finite alphabet Σ, assumed to be ordered, a $\log \mathrm{card}\Sigma$ factor has to be added to almost all running times given in the following. This corresponds to the branching operation involved in the respective data structures.

Indexes are powerful tools that have many applications. Here is a nonexhaustive list of them, assuming an index on the text y.

- Membership: testing if a string x occurs in y.
- Occurrence number: producing the number of occurrences of a string x in y.
- List of positions: analogue of the string-matching problem of Section 11.2.
- Longest repeated factor: locating the longest factor of y occurring at least twice in y.
- Longest common factor: finding a longest string that occurs both in a string x and in y.

Solutions to some of these problems are first considered with suffix trees, then with suffix automata. Suffix arrays is another data structure that provides solution running slightly slower. They are shortly described at the end of the section.

Suffix Trees

The suffix tree $\mathcal{T}(y)$ of a nonempty string y of length n is a data structure containing all the suffixes of y. In order to simplify the statement, it is assumed that y ends with a special symbol of the alphabet occurring nowhere else in y (this special symbol is denoted by \$ in the examples). The suffix tree of y is a trie which satisfies the following properties:

- The branches from the root to the external nodes spell the nonempty suffixes of y, and each external node is marked by the position of the occurrence of the corresponding suffix in y;
- The internal nodes have at least two successors, except if y is a one-length string;
- The edges outgoing an internal node are labeled by factors starting with different symbols;
- Any string that labels an edge is represented by the couple of integers corresponding to its position in y and its length.

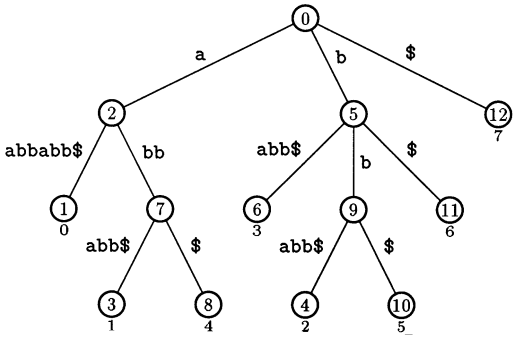

FIGURE 11.10 The suffix tree $\mathcal{T}(y)$ of the string $y = \texttt{aabbabb\$}$. The nodes are numbered from 0 to 12, according to the order in which they are created by the construction algorithm described in the present section. Each of the eight external nodes of the trie is marked by the position of the occurrence of the corresponding suffix in y. Hence, the branch (0, 5, 9, 4), running from the root to an external node, spells the string `bbabb$`, which is the suffix of y starting at position 2.

(An example of suffix tree is displayed in Fig. 11.10.) The special symbol at the end of y avoids marking nodes, and implies that $\mathcal{T}(y)$ has exactly n external nodes. The other properties then imply that the total size of $\mathcal{T}(y)$ is $O(n)$, which makes it possible to design a linear-time construction of the data structure. The algorithm described in the following and implemented by the procedure SUFFIX-TREE given further has this time complexity.

The construction algorithm works as follows. It inserts the nonempty suffixes $y[i\,..\,n-1]$, $0 \leq i < n$, of y in the data structure from the longest to the shortest suffix. In order to explain how this is performed, we introduce the two notations

$$h_i = \text{the longest prefix of } y[i\,..\,n-1] \text{ that is a prefix of some stricly longest suffix of } y\ ,$$

and

$$t_i = \text{the string } w \text{ such that } y[i\,..\,n-1] \text{ is identical with } h_i w\ ,$$

defined for each $i \in \{1, \ldots, n-1\}$. The strategy to insert the suffixes is precisely based on these definitions. Initially, the data structure contains only the string y. Then, the insertion of the string $y[i\,..\,n-1]$, $1 \leq i < n$, proceeds in two steps:

- first, the "head" in the data structure, that is, the node h corresponding to string h_i, is located, possibly breaking an edge;
- second, a node called the "tail," say t, is created, added as successor of node h, and the edge from h to t is labeled with string t_i.

The second step of the insertion is clearly performed in constant time. Thus, finding the head is critical for the overall performance of the construction algorithm. A brute-force method to find the head consists in spelling the current suffix $y[i\,..\,n-1]$ from the root of the trie, giving an $O(|h_i|)$ time complexity for the insertion at step i, and an $O(n^2)$ running time to build the suffix tree $\mathcal{T}(y)$. Adding "short-circuit" links leads to an overall $O(n)$ time complexity, although there is no guarantee that the insertion at any step i is realized in constant time.

Observe that in any suffix tree, if the string corresponding to a given internal node p in the data structure is in the form au with $a \in \Sigma$ and $u \in \Sigma^*$, then there exists an unique internal node corresponding to the

string u. From this remark are defined the suffix links by

$$\begin{aligned} link[p] \quad = \quad & \text{the node } q \text{ corresponding to the string } u \\ & \text{when } p \text{ corresponds to the string } au \text{ for some symbol } a \in \Sigma \end{aligned}$$

for each internal node p that is different from the root. The links are useful when computing h_i from h_{i-1} because of the property: if h_{i-1} is in the form aw for some symbol $a \in \Sigma$ and some string $w \in \Sigma^*$, then w is a prefix of h_i.

We explain in three following paragraphs how the suffix links help to find the successive heads efficiently. We consider a step i in the algorithm assuming that $i \geq 1$. We denote by g the node that corresponds to the string h_{i-1}. The aim is both to insert $y[i\,..\,n-1]$ and to find the node h corresponding to the string h_i. We first study the most general case of the insertion of the suffix $y[i\,..\,n-1]$. Particular cases are studied after.

We assume in the present case that the predecessor of g in the data structure, say g', is both defined and different from the root. Then h_{i-1} is in the form auv where $a \in \Sigma$, $u, v \in \Sigma^*$, au corresponds to the node g', and v labels the edge from g' to g. Since the string uv is a prefix of h_i, it can be fully spelled from the root. Moreover, the spelling operation of uv from the root can be short-circuited by spelling only the string v from the node $link[g']$. The node q reached at the end of the spelling operation (possibly breaking the last partially taken down edge) is then exactly the node $link[g]$. It remains to spell the string t_{i-1} from q for completely inserting the string $y[i\,..\,n-1]$. The spelling stops on the expected node h (possibly breaking again an edge) which becomes the new head in the data structure. The suffix of t_{i-1} that has not been spelled so far, is exactly the string t_i. (An example for the whole previous statement is given in Fig. 11.11.)

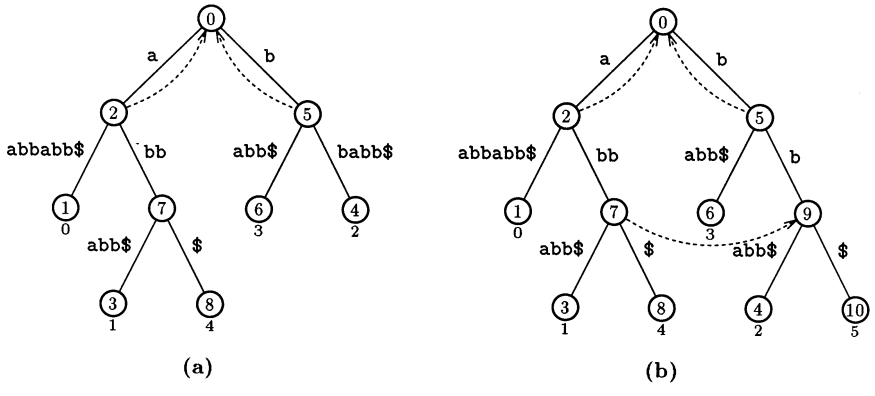

FIGURE 11.11 During the construction of the suffix tree $\mathcal{T}(y)$ of the string $y = \texttt{aabbabb\$}$, the step 5, that is, the insertion of the suffix $\texttt{bb\$}$. The defined suffix link are depicted with discontinuous nonlabeled directed edges. **(a)** Initially, the head in the data structure is node 7, and its suffix link is not yet defined. The predecessor of node 7, node 2, is different from the root, and the factor of y that is spelled from the root to node 7, namely $h_4 = \texttt{abb}$, is in the form auv, where $a \in \Sigma$, $u \in \Sigma^*$, and v is the string of Σ^* labeling the edge from node 2 to node 7. Here, $a = \texttt{a}$, u is the empty string, and $v = \texttt{bb}$. Then, the string $uv = \texttt{bb}$ is spelled from the node linked with node 2, that is, from node 0; the spelling operation stops on the edge from node 5 to node 4; this edge is broken, which creates node 9. Node 9 is linked to node 7. The string $t_4 = \$$ is spelled from node 9; the spelling operation stops on node 9, which becomes the new head in the data structure. **(b)** Node 10 is created, added as successor of node 9, and the edge from node 9 to node 10 is labeled by the string \$, remainder of the last spelling operation.

The second case is when g is a (direct) successor of the root. The string h_{i-1} is then in the form au where $a \in \Sigma$ and $u \in \Sigma^*$. Similarly to the above case, the string u can be fully spelled from the root. The spelling of u gives a node q, which is then linked with g. Afterwards, the string t_{i-1} is spelled from q.

The last case is when g is the root itself. The string t_{i-1} minus its first symbol has to be spelled from the root. Which ends the study of all the possible cases that can arise.

The important aspect of the algorithm is the use of two different implementations for the two spelling operations pointed out above. The first one, given in the pseudocode below as the function FAST-FIND, deals with the situation where we know in advance that a given factor $y[j\,..\,j+k-1]$ of y can be fully spelled from a given node p of the trie. It is then sufficient to scan only the first symbols of the labels of the encountered nodes, which justifies the name of the function. The second implementation of the spelling operation spells a factor $y[j\,..\,j+k-1]$ of y from a given node p too, but, this time, the spelling is performed symbol by symbol. The corresponding function is implemented after as the function SLOW-FIND. Before giving the pseudocode of the functions, we precise the notations used in the following.

- For any input (y, p, j), the function SUCCESSOR-BY-ONE-SYMBOL returns the node q such that q is a successor of the node p and the first symbol of the label of the edge from p to q is $y[j]$; if such a node q does not exist, it returns NIL.
- For any input (p, q), the function LABEL returns the two integers that represents the label of the edge from the node p to the node q.
- The function NEW-NODE creates and returns a new node.
- For any input (p, j, k, q, ℓ), the function NEW-BREAKING-NODE creates and returns the node r breaking the edge $(p, y[j\,..\,j+k-1], q)$ at the position ℓ in the label $y[j\,..\,j+k-1]$. (Which gives the two edges $(p, y[j\,..\,j+\ell-1], r)$ and $(r, y[j+\ell\,..\,j+k-1], q)$.)

Function FAST-FIND returns a couple of nodes such that the second one is the node reached by the spelling, and the first one is its predecessor.

```
FAST-FIND(y, p, j, k)
1   p' ←NIL
2   while k > 0
3      loop p' ← p
4           q ← SUCCESSOR-BY-ONE-SYMBOL (y, p, j)
5           (r, s) ← LABEL(p, q)
6           if s ≤ k
7              then p ← q
8                   j ← j + s
9                   k ← k − s
10             else p ← NEW-BREAKING-NODE (p, r, s, q, k)
11                  k ← 0
12  return (p', p)
```

Compared to function FAST-FIND, function SLOW-FIND considers an extra-input that is the predecessor of node p (denoted by p'). It considers in addition two extra-outputs that are the position and the length of the factor that remains to be spelled.

```
SLOW-FIND(y, p', p, j, k)
1  b ← FALSE
2  loop   q ← SUCCESSOR-BY-ONE-SYMBOL(y, p, j)
3         if q = NIL
4            then b ← TRUE
5            else (r, s) ← LABEL (p, q)
6                 ℓ ← 1
7                 while ℓ < s and y[j + ℓ] = y[r + ℓ]
8                       loop ℓ ← ℓ + 1
9                 j ← j + ℓ
10                k ← k + ℓ
11                p' ← p
12                if ℓ = s
13                   then p ← q
14                   else p ← NEW-BREAKING-NODE(p, r, s, q, ℓ)
15                        b ← TRUE
16   while b = FALSE
17 return (p', p, j, k)
```

The complete construction algorithm is implemented as the function SUFFIX-TREE given below. The function returns the root of the constructed suffix-tree. Memorizing systematically the predecessors h' and q' of the nodes h and q avoids considering doubly linked tries. The name of the attribute which marks the positions of the external nodes is made explicit.

```
SUFFIX-TREE(y, n)
1  p ← NEW-NODE
2  h' ←NIL
3  h ← p
4  r ← −1
5  s ← n + 1
6  for i from 0 up to n − 1
7    loop if h' = NIL
8            then (h', h, r, s) ← SLOW-FIND(y, NIL,p, r + 1, s − 1)
9            else  (j, k) ← LABEL (h', h)
10                 if h' = p
11                      then(q', q) ← FAST-FIND (y, p, j + 1, k − 1)
12                      else (q', q) ← FAST-FIND (y, link[h'], j, k)
13                 link[h] ← q
14                 (h', h, r, s) ← SLOW-FIND (y, q', q, r, s)
15         t ← NEW-NODE
16         MAKE-EDGE (h, (r, s), t)
17         position[t] ← i
18 return p
```

The algorithm runs in time $O(n)$ (more precisely $O(n \times \log \operatorname{card}\Sigma)$ if we take into account the branching in the data structure). Indeed, the instruction at line 4 in function FAST-FIND is performed less than $2n$ times, and the number of symbol comparisons done at line 7 in function SLOW-FIND is less than n.

Once the suffix tree of y is build, some operations can be performed rapidly. We describe four applications in the following. Let x be a string of length m.

Testing whether x occurs in y or not can be solved in time $O(m)$ by spelling x from the root of the trie symbol by symbol. If the operation succeeds, x occurs in y. Otherwise, we get the longest prefix of x occurring in y.

Producing the number of occurrences of x in y starts identically by spelling x. Assume that x occurs actually in y. Let p be the node at the extremity of the last taken down edge, or be the root itself if x is empty. The expected number, say k, is then exactly the number of external nodes of the sub-trie of root p. This number can be computed by traversing the sub-trie. Since each internal node of the sub-trie has at least two successors, the total size of the sub-trie is $O(k)$, and the traversal of the sub-trie is performed in time $O(k)$ (independently of Σ). The method can be improved by precomputing in time $O(n)$ (independently of Σ) all the values associated with each internal node; the whole operation is then performed in time $O(m)$, whatever is the number of occurrences of x.

The method for reporting the list of positions of x in y proceeds in the same way. The running time needed by the operation is $O(m)$ to locate x in the trie, plus $O(k)$ to report each of the positions associated with the k external nodes.

Finding the longest repeated factor of y remains to compute the "deepest" internal node of the trie, that is, the internal node corresponding to a longest possible factor in y. This is performed in time $O(n)$.

Suffix Automata

The **suffix automaton** $\mathcal{S}(y)$ of a string y is the minimal deterministic automaton recognizing Suff(y), that is, the set of suffixes of y. This automaton is minimal among all the deterministic automata recognizing the same language, which implies that it is not necessarily complete. An example is given in Fig. 11.12.

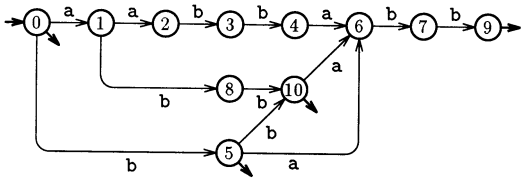

FIGURE 11.12 The suffix automaton $\mathcal{S}(y)$ of the string $y =$ `aabbabb`. The states are numbered from 0 to 10, according to the order in which they are created by the construction algorithm described in the present section. The initial state is state 0, terminal states are states 0, 5, 9, and 10. This automaton is the minimal deterministic automaton accepting the language of the suffixes of y.

The main point about suffix automata is that their size is asymptotically linear in the length of the string. More precisely, given a string y of length n, the number of states of $\mathcal{S}(y)$ is equal to $n+1$ when $n \leq 2$, and is bounded by $n+1$ and $2n-1$ otherwise; as to the number of edges, it is equal to $n+1$ when $n \leq 1$, it is 2 or 3 when $n = 2$, and it bounded by n and $3n-4$ otherwise.

The construction of the suffix automaton of a string y of length n can be performed in time $O(n)$, or, more precisely, in time $O(n \times \log \mathrm{card}\Sigma)$ on an arbitrary alphabet Σ. It makes use of a failure function *fail* defines on the states of $\mathcal{S}(y)$. The set of states of $\mathcal{S}(y)$ identifies with the quotient sets

$$u^{-1}\mathrm{Suff}(y) = \left\{v \in \Sigma^* \mid uv \in \mathrm{Suff}(y)\right\}$$

for the strings u in the whole set of factors of y. One may observe that two sets in the form $u^{-1}\mathrm{Suff}(y)$ are either disjoint or comparable. This allows to set

$$\mathit{fail}[p] = \text{ the smallest quotient set stricly containing the quotient set identified with } p\ ,$$

for each state p of the automaton different from the initial state of the automaton. The function given below as the function SUFFIX-AUTOMATON builds the suffix automaton of y, and returns the initial state, say i, of the automaton. The construction is on-line, which means that at each step of the construction, just after processing a prefix y' of y, the suffix automaton $\mathcal{S}(y')$ is build. Denoting by t the state without outgoing edge in the automaton $\mathcal{S}(y')$, terminal states of $\mathcal{S}(y')$ are implicitly known by the "suffix path" of t, that is, the list of the states

$$t, \mathit{fail}[t], \mathit{fail}[\mathit{fail}[t]], \ldots, i \ .$$

The algorithm uses the function *length* defined for each state p of $\mathcal{S}(y)$ by

$$\mathit{length}[p] = \text{ the length of the longest string spelled from } i \text{ to } p \ .$$

```
SUFFIX-AUTOMATON(y)
1  i ←NEW-STATE
2  terminal[i] ←FALSE
3  length[i] ← 0
4  fail[i] ← NIL
5  t ← i
6  for symbol a from first to last symbol of y
7     loop t ← SUFFIX-AUTOMATON-EXTENSION(i, t, a)
8  p ← t
9  loop terminal[p] ← TRUE
10       p ← fail[p]
11    while p ≠ NIL
12 return i
```

The on-line construction is based on the function SUFFIX-AUTOMATON-EXTENSION that is implemented below. The latter function processes the next symbol, say a, of the string y. If y' is the prefix of y preceding a, it transforms the suffix automaton $\mathcal{S}(y')$ already build into the suffix automaton $\mathcal{S}(y'a)$.

```
SUFFIX-AUTOMATON-EXTENSION(i, t, a)
1  t' ← t
2  t ← NEW-STATE
3  terminal[t] ← FALSE
4  length[t] ← length[t'] + 1
5  p ← t'
6  loop MAKE-EDGE(p, a, t)
7       p ← fail[p]
8    while p ≠ NIL and TARGET(p, a) = NIL
9  if p = NIL
10   then fail[t] ← i
11   else q ← TARGET(p, a)
12        if length[q] = length[p] + 1
13             then fail[t] ← q
14             else r ← NEW-STATE
15                  terminal[r] ← FALSE
16                  for each letter b such that TARGET(q, b) ≠ NIL
17                       loop MAKE-EDGE(r, b, TARGET(q, b))
18                  length[r] ← length[p] + 1
```

```
19                          fail[r] ← fail[q]
20                          fail[q] ← r
21                          fail[t] ← r
22                          loop CANCEL-EDGE(p, a TARGET(p, a))
23                              MAKE-EDGE (p, a, r)
24                              p ← fail[p]
25                            while p ≠ NIL and TARGET(p, a) = q
26  return t
```

We illustrate the behavior of function SUFFIX-AUTOMATON-EXTENSION in Fig. 11.13.

With the suffix automaton $\mathcal{S}(y)$ of y, several operations can be solved efficiently. We describe three of them. Let x be a string of length m.

Membership test solves in time $O(m)$ by spelling x from the initial state of the automaton. If the entire string is spelled, x occurs in y. Otherwise we get the longest prefix of x occurring in y.

Computing the number k of occurrences of x in y (assuming that x is a factor of y) starts similarly. Let p be the state reached after the spelling of x from the initial state. Then k is exactly the number of terminal states accessible from p. The number k associated with each state p can be precomputing in time $O(n)$ (independently of the alphabet) by a depth-first traversal of the graph underlying the automaton. The query for x is then performed in time $O(m)$, whatever is k.

The base of an algorithm for computing a longest factor common to x and y is implemented in the procedure ENDING-FACTORS-MATCHER given below. This procedure reports at each position in y the length of the longest factor of x ending here. It can obviously be used for string matching. It works as the procedure AHO-CORASICK-MATCHER in the use of the failure function. The running time of the search phase of the procedure is $O(m)$.

```
ENDING-FACTORS-MATCHER(y, x)
1   i ← SUFFIX-AUTOMATON(y)
2   ℓ ← 0
3   p ← i
4   for symbol a from first to last symbol of x
5     loop if TARGET(p, a) ≠ NIL
6           then ℓ ← ℓ + 1
7                p ← TARGET(p, a)
8           else loop  p ← fail[p]
9             while p ≠ NIL and TARGET(p, a) ≠ NIL
10            if p = NIL
11                    then ℓ ← 0
12                         p ← i
13                    else ℓ ← length[p] + 1
14                         p ← TARGET (p, a)
15          report ℓ
```

Retaining a largest value of the variable ℓ in the procedure (instead of reporting all values) solves the longest common factor problem.

Suffix Arrays

There is a clever an rather simple way to deal with all suffixes of a text of length n: to arrange their list in increasing lexicographic order to be able to perform binary searches on them. The implementation of this idea leads to a data structure called suffix array. It is an efficient representation in the sense that

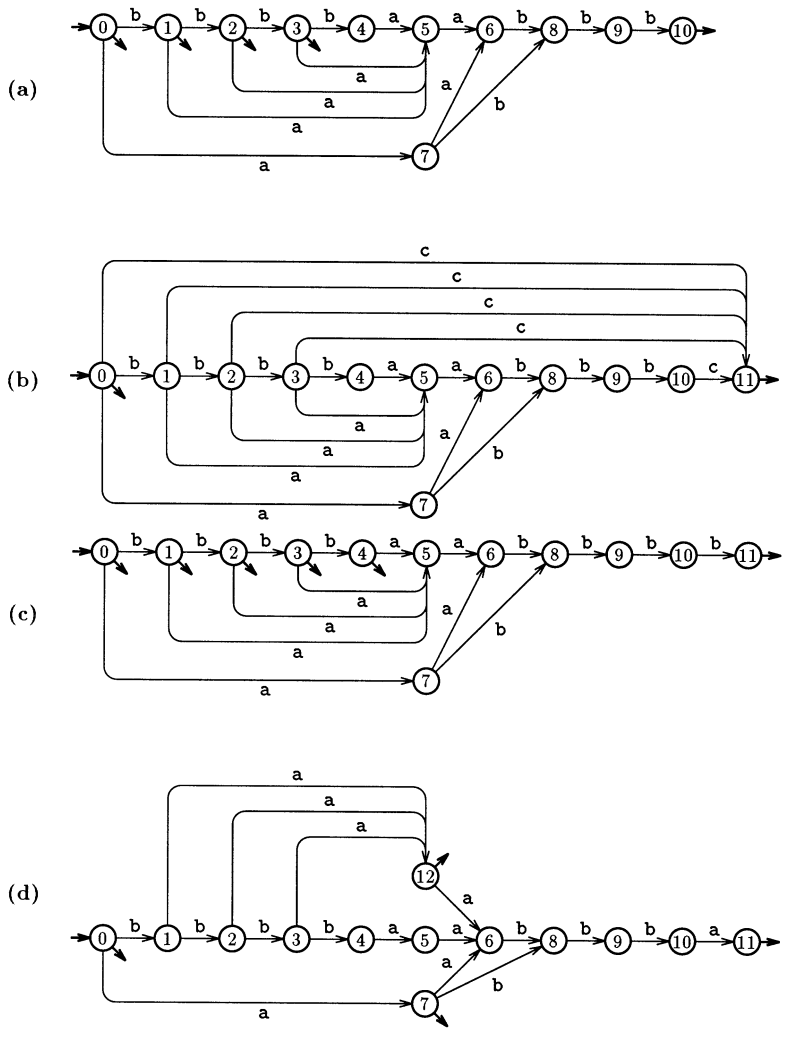

FIGURE 11.13 An illustration of the behavior of function SUFFIX-AUTOMATON-EXTENSION. The function transforms the suffix automaton $\mathcal{S}(y')$ of a string y' in the suffix automaton $\mathcal{S}(y'a)$ for any given symbol a (the terminal states being implicitly known). Let us consider that $y' =$ `bbbbaabbb`, and let us examine three possible cases according to a, namely $a =$ `c`, $a =$ `b`, and $a =$ `a`. **(a)** The automaton $\mathcal{S}$(`bbbbaabbb`). The state denoted by t' is state 10, and the suffix path of t' is the list of the states 10, 3, 2, 1, and 0. During the execution of the first loop of the function, state p runs through a part of the suffix path of t'. At the same time, edges labeled by a are created from p the newly created state $t = 11$, unless such an edge already exists in which case the loop stops. **(b)** If $a =$ `c`, the execution stops with an undefined value for p. The edges labeled by `c` start at terminal states, and the failure of t is the initial state. **(c)** If $a =$ `b`, the loop stops on state $p = 3$, because an edge labeled by `b` is defined on it. The condition at line 12 of function SUFFIX-AUTOMATON-EXTENSION is satisfied, which means that the edge labeled by a from p is not a short-circuit. In this case, the state ending the previous edge is the failure of t. **(d)** Finally, when $a =$ `a`, the loop stops on state $p = 3$ for the same reason, but the edge labeled by a from p is a short-circuit. The string `bbba` is a suffix of the (newly considered) string `bbbbaabbba`, but `bbbba` is not. Since these two strings reach state 5, this state is duplicated into a new state $r = 12$ that becomes terminal. Suffixes `bba` and `ba` are redirected to this new state. The failure of t is r.

- It has $O(n)$ size,
- It can be constructed in $O(n \log n)$ time,
- It allows the computation of the membership test of a string of length m in the text in time $O(m + \log n)$.

So, the time required to construct and use the structure is slightly greater than that needed to compute the suffix tree. But suffix arrays have two advantages:

- Their constructions is rather simple. It is even commonly admitted that, in practice, it behaves better than the construction of suffix trees.
- It consists of two linear size arrays which, in practice again, take little memory space.

11.4 Research Issues and Summary

String searching by hashing was introduced by Harrison [23], and later fully analyzed in [26]

The first linear-time string-matching algorithm is due to Knuth et al. [27]. It can be proved that, during the search, the delay, that is, the number of times a symbol of the text is compared to symbols of the pattern, is less than $\lfloor \log_\Phi(m+1) \rfloor$, where Φ is the golden ratio $(1+\sqrt{5})/2$. Simon [32] gives a similar algorithm but with a delay bounded by the size of the alphabet (of the pattern). Hancart [22] proves that the delay of Simon's algorithm is less than $1 + \lfloor \log_2 m \rfloor$. This paper also proves that this is optimal among algorithms processing the text with a one-symbol buffer. The bound becomes $O(\log \min\{1 + \lfloor \log_2 m \rfloor, \text{card}\Sigma\})$ using an ordering on the alphabet Σ, which is not a restriction in practice.

Galil [19] gives a general criterion to transform string-matching algorithms that work sequentially on the text into real-time algorithms.

The Boyer–Moore algorithm was designed in [7] The version given in this chapter follows [27]. This paper contains the first proof on the linearity of the algorithm when restricted to the search of the first occurrence of the pattern. Cole [9] proves that the maximum number of symbol comparisons is bounded by $3n$ for nonperiodic patterns, and that this bound is tight.

Knuth et al. [27] considers a variant of the Boyer–Moore algorithm in which all previous matches inside the current window are memorized. Each window configuration becomes the state of what is called the Boyer–Moore automaton. It is still unknown whether the maximum number of states of the automaton is polynomial or not.

Several variants of the Boyer–Moore algorithm avoid the quadratic behavior when searching for all occurrences of the pattern. Among the most efficient in terms of the number of symbol comparisons are the algorithm of Apostolico and Giancarlo (1986), Turbo-BM algorithm by Crochemore et al. [16] (the two previous algorithms are analyzed in [28], and the algorithm of Colussi [11].

The Horspool algorithm is from [24]. The paper contains practical aspects of string matching that are developed in [25].

The optimal bound on the expected time complexity of string matching is $O(\frac{\log m}{m} n)$ (see [27] and the paper of Yao [38]).

String matching can be solved by linear-time algorithms requiring only a constant amount of memory in addition to the pattern and the (window on the) text. This can be proved by different techniques presented in [15]. The most recent solution is by Gąsieniec, Plandowski, and Rytter [18].

Cole et al. [10] shows that, in the worst case, any string-matching algorithm working with symbol comparisons makes at least $n + \frac{9}{4m}(n-m)$ comparisons during its search phase. Some string-matching algorithms make less than $2n$ comparisons. The presently known upper bound on the problem is $n + \frac{8}{3(m+1)}(n-m)$, but with a quadratic-time preprocessing phase (see Cole et al. [10]). With a linear-time preprocessing phase, the current upper bounds are $\frac{4}{3}n - \frac{1}{3}m$ and $n + \frac{4\log m + 2}{m}(n-m)$ (see, respectively,

[20] and [8]). Except in a few cases (patterns of length 3 for example), lower and upper bounds do not meet. So, the problem of the exact complexity of string matching is open.

The Aho–Corasick algorithm is from [2]. Commentz-Walter [12] has designed an extension of the Boyer–Moore algorithm that solves the dictionary-matching problem. It is fully described in [1].

Ideas of "Small Patterns" are from [4] and [36]. An implementation of the method given in "Small Patterns" is the `agrep` command of UNIX [36].

The suffix-tree construction of "Suffix Trees" is from [29]. An on-line version is by Ukkonen [34]. A previous algorithm by Weiner [35] relates suffix trees to a data structure close to suffix automata.

The construction of suffix automata, also described as direct acyclic word graphs and often denoted by the acronym DAWG, is from Blumer et al. [5] and from [14]. An application to data retrieval by the mean of inverted files is described in Blumer et al. [6].

The alternative data structure for indexes given in "Suffix Arrays" is by [30].

11.5 Defining Terms

Border: A string v is a border of a string u if v is both a prefix and a suffix of u. String v is said to be the border of u if it is the longest proper border of u.

Factor: A string v is a factor of a string u if $u = u'vu''$ for some strings u' and u''.

Occurrence: A string v occurs in a string u if v is a factor of u.

Pattern: A finite number of strings that are searched for in texts.

Prefix: A string v is a prefix of a string u if $u = vu''$ for some string u''.

Proper: Qualifies a factor of a string that is not equal to the string itself.

Suffix: A string v is a suffix of a string u if $u = u'v$ for some string u'.

Suffix tree: Trie containing all the suffixes of a string.

Suffix automaton: Smallest automaton accepting the suffixes of a string.

Text: A stream of symbols that is searched for occurrences of patterns.

Trie: Digital tree, tree in which edges are labeled by symbols or strings.

Window: Factor of the text that is aligned with the pattern.

Further Information

Problems and algorithms presented in the chapter are just a sample of questions related to pattern matching. They share the formal methods used to design efficient algorithms. A wider panorama of algorithms on texts may be found in a few books such as [15] and [33].

Research papers in pattern matching are disseminated in a few journals, among which are *Communications of the ACM, Journal of the ACM, Theoretical Computer Science, Journal of Algorithms, SIAM Journal on Computing, Algorithmica.*

Two main annual conferences present the latest advances of this field of research:

- *Combinatorial Pattern Matching,* which started in 1990 in Paris (France), and was held since in London (England), Tucson (Arizona), Padova (Italy), Asilomar (California), Helsinki (Finland), Laguna Beach (California).
- *Workshop on String Processing,* which started in 1993 in Belo Horizonte (Brazil), and was held since in Valparaiso (Chile), and Recife (Brazil).

But general conferences in computer science often have sessions devoted to pattern matching.

Information retrieval questions are treated in [17], where the reader can find references on the problem.

Several books on the design and analysis of general algorithms contain a chapter devoted to algorithms on texts. Here is a sample of these books [3, 13, 21, 31]. During the production of this book, a new book has appeared titled *Algorithms on Strings, Trees and Sequences,* by D. Gusfield, Cambridge University Press (1997).

12.1 Text Compression

The chapter describes a few algorithms that compress texts. Compression serves both to save storage space and to save transmission time. We shall assume that the text is stored in a file. The aim of compression algorithms is to produce a new file, as short as possible, containing the compressed version of the same text. Methods presented here reduce the representation of text without any loss of information, so that decoding the compressed text restores exactly the original data.

The term "text" should be understood in a wide sense. It is clear that texts can be written in natural languages or can be texts usually generated by translators (like various types of compilers). But texts can also be images or other kinds of structures as well provided the data are stored in linear files.

The interest in data compression techniques remains important even if mass storage systems improve regularly because the amount of data grows accordingly. Moreover, a consequence of the extension of computer networks is that the quantity of data they exchange grows exponentially, so it is often necessary to reduce the size of files to reduce proportionally their transmission times. Other advantages in compressing files regard two connected issues: integrity of data and security. While the first is easily accomplished through redundancy checks during the decompression phase, the second often requires data compression before applying cryptography.

This chapter contains three classical text compression algorithms. Variants of these algorithms are implemented in practical compression software, in which they are often combined together or with other elementary methods. Moreover, we present all-purpose methods, that is, methods in which no sophisticated modeling of the statistics of texts is done. An adequate modeling of a well-defined family of texts may increase significantly the compression when coupled with the coding algorithms of this chapter.

Compression ratios of the methods depend on the input data. However, most often, the size of compressed text vary from 30% to 50% of the size of the input. At the end of this chapter, we present ratios obtained by the methods on several example texts. Results of this type can be used to compare the efficiency of methods in compressing data. But, the efficiency of algorithms is also evaluated by their running times, and sometimes by the amount of memory space they require at run time. These elements are important criteria of choice when a compression algorithm is to be implemented in a telecommunication software.

Two strategies are applied to design the algorithms. The first strategy is a statistical method that takes into account the frequencies of symbols to build a uniquely decipherable code optimal with respect to the compression (Sections 12.2 and 12.3). Section 12.4 presents a refinement of the coding algorithm of Huffman based on the binary representation of numbers. Huffman codes contain new codewords for the symbols occurring in the text. In this method fixed-length blocks of bits are encoded by different codewords. *A contrario* the second strategy encodes variable-length segments of the text (Section 12.5). To put it simply, the algorithm, while scanning the text, replaces some already read segments by just a pointer to their first occurrences. This second strategy often provides better compression ratios.

12.2 Static Huffman Coding

The Huffman method is an optimal statistical coding. It transforms the original code used for characters of the text (ASCII code on 8 bits, for instance). Coding the text is just replacing each symbol (more exactly each occurrence of it) by its new **codeword**. The method works for any length of blocks (not only 8 bits), but the running time grows exponentially with the length. In the following, we assume that symbols are originally encoded on 8 bits to simplify the description.

The Huffman algorithm uses the notion of **prefix code**. A prefix code is a set of words containing no word that is a **prefix** of another word of the set. The advantage of such a code is that decoding is immediate. Moreover, it can be proved that this type of code does not weaken the compression.

A prefix code on the binary alphabet $\{0, 1\}$ corresponds to a binary tree in which the links from a node to its left and right children are labeled by 0 and 1, respectively. Such a tree is called a (digital) **trie**. Leaves of the trie are labeled by the original characters, and labels of branches are the words of the code (codewords of characters). Working with prefix code implies that codewords are identified with leaves only. Moreover, in the present method codes are complete: they correspond to complete tries, i.e., tree in which internal nodes have all exactly two children.

In the model where characters of the text are given new codewords, the Huffman algorithm builds a code that is optimal in the sense that the compression is the best possible (if the model of the source text is a zero-order Markov process, that is if the probability of symbol occurrence are independent). The length of the encoded text is minimum. The code depends on the input text, and more precisely on the frequencies of characters in the text. The most frequent characters are given shortest codewords, while the least frequent symbols correspond to the longest codewords.

Encoding

The complete compression algorithm is composed of three steps: count of character frequencies, construction of the prefix code, encoding of the text. The last two steps use information computed by their preceding step.

The first step consists in counting the number of occurrences of each character in the original text (see Fig. 12.1). We use a special end marker, denoted by `END`, which virtually appears only once at the end of the text. It is possible to skip this first step if fixed statistics on the alphabet are used. In this case, however, the method is optimal according to the statistics, but not necessarily for the specific text.

The second step of the algorithm builds the tree of a prefix code, called a Huffman tree, using the character frequency $freq(a)$ of each character a in the following way:

```
H-COUNT (fin)
1  for each character a ∈ Σ
2      do freq(a) ← 0
3  while not end of file fin and a is the next symbol
4      do freq(a) ← freq(a) + 1
5  freq(END) ← 1
```

FIGURE 12.1 Counts the character frequencies.

- Create a one-node tree t for each character a, setting $weight(t) = freq(a)$ and $label(t) = a$,
- Repeat
  - Extract the two least weighted trees t_1 and t_2,
  - Create a new tree t_3 having left subtree t_1, right subtree t_2, and weight $weight(t_3) = weight(t_1) + weight(t_2)$,
- Until only one tree remains.

The tree is constructed by the algorithm H-BUILD-TREE in Fig. 12.2. The implementation uses two linear lists. The first list, *lleaves*, contains the leaves of the future tree associated each with a symbol. The list is sorted in increasing order of weights of leaves (frequencies of symbols). The second list, *ltrees*, contains the newly created trees. The operation of extracting the two least weighted trees is done by checking the two first trees of the list *lleaves* and the two first trees of the list *ltrees*. Each new tree is inserted at the end of the list of the trees. The only tree remaining at the end of the procedure is the coding tree.

```
H-BUILD-TREE
1   for each a ∈ Σ ∪ {END}
2       do if freq(a) ≠ 0
3             then create a new node t
4                  weight(t) ← freq(a)
5                  label(t) ← a
6   lleaves ← list of all created nodes in increasing order of weight
7   ltrees ← empty list
8   while LENGTH (lleaves) + LENGTH (ltrees) > 1
9       do (l, r) ← extract two nodes of smallest weight (among the two nodes at the
                beginning of lleaves and the two nodes at the beginning of ltrees)
10        create a new node t
11        weight(t) ← weight(l) + weight(r)
12        left(t) ← l
13        right(t) ← r
14        insert t at the end of ltrees
16  return t
```

FIGURE 12.2 Builds the Huffman coding tree.

After the coding tree is built, it is possible to recover the codewords associated with characters by a simple depth-first-search of the tree (see Fig. 12.3); $codeword(a)$ denotes the binary codeword associated with the character a.

In the third step, the original text is encoded. Since the code depends on the original text, in order to be able to decode the compressed text, the coding tree and the original codewords of symbols must be stored together with the compressed text.

This information is placed in a header of the compressed file, to be read at decoding time just before the decompression starts. The header is written during a depth-first traversal of the tree. Each time an internal node is encountered a 0 is produced. When a leaf is encountered a 1 is produced followed by the

```
H-BUILD-CODE (t, length)
1  if t is not a leaf
2     then temp[length] ← 0
3          H-BUILD-CODE (left(t), length + 1)
4          temp[length] ← 1
5          H-BUILD-CODE (right(t), length + 1)
6     else codeword(label(t)) ← temp[0 . . . length − 1]
```

FIGURE 12.3 Builds character codewords from the coding tree.

original code of the corresponding character on 9 bits (so that the end marker can be equal to 256 if all the 8-bit characters appear in the original text). This part of the encoding algorithm is shown in Fig. 12.4.

```
H-ENCODE-TREE (fout, t)
1  if t is not a leaf
2     then write a 0 in the file fout
3          H-ENCODE-TREE (fout, left(t))
4          H-ENCODE-TREE (fout, right(t))
5     else write a 1 in the file fout
6          write the original code of label(t) in the file fout
```

FIGURE 12.4 Stores the coding tree in the compressed file.

After the header of the compressed file is made, the encoding of the original text is realized by the algorithm of Fig. 12.5.

A complete implementation of the Huffman algorithm, composed of the three steps described above, is given in Fig. 12.6.

```
H-ENCODE-TEXT (fin, fout)
1  while not end of file fin and a is the next symbol
2     do write codeword(a) in the file fout
3  write codeword(END) in the file fout
```

FIGURE 12.5 Encodes the characters in the compressed file.

H-ENCODING (fin, fout)
1  H-COUNT (fin)
2  t ← H-BUILD-TREE
3  H-BUILD-CODE (t, 0)
4  H-ENCODE-TREE (fout, t)
5  H-ENCODE-TEXT (fin, fout)
```

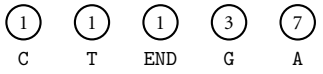
FIGURE 12.6 Complete function for Huffman encoding.

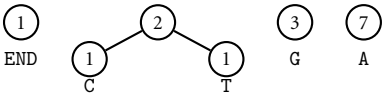
EXAMPLE 12.1:

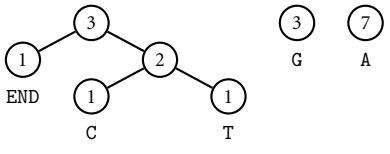
$y =$ ACAGAATAGAGA
Length of $y = 12 \times 8 = 104$ bits (assuming an 8-bit code)
Character frequencies:

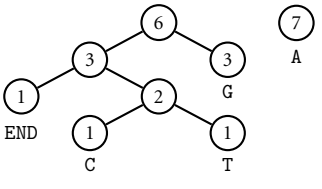
A	C	G	T	END
7	1	3	1	1

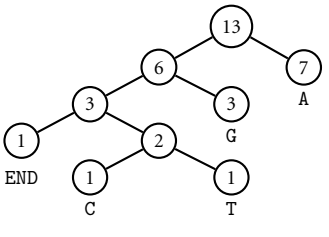
Different steps during the construction of the coding tree:











character codewords:

A	C	G	T	END
1	0010	01	0011	000

Encoded tree: 0001 *binary*(END,9)01 *binary*(C,9)1 *binary*(T,9)1 *binary*(G,9)1*binary*(A,9),
which produces a header of length 54 bits:
0001 100000000 01 001000011 1 001010100 1 001000111 1 001000001

Encoded text:

$$\underbrace{1}_{A}\ \underbrace{0010}_{C}\ \underbrace{1}_{A}\ \underbrace{01}_{G}\ \underbrace{1}_{A}\ \underbrace{1}_{A}\ \underbrace{0011}_{T}\ \underbrace{1}_{A}\ \underbrace{01}_{G}\ \underbrace{1}_{A}\ \underbrace{01}_{G}\ \underbrace{1}_{A}\ \underbrace{000}_{END}$$

of length 24 bits
Total length of the compressed file: 78 bits.

The construction of the tree takes $O(\sigma \log \sigma)$ time if the sorting of the list of the leaves is implemented efficiently. The rest of the encoding process runs in time linear in the sum of the sizes of the original and compressed texts.

Decoding

Decoding a file containing a text compressed by Huffman algorithm is a mere programming exercise. First, the coding tree is rebuilt by the algorithm of Fig. 12.7. Then, the original text is recovered by parsing the compressed text with the coding tree. The process begins at the root of the coding tree, and follows a left edge when a 0 is read or a right edge when a 1 is read. When a leaf is encountered, the corresponding character (in fact the original codeword of it) is produced and the parsing resumes at the root of the tree. The process ends when the codeword of the end marker is encountered. An implementation of the decoding of the text is presented in Fig. 12.8.

```
H-REBUILD-TREE (fin, t)
1   read bit b from fin
2   if b = 1
3      then make t a leaf
4           label(t) ← symbol corresponding to the 9 next bits read from fin
5      else create a new node l
6           left(t) ← l
7           H-REBUILD-TREE (fin, l)
8           create a new node r
9           right(t) ← r
10          H-REBUILD-TREE (fin, r)
```

FIGURE 12.7 Rebuilds the tree from the header of compressed file.

```
H-DECODE-TEXT (fin, fout, root)
1   t ← root
2   while label(t) ≠ END
3      do if t is a leaf
4         then write label(t) in the file fout
5              t ← root
6         else read bit b from fin
7              if b = 1
8                 then t ← right(t)
9                 else t ← left(t)
```

FIGURE 12.8 Recovers the original text.

The complete decoding program is given in Fig. 12.9. It calls the preceding functions. The running time of the decoding program is linear in the sum of the sizes of the texts it manipulates.

```
H-DECODING (fin, fout)
1   create a new node root
2   H-REBUILD-TREE (fin, root)
3   H-DECODE-TEXT (fin, fout, root)
```

FIGURE 12.9 Complete function for Huffman decoding.

12.3 Dynamic Huffman Coding

The two main drawbacks of the static Huffman method are: first, if the frequencies of characters the source text are not known *a priori*, the source text has to be read twice; second, the coding tree must be included in the compressed file. This is avoided by a dynamic method where the coding tree is updated each time a symbol is read from the source text. The current tree is a Huffman tree related to the part of the text that is already treated. The tree evolves exactly in the same way during the decoding process. The efficiency of the method is based on a characterization of Huffman trees, known as the *siblings property*.

Siblings property: Let T be a Huffman tree with n leaves (a complete binary weighted tree built by the procedure H-BUILD-TREE in which all leaves have positive weights). Then the nodes of T can be arranged in a sequence $(x_0, x_1, \ldots, x_{2n-2})$ such that:

1. The sequence of weights $(weight(x_0), weight(x_1), \ldots, weight(x_{2n-2}))$ is in decreasing order;
2. For any i $(0 \leq i \leq n-2)$, the consecutive nodes x_{2i+1} and x_{2i+2} are siblings (they have the same parent).

The compression and decompression processes initialize the dynamic Huffman tree by a one-node tree that correspond to an artificial character, denoted by `ART`. The weight of this single node is 1.

Encoding

Each time a symbol a is read from the source text, its codeword in the tree is sent. However this happens only if a appeared previously. Otherwise the code of `ART` is sent followed by the original codeword of a. Afterwards, the tree is modified in the following way: first, if a never occurred before, a new internal node is created and its two children are a new leaf labeled by a and the leaf `ART`; then, the tree is updated (see below) to get a Huffman tree for the new prefix of text.

Implementation

Each node is identified with an integer n, the root is the integer 0. The invariant of compression and decompression algorithms is that, if the tree has m nodes, the sequence of nodes $(m-1, \ldots, 1, 0)$ satisfies the siblings property. The tree is stored in a table, and we use the next notations, for a node n:

- $parent(n)$ is the parent of n ($parent(root) =$ `UNDEFINED`),
- $child(n)$ is the left child of n (if n is an internal node, otherwise $child(n) =$ `UNDEFINED`), and $child(n)+1$ is its right child (this is useful only at decoding time),
- $label(n)$ is the symbol associated with n when n is a leaf,
- $weight(n)$ is the weight of n (it is the frequency of $label(n)$ if n is a leaf).

Indeed, the child link is useful only at decoding time so that the implementation may differ between the two phases of the algorithm. But, to simplify the description and give a uniform treatment of the data structure, we assume the same implementation during the encoding and the decoding steps. Weights of nodes are handled by the procedure DH-UPDATE.

The correspondence between symbols and leaves of the tree is done by a table called *leaf*: for each symbol $a \in \Sigma \cup \{$`END`$\}$ $leaf[a]$ is the corresponding leaf of the tree, if any.

The coding tree initially contains only one node labeled by symbol `ART`. The initialization is given in Fig. 12.10.

Encoding the source text is a succession of three steps: read a symbol a from the source text, encode the symbol a according to the current tree, update the tree. It is described in Fig. 12.11.

Encoding a symbol a already encountered consists in accessing its associated leaf $leaf[a]$, then computing its codeword by a bottom-up walk in the tree (following the *parent* links up to the root). Each time a node n ($\neq$ root) is encountered if n is odd a 1 is sent (n is the right child of its parent), and if n is even a 0 is sent (n is then the left child of its parent). As the codeword of a is read in reverse direction a stack S

```
DH-INIT
1   root ← 0
2   child(root) ← UNDEFINED
3   weight(root) ← 1
4   parent(root) ← UNDEFINED
5   for each letter a ∈ Σ ∪ {END}
6       do    leaf[a] ← UNDEFINED
7   leaf[ART] ← root
```

FIGURE 12.10 Initializes the dynamic Huffman tree.

```
DH-ENCODING (fin, fout)
1   DH-INIT
2   while not end of file fin and a is the next symbol
3       do    DH-ENCODE-SYMBOL (a, fout)
4             DH-UPDATE (a)
5   DH-ENCODE-SYMBOL (END, fout)
```

FIGURE 12.11 Complete function for dynamic Huffman encoding.

is used to temporarily store the bits and send them properly. The procedure SEND (S, *fout*) send the bits of the stack S in the correct order to the file *fout*.
If a has not been encountered yet, then the code of ART is sent followed by the original codeword of a on 9 bits, and a new leaf is created for a (see Figs. 12.12 and 12.13).

```
DH-ENCODE-SYMBOL (a, fout)
1   S ← empty stack
2   n ← leaf[a]
3   if n = UNDEFINED
4       then n ← leaf[ART]
5   while n ≠ root
6       do    if n is odd
7                 then PUSH (S, 1)
8                 else PUSH (S, 0)
9             n ← parent(n)
10  SEND (S, fout)
11  if leaf[a] = UNDEFINED
12      then write in fout the original codeword of a on 9 bits
13           DH-ADD-NODE (a)
```

FIGURE 12.12 Encodes one symbol.

Decoding

At decoding time the compressed text is parsed with the coding tree. The current node is initialized with the root like in the encoding algorithm, and then the tree evolves symmetrically. Each time a 0 is read from the compressed file the walk down the tree follows the left link, and it follows the right link if a 1 is read. When the current node is a leaf, its associated symbol is written in the output file and the tree is updated exactly as it is done during the encoding phase.

Implementation

As for the encoding process the current Huffman tree is stored in a table, and it is initialized with the artificial symbol ART. The same elements of the data structure are used during the decompression. Note that the next node when parsing a bit b from node n is just $child(n) + b$ with the convention on left-

```
DH-ADD-NODE (a)
1   transform leaf[ART] into
2       an internal node of weight 1 with
3           a left child of weight 0 for leaf[a],
4           a right child of weight 1 for leaf[ART].
```

FIGURE 12.13 Adds a new symbol in the tree.

right links and 0-1 bits. The tree is updated by the procedure DH-UPDATE used previously and that is described in the next section. Figures 12.14 and 12.15 display the decoding mechanism.

```

3       do read bit b from fin
4              n ← child(n) + b
5   a ← label(n)
6   if a = ART
7       then a ← symbol corresponding to the next 9 bits read from fin
8            DH-ADD-NODE (a)
9   return (a)
```

FIGURE 12.15 Decodes one symbol from the input file.

Updating

During encoding and decoding phases the current tree has to be updated to take into account the correct frequency of symbols. When a new symbol is considered the weight of its associated leaf is incremented by 1, and the weights of ancestors have to be modified correspondingly. The procedure that realizes the operation is shown in Fig. 12.16. Its proof of correctness is based on the siblings property.

We explain how the procedure DH-UPDATE works.

First, the weight of the leaf n corresponding to a is incremented by 1. Then, if point 1 of the siblings property is no longer satisfied, node n is exchanged with the closest node m ($m < n$) in the list such that $weight(m) < weight(n)$. Doing so, the nodes remain in decreasing order of their weights. It is important here that leaves have positive weights, because this guarantees that m is not a parent nor an ancestor of node n. Afterwards, the same operation is repeated on the parent of n until the root of the tree is reached.

The aim of procedure DH-SWAP-NODES used in Fig. 12.16 is to exchange the subtrees rooted at its input nodes m and n. In concrete terms, this remains to exchange the records stored at the two nodes in the table. It is meant that nothing is to be done if $m = n$.

```
DH-UPDATE (a)
1  n ← leaf[a]
2  while n ≠ root
3     do   weight(n) ← weight(n) + 1
4          m ← n
5          while weight(m − 1) < weight(n)
6             do   m ← m − 1
7          DH-SWAP-NODES (m, n)
8          n ← parent(m)
9  weight(root) ← weight(root) + 1
```

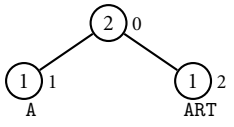
FIGURE 12.16 Updates the current Huffman tree.

EXAMPLE 12.2:

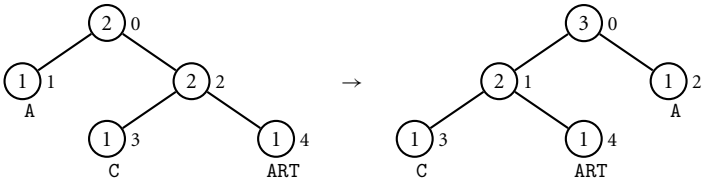
$y =$ ACAGAATAGAGA

Initial tree:

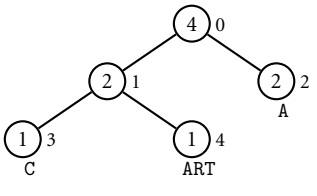
Next symbol is A:
The ASCII code of A is sent on 9 bits;
Bits sent: 001000001



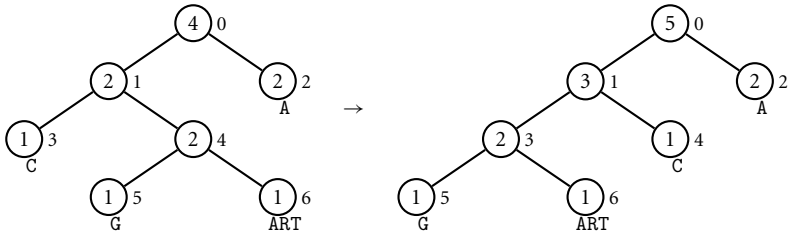
Next symbol is C:
The code of ART is sent followed by the ASCII code of C on 9 bits;
Bits sent: 1 001000011
Nodes 1 and 2 are swapped.



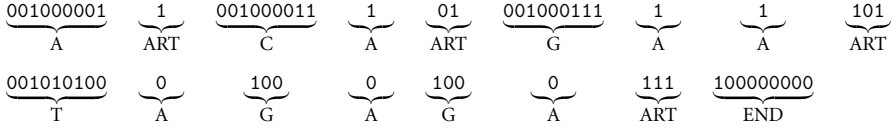
Next symbol is A:
The code of A is sent;
Bit sent: 1



Next symbol is G:
The code of ART is sent followed by the ASCII code of G on 9 bits;
Bits sent: 01 001000111
Nodes 3 and 4 are swapped.



Finally, the entire sequence of bits sent is the following:



The total length of the compressed text is 66.

12.4 Arithmetic Coding

Encoding

The basic idea of arithmetic coding is to consider symbol as digits of a numeration system, and texts as decimal parts of numbers between 0 and 1. The length of the interval attributed to a digit (it is 0.1 for digits in the usual base 10 system) is made proportional to the frequency of the digit in the text. The encoding is thus assimilated to a change in the base of a numeration system. To cope with precision problems, the number corresponding to a text is handled via a lower bound and an upper bound, which remains to associate with a text a subinterval of $[0, 1[$. The compression comes from the fact that large intervals require less precision to separate their bounds.

More formally, the interval associated with each symbol $a_i \in \Sigma\ (1 \leq i \leq \sigma)$ is denoted $I(a_i) = [l_i, h_i[$. The intervals satisfy the conditions: $l_1 = 0$, $h_\sigma = 1$, and $l_i = h_{i-1}$ for $1 < i \leq \sigma$. Note that $I(a_i) \cap I(a_j) = \emptyset$ if $a_i \neq a_j$.

The encoding phase consists in computing the interval corresponding to the input text. The basic step that deals with a symbol a_i of the source text transforms the current interval $[l, h[$ into $[l', h'[$ where $l' = l + (h - l) * l_i$ and $h' = l + (h - l) * h_i$, starting with the initial interval $[0, 1[$ (see Fig. 12.17). Indeed, in a theoretical approach, l only is needed to encode the input text.

```
AR-ENCODE (fin)
1  l ← 0
2  h ← 1
3  while not end of file fin and a_i is the next symbol
4     do   l ← l + (h − l) * l_i
5          h ← l + (h − l) * h_i
6  return(l)
```

FIGURE 12.17 Basic arithmetic encoding.

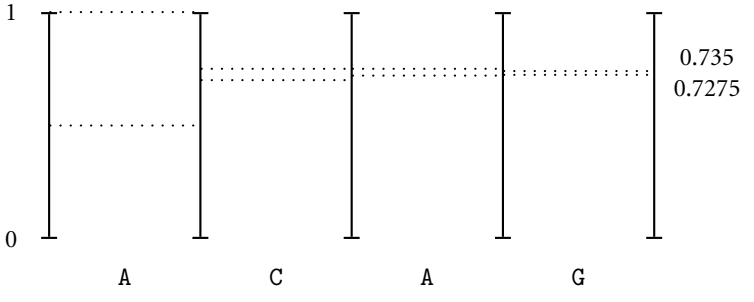
EXAMPLE 12.3:

$\Sigma = \{\mathtt{A}, \mathtt{C}, \mathtt{G}, \mathtt{T}\}, \sigma = 4$

$$I(\mathtt{A}) = [0.5, 1[, \quad I(\mathtt{C}) = [0.4, 0.5[, \quad I(\mathtt{G}) = [0.1, 0.4[, \quad I(\mathtt{T}) = [0, 0.1[$$

Encoding ACAG gives:

symbol	l	h
	0	1
A	0.5	1
C	0.7	0.75
A	0.725	0.75
G	0.7275	0.735



Decoding

The reverse operation of decoding a text compressed by the previous algorithm theoretically requires only the lower bound l of the interval. Decoding the number l is done as follows: first find the symbol a_i such that $l \in I(a_i)$, produced the symbol a_i, and then replace l by l' defined by:

$$l' \leftarrow \frac{l - l_i}{h_i - l_i}.$$

The same process is repeated until $l = 0$ (see Fig. 12.18). Indeed, the implementation of the decoding phase simulates what is done on the current interval considered at encoding time.

```
AR-DECODE (l, fout)
1   while l ≠ 0
2       do   find a_i such that l ∈ I(a_i)
3            write a_i in file fout
4            l ← (l − l_i)/(h_i − l_i)
```

FIGURE 12.18 Basic arithmetic decoding.

EXAMPLE 12.4:

$\Sigma = \{\mathtt{A}, \mathtt{C}, \mathtt{G}, \mathtt{T}\}, \sigma = 4$

$$I(\mathtt{A}) = [0.5, 1[, \quad I(\mathtt{C}) = [0.4, 0.5[, \quad I(\mathtt{G}) = [0.1, 0.4[, \quad I(\mathtt{T}) = [0, 0.1[$$

Decoding $l = 0.7275$:

l	a_i
0.7275	A
0.455	C
0.55	A
0.1	G
0	

Implementation

The main problem when implementing the arithmetic coding compression algorithm is to cope with precision on real numbers operations. The $[0, 1[$ interval of real numbers is substituted by the interval of integers $[0, 2^N - 1[$, where N is a fixed integer.

```
AR-ENCODING (fin, fout)
1   Initialize tables freq and cum-freq
2   l ← 0
3   h ← 2^N − 1
4   waiting-counter ← 0
5   while not end of file fin and a_i is the next symbol
6      do   AR-ENCODE-SYMBOL (a_i)
7           Update tables freq and cum-freq
8           Maintain symbols in decreasing order of frequencies
9   AR-ENCODE-SYMBOL (END)
10  waiting-counter ← waiting-counter + 1
11  AR-SEND-BIT (leftmost bit of h)
```

FIGURE 12.19 Complete arithmetic encoding function.

```
AR-ENCODE-SYMBOL (a_i)
1   l ← l + ((h − l + 1) * cum-freq[i])/cum-freq[0]
2   h ← l + ((h − l + 1) * cum-freq[i − 1])/cum-freq[0] − 1
3   repeat
4      if leftmost bit of l = leftmost bit of h
5         then AR-SEND-BIT (leftmost bit of h)
6              l ← 2 * l
7              h ← 2 * h + 1
8         else if h − l < cum-freq[0]
9                 then l ← 2 * (l − 2^(N−2))
10                     h ← 2 * (h − 2^(N−2)) + 1
11                     waiting-counter ← waiting-counter + 1
12  until leftmost bit of l ≠ leftmost bit of h and h − l ≥ cum-freq[0]
```

FIGURE 12.20 Encodes one symbol.

So, the algorithms work with integral values of size N. During the process, each time the binary representation of bounds l and h have a common prefix this prefix is sent and l is shifted to the left and filled with 0's while h is shifted to the left and filled with 1's.

The intervals associated with symbols of the alphabet are computed with the help of symbol frequencies, in a dynamic way: each character frequency is initialized with 1 and is incremented each time the symbol is encountered.

```
AR-SEND-BIT (bit, fout)
1   write bit in fout
2   while waiting-counter > 0
3      do   if bit = 0
4              then write 1 in fout
5                   write 0 in fout
6           waiting-counter ← waiting-counter − 1
```

FIGURE 12.21 Sends one bit followed by the waiting bits, if any.

We denote by $freq[i]$ the frequency of symbol a_i of the alphabet. We also consider the cumulative frequency of symbols, and set $cum\text{-}freq[i] = \Sigma_{j=i+1}^{\sigma} freq[j]$. Then $cum\text{-}freq[0]$ is the cumulative frequency of all symbols. Note that $cum\text{-}freq[0] - \sigma - 1$ is the length of the prefix of the input scanned so far. The symbols are maintained in decreasing order of their frequencies. This obviously save on the expected number of operations to update the table *cum-freq*.

Then when a symbol a_i is read from the source text, the current interval $[l, h[$ is updated in the following way:

$$l \leftarrow l + \frac{(h-l+1)*cum\text{-}freq[i]}{cum\text{-}freq[0]}$$

$$h \leftarrow l + \frac{(h-l+1)*cum\text{-}freq[i-1]}{cum\text{-}freq[0]} - 1$$

The common prefix (if any) of l and h is sent and l and h are shifted and filled (respectively, with 0's and 1's). At this point, if the interval is too short (if $h - l < cum\text{-}freq[0]$) it is extended to $[2 * (l - 2^{N-2}), 2 * (h - 2^{N-2}) + 1[$ and a waiting counter is incremented by 1. And the same operation is repeated as long as the interval is too short. After that, when a bit is sent, the reverse bit is sent the number of times indicated by the waiting counter.

EXAMPLE 12.5:

$\Sigma = \{\mathtt{A}, \mathtt{C}, \mathtt{G}, \mathtt{T}\}$, $N = 8$

		A	C	G	T	END

```
AR-DECODING (fin, fout)
1   Init the tables freq and cum-freq
2   value ← 0
3   for i ← 1 to N
4       do    read bit b from fin
5             value ← 2 * value + b
6   l ← 0
7   h ← 2^N − 1
8   repeat
9       i ← AR-DECODE-SYMBOL (fin)
10      if a_i ≠ END
11          then write a_i in fout
12               Update the tables freq and cum-freq
13               Maintain symbols in decreasing order of frequencies
14  until a_i = END
```

FIGURE 12.22 Complete arithmetic decoding function.

The decoding process is exactly the reverse of the coding process. It uses a window of size N on the compressed file. First, the window is filled with the first N bits of the compressed file and *value* is the corresponding base 2 number. The current interval is initialized with $l = 0$ and $h = 2^N - 1$.

```
AR-DECODE-SYMBOL (fin)
1   cum ← ((value − l + 1) ∗ cum-freq[0] − 1)/(h − l + 1)
2   i ← 1
3   while cum-freq[i] > cum
4      do   i ← i + 1
5   l ← l + ((h − l + 1) ∗ cum-freq[i])/cum-freq[0]
6   h ← l + ((h − l + 1) ∗ cum-freq[i − 1])/cum-freq[0] − 1
7   repeat
8      if leftmost bit of l = leftmost bit of h
9         then l ← 2 ∗ l
10              h ← 2 ∗ h + 1
11              read bit b from fin
12              value ← 2 ∗ value + b
13        else  if h − l < cum-freq[0]
14                 then l ← 2 ∗ (l − 2^(N−2))
15                      h ← 2 ∗ (h − 2^(N−2)) + 1
16                      read bit b from fin
17                      value ← 2 ∗ (value − 2^(N−2)) + b
18  until leftmost bit of l ≠ leftmost bit of h and h − l ≥ cum-freq[0]
19  return i
```

FIGURE 12.23 Decodes one symbol.

Then, the symbol a_i to be produced is the first character such that

$$cum\text{-}freq[i] > \frac{(value - l + 1) * cum\text{-}freq[0] - 1)}{h - l + 1},$$

and l and h are then updated exactly in the same way than during the coding process. If the binary representations of l and h have a common prefix of length p they are both shifted p binary position to the left and l is filled by 0's, h is filled with 1's. The window on the compressed file is shifted p symbols to the right and the variable *value* is updated correspondingly. The tables *freq* and *cum-freq* are updated and the symbols are maintained in decreasing order of the frequencies as in the coding process.

This is repeated until the symbol END is produced.

EXAMPLE 12.6:

Decoding the text 11101100111011111010000010001110
$\Sigma = \{\mathtt{A}, \mathtt{C}, \mathtt{G}, \mathtt{T}\}$

		A	C	G	T	END

$cum = 5$
$[96, 231[\xrightarrow{A} [193, 231[= [11000001_2, 11100111_2[$: shift by 2
The next interval is $[00000100_2, 10011111_2[$ and $value = 00111011_2 = 59$

Next symbols are GAATAG and the current interval becomes $[111, 139[$ and $value = 132 = 10000100_2$

$cum = 10$
$[111, 139[\xrightarrow{A} [127, 139[= [01111111_2, 10001011_2[$: no shift
The interval is too short and is replaced by $[01111110_2, 10010111_2[$ and $value = 10001000_2 = 136$

$value = 136 = 10001000_2$
$cum = 6$
$[126, 151[\xrightarrow{G} [134, 138[= [10000110_2, 10001010_2[$: shift by 4
The next interval $[01100000_2, 10101111_2[$ and $value = 10001110_2 = 142$

$value = 142 = 10001110_2$
$cum = 9$
$[96, 175[\xrightarrow{A} [141, 175[= [10001101_2, 10101111_2[$: shift by 2
The next interval $[00110100_2, 10111111_2[$ and $value = 00111000_2 = 56$

$value = 56 = 00111000_2$
$cum = 0$
The symbol is END, the decoding process is over.

Maintaining the symbols in decreasing order of frequencies can be done in $O(\log \sigma)$ using a suitable data structure (see [6]).

12.5 LZW Coding

Ziv and Lempel designed a compression method using encoding **segments**. These segments of the original text are stored in a dictionary that is built during the compression process. When a segment of the dictionary is encountered later while scanning the text it is substituted by its index in the dictionary. In the model where portions of the text are replaced by pointers on previous occurrences, the Ziv–Lempel compression

scheme can be proved to be asymptotically optimal (on large enough texts satisfying good conditions on the probability distribution of symbols).

The dictionary is the central point of the algorithm. It has the property of being prefix-closed (every prefix of a word of the dictionary is in the dictionary), so that it can be implemented efficiently as a trie. Furthermore, a hashing technique makes its implementation efficient. The version described in this section is called the Lempel–Ziv–Welsh method after several improvements introduced by Welsh. The algorithm is implemented by the `compress` command existing under the UNIX operating system.

Encoding

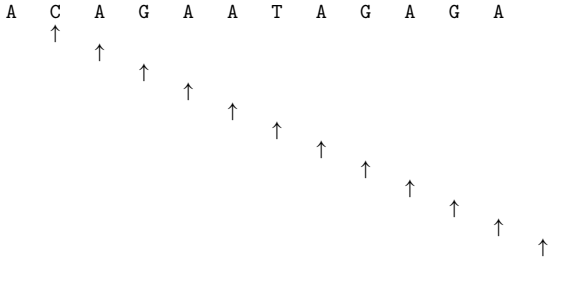
We describe the scheme of the coding method. The dictionary is initialized with all strings of length 1, the characters of the alphabet. The current situation is when we have just read a segment w of the text. Let a be the next symbol (just following the given occurrence w). Then we proceed as follows:

- If wa is not in the dictionary, we write the index of w in the output file, and add wa to the dictionary. We then reset w to a and process the next symbol (following a).
- If wa is in the dictionary we process the next symbol, with segment wa instead of w.

Initially, the segment w is set to the first symbol of the source text, so that it is clear that "w belongs to the dictionary" is an invariant of the operations described above.

EXAMPLE 12.7:

The alphabet is the 8-bit ASCII alphabet, $y =$ `ACAGAATAGAGA`
The dictionary initially contains the ASCII symbols, their indices are their ASCII codewords.



w	written	added
A	65	AC, 257
C	67	CA, 258
A	65	AG, 259
G	71	GA, 260
A	65	AA, 261
A	65	AT, 262
T	84	TA, 263
A		
AG	259	AGA, 264
A		
AG		
AGA	264	
	256	

Decoding

The decoding method is symmetric to the coding algorithm. The dictionary is recovered while the decompression process runs. It is basically done in this way:

- Read a code c in the compressed file,
- Write in the output file the segment w having index c in the dictionary,
- Add the word wa to the dictionary where a is the first letter of the next segment.

In this scheme, the dictionary is updated after the next segment is decoded because we need its first symbol a to concatenate at the end of the current segment w. So, a problem occurs if the next index computed at encoding time is precisely the index of the segment wa. Indeed, this happens only in a very special case, in which the symbol a is also the first symbol of w itself. This arises if the rest of the text to encode starts with a segment $azazax$ (a a symbol, z a string) for which az belongs to the dictionary but aza does not. During the compression process the index of az is output, and aza is added to the dictionary. Next, aza

is read and its index is output. During the decompression process the index of aza is read while the first occurrence of az has not been completed yet, the segment aza is not already in the dictionary. However, since this is the unique case where the situation occurs, the segment aza is recovered by taking the last segment az added to the dictionary concatenated with its first letter a.

EXAMPLE 12.8:

Decoding the sequence 65, 67, 65, 71, 65, 65, 84, 259, 264, 256
The dictionary initially contains the ASCII symbols, their indices are their ASCII codewords.

read	written	added
65	A	
67	C	AC, 257
65	A	CA, 258
71	G	AG, 259
65	A	GA, 260
65	A	AA, 261
84	T	AT, 262
259	AG	TA, 263
264	AGA	AGA, 264
256		

The critical situation occurs when reading the index 264 because, at that moment, no word of the dictionary has this index.

Implementation

We describe how the dictionary, which is the main data structure of the method, can be implemented. It is natural to consider two implementations adapted for the two phases respectively, because the dictionary is not manipulated in the same manner during these phases. They have in common a dictionary implemented as a trie stored in a table D. A node p of the trie is just an index on the table D. It has the three following components:

- $parent(p)$, a link to the parent node of p,
- $label(p)$, a character,
- $code(p)$, the codeword (index in the dictionary) associated with p.

In the compression algorithm shown in Fig. 12.24, for a node p we need to compute its child according to some letter a. This is done with by hashing, with a hashing function defined on pairs in the form (p, a). This provides a fast access to the children of a node.

The function HASH-SEARCH, with input $(D, (p, a))$, returns the node q such that $parent(q) = p$ and $label(q) = a$, if such a node exists and NIL otherwise. The procedure HASH-INSERT, with input $(D, (p, a, c))$, inserts a new node q in the dictionary D with $parent(q) = p$, $label(q) = a$ and $code(q) = c$.

For the decompression algorithm, no hashing technique is necessary on the table representation of the trie that implements the dictionary. Having the index of the next segment, a bottom-up walk in the trie produces the mirror image of the expected segment. A stack is then used to reverse it. We assume that the function $string(c)$ performs this specific work for a code c. The bottom-up walk follows the parent links of the data structure. The function $first(w)$ gives the first character of the word w. These features are part of the decompression algorithm displayed in Fig. 12.25.

The Ziv–Lempel compression and decompression algorithms run both in time linear in the sizes of the files provided the hashing technique is implemented efficiently. Indeed, it is very fast in practice, except when the table becomes full and should be reset. In this situation, usual implementations also reset the whole dictionary to its initial value.

The main advantage of Ziv–Lempel compression method, compared to Huffman coding, is that it captures long repeated segments in the source file and thus often yields better compression ratios.

```
LZW-CODING (fin, fout)

14                p ← HASH-SEARCH (D, (−1, a))
15           else p ← q
16  write p on 1 + log(count) bits in fout
17  write code(HASH-SEARCH (D, (−1, END)) in 1 + log(count) bits in fout
```

FIGURE 12.24 LZW encoding algorithm.

12.6 Experimental Results

The table of Fig. 12.26 contains a sample of experimental results showing the behavior of compression algorithms on different types of texts. The table is extracted from [16].

The source files are French text, C sources, Alphabet, and Random. Alphabet is a file containing a repetition of the line `abc...zABC...Z`. Random is a file where the symbols have been generated randomly, all with the same probability and independently of each others.

The compression algorithms reported in the table are the Huffman algorithm of Section 12.2, the Ziv–Lempel algorithm of Section 12.5, and a third algorithm called Factor. This latter algorithm encodes segments of the source text as Ziv–Lempel algorithm does. But the segments are taken among all segments already encountered in the text before the current position. The method gives usually better compression ratio but is more difficult to implement. Compression based on arithmetic as presented in this chapter gives compression ratios slightly better than Huffman coding.

The table of Fig. 12.26 gives in percentage the sizes of compressed files. Results obtained by Ziv–Lempel and Factor algorithms are similar. Huffman coding gives the best result for the Random file. Finally, experience shows that exact compression methods often reduce the size of data to 30–50% of their original size.

12.7 Research Issues and Summary

The statistical compression algorithm is from Huffman [9]. The UNIX command `pack` implements the algorithm.

The dynamic version was discovered independently by Faller [5] and Gallager [7]. Practical versions were given by Cormack and Horspool [3] and Knuth [10]. A precise analysis leading to an improvement was presented in [13]. The command `compact` of UNIX implements the dynamic Huffman coding.

It is unclear to whom precisely should be attributed the idea of data compression using arithmetic coding. It is sometimes attributed to Elias [4], and has become popular after the publication of the article of Witten, Neal, and Cleary [15]. An efficient data structure for the tables of frequencies is due to Fenwick [6]. The main interest in arithmetic coding for text compression is that the two different processes "modeling" the statistics of texts and "coding" can be made independent modules.

FIGURE 12.26 Sizes of texts compressed with three algorithms.

Several variants of the Ziv–Lempel algorithm exist. The reader can refer to the books of Bell, Cleary, and Witten [1] or Storer [12] for a discussion on them.

The books of Held [8] and Nelson [11] present practical implementations of various compression algorithms, while the book of Crochemore and Rytter [2] overflows the strict topic of text compression and described more algorithms and data structures related to texts manipulations.

Defining Terms

Codeword: Sequence of bits of a code corresponding to a symbol.

Prefix: A word $u \in \Sigma^*$ is a prefix of a word $w \in \Sigma^*$ if $w = uz$ for some $z \in \Sigma^*$.

Prefix code: Set of words such that no word of the set is a prefix of another word contained in the set. A prefix code is represented by a coding tree.

Segment: A word $u \in \Sigma^*$ is a segment of a word $w \in \Sigma^*$ if u occurs in w, i.e., $w = vuz$ for two words $v, z \in \Sigma^*$. (u is also referred to as a factor or a subword of w.)

Trie: Tree in which edges are labeled by letters or words.

Further Information

The set of algorithms presented in this chapter provides the basic methods for data compression. In commercial software they are often combined with other more elementary techniques that are described in textbooks. A wider panorama of data compression algorithms on texts may be found in several books such as:

- Bell, T.C., Cleary, J.G., Witten, I.H. 1990. *Text Compression*. Prentice Hall, Englewood Cliffs, NJ.
- Crochemore, M., Rytter, W. 1994. *Text Algorithms.* Oxford University Press.
- Held, G. 1991. *Data Compression*. John Wiley & Sons, New York.
- Nelson, M. 1992. *The Data Compression Book.* M&T Books.
- Storer, J.A. 1988. *Data Compression: Methods and Theory.* Computer Science Press.

Research papers in text data compression are disseminated in a few journals, including *Communications of the ACM, Journal of the ACM, Theoretical Computer Science, Algorithmica, Journal of Algorithms, SIAM Journal on Computing, IEEE Trans. Information Theory.*

An annual conference presents the latest advances of this field of research:

- *Data Compression Conference,* which is regularly held at Snowbird (Utah) in spring.

Two other conferences on pattern matching also present research issues in this domain:

- *Combinatorial Pattern Matching*, which started in 1990 and was held in Paris (France), London (England), Tucson (Arizona), Padova (Italy), Asilomar (California), Helsinki (Finland), Laguna Beach (California), Aarhus (Denmark).
- *Workshop on String Processing,* which started in 1993 and was held in Belo Horizonte (Brasil), Valparaiso (Chile), and Recife (Brasil).

And general conferences in computer science often have sessions devoted to data compression algorithms.

Università di Padova

13.1 Introduction

This chapter reviews combinatorial and algorithmic problems related to searching and matching of strings and slightly more complicated structures such as arrays and trees. These problems arise in a vast variety of applications and in connection with various facets of storage, transmission, and retrieval of information. A list would include the design of structures for the efficient management of large repositories of strings, arrays and special types of graphs, fundamental primitives such as the various variants of exact and approximate searching, specific applications such as the identification of periodicities and other regularities, efficient implementations of ancillary functions such as compression and encoding of elementary discrete objects, etc. The main objective of studies in pattern matching is to abstract and identify some primitive manipulations, develop new techniques and efficient algorithms to perform them, both by serial and parallel or distributed computation, and implement the new algorithms.

Some initial pattern matching problems and techniques arose in the early 1970s in connection with emerging technologies and problems of the time, e.g., compiler design. Since then, the range of applications of the tools and methods developed in pattern matching has expanded to include text, image and signal processing, speech analysis and recognition, data compression, computational biology, computational chemistry, computer vision, information retrieval, symbolic computation, computational learning, computer security, graph theory and VLSI, etc. In little more than two decades, an initially sparse set of

more or less unrelated results has grown into a considerable body of knowledge. A complete bibliography of string algorithms would contain more than 500 articles. A.V. Aho [2] references over 140 papers in his recent survey of string-searching algorithms alone; advanced workshops and schools, books and special issues in major journals have already been dedicated to the subject and more are planned for the future. The interested reader will find a few reference books and conference proceedings in the bibliography of this chapter.

While each application domain presents peculiarities of its own, a number of pattern matching primitives are shared, in nearly identical forms, within wide spectra of distant and diverse areas. For instance, searching for identical or similar substrings in strings is of paramount interest to software development and maintenance, philology or plagiarism detection in the humanities, inference of common ancestries in molecular genetics, comparison of geological evolutions, stereo matching for robot vision, etc. Checking the equivalence (i.e., identity up to a rotation) of circular strings finds use in determining the homology of organisms with circular genomes, comparing closed curves in computer vision, establishing the equivalence of polygons in computer graphics, etc. Finding repeated patterns, symmetries, and cadences in strings is of interest to data compression, detection of recurrent events in symbolic dynamics, genome studies, intrusion detection in distributed computer systems, etc. Similar considerations hold for higher structures. In general, an intermediate objective of studies in pattern matching is to understand and characterize combinatorial structures and properties that are susceptible of exploitation in computational matching and searching on discrete elementary structures.

Most pattern matching issues are still subject to extensive investigation both within serial and parallel models of computation. This survey concentrates on sequential algorithms, but the reader is encouraged to explore for himself the rich repertoire of parallel algorithms developed in recent years. Most of these algorithms bear very little resemblance to their serial counterparts. Similar considerations apply to some algorithms formulated in a probabilistic setting.

Pattern matching problems may be classified according to a number of paradigms. One way is based on the type of structure (strings, arrays, trees, etc.) in terms of which they are posed. Another, is according to the model of computation used, e.g., RAM, PRAM, Turing machine. Yet another one is according to whether the manipulations that one seeks to optimize need be performed on-line, off-line, in real time, etc. One could distinguish further between matching and searching and, within the latter, between exact and approximate searches, or vice versa. The classification used here is thus somewhat arbitrary. We assume some familiarity of the reader with exact string searching, both on- and off-line, which is covered in a separate chapter of this volume. We start by reviewing some basic variants of string searching where occurrences of the pattern need not be exact. Next, we review algorithms for string comparisons. Then, we consider pattern matching on two-dimensional arrays and finally on rooted trees.

13.2 String Searching with Don't-Care Symbols

As already mentioned, we assume familiarity of the reader with the problem of **exact string searching,** in which we are interested in finding all the occurrences of a pattern string y into a textstring x. One of the natural departures from this formulation consists of assuming that a symbol can (perhaps only at some definite positions) match a small group of other symbols. At one extreme we may have, in addition to the symbols in the input alphabet Σ, a **don't care** symbol ϕ with the property that ϕ matches any other character in Σ. This gives raise to variants of string searching where, in principle, ϕ appears (i) only in the pattern, (ii) only in the text, or (iii) both in pattern and text. There seems to be no peculiar result on variant (ii), whence we shall consider this as just a special case of (iii). The situation is different with variant (i), which warrants the separate treatment which is given next.

Don't-Cares in Pattern Only

Fischer and Paterson [20] and Pinter [45] discuss the problem faced if one tried to extend the KMP string searching algorithm [33] in order to accommodate don't cares in the pattern: the obvious transitivity on character equality, that subtends those and other exact string searching, is lost with don't cares. Pinter noted that a partial recovery is possible if the number and positions of don't cares is fixed. In fact, in this case one may resort to ideas used by Aho and Corasick [3] in connection with exact multiple string searching and solve the problem within the same time complexity $O(n + m + r) \log |\Sigma|$ time, where $n = |x|$ is the length of the textstring, $m = |y|$ is the length of the pattern, and r is the total number of occurrences of the fragments of the pattern that would be obtained by cleaving the latter at don't cares.

We outline Pinter's approach. Since the don't cares appear in fixed known positions, we may consider the pattern decomposed into **segments** of Σ^+, say, $\hat{y_1}, \hat{y_2}, \ldots, \hat{y_p}$ and ϕ-**blocks** consisting of runs of occurrences of ϕ, respectively. Each $\hat{y_i}$ can be treated as an individual pattern in a multiple pattern matching machine. Through the search, one computes for each $\hat{y_i}$ a list of its occurrences in x. Let d_i be the known distance between the starting positions of $\hat{y_i}$ and $\hat{y}_{i+1}$. We may now merge the occurrence list while keeping track of these distances, using the natural observation that if a match occurred starting at position j, then the $\hat{y_i}$'s will appear in the same order and intersegment distance as they appear in the pattern. Here the merge process takes place after the search. To make his algorithm work in real time applications, Pinter used an array of counters, a data structure originally proposed by R.L. Rivest. Instead of merging lists, counters count from 0 to p while collecting evidence of a pattern occurrence. Specifically, the counting mechanism is as follows. Let the **offset** of a segment be the distance from the beginning of the pattern to the end of that segment. Whenever a segment match is detected ending at position j, then its offset f_j is subtracted from j, thus yielding the starting position $j - f_i$ of a corresponding candidate occurrence of the pattern. Next, the counter assigned to position $1 + (j - f_i) \bmod m$ is incremented by 1. Therefore, a counter initialized to zero reaches p iff the last m characters examined on the text matched the pattern. A check whether a counter has reached p is performed each time that counter is reused.

Manber and Baeza-Yates [39] consider the case where the pattern embeds a string of at most k don't cares, i.e., has the form $y = u\phi^i v$, where $i \leq k$, $u, v \in \Sigma^*$, and $|u| \leq m$ for some given k, m. Their algorithm is off-line in the sense that the text x is preprocessed to build the suffix array [40] associated with it. This operation costs $O(n \log |\Sigma|)$ time in the worst case. Once this is done, the problem reduces to one of efficient implementation of 2-dimensional orthogonal range queries (for these latter see, e.g., [16, 60]).

One more variant of string searching with don't care in pattern only is discussed in [55]. Also Takeda's algorithm is based on the algorithm in [4]. The problem is stated as follows. Consider a set $A = \{A_1, A_2, \ldots, A_p\}$, where each $A_i \subseteq \Sigma$ is a nonempty set called a **picture** and pictures are mutually disjoint. While a don't care symbol matches all symbols, a picture matches a subset of the alphabet. For any pattern y, we have now that $y \in (\Sigma \cup A)^+$. Then, given a set of patterns $Y = \{y^{(1)}, \ldots, y^{(k)}\}$, the problem is to find all occurrences of $y^{(i)}$ for $i = 1, ..., k$. Thus, when $A = \Sigma$, the problem reduces to plain string searching with don't cares. A pattern matching machine for such a family can be quite time consuming to build. Takeda managed to improve on time efficiency by saving on the number of explicit "goto" edges created in that machine.

Takeda's variant finds natural predecessors in an even more general class considered by K. Abrahamson [1]. This latter paradigm applies to an unbounded alphabet Σ, as long as individual symbols have finite encodings. Let $P = \{P_1, P_2, \ldots, P_k\}$ be a set of **pattern elements,** where each pattern element is a subset of Σ. There are **positive** and **negative** pattern elements. A positive element, is denoted by $< \sigma_1, \ldots, \sigma_f >$ and has the property of matching each one of the characters $\sigma_1, \sigma_2, \ldots, \sigma_f$. A negative element is denoted by $[\sigma_1, \ldots, \sigma_f]$ and will match any character of Σ except characters $\sigma_1, \sigma_2, \ldots, \sigma_f$. A pattern $y \in P^+$ identifies now a family of strings, namely, all strings in the form $y_1 y_2 \ldots y_m$ such that $y_i \in \Sigma$ is compatible with the element of P used to identify the ith element of y. Using a time–space tradeoff proof technique

due to Borodin, Abrahamson proved that the time-space lower bound on a subproblem with $n = 2m$ is $\Omega(m^2/\log m)$.

By combining **divide and conquer** with an idea of Fischer and Paterson [20] which will be discussed more thoroughly later, Abrahamson designed an algorithm taking time $O(N + M + n\hat{M}^{1/2} \log m \log^{1/2} m)$, where N and M denote the lengths of the encodings (e.g., in bits) of x and y, respectively, and $\hat{M}$ represents the number of distinct elements of Σ which are present in the pattern.

Don't-Cares in Pattern and Text

In an elegant, landmark paper, Fischer and Paterson [20] exposed the similarity of string searching to multiplication, thereby obtaining a number of interesting algorithms for exact string searching and some of its variants. It is not difficult to see that string matching problems can be rendered as special cases of a general linear product. Given two vectors X and Y, their **linear product** with respect to two suitable operations $\otimes$ and $\oplus$, is denoted by $X \begin{smallmatrix}\otimes\\ \oplus\end{smallmatrix} Y$, and is a vector $Z = Z_0 Z_1 \ldots Z_{m+n}$ where $Z_k = \bigoplus_{i+j=k} X_i \bigotimes Y_j$ for $k = 0, \ldots, m+n$. If we interpret $\oplus$ as the Boolean $\wedge$ and $\otimes$ as the symbol equivalence $\equiv$, then a match of the reverse Y^R of Y, occurs ending at position k in X, where $m \leq k \leq n$, if $[X_{k-m} \ldots X_k] \equiv [Y_m \ldots Y_0]$, that is, with obvious meaning, if $(X \begin{smallmatrix}\equiv\\ \wedge\end{smallmatrix} Y)_k$ =TRUE. This observation brings string searching into the family of Boolean, polynomial, and integer multiplications, and leads quickly to an $O(n \log m \log\log m)$ time solution even in the presence of don't cares, provided that the size of Σ is fixed.

To see this, we show first that string searching can be regarded as a Boolean linear product, i.e., one where $\oplus$ is $\vee$ and $\otimes$ is $\wedge$. Let the textstring be specified as $x = x_0 x_1 x_2 \ldots x_n$ and similarly let $y = y_0 y_1 y_2 \ldots y_m$ be the pattern. Recall that we assume a finite alphabet Σ, and that both x and y may contain some don't cares. For each $\rho \in \Sigma$, define $H_\rho(X_i) = 1$ if $x_i = \rho$, and $H_\rho(X_i) = 0$ if $x_i \neq \rho$ or $x_i = \phi$. Assume now that the vector X corresponding to string x contains only symbol σ and ϕ while Y, corresponding to string y, contains only symbol $\tau \neq \sigma$ and ϕ, with both σ and $\tau \in \Sigma$. Then $\bigwedge_{i+j=k} X_i \equiv Y_j$ means that $\bigwedge_{i+j=k} \neg H_\sigma(X_i) \vee \neg H_\tau(Y_j) \Longleftrightarrow \neg \bigvee_{i+j=k} H_\sigma(X_i) \wedge H_\tau(Y_j)$. The last term is a boolean product, whence such a product is not harder than string searching. On the other hand, $Z = X \begin{smallmatrix}\equiv\\ \wedge\end{smallmatrix} Y = \neg \bigvee_{\sigma \neq \tau; \sigma, \tau \in \Sigma} H_\sigma(X) \begin{smallmatrix}\wedge\\ \vee\end{smallmatrix} H_\tau(Y)$.

As is well known, the Boolean product can be obtained by performing the polynomial product, in which $\oplus$ is + and $\otimes$ is $\times$. For this, just encode TRUE and FALSE as 1 and 0, respectively. One way to compute the polynomial product is to embed the product in a single large integer multiplication. There are well known fast solutions for the latter problem. For the $\{0, 1\}$ string vectors X and Y, the maximum coefficient is $m + 1$, so if we choose r such that $2^r > m + 1$, compute the integers $X(2^r) = \Sigma_{i=0}^{n} X_i \cdot 2^{ri}$ and $Y(2^r) = \Sigma_{j=0}^{m} Y_j \cdot 2^{rj}$ and then multiply $X(2^r)$ and $Y(2^r)$, the result will be the product evaluated at 2^r. The consecutive blocks of length r in the binary representation of $Z(2^r)$ will give the coefficients of Z, which can be transferred back to the Boolean product, and from there back to the string matching product. The Schönhage–Strassen [53] algorithm multiplies an N-digit number by an M-digit number in time $O(N \cdot \log M \cdot \log\log M)$, for $N > M$, using a multi-tape Turing machine. For the string matching product, $N = nr = O(n \log m)$, $M = mr = O(m \log m)$, so that the problem is solved on that machine in time $O(n \log^2 m \log\log m)$. The algorithm as presented assumes that the alphabet finite. For any alphabet Σ of size polynomial in n, however, we can always encode the two input strings in binary at a cost of a multiplicative factor $O(\log |\Sigma|)$, and then execute just two Boolean products. This results in an extra $O(\log m)$ factor in the time complexity.

Note the adaptation of fast multiplication to string searching provides a basis for counting the mismatches generated by a pattern y at every position of a text x. This results from treating all symbols of Σ separately, and thus in overall time $O(n(|\Sigma|) \log^2 m \log\log m)$. This latter complexity is comparable to the above only for finite Σ. However, we shall see later that better bounds are achievable under this approach.

13.3 String Editing and Longest Common Subsequences

We now introduce three **edit operations** on strings. Namely, given any string w we consider the **deletion** of a symbol from w, the **insertion** of a new symbol in w, and the **substitution** of one of the symbols of w with another symbol from Σ. We assume that each edit operation has an associated nonnegative real number representing the **cost** of that operation. More precisely, the cost of deleting from w an occurrence of symbol a is denoted by $D(a)$, the cost of inserting some symbol a between any two consecutive positions of w is denoted by $I(a)$, and the cost of substituting some occurrence of a in w with an occurrence of b is denoted by $S(a, b)$. An **edit script** on w is any sequence Γ of viable edit operations on w, and the cost of Γ is the sum of all costs of the edit operations in Γ.

Now, let x and y be two strings of respective lengths $|x| = n$ and $|y| = m \leq n$. The **string editing problem** for input strings x and y consists of finding an edit script Γ' of minimum cost that transforms y into x. The cost of Γ' is the **edit distance from** y *to* x. Edit distances where individual operations are assigned integer or unit costs occupy a special place. Such distances are often called Levenshtein distances, since they were introduced by Levenshtein [38] in connection with error correcting codes. String editing finds applications in a broad variety of contexts, ranging from speech processing to geology, from text processing to molecular biology.

It is not difficult to see that the general (i.e., with unbounded alphabet and unrestricted costs) problem of edit distance computation is solved by a serial algorithm in $\Theta(mn)$ time and space, through dynamic programming. Due to widespread application of the problem, however, such a solution and a few basic variants were discovered and published in literature catering to diverse disciplines (see, e.g., [44, 47, 49, 59]). In computer science, the problem was dubbed "the string-to-string correction problem." The CS literature was possibly the last one to address the problem, but the interest in the CS community increased steadily in subsequent years. By the early 1980s, the problem had proved so pervasive, especially in biology, that a book by Sankoff and Kruskal [1983] was devoted almost entirely to it. Special issues of the *Bulletin of Mathematical Biology* and various other books and journals routinely devote significant portions to it.

An $\Omega(mn)$ lower bound was established for the problem by Wong and Chandra [61] for the case where the queries on symbols of the string are restricted to tests of equality. For unrestricted tests, a lower bound $\Omega(n \log n)$ was given by Hirschberg [27]. Algorithms slightly faster than $\Theta(mn)$ were devised by Masek and Paterson [41], through resort to the so-called "Four Russians Trick." The "Four Russians" are Arlazarov, Dinic, Kronrod, and Faradzev [8]. Along these lines, the total execution time becomes $\Theta(n^2/\log n)$ for bounded alphabets and $O(n^2(\log\log n)/\log n)$ for unbounded alphabets. The method applies only to the classical Levenshtein distance metric, and does not extend to general cost matrices. To this date, the problem of finding either tighter lower bounds or faster algorithms is still open.

The criterion that subtends the computation of edit distances by dynamic programming is readily stated. For this, let $C(i, j)$, $(0 \leq i \leq |y|,\ 0 \leq j \leq |x|)$ be the minimum cost of transforming the prefix of y of length i into the prefix of x of length j. Let w_k denote the kth symbol of string w. Then $C(0, 0) = 0$, $C(i, 0) = C(i-1, 0) + D(y_i)$ $(i = 1, 2, \ldots, |y|)$, $C(0, j) = C(0, j-1) + I(x_j)$ $(j = 1, 2, \ldots, |x|)$, and

$$C(i, j) = \min\left\{C(i-1, j-1) + S\left(y_i, x_j\right),\ C(i-1, j) + D\left(y_i\right),\ C(i, j-1) + I\left(x_j\right)\right\}$$

for all i, j, $(1 \leq i \leq |y|, 1 \leq j \leq |x|)$. Observe that, of all entries of the C-matrix, only the three entries $C(i-1, j-1)$, $C(i-1, j)$, and $C(i, j-1)$ are involved in the computation of the final value of $C(i, j)$. Hence, $C(i, j)$ can be evaluated row-by-row or column-by-column in $\Theta(|y||x|) = \Theta(mn)$ time. An optimal edit script can be retrieved at the end by backtracking through the local decisions that were made by the algorithm.

A few important problems are special cases of string editing, including the **longest common subsequence** problem, **local alignment,** i.e., the detection of local similarities of the kind sought typically in the analysis of molecular sequences such as DNA and proteins, and some important variants of **string searching with**

errors, or searching for approximate occurrences of a pattern string in a text string. As highlighted in the following brief discussion, a solution to the general string editing problem implies typically similar bounds for all these special cases.

Longest Common Subsequences

Perhaps the single most widely studied special case of string editing is the so-called longest common subsequence (LCS) problem. The problem is defined as follows. Given a string z over an alphabet $\Sigma = (i_1, i_2, \ldots i_s)$, a **subsequence** of z is any string w that can be obtained from z by deleting zero or more (not necessarily consecutive) symbols. The **longest common subsequence problem** for input strings $x = x_1 x_2 \ldots x_n$ and $y = y_1 y_2 \ldots y_m$ $(m \leq n)$ consists of finding a third string $w = w_1 w_2 \ldots w_l$ such that w is a subsequence of x and also a subsequence of y, and w is of maximum possible length. In general, string w is not unique.

Like the string editing problem itself, the LCS problem arises in a number of applications spanning from text editing to molecular sequence comparisons, and has been studied extensively over the past. Its relation to string editing can be understood as follows.

Observe that the effect of a given substitution can be always achieved, alternatively, through an appropriate sequence consisting of one deletion and one insertion. When the cost of a nonvacuous substitution (i.e., a substitution of a symbol with a different one) is higher than the global cost of one deletion followed by one insertion, then an optimum edit script will always avoid substitutions and produce instead y from x solely by insertions and deletions of overall minimum cost. Specifically, assume that insertions and deletions have unit costs, and that a cost higher than 2 is assigned to substitutions. Then, the pairs of matching symbols preserved in an optimal edit script constitute a longest common subsequence of x and y. It is not difficult to see that the cost e of such an optimal edit script, the length l of an LCS and the lengths of the input strings obey the simple relationship: $e = n + m - 2l$. Similar considerations can be developed for the variant where matching pairs are assigned weights and a **heaviest** common subsequence is sought (see, e.g., Jacobson and Vo [31]).

Lower bounds for the LCS problem are time $\Omega(n \log n)$ or linear time, according to whether the size s of Σ is unbounded or bounded [27]. Aho, Hirschberg and Ullman [4] showed that, for unbounded alphabets, any algorithm using only "equal–unequal" comparisons must take $\Omega(mn)$ time in the worst case. The asymptotically fastest general solution rests on the corresponding solution by Masek and Paterson [41] to the string editing, hence takes time $O(n^2 \log\log n / \log n)$. Time $\Theta(mn)$ is achieved by the following dynamic programming algorithm from Hirschberg [26].

Let $L[0 \ldots m, 0 \ldots n]$ be an integer matrix initially filled with zeroes.

The following code transforms L in such a way that $L[i, j]$ $(1 \leq i \leq m, 1 \leq j \leq n)$ contains the length of an LCS between $y_1 y_2 \ldots y_i$ and $x_1 x_2 \ldots x_j$.

for $i = 1$ **to** m **do**
  for $j = 1$ **to** n **do if** $y_i = x_j$ **then** $L[i, j] = L[i-1, j-1] + 1$
    else $L[i, j] = \text{Max}\{L[i, j-1], L[i-1, j]\}$

The correctness of this strategy follows from the obvious relations:

$$\begin{array}{lcccl} L[i-1, j] & \leq & L[i, j] & \leq & L[i-1, j] + 1\,; \\ L[i, j-1] & \leq & L[i, j] & \leq & L[i, j-1] + 1\,; \\ L[i-1, j-1] & \leq & L[i, j] & \leq & L[i-1, j-1] + 1\,. \end{array}$$

If only the length l of an LCS is desired, then this code can be adapted to use only linear space. If an LCS is required at the outset, then it is necessary to keep track of the decision made at every step by the algorithm, so that an LCS w can be retrieved at the end by backtracking. The early $\Theta(mn)$ time algorithm by Hirschberg [27] achieved both a linear space bound and the production of an LCS at the outset, through

a combination of dynamic programming and divide-and-conquer. Subsequent approaches to the LCS problem achieve time complexities better than $\Theta(mn)$ in favorable cases, though a quadratic performance is always touched and sometimes even exceeded in the worst cases. These approaches exploit in various ways the **sparsity** inherent to the LCS problem. Sparsity allows us to relate algorithmic performances to parameters other than the lengths of the input. Some such parameters are introduced next.

The ordered pair of positions i and j of L, denoted $[i, j]$, is a **match** iff $y_i = x_j$, and we use r to denote the total number of matches between x and y. If $[i, j]$ is a match, and an LCS $w_{i,j}$ of $y_1 y_2 \ldots y_i$ and $x_1 x_2 \ldots x_j$ has length k, then k is the **rank** of $[i, j]$. The match $[i, j]$ is **k-dominant** if it has rank k and for any other pair $[i', j']$ of rank k either $i' > i$ and $j' \leq j$ or $i' \leq i$ and $j' > j$. A little reflection establishes that computing the k-dominant matches ($k = 1, 2, \ldots, l$) is all is needed to solve the LCS problem (see, e.g., [7, 26]). Clearly, the LCS of x and y has length l iff the maximum rank attained by a dominant match is l. It is also useful to define, on the set of matches in L, the following partial order relation $\mathcal{R}$: match $[i, j]$ precedes match $[i', j']$ in $\mathcal{R}$ if $i < i'$ and $j < j$. A set of matches such that in any pair one of the matches always precedes the other in $\mathcal{R}$ constitutes a **chain** relative to the partial order relation $\mathcal{R}$. A set of matches such that in any pair neither match precedes the other in $\mathcal{R}$ is an **antichain**. Then, the LCS problem translates into the problem of finding a longest chain in the **poset** (partially ordered set) of matches induced by $\mathcal{R}$ (cf. [48]). A decomposition of a poset into antichains is **minimal** if it partitions the poset into the minimum possible number of antichains (refer, e.g., to [12]).

THEOREM 13.1 *[17] A maximal chain in a poset P meets all antichains in a minimal antichain decomposition of P.*

In other words, the number of antichains in a minimal decomposition represents also the length of a longest chain. Even though it is never explicitly stated, most known approaches to the LCS problem in fact compute a minimal antichain decomposition for the poset of matches induced by $\mathcal{R}$. The kth antichain in this decomposition is represented by the set of all matches having rank k. For general posets, a minimal antichain decomposition is computed by flow techniques [12], although not in time linear in the number of elements of the poset. Most LCS algorithms that exploit sparsity have their natural predecessors in either [30] or [26]. In terms of antichain decompositions, the approach of Hirschberg [26] consists of computing the antichains in succession, while that of Hunt and Szymanski [30] consists of extending partial antichains relative to all ranks already discovered, one new symbol of y at a time. The respective time complexities are $O(nl + n \log s)$ and $O(r \log n)$. Thus, the algorithm of Hunt and Szymanski is favorable in very sparse cases, but worse than quadratic when r tends to mn. An important specialization of this algorithm is that to the problem of finding a longest ascending subsequence in a permutation of the integers from 1 to n. Here, the total number of matches is n, which results in a total complexity $O(n \log n)$. Resort to the "fat-tree" structures introduced by Van Emde Boas [19] leads to $O(n \log \log n)$ for this problem, a bound which had been shown to be optimal by Fredman [21].

Figure 13.1 illustrates the concepts introduced thus far, displaying the final L-matrix for the strings $x =$ cbadbb and $y =$ abcabccbc. We use circles to represent matches, with bold circles denoting dominant matches. Dotted lines thread antichains relative to $\mathcal{R}$ and also separate regions.

Hirschberg's Paradigm: Finding Antichains One at a Time

We outline a $\Theta(mn)$ time LCS algorithm in which antichains of matches relative to the various ranks are discovered one after the other. Consider the *dummy* pair $[0, 0]$ as a "0-dominant match," and assume that all $(k-1)$-dominant matches for some k, $0 \leq k \leq l-1$ have been discovered at the expense of scanning the part of the L-matrix that would lie above or to the left of the antichain $(k-1)$, inclusive. To find the kth antichain, scan the unexplored area of the L-matrix from right to left and top-down, until a stream of matches is found occurring in some row i. The leftmost such match is the k-dominant match $[i, j]$ with

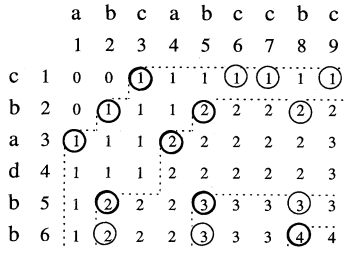

FIGURE 13.1 Illustrating antichain decompositions.

smallest i-value. The scan continues at next row and to the left of this match, and the process is repeated at successive rows until all of the kth antichain has been identified. The process may be illustrated like in Fig. 13.2. The large circles denote "pebbles" used to intercept the matches in an antichain. Initially, the pebbles are positioned on the matches created in the last column by the *ad-hoc* wildcard symbol \$. Next, pebbles are considered in succession from the top, and each pebble is moved to the leftmost match it can reach without crossing a previously discovered antichain. Once all pebbles have been considered, those contributing to the new antichain are identified easily.

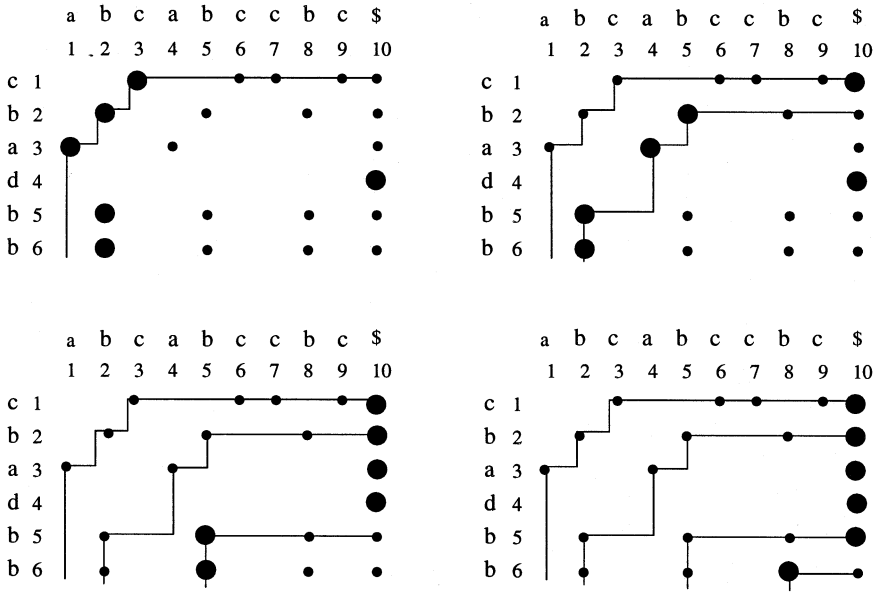

FIGURE 13.2 Hirschberg's paradigm: discovering one antichain at a time. The positions occupied by the pebbles at the end of consecutive antichain constructions are displayed clockwise from left-top.

Note that for each k the list of $(k-1)$-dominant matches is enough to describe the shape of the antichain and also to guide the searches involved at the subsequent stage. Thus, also in this case linear space is sufficient if one wishes to compute only the length of w.

An efficient implementation of this scheme leads to the algorithm by Hirschberg [26], which takes time $O(nl + n \log s)$ and space $O(d + n)$, where d is the number of dominant matches.

Incremental Antichain Decompositions and the Hunt–Szymanski Paradigm

When the number r of matches is small compared to m^2 (or to the expected value of lm), an algorithm with running time bounded in terms of r may be advantageous. Along these lines, Hunt and Szymanski [30] set up an algorithm (HS) with a time bound of $O((n + r) \log n)$. This algorithm works by computing, row after row, the ranks of all matches in each row. The treatment of a new row corresponds thus to extending the antichain decomposition relative to all preceding rows. A same match is never considered more than once. On the other hand, the time required by HS degenerates as r gets close to mn. In these cases this algorithm is outperformed by the algorithm of Hirschberg [26], which exhibits a bound of $O(ln)$ in all situations.

Algorithm HS is reproduced below. Essentially, it scans the list of matching positions $MATCHLIST$ associated with the ith row of L and considers those matches in succession, from right to left. For each match, HS decides whether it is a k-dominant match for some k through a binary search in the array $THRESH$ which maintains the leftmost previously discovered k-dominant match for each k. If the current match forces an update for rank k, then the contents of $THRESH[k]$ is modified accordingly. Observe that considering the matches in reverse order is crucial to the correct operation of HS. The details are found in the code below.

Algorithm "HS": element array $y[1 : m], x[1 : n]$;
integer array $THRESH[0 : m]$; list array $MATCHLIST[1 : m]$;
pointer array $LINK[1 : m]$; pointer PTR;
begin (*PHASE* 1: initializations
  for $i = 1$ **to** m **do**
  begin
    $MATCHLIST[i] = \{ j_1, j_2, ..., j_p\}$
    such that $j_1 > j_2 > \cdot > j_p$
    and $y_i = x_{j_q}$ *for* $1 \le q \le p$
    $THRESH[i] = n + 1$ *for* $1 \le i \le m$;
  end
  $THRESH[0] = 0$; $LINK[0] = null$;
PHASE 2 : find k-dominant matches)
  for $i = 1$ to m do
    for j *on* $MATCHLIST[i]$ do
      begin *find k such that*
        $THRESH[k-1] < j \le THRESH[k]$;
      if $j < THRESH[k]$ **then**
        begin
        $THRESH[k] = j$;
          $LINK[k] = newnode(i, j, LINK[k-1])$
        end
      end
(*PHASE* 3 : recover LCS w in reverse order)
  $\hat{k}$ = *largest k such that* $THRESH[k] \neq n + 1$;
  $PTR = LINK[\hat{k}]$;
  while $PTR \neq null$ **do begin**
  print the match $[i, j]$ *pointed to by* PTR;
  advance PTR **end**
end.

The total time spent by HS is bounded by $O((r + m) \log n + n \log s)$, where the $n \log s$ term is

charged by the preprocessing needed to create the lists of matches. The space is bounded by $O(d+n)$. As mentioned, this is good in sparse cases but becomes worse than quadratic for dense r.

13.4 String Searching with Errors

In this section, we assume unit cost for all edit operations. Given a pattern y and a text x, the most general variant of the problem consists of computing, for every position of the text, the best edit distance achievable between y and any substring w of x ending at that position. It is not difficult to express a solution in terms of a suitable adaptation of the recurrence previously introduced in connection with string editing. The first obvious change consists of setting all costs to 1 except that $S(y_i, x_j) = 0$ for $y_i = x_j$. Thus, we have now, for all i, j, $(1 \leq i \leq |y|, 1 \leq j \leq |x|)$,

$$C(i, j) = \min\{C(i-1, j-1) + 1,\ C(i-1, j) + 1,\ C(i, j-1) + 1\}\ .$$

A second change consists of setting the initial conditions so that $C(0,0) = 0$, $C(i,0) = i$ $(i = 1, 2, \ldots, m)$, $C(0, j) = 0$ $(j = 1, 2, \ldots, n)$. This has the effect of setting to zero the cost of prefixing y by any prefix of x. In other words, any prefix of the text can be skipped free of charge in an optimum edit script.

Clearly, the computation of the final value of $C(i, j)$ may proceed as in the general case, and it will still take $\Theta(|y||x|) = \Theta(mn)$ time. Note, however, that we are interested now in the entire last row of matrix C at the outset. Although we assumed unit costs, the validity of the method extends clearly to the case of general positive costs.

In practice, it is often more interesting to locate only those segments of x that present a high similarity with y under the adopted measure. Formally, given a pattern y, a text x and an integer k, this restricted version of the problem consists of locating all terminal positions of substrings w of x such that the edit distance between w and y is at most k. The recurrence given above will clearly produce this information. However, there are more efficient methods to deal with this restricted case. In fact, a time complexity $O(kn)$ and even sublinear expected time are achievable. We refer to Landau and Vishkin [36, 37], Sellers [49], Ukkonen [57], Galil and Giancarlo [22], Chang and Lawler [14], for detailed discussions. In the following, we review some basic principles subtending an $O(kn)$ algorithm for string searching with k differences. Note that when k is a constant the corresponding time complexity is linear.

The crux of the method is to limit computation to $O(k)$ elements in each diagonal of the matrix C. These entries will be called **extremal** and may be defined as follows: a diagonal entry is d-extremal if it is the deepest entry on that diagonal to be given value d $(d = 1, 2, \ldots, k)$. Note that a diagonal might not feature any, say, 1-extremal entry, in which case it would correspond to a perfect match of the pattern. The identification of d-extremal entries proceeds from extension of entries already known to be $(d-1)$-extremal. Specifically, assume we knew that entry $C(i, j)$ is $(d-1)$-extremal. Then, any entry reachable from $C(i, j)$ through a unit vertical, horizontal, or diagonal-mismatch step possibly followed by a maximal diagonal stream of matches is d-extremal at worst. In fact, the cost of a diagonal stream of matches is 0, whence the cost of an entry of the type considered cannot exceed d. On the other hand, that cost cannot be smaller than $d-1$, otherwise this would contradict the assumption $C(i, j) = d-1$. Let entries reachable from a $(d-1)$-extremal entry $C(i, j)$ through a unit vertical, horizontal, or diagonal-mismatch step be called d-**adjacent**. Then the following program encapsulates the basic computations.

Algorithm "KERR" :
element array $x[1:n]$, $y[1:m]$, $C[0:m; 0:n]$; integer k
begin
(*PHASE* 1 : initializations)
set first row of C to 0;
find the boundary set S_0 of 0-extremal entries by exact string searching;

```
(PHASE 2 :  identify k-extremal entries )
    for d = 1 to k do
        begin
        walk one step horizontally, vertically and (on mismatch) diagonally
        from each (d − 1)-extremal entry in set S_(d−1) to find d-adjacent entries;
        from each d-adjacent entry, compute the farthest d-valued
        entry reachable diagonally from it;
        end
    for i = 1 to n − m + 1 do
        begin
        select lowest d-entry on diagonal i
        and put it in the set S_d of d-extremal entries
        end
end.
```

It is easy to check that the algorithm performs k iterations in each one of which it does essentially a constant number of manipulations on each of the n diagonals. In turn, each one of these manipulations takes constant time except at the point where we ask to reach the farthest d-valued entry from some other entry on a same diagonal. We would know how to answer quickly that question if we knew how to handle the following query: given two arbitrary positions i and j in the two strings y and x, respectively, find the longest common prefix between the suffix of y that starts at position i and the suffix of x that starts at position j. In particular, our bound would follow if we knew how to process each query in constant time. It is not known how that could be done without preprocessing becoming somewhat heavy. On the other hand, it is possible to have it such that *all* queries have a cumulative amortized cost of $O(kn)$. This possibility rests on efficient algorithms for performing **lowest common ancestor** queries in trees. Space limitations do not allow us to belabor this point any further.

Note that the special case where insertions and deletions are forbidden is also solved by an algorithm very similar to the above and within the same time bound. This variant of the problem is often called **string searching with mismatches**. A probabilistic approach to this problem is implicit in [14], one more is described in [9]. When k cannot be considered a constant, an interesting alternative results from Abrahamson's approach to multiple-value string searching.

Specifically, this algorithm of Abrahamson's combines divide and conquer with the idea of Fischer and Paterson [20] which was discussed earlier. In divide-and-conquer, the problem is first partitioned into subproblems; these are then solved by ad-hoc techniques, and finally the partial solutions are combined. One possible way to "divide" is to take projections of the pattern into two complementary subsets, another is to split and handle separately the positive and negative portions of the pattern. We have already seen that the adaptation of fast multiplication to string searching leads to a time bound $O(n(|\Sigma|)\log^2 m \log\log m)$.

This performance is good for bounded Σ but quite poor when Σ is unbounded. In this latter case, however, some of the symbols must be very unfrequent. Using this observation, Abrahamson designed a projection into $\Sigma' = \{\sigma \in \Sigma : \sigma$ occurs at most z times in $y\}$ and the corresponding complement set Σ''. The rare symbols can be handled efficiently by some direct match-counting, since they cannot produce more than zn matches in total. The frequent ones are limited in number to m/z and we can apply multiplication to each one of them separately. The overall result is time $O(nm/z \log^2 m \log\log m)$, which becomes $O(nm^{1/2} \log m \log\log^{1/2} m)$ if we pick $z = m^{1/2} \log m \log\log^{1/2} m$.

13.5 Two-Dimensional Matching

The problem of matching and searching of two-dimensional objects arises in as many applications as there are ways to involve pictures and other planar representations and objects. Just like the full-fledged problem of recognizing the digitized signal of a spoken word in a speech finds a first rough approximation

in string searching, the problem of recognizing a particular subject in a scene finds a first, simplistic model in the computational task that we consider in this section: locating occurrences of a small array into a larger one. Even at this level of simplification, this task is enough complicated already that we shall ignore such variants as those allowing for different shapes and rotations, variants that do not appear in the one dimensional searches.

Two-dimensional matching may be exact and approximate just like with strings, but edit operations of insertion and deletion denature the structure of an array and thus may be meaningless in most settings. The literature on two-dimensional searching concentrates on exact matching, and so does the treatment of this section.

Searching with Automata

In exact two-dimensional searching, the input consists of a "text" array $X[n \times n]$ and a "pattern" array $Y[m \times m]$. The output consists of all locations (i, j) in X where there is an occurrence of Y, where the word "occurrence" is to be interpreted in the obvious sense that $X_{i+k,j+l} = Y_{k+1,l+1}, 0 \leq k, l \leq m-1$.

The naive attack leads to an $O(n^2m^2)$ solution for the problem. It is not difficult to reduce this down to $O(n^2m)$ by resorting to established string searching tools. This may be seen as follows. Imagine to build a linear pattern y where each character consists of one of the consecutive rows of Y. Now, build similarly the family of textstrings $x_1^{(i)}x_2^{(i)}\ldots x_{n-m+1}^{(i)}$ $(1 \leq i \leq n)$ such that $x_j^{(i)}$ is the character for $X_{i,j}X_{i,j+1}\cdots X_{i,j+m-1}$. Clearly, Y occurs at $X_{i,j}$ iff y occurs at $x_j^{(i)}$. If one could assume a constant cost for comparing a character of y with one of $x^{(i)}$, it would take $O(n)$ time by any of the known fast string searching to find the occurrences on y in each $x^{(i)}$. Hence, it would take optimal time $O(n^2)$ for the n strings in the global problem. Since comparing two strings of m characters each charges in fact m comparisons, then the overall bound becomes $O(n^2m)$, as stated.

Automata-based techniques were developed along these lines by Bird [11] and Baker [10]. Later efforts exposed also a germane problem which came to be called "dictionary matching" and acquired some independent interest. Some details of such an automata-based two-dimensional searching are given next.

The main idea is to build on the distinct rows of the pattern Y the Aho–Corasick [3] automaton for multiple string searching. Once this connection is made, it becomes possible to solve the problem at a cost of preprocessing time $O(m^2 \log|\Sigma|)$ (to build the automaton for at most m patterns with m characters each), and time $O(n^2 \log|\Sigma| + tocc)$ to scan the text. Here $tocc$, stands for total number of occurrences, i.e., is the size of the output. In multiple string matching, the parameter $tocc$ may play havoc with time linearity, since more than one pattern might end and thus have to be outputted at any given position. Here, however, the rows of Y are all of the same size, whence only one such row may occur at any given position.

Periods and Witnesses in Two Dimensions

Automata-based approaches such as those just discussed result in time complexities that carry a dependence to alphabet size. This is caused by the branching of forward transitions that leave the states of the machine in multiple string searching. Single string searching is not affected by this problem. In fact, single string searching found quickly linear solutions without alphabet dependency. In contrast, several years elapse before alphabet dependency was eliminated from two-dimensional searching.

Alphabet dependency was eliminated in steps, first from the search phase only, and finally also from preprocessing. A key factor in the first step of progress was offered by a two-dimensional extension of the notion of a **witness,** a concept first introduced and used by Vishkin [58] in connection with parallel exact string searching. It is certainly rare, and therefore quite remarkable, that a tool devised specifically to speed-up a *parallel* algorithm would find use in designing a better serial algorithm.

It is convenient to illustrate the idea of a witness on strings. Assume then to be given two copies of a pattern y, reciprocally aligned in such a way that the top copy is displaced, say, d positions ahead of the bottom one. A witness for d, if it exists, is any pair of mismatching characters that would prevent the two superimposed copies of y to coexist. Thus, if we were to be given two d-spaced, overlapping candidate occurrences of y on a text x, and a witness were defined for d, then at least one of the candidate occurrences of y in x will necessarily fail. One alternative way to regard a witness at d is as a counterexample to the claim that d is a period for y. The latter is a necessary, though not sufficient condition for having y occur twice, d positions apart.

The use of witnesses during the search phase presupposes preparation of appropriate tables. These tables essentially provide, for each d where this is true, a mismatch proving the incompatibility of two overlapping matches at a distance of d. The notion of a witness generalizes naturally to higher dimensions. In two dimensions two witnesses tables were introduced by Amir, Benson and Farach [5] as follows. Witness $Wit_{i,j}$ is any position (p, q) such that $X_{i+p,j+q}$ does not match $X_{i,j}$ or else it is 0. Note that, given an array W, there are essentially only two ways of superpositions one of thet two copies onto the other. These consist, respectively, of shifting one of the copies toward the right and bottom or toward the right and top of the other. These two families correspond to two witness tables that depend on whether $i < 0$ or $i \geq 0$. Amir, Benson and Farach [5] showed how to build the witness table in time $O(m^2 \log |\Sigma|)$.

Once the table is available, the search phase is performed in two stages that are called respectively **candidate consistency testing** and **candidate verification**. The candidates are the positions of X, interpreted as top-left corners of potential occurrences of the pattern. At the beginning each position is a viable candidate. A pair of candidates is consistent if the pattern could be placed at both places without conflicting with the witness tables. The task of the first phase is to use the witness tables to remove one in each pair of inconsistent candidates. Clearly, one character comparison with the position of the text array that corresponds to the witness suffices to carry out this "duel" between the candidates. Note that a duel might rule out both candidates, however, eliminating one will do.

At the end of the consistency check we can verify the surviving candidates. A same text symbol could belong to several candidates, but all of these candidates must agree on that symbol. Thus, each position in the text can be labeled true or false according to whether or not it complies with what all partecipating candidates surrounding it prescribe for that position. Conversely, whenever a candidate covers a position of the text that is labeled as false, then that candidate can no longer survive. A procedure set up along these lines leads to an $O(n^2)$ search phase, within a model of computation in which character comparisons take constant time and only result in assessing whether the characters are equal or unequal.

The preprocessing in this approach is still dependent on the size of the alphabet. Alphabet independent preprocessing and overall linear time algorithm was achieved by Galil and Park [24]. Like with strings, one may build an index structure based on preprocessing of the text and then run faster queries off-line with varying patterns. Details can be found in, e.g., [25].

13.6 Tree Matching

The discrete structures considered in this section are labeled, rooted trees, with the possible additional constraint that children of each node be ordered. Recall that a **tree** is any undirected, connected and acyclic graph. Choosing one of the vertices as the **root** makes the tree **rooted,** and fixing an order among the children of each node makes the tree **ordered**. Like with other classes of discrete objects, there is exact and approximate searching and matching of trees. We examine both of these issues next.

Exact Tree Searching

In exact tree searching, we are given two ordered trees, namely, a "pattern" tree P with m nodes and a "text" tree T with n nodes, and we are asked to find all occurrences of P in T. An occurrence of P in T

is an ordered subtree P' rooted at some node v of T such that P could be rigidly superimposed onto P' without any label mismatch or edge skip. The second condition means that the kth child of a node of P matches precisely the kth child of a node of T.

An $O(nm^{0.75}\text{polylog}(m))$ improvement over the trivial $O(mn)$ time algorithm was designed by Kosaraju [34]. A faster, $O(n\sqrt{m})polylog(m))$ algorithm, is due to Dubiner, Galil and Magen [18]. Their approach is ultimately reminiscent of Abrahamson's pidgeon-hole approach to generalizations of string searching such as those examined earlier in our discussion. It is based on a combination of periodicity properties in strings and some techniques of tree partitioning that achieve succint representations of long paths in the pattern.

Some notable variants of exact tree pattern matching arise in applications such as code generation and unification for logic programming and term-rewriting systems. In this context, a label can be a constant or a variable, where a variable at a leaf may match an entire subtree. In the most general setting, the input consists of a set S of patterns, rather than a single pattern, and of course of a text T. Early analyses and algorithms for the general problem are due to Hoffman and O'Donnel [29]. Two basic families of treatment descend, respectively, from matching the text tree from the root or from the leaves. The bottom-up approach is the more convenient of the two in the context of term rewriting systems. This approach is heavy on pattern preprocessing, where it may require exponential time and space, although essentially linear in the processing phase. Improvements and special cases are treated by Chase [15], Cai, Paige and Tarjan [13], and Thorup [56].

Tree Editing

The editing problem for unordered trees is NP-complete. However, much faster algorithms can be obtained for ordered trees. Early definitions and algorithms may be traced back to Selkow [50] and Tai [54]. In more recent years, the problem and some of its basic variants have been studied extensively by Shasha and Zhang and their co-authors. The outline given below concentrates on some of their work.

Let T be a tree of $|T| = n$ nodes, each node labeled with a symbol from some alphabet Σ. We consider three edit operations on T, consisting, respectively, of the deletion of a node v from T (followed by the reassignment of all children of v to the node of which v was formerly a child), the insertion of a new node along some consecutive arcs departing from a same node of T, and the substitution of the label of one of the nodes of T with another label from Σ. Like with strings, we assume that each edit operation has an associated nonnegative real number representing the cost of that operation. We similarly extend the notion of edit script on T to be any consistent sequence Γ of edit operations on T, and define the cost of Γ as the sum of all costs of the edit operations in Γ. These notions generalize easily to any ordered **forest** of trees.

Now, let F and F' be two forests of respective sizes $|F| = n$ and $|F'| = m$. The **forest editing problem** for input F and F' consists of finding an edit script Γ' of minimum cost that transforms F into F'. The cost of Γ' is the edit distance from F to F'. When F and F' consist each of exactly one tree, then we speak of the **tree editing problem**.

A convenient way to visualize the editing of trees or forests is by means of a mapping of nodes from one of two structures to the other. The map is represented by a set of links between node pairs (v, v') such that either these two nodes have precisely the same label—and thus node v is exactly conserved as v'—or else the label of v gets substituted with that of v'. Each node takes part in at most one link. The unaffected nodes of F (respectively, F') represent deletions (respectively, insertions). A mapping defined along these lines has the property of preserving both ancestor-descendant and sibling orders. In other words, a link from a descendant of v may only reach a descendant of v', and, similarly, links from two siblings to two others must not cross each other.

Early dynamic programming solutions for tree editing consume $\Theta(|F|^3|F'|^3)$ time. Much faster algorithms have been set up subsequently. Some other interesting problems are special cases of forest editing, including "tree alignment," the "largest common subtree" problem, and the problem of "approximate tree

matching" between a pattern tree and text tree. While any solution to the general tree editing problem implies similar bounds for all these special cases, some of the latter admit a faster treatment.

We review the criterion that subtends the computation of tree edit distances by dynamic programming after Zhang and Shaha [62]. This leads to an algorithm with time bounded by the product of the squares of the sizes of the trees. A convenient preliminary step is to resort to a linear representation for the trees involved. The discussion on mappings suggests that such a representation consist of assigning to each node its ordinal number in the postorder visit of the tree. Let x and y be the strings representing the postorder visits of two trees T and T'. Then a prefix of, say, x will identify in general some forest of subtrees each rooted at some descendant of the root of T. Note that the leftmost leaf in the leftmost tree is denoted precisely x_1. Let i_1 be the corresponding root, and let *forestdist*(i, j) represent the cost of transforming the subforest of T corresponding to $x_1 \ldots x_i$ into the subforest of T' corresponding to $y_1 \ldots y_j$. Let *treedist*(i, j) be the cost of transforming the tree rooted at x_i into the tree rooted at y_j. Then, in the most general case, these costs are dictated by the following recurrence:

$$\textit{forestdist}\ (i, j) = \min \begin{cases} \textit{forestdist}\ (i-1, j) + D\,(x_i) \\ \textit{forestdist}\ (i, j-1) + I\,(y_j) \\ \textit{forestdist}\ (l(i)-1, l(j)-1) + \textit{treedist}\ (i, j) \end{cases}$$

Here $l(i)$ (respectively, $l(j)$) is the index in x (respectively, y) of the leftmost leaf in the subtree rooted at the node x_i (x_j). We leave the initialization conditions for an exercise. Note that *treedist* is little more than a notational convention, since it is a special case of *forestdist*, and thus is computed essentially through the same recursion. In fact, a recursion in the above form can be applied to any pair of substrings of x and y, with obvious meaning. In the special case where both forests consist of a single tree, i.e., x_i and y_j have x_1 and y_1 as their respective leftmost leaves, then *treedist*(i, j) becomes the substitution cost $S(x_i, y_j)$.

Building the algorithm around the above recurrence, and the subtended postorder visits, brings about an important advantage: each time that *treedist* is invoked, the main ingredients for its computation (namely, the pairwaise distances of subtrees thereof) are already in place and thus need not be recomputed from scratch. We illustrate this point using $C(i, j)$, $(0 \le i \le |x|,\ 0 \le j \le |y|)$ as shorthand for *forestdist*. Observe that the recurrence above indicates that the value of $C(i, j)$ depends, in addition to the two neighboring values $C(i-1, j)$ and $C(i, j-1)$, on one generally more distant value $C(i', j')$. The pair (i', j') is called the *conjugate* of pair (i, j). The following facts are easy to check.

FACT 13.1 *Every pair (i, j) has at most one conjugate.*

FACT 13.2 *If (i, j) has conjugate (i', j'), then, for any pair (k, l) with $i' \le k \le i$ and $j' \le l \le j$ we also have $i' \le k' \le i$ and $j' \le l' \le j$.*

Figuratively, Fact 13.1 states that each pair (i, j) of C is associated with exactly one (possibly empty) submatrix of C, with upper-left corner at the conjugate (i', j') of (i, j) (inclusive) and lower right corner at $(i-1, j-1)$ (inclusive). Fact 13.2 states that the submatrices defined by two pairs and their corresponding conjugates are either nested or disjoint.

Like in the case of string editing, the "close" interdependencies among the entries of the C-matrix induce an $(|x|+1) \times (|y|+1)$ "grid directed acyclic graph" (GDAG for short). String editing can be viewed as a shortest-path problem on a GDAG. To take care also of the interdependencies by conjugacy that appear in tree editing, however, the GDAG must be augented by adding to the grid outerplanar edges connecting pairs of conjugate points.

Formally, an $l_1 \times l_2$ augmented GDAG (or AGDAG) is a directed acyclic graph whose vertices are the $l_1 l_2$ points of an $l_1 \times l_2$ grid, and such that the only edges from point (i, j) are to grid points $(i, j+1)$, $(i+1, j)$, $(i+1, j+1)$ and $(i'-1, j'-1)$, where (i, j) is the conjugate of (i', j'). We refer to Fig. 13.3

for an example. We make the convention of drawing the points such that point (i, j) is at the ith row from the top and jth column from the left. The top-left point is $(0, 0)$ and has no edge entering it (i.e., is a "source"), and the bottom-right point is (m, n) and has no edge leaving it (i.e., is a "sink").

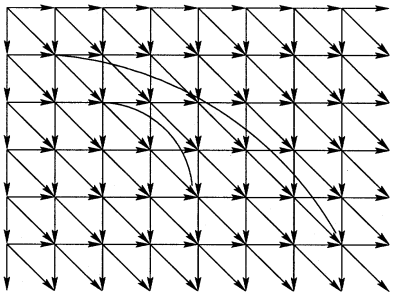

FIGURE 13.3 The upper-left corner of an AGDAG highlights the basic structure of such graphs: a grid with occasional outer-planar edges.

We associate an $(|x| + 1) \times (|y| + 1)$ AGDAG G with the tree editing problem in the natural way: the $(|x| + 1)(|y| + 1)$ vertices of G are in one-to-one correspondence with the $(|x| + 1)(|y| + 1)$ entries of the C-matrix. We draw edges connecting a point to its neighbors in the planar grid of the AGDAG, while the edge that is incident on point $(i - 1, j - 1)$ from the unique conjugate of (i, j), if the latter exists, are drawn outerplanar. Clearly, the cost of a grid edge from vertex (k, l) to vertex (i, j) is equal to $I(y_j)$ if $k = i$ and $l = j - 1$, to $D(x_i)$ if $k = i - 1$ and $l = j$, to $S(x_i, y_j)$ if $k = i - 1$ and $l = j - 1$. The cost of an outerplanar edge is the cost of the optimal solution to the submatrix associated with that edge. Thus, edit scripts that transform x into y or vice versa are in one-to-one correspondence to certain weighted paths of G that originate at the source (which corresponds to $C(0, 0)$) and end on the sink (which corresponds to $C(|x|, |y|)$). Specifically, in any such path horizontal or vertical edges can be traversed unconditionally, but the traversal of a diagonal edge from $(i - 1, j - 1)$ to (i, j) is allowed only if it follows the traversal of the outerplanar edge that is incident upon $(i - 1, j - 1)$ (if it exists). The details are left for an exercise.

13.7 Research Issues and Summary

The focus of this chapter is represented by combinatorial and algorithmic issues of searching and matching with strings and other simple structures like arrays and trees. We have reviewed the basic variants of these problems, with the notable exception of exact string searching. The latter is definitely the primeval problem in the set, and has been devoted so much study to warrant a separate chapter in the present Handbook.

We started by reviewing, in Section 13.2, string searching in the presence of don't care symbols. In Section 13.3, we considered the problem of comparing two strings for similarity, under some basic sets of edit operations. This latter problem subtends the important variants of string searching where the occurrences of the pattern need not be exact; rather, they might be corrupted by a number of mismatches, and possibly by insertions and deletions of symbols as well. We abandoned the realm of one-dimensional pattern matching in Section 13.5, in which we highlighted the comparatively less battered topics of exact searching on two-dimensional arrays. Finally, in Section 13.6, we reviewed exact and approximate searching on rooted trees.

As said at the beginning, most pattern matching issues are still subject to extensive investigation. Meanwhile, new problems and variants continue to arise in application areas that feature, in prominent position, the very information infrastructure under development. In most cases, the goal of current studies is to design better serial algorithms than those previously available. Parallel or distributed versions of the prob-

lems are also investigated. Typically, the solutions of such versions may be expected not to resemble in any significant way their serial predecessors. In fact (as exemplified by the previously encountered notion of a witness) they are more likely to expose novel combinatorial properties, some of which of intrinsic interest. Whether a problem be regarded within a serial, parallel, or distributed computational context, algorithms are also sought that display a good expected, rather than worst-case, performance. Relatively little work has been performed from this perspective, which requires often a thorough reexamination of the problem and may result in a totally new line of attack, as experienced in such classical instances as the Boyer–Moore string searching algorithm and Quicksort.

An exhausitve list of specific open problems of pattern matching would be impossible. Here we limit mention to a few important ones.

For problems of searching with don't care, string editing, longest common subsequence, and variations thereof, there are still wide and little understood gaps between the known, often trivial lower bounds and the efficiency of available algorithms. Likewise, relatively little is known in terms of nontrivial lower bounds for two-dimensional searches with mismatches, and also for both exact and approximate tree matching. Some general problems of fundamental nature remain unexplored across the entire board of pattern structures, problem variations, and computational models. Notable among these is the problem of preprocessing the "text" structure so that "patterns" presented on-line can be searched quickly thereafter. Such an approach has long been known to be elegantly and efficiently viable for exact searching on strings, but remains largely unexplored for approximate searches of all kind of patterns. The latter represent possibly the most recurrent queries in applications of molecular biology, information retrieval and other fields, so that progress in this direction would be valued enormously.

13.8 Defining Terms

Antichain: A subset of mutually incomparable elements in a partially ordered set.

Block: A sequence of don't care symbols.

Candidate consistency testing: The stage of two-dimensional matching where it is checked whether a candidate occurrence of the pattern is checked against the "witness" table.

Candidate verification: The stage of two-dimensional searching where candidate occurrences of the pattern, not ruled out previously as mutually incompatible, are actually tested.

Chain: A linearly ordered subset of a partially ordered set.

D-adjacent: An entry reachable from a $(d-1)$-extremal entry through a unit vertical, horizontal, or diagonal-mismatch step.

Divide and conquer: One of the basic paradigms of problem solving, in which the problem is decomposed (recursively) into smaller parts; solutions are then sought for the subproblems and finally combined in a solution for the whole.

Don't care: A "wildcard" symbol matching any other symbol of a given alphabet.

Edit operation: On a string, the operation of deletion, or insertion, or substitution, performed on a single symbol. On a tree T, the deletion of a node v from T followed by the reassignment of all children of v to the node of which v was formerly a child, or the insertion of a new node along some consecutive arcs departing from a same node of T, or the substitution of the label of one of the nodes of T with another label from Σ. Each edit operation has an associated nonnegative real number representing its cost.

Edit distance: For two given strings, the cost of a cheapest edit script transforming one of the strings into the other.

Edit script: A sequence of viable edit operations on a string.

Exact string searching: The algorithmic problem of finding all occurrences of a given string usually called "the pattern" in another, larger "text" string.

Extremal: Some of the entries of the auxiliary array used to perform string searching. An entry is d-extremal if it is the deepest entry on its diagonal to be given value d.

Forest: A collection of trees.

Forest editing problem: The problem of transforming one of two given forests into the other by an edit script of minimum cost.

Linear product: For two vectors X and Y, and with respect to two suitable operations $\otimes$ and $\oplus$, is a vector $Z = Z_0 Z_1 \ldots Z_{m+n}$ where $Z_k = \bigoplus_{i+j=k} X_i \bigotimes Y_j$ $(k = 0, \ldots, m+n)$.

Local alignment: The detection of local similarities among two or more strings.

Longest (or heaviest) common subsequence problem: The problem of finding a maximum-length (or maximum weight) subsequence for two or more input strings.

Lowest common ancestor: The deepest node in a tree that is an ancestor of two given leaves.

K-dominant match: A match $[i, j]$ having rank k and such that for any other pair $[i', j']$ of rank k either $i' > i$ and $j' \leq j$ or $i' \leq i$ and $j' > j$.

Match: The result of comparing two instances of a same symbol.

Minimal antichain decomposition: A decomposition of a poset into the minimum possible number of antichains.

Offset: The distance from the beginning of a string to the end of a segment in that string.

Pattern element: A positive (negative) pattern element is a "partial wildcard" presented as a subset of the alphabet Σ, with the symbols in the subset specifying which symbols of Σ are matched (mismatched) by the pattern element.

Picture: A collection of mutually disjoint subsets of an alphabet.

Poset: A set the elements of which are subject to a partial order.

Rank: For a given match, this is the number of matches in a longest chain terminating with that match, inclusive.

Segment: The substring of a pattern delimited by two don't cares or one don't care and one pattern boundary.

Sparsity: Used here to refer to LCS problem instances in which the number of matches is small compared to the product of the lengths of the input strings.

String editing problem: For input strings x and y, is the problem of finding an edit script of minimum cost that transforms y into x.

String searching with errors: Searching for approximate (e.g., up to a predefined number of symbol mismatches, insertions, and deletions) occurrences of a pattern string in a text string.

String searching with mismatches: The special case of string matching with errors where mismatches are the only type of error allowed.

Subsequence: Of a string, is any string that can be obtained by deleting zero or more symbols from that string.

Tree: A graph undirected, connected, and acyclic. In a rooted tree, a special node is selected and called the root: the nodes reachable from a node by crossing arcs in the direction away from the root are the children of that node. In unordered rooted trees, there is no pre-set order among the children of a node. Assuming such an order makes the tree ordered.

Tree editing problem: The problem of transforming one of two given trees into the other by an edit script of minimum cost.

Witness: A mismatch of two symbols of string y at a distance of d is a "witness" to the fact that in no subject y could occur twice at a distance of exactly d positions (equivalently, that d cannot be a period of y).

Acknowledgments

This work was supported in part by NSF Grants CCR-9201078 and CCR-9700276, by NATO Grant CRG 900293, by the National Research Council of Italy, by British Engineering and Physical Sciences Research Council Grant GR/L19362. Xuyan Xu contributed to Section 13.2 through bibliographic searching and drafting. The referees carried out a very careful scrutiny of the manuscript and made many helpful comments.

Further Information

Most books on design and analysis of algorithms devote one or more chapters to pattern matching. Here, we limit mention to specialized sources.

The collection of essays *Combinatorics on Words,* published in 1982 by Addison Wesley under a fictitious editorship (M. Lothaire) contains most of the basic properties used in string searching, and more. An early attempt at unified coverage of string algorithmics is found in *Combinatorial Algorithms on Words,* edited by A. Apostolico and Z. Galil in 1985 for Springer-Verlag. *Time Warps, String Edits and Macromolecules: The Theory and Practice of Sequence Comparison,* edited by D. Sankoff and J. B. Kruskal (Addison-Wesley, 1983), represents still a valuable source for sequence analysis and comparison tools in computational biology and other areas. A few more volumes of recent years are, in order of appearance: *Text Algorithms*

by M. Crochemore and W. Rytter (Oxford University Press, 1994), *String Searching Algorithms* by G.A. Stephen (World Scientific, 1994), *Pattern Matching Algorithms,* edited by A. Apostolico and Z. Galil (Oxford University Press, 1997), and *Algorithms on Strings, Trees and Sequences* by D. Gusfield (Cambridge University Press, 1997). This last volume puts particular emphasis on issues arising in computational biology. A broader treatment of this field can be found in *Introduction to Computational Biology* by M.S. Waterman (Chapman & Hall, 1995). *Data Compression, Methods and Theory* by J.A. Storer (Computer Science Press, 1988) describes applications of pattern matching to the important family of compression methods by "textual substitution."

A rich bibliography on "words, automata and algorithms" is maintained by I. Simon of the University of Saõ Paulo (Brazil). One on "sequence analysis and comparison" is maintained by William H. E. Day in Port Maitland, Canada. A collection of "pattern matching pointers" is currently maintained by S. Lonardi at http://www.cs.purdue.edu/homes/stelo/pattern.html.

Papers on the subject of pattern matching appear primarily in archival journals of theoretical computer science, but important contributions are also found in journals of application areas such as computational biology (notably, *CABIOS* and *Journal of Computational Biology*) and various specialties of computer science (cf., e.g., *IEEE Transactions* on Information Theory, Pattern Recognition, Machine Intelligence, Software, etc.). Special issues have been dedicated to pattern matching by *Algorithmica* and *Theoretical Computer Science.* Papers on the subject are presented at most major conferences. The *International Symposia on Combinatorial Pattern Matching* have gathered yearly since 1990. Beginning in 1992, proceedings have been published in the Lecture Notes in Computer Science Series of Springer-Verlag (serial numbers of volumes already published: 644, 684, 807, 937, 1075, 1264). Specifically flavored contributions appear also at conferences such as *RECOMB* (International Conference on Computational Molecular Biology), the *IEEE Annual Data Compression Conference,* the *South American Workshop on String Processing,* and others.

Average Case Analysis of Algorithms[1]

Wojciech Szpankowski
Purdue University

14.1 Introduction

An *algorithm* is a finite set of instructions for a treatment of *data* to meet some desired objectives. The most obvious reason for *analyzing* algorithms and data structures is to discover their characteristics in order to evaluate their suitability for various applications, or to compare them with other algorithms for the same application. Needless to say, we are interested in *efficient* algorithms in order to use efficiently such scarce resources as computer space and time.

Most often algorithm designs aim to optimize the asymptotic *worst case* performance, as popularized by Aho et al. [2]. Insightful, elegant, and generally useful constructions have been set up in this endeavor.

[1]This research was partially supported by NSF Grants NCR-9206315, 9415491, and CCR-9804760, and NATO Collaborative Grant CRG.950060.

Along these lines, however, the design of an algorithm is usually targeted at coping efficiently sometimes with unrealistic, even pathological inputs and the possibility is neglected that a simpler algorithm that works fast "on average" might perform just as well, or even better in practice. This alternative solution, called also a probabilistic approach, became an important issue two decades ago when it became clear that the prospects for showing the existence of polynomial time algorithms for NP-hard problems, were very dim. This fact, and the apparently high success rate of heuristic approaches to solving certain difficult problems, led Richard Karp [34] to undertake a more serious investigation of probabilistic analysis of algorithms. (But, one must realize that there are problems which are also hard "on average" as shown by Levin [42].) In the last decade we have witnessed an increasing interest in the probabilistic (also called *average case*) analysis of algorithms, possibly due to the high success rate of randomized algorithms for computational geometry, scientific visualization, molecular biology, etc. (e.g., see [46, 60]). Finally, we should point out that probabilistic analysis often depends on the input distribution which is usually unknown up front, and this might lead to unrealistic assumptions.

The *average case* analysis of algorithms can be roughly divided into two categories, namely: *analytic* in which complex analysis plays a pivotal role, and *probabilistic* in which probabilistic and combinatorial techniques dominate. The former was popularized by Knuth's monumental three volumes *The Art of Computer Programming* [39, 40, 41], whose prime goal was to accurately predict the performance characteristics of an algorithm. Such an analysis often sheds light on properties of computer programs and provides useful insights of combinatorial behaviors of such programs. Probabilistic methods were introduced by Erdös and Rényi and popularized by Alon and Spencer in their book [3]. In general, nicely structured problems are amiable to an analytic approach that usually gives much more precise information about the algorithm under consideration. On the other hand, structurally complex problems are more likely to be first solved by a probabilistic tool that later could be further enhanced by a more precise analytical approach. The average case analysis of algorithms, as a discipline, uses a number of branches of mathematics: combinatorics, probability theory, graph theory, real and complex analysis, and occasionally algebra, geometry, number theory, operations research, and so forth.

In this chapter, we choose one facet of the theory of algorithms, namely that of algorithms and data structures on words (strings) and present a brief exposition on certain analytic and probabilistic methods that have become popular. Our choice of the area stems from the fact that there has been a resurgence of interest in *string algorithms* due to several novel applications, most notably in computational molecular biology and data compression. Our choice of methods covered here is aimed at closing a gap between analytic and probabilistic methods. There are excellent books on analytic methods (cf. Knuth's three volumes [39, 40, 41], Sedgewick and Flajolet [49]) and probabilistic methods (cf. Alon and Spencer [3], Coffman and Lueker [10], and Motwani and Raghavan [46]), however, remarkably very few books have been dedicated to both analytic and probabilistic analysis of algorithms (with possible exceptions of Hofri [28] and Mahmoud [44]). Finally, before we launch our journey through probabilistic and analytic methods, we should add that in recent years several useful surveys on analysis of algorithms have been published. We mentioned here: Frieze and McDiarmid [22], Karp [35], Vitter and Flajolet [59], and Flajolet [16].

This chapter is organized as follows: In the next section we describe some algorithms and data structures on words (e.g., digital trees, suffix trees, edit distance, Lempel–Ziv data compression algorithm, etc.) that we use throughout to illustrate our ideas and methods of analysis. Then, we present probabilistic models for algorithms and data structures on words together with a short review from probability and complex analysis. Section 14.4 is devoted to probabilistic methods and discusses the sieve method, first and second moment methods, subadditive ergodic theorem, techniques of information theory (e.g., entropy and its applications), and large deviations (i.e., Chernoff's bound) and Azuma's type inequality. Finally, in the last section we concentrate on analytic techniques in which complex analysis plays a pivotal role. We shall discuss analytic techniques for recurrences and asymptotics (i.e., Rice's formula, singularity analysis, etc.), Mellin transform and its applications, and poissonization and depoissonization. In the future we plan to expand this chapter to a book.

14.2 Data Structures and Algorithms on Words

As mentioned above, in this survey we choose one facet of the theory of algorithms, namely that of data structures and algorithms on words (strings) to illustrate several probabilistic and analytic techniques of the analysis of algorithms. In this section, we briefly recall certain data structures and algorithms on words that we use throughout this chapter.

Algorithms on words have experienced a new wave of interest due to a number of novel applications in computer science, telecommunications, and biology. Undoubtly, the most popular data structures in algorithms on words are digital trees [41, 44] (e.g., tries, PATRICIA, digital search trees), and in particular suffix trees [2, 12, 54]. We discuss them briefly below, together with general *edit distance* problem [4, 9, 12, 60], and the *shortest common superstring* [7, 23, 58] problem, which recently became quite popular due to possible application to the DNA sequencing problem.

Digital Trees

We start our discussion with a brief review of **digital trees**. The most basic digital tree known as a **trie** (the name comes from re*trie*val) is defined first, and then other digital trees are described in terms of the trie.

The primary purpose of a trie is to store a set S of strings (words, keys), say $S = \{X_1, \ldots, X_n\}$. Each word $X = x_1x_2x_3\ldots$ is a finite or infinite string of symbols taken from a finite alphabet $\Sigma = \{\omega_1, \ldots, \omega_V\}$ of size $V = |\Sigma|$. A string will be stored in a leaf of the trie. The trie over S is built recursively as follows: For $|S| = 0$, the trie is, of course, empty. For $|S| = 1$, $trie(S)$ is a single node. If $|S| > 1$, S is split into V subsets $S_1, S_2, \ldots, S_V$ so that a string is in S_j if its first symbol is ω_j. The tries $trie(S_1), trie(S_2), \ldots, trie(S_V)$ are constructed in the same way except that at the kth step, the splitting of sets is based on the kth symbol. They are then connected from their respective roots to a single node to create $trie(S)$. Figure 14.1 illustrates such a construction (cf. [2, 41, 44]).

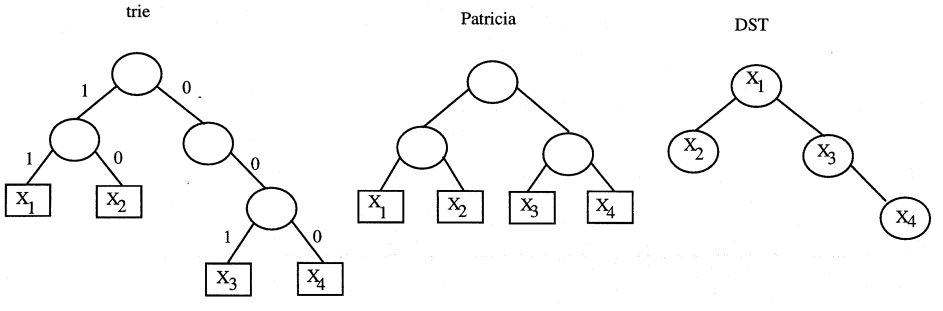

FIGURE 14.1 A trie, Patricia trie, and a digital search tree (DST) built from the following four strings $X_1 = 11100\ldots$, $X_2 = 10111\ldots$, $X_3 = 00110\ldots$, and $X_4 = 00001\ldots$.

There are many possible variations of the trie. The **PATRICIA trie** eliminates the waste of space caused by nodes having only one branch. This is done by collapsing one-way branches into a single node. In a **digital search tree** keys (strings) are directly stored in nodes, and hence, external nodes are eliminated. The branching policy is the same as in tries. Figure 14.1 illustrates these definitions (cf. [41, 44]).

The **suffix tree** and the *compact suffix tree* are similar to the trie and PATRICIA trie, but differ in the structure of the words that are being stored. In suffix trees and compact suffix trees, the words are suffixes of a given string X; that is, the word $X_j = x_jx_{j+1}x_{j+2}\ldots$ is the suffix of X which begins at the jth position of X (cf. [2]).

Certain characteristics of tries and suffix trees are of primary importance. Hereafter, we assume that a digital tree is built from n strings or a suffix tree is constructed from a string of length n. The *m-depth* $D_n(m)$ of the mth leaf in a trie is the number of internal nodes on the path from the root to the leaf. The (typical) depth of the trie D_n then, is the average depth over all its leaves, that is, $\Pr\{D_n \leq k\} = \frac{1}{n}\Sigma_{m=1}^{n}\Pr\{D_n(m) \leq k\}$. The *path length* L_n is the sum of all depths, that is, $L_n = \Sigma_{m=1}^{n} D_n(m)$. The *height* H_n of the trie is the maximum depth of a leaf in the trie and can also be defined as the length of the longest path from the root to a leaf, that is, $H_n = \max_{1\leq m\leq n}\{D_n(m)\}$. These characteristics are very useful in determining the expected size and shape of the data structures involved in algorithms on words. We study some of them in this chapter.

String Editing Problem

The string editing problem arises in many applications, notably in text editing, speech recognition, machine vision and, last but not least, molecular sequence comparison (cf. [60]). Algorithmic aspects of this problem have been studied rather extensively in the past. In fact, many important problems on words are special cases of string editing, including the *longest common subsequence* problem (cf. [9, 12]) and the problem of *approximate pattern matching* (cf. [12]). In the following, we review the string editing problem and its relationship to the longest path problem in a special grid graph.

Let Y be a string consisting of ℓ symbols on some alphabet Σ of size V. There are three operations that can be performed on a string, namely *deletion* of a symbol, *insertion* of a symbol, and *substitution* of one symbol for another symbol in Σ. With each operation is associated a *weight* function. We denote by $W_I(y_i)$, $W_D(y_i)$, and $W_Q(x_i, y_j)$ the weight of insertion and deletion of the symbol $y_i \in \Sigma$, and substitution of x_i by $y_j \in \Sigma$, respectively. An *edit script* on Y is any sequence of edit operations, and the total weight of it is the sum of weights of the edit operations.

The **string editing** problem deals with two strings, say Y of length ℓ (for ℓong) and X of length s (for $s$hort), and consists of finding an edit script of minimum (maximum) total weight that transforms X into Y. The maximum (minimum) weight is called the *edit distance from X to Y*, and its is also known as the Levenshtein distance. In molecular biology, the Levenshtein distance is used to measure similarity (homogeneity) of two molecular sequences, say DNA sequences (cf. [60]).

The string edit problem can be solved by the standard dynamic programming method. Let $C_{\max}(i, j)$ denote the maximum weight of transforming the prefix of Y of size i into the prefix of X of size j. Then

$$\begin{aligned} C_{\max}(i, j) \quad = \quad & \max\left\{C_{\max}(i-1, j-1) + W_Q\left(x_i, y_j\right), C_{\max}(i-1, j)\right. \\ & \left. + W_D\left(x_i\right), C_{\max}(i, j-1) + W_I\left(y_j\right)\right\} \end{aligned}$$

for all $1 \leq i \leq \ell$ and $1 \leq j \leq s$. We compute $C_{\max}(i, j)$ row by row to obtain finally the total cost $C_{\max} = C_{\max}(\ell, s)$ of the maximum edit script.

The key observation for us is to note that interdependency among the partial optimal weights $C_{\max}(i, j)$ induce an $\ell \times s$ grid-like directed acyclic graph, called further a *grid graph.* In such a graph vertices are points in the grid and edges go only from (i, j) point to neighboring points, namely $(i, j+1)$, $(i+1, j)$ and $(i+1, j+1)$. A horizontal edge from $(i-1, j)$ to (i, j) carries the weight $W_I(y_j)$; a vertical edge from $(i, j-1)$ to (i, j) has weight $W_D(x_i)$; and a diagonal edge from $(i-1, j-1)$ to (i, j) has weight $W_Q(x_i, y_j)$. Figure 14.2 shows an example of such an edit graph. The edit distance is the longest (shortest) path from the point $O = (0, 0)$ to $E = (\ell, s)$.

Shortest Common Superstring

Various versions of the **shortest common superstring** (in short: SCS) problem play important roles in data compression and DNA sequencing. In fact, in laboratories DNA sequencing (cf. [60]) is routinely done by sequencing large numbers of relatively short fragments, and then heuristically finding a short common

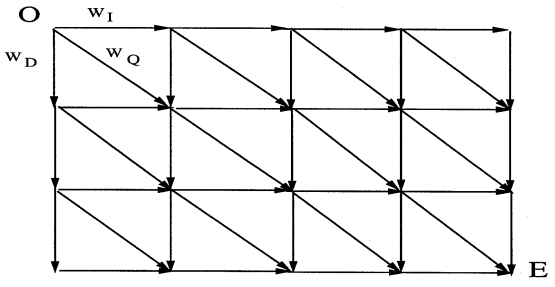

FIGURE 14.2 Example of a grid graph of size $\ell = 4$ and $s = 3$.

superstring. The problem can be formulated as follows: given a collection of strings, say $X_1, X_2, \ldots, X_n$ over an alphabet Σ, find the shortest string Z such that each of X_i appears as a substring (a consecutive block) of Z.

It is known that computing the shortest common superstring is NP-hard. Thus, constructing a good approximation to SCS is of prime interest. It has been shown recently, that a greedy algorithm can compute in $O(n \log n)$ time a superstring that in the worst case is only β times (where $2 \leq \beta \leq 4$) longer than the shortest common superstring [7, 58]. Often, one is interested in maximizing total overlap of SCS using a greedy heuristic and to show that such a heuristic produces an overlap O_n^{gr} that approximates well the optimal overlap O_n^{opt} where n is the number of strings.

More precisely, suppose $X = x_1 x_2 \ldots x_r$ and $Y = y_1 y_2 \ldots y_s$ are strings over the same finite alphabet Σ. We also write $|X|$ for the length of X. We define their *overlap* $o(X, Y)$ by

$$o(X, Y) = \max \left\{ j : \; y_i = x_{r-i+1}, \; 1 \leq i \leq j \right\} .$$

Let $\mathcal{S}$ be a set of all superstrings built over the strings $X_1, \ldots, X_n$. Then

$$O_n^{\text{opt}} = \sum_{i=1}^{n} |X_i| - \min_{Z \in \mathcal{S}} |Z|$$

represents the optimal overlap over $\mathcal{S}$.

14.3 Probabilistic Models

In this section, we first discuss a few probabilistic models of randomly generated strings. Then, we briefly review some basic facts from probability theory (e.g., types of stochastic convergence), and finally we provide some elements of complex analysis that we shall use in this chapter.

Probabilistic Models of Strings

As expected, random shape of data structures on words depends on the underlying probabilistic assumptions concerning the strings involved. Below, we discuss a few basic probabilistic models that one often encounters in the analysis of problems on words.

We start with the most elementary model, namely the **Bernoulli model** that is defined as follows:

(B) BERNOULLI MODEL
Symbols of the alphabet $\Sigma = \{\omega_1, \ldots, \omega_V\}$ occur independently of one another; and $\mathsf{Pr}\{x_j = \omega_i\} = p_i$ with $\Sigma_{i=1}^{V} p_i = 1$. If $p_1 = p_2 = \ldots = p_V = 1/V$, then the model is called *symmetric;* otherwise, it is *asymmetric.* Throughout the paper we only consider *binary alphabet* $\Sigma = \{0, 1\}$ with $p := p_1$ and $q := p_2 = 1 - p$.

In many cases, assumption (B) is not very realistic. For instance, if the strings are words from the English language, then there certainly is a dependence among the symbols of the alphabet. As an example, h is much more likely to follow an s than a b. When this is the case, assumption (B) can be replaced by

(M) MARKOVIAN MODEL
There is a Markovian dependency between consecutive symbols in a key; that is, the probability $p_{ij} = \Pr\{X_{k+1} = \omega_j | X_k = \omega_i\}$ describes the conditional probability of sampling symbol ω_j immediately after symbol ω_i.

There is another generalization of the Markovian model, namely the *mixing model,* which is very useful in practice, especially when dealing with problems of data compression or molecular biology when one expects long dependency among symbols of a string.

(MX) MIXING MODEL
Let $\mathcal{F}_m^n$ be a σ-field generated by $\{X_k\}_{k=m}^n$ for $m \leq n$. There exists a function $\alpha(\cdot)$ of g such that: (i) $\lim_{g\to\infty} \alpha(g) = 0$, (ii) $\alpha(1) < 1$, and (iii) for any m, and two events $A \in \mathcal{F}_{-\infty}^m$ and $B \in \mathcal{F}_{m+g}^{\infty}$ the following holds;

$$(1 - \alpha(g))\Pr\{A\}\Pr\{B\} \leq \Pr\{AB\} \leq (1 + \alpha(g))\Pr\{A\}\Pr\{B\} .$$

In words, model (MX) says that the dependency between $\{X_k\}_{k=1}^m$ and $\{X_k\}_{k=m+g}^{\infty}$ is getting weaker and weaker as g becomes larger (note that when the sequence $\{X_k\}$ is i.i.d., then $\Pr\{AB\} = \Pr\{A\}\Pr\{B\}$). The "quantity" of dependency is characterized by $\alpha(g)$ (cf. [8]).

Quick Review from Probability: Types of Stochastic Convergence

We begin with some elementary definitions from probability theory. The reader is referred to [14, 15] for more detailed discussions. Let the random variable X_n denote the value of a parameter of interest depending on n (e.g., depth in a suffix tree and/or trie built over n strings). The expected value $\mathbf{E}[X_n]$ or mean and the variance $\mathbf{Var}[X_n]$ can be computed as $\mathbf{E}[X_n] = \Sigma_{k=0}^{\infty} k\Pr\{X_n = k\}$ and $\mathbf{Var}[X_n] = \Sigma_{k=0}^{\infty}(k - \mathbf{E}[X_n])^2\Pr\{X_n = k\}$.

Convergence of Random Variables

It is important to note the different ways in which random variables are said to converge. To examine the different methods of convergence, let X_n be a sequence of random variables, and let their distribution functions be $F_n(x)$, respectively.

The first notion of convergence of a sequence of random variables is known as **convergence in probability**. The sequence X_n converges to a random variable X *in probability,* denoted $X_n \to X$ (pr.) or $X_n \xrightarrow{p} X$, if for any $\epsilon > 0$,

$$\lim_{n\to\infty} \Pr\{|X_n - X| < \epsilon\} = 1 .$$

Note that this does not say that the difference between X_n and X becomes very small. What converges here is the *probability* that the difference between X_n and X becomes very small. It is, therefore, possible, although unlikely, for X_n and X to differ by a significant amount and for such differences to occur infinitely often.

A stronger kind of convergence that does not allow such behavior is called **almost sure convergence** or **strong convergence**. A sequence of random variables X_n converges to a random variable X *almost surely,* denoted $X_n \to X$ (a.s.) or $X_n \xrightarrow{(a.s.)} X$, if for any $\epsilon > 0$,

$$\lim_{N\to\infty} \Pr\left\{\sup_{n\geq N} |X_n - X| < \epsilon\right\} = 1 .$$

From this formulation of almost sure convergence, it is clear that if $X_n \to X$ (a.s.), the probability of infinitely many large differences between X_n and X is zero. The sequence X_n in this case is said to satisfy the strong law of large numbers. As the term strong implies, almost sure convergence implies convergence in probability.

A simple criterion for almost sure convergence can be inferred from the *Borel–Cantelli lemma.* We give it in the following corollary.

LEMMA 14.1 **(Borel–Cantelli)** Let $\epsilon > 0$. If $\Sigma_{n=0}^{\infty} \mathsf{Pr}\{|X_n - X| > \epsilon\} < \infty$, then $X_n \to X$ (a.s.).

PROOF It follows directly from the following chain of inequalities (the reader is referred to "Sieve Methods and Its Variations" for more explanations on these inequalities):

$$\mathsf{Pr}\left\{\sup_{n\geq N} |X_n - X| \geq \epsilon\right\} = \mathsf{Pr}\left\{\bigcup_{n\geq N} (|X_n - X| \geq \epsilon)\right\} \leq \sum_{n\geq N} \mathsf{Pr}\{|X_n - X| \geq \epsilon\} \to 0 .$$

The last convergence is a consequence of our assumption that $\Sigma_{n=0}^{\infty} \mathsf{Pr}\{|X_n - X| > \epsilon\} < \infty$.

A third type of convergence is defined on the distribution functions $F_n(x)$. The sequence of random variables X_n **converges in distribution** or **converges in law** to the random variable X, denoted $X_n \xrightarrow{d} X$, if $\lim_{n\to\infty} F_n(x) = F(x)$ for each point of continuity of $F(x)$. Almost sure convergence implies convergence in distribution.

Finally, the convergence *in mean of order p* implies that $\mathbf{E}[|X_n - X|^p] \to 0$ as $n \to \infty$, and convergence *in moments* requires $\mathbf{E}[X_n^p] \to \mathbf{E}[X^p]$ for any p as $n \to \infty$. It is well known that almost sure convergence and convergence in mean imply the convergence in probability. On the other hand, the convergence in probability leads to the convergence in distribution. If the limiting random variable X is a constant, then the convergence in distribution also implies the convergence in probability (cf. [14]).

Generating Functions

The distribution of a random variable can also be described using generating functions. The *ordinary generating function* $G_n(u)$, and a bivariate *exponential generating function* $g(z, u)$ are defined as

$$G_n(u) = \mathbf{E}\left[u^{X_n}\right] = \sum_{k=0}^{\infty} \mathsf{Pr}\{X_n = k\}\, u^k$$

and $g(z, u) = \Sigma_{n=0}^{\infty} G_n(u) \frac{z^n}{n!}$, respectively. These functions are well-defined for any complex numbers z and u such that $|u| < 1$. Observe that

$$\begin{aligned} \mathbf{E}[X_n] &= G_n'(1) , \\ \mathbf{Var}[X_n] &= G_n''(1) + G_n'(1) - \left[G_n'(1)\right]^2 . \end{aligned}$$

Levy's Continuity Theorem

Our next step is to relate convergence in distribution to convergence of generating functions. The following results, known as *Levy's continuity theorem* is an archi-fact for most distributional analysis. For our purpose we formulate it in terms of the Laplace transform of X_n, namely $G_n(e^{-t}) = \mathbf{E}[e^{-tX_n}]$ for real t (cf. [14]).

THEOREM 14.1 **(Continuity Theorem)** *Let X_n and X be random variables with Laplace transforms*

$G_n(e^{-t})$ and $G(e^{-t})$, respectively. A necessary and sufficient condition for $X_n \xrightarrow{d} X$ is that $G_n(e^{-t}) \to G(e^{-t})$ for all $t \geq 0$.

The above theorem holds if we set $t = i\nu$ for $-\infty < \nu < \infty$ (i.e., we consider characteristic functions). Moreover, if the above holds for t complex number, then we automatically derive convergence in moments due to the fact that an analytical function possesses all its derivatives.

Finally, in order to establish central limit theorem (i.e., convergence to a normal distribution) a theorem by Goncharov (cf. [39], Chap 1.2.10, Ex. 13) is useful (it follows directly from the Continuity Theorem). This theorem states that a sequence of random variables X_n with mean $\mathbf{E}[X_n] = \mu_n$ and standard deviation $\sigma_n = \sqrt{\mathbf{Var}[X_n]}$ approaches a normal distribution if the following holds:

$$\lim_{n\to\infty} e^{-\tau\mu_n/\sigma_n} G_n\left(e^{\tau/\sigma_n}\right) = e^{\tau^2/2}$$

for all $\tau = i\nu$ and $-\infty < \nu < \infty$, and X_n converges in moments if τ is a complex number.

Review from Complex Analysis

Much of the necessary complex analysis involves the use of Cauchy's integral formula and Cauchy's residue theorem. We briefly recall a few facts from analytic functions, and then discuss the above two theorems. For precise definitions and formulations the reader is referred to [27]. We shall follow here Flajolet and Sedgewick [21].

A function $f(z)$ of complex variable z is analytic at point $z = a$ if it is differentiable in a neighborhood of $z = a$ or equivalently it has a convergent series representation around $z = a$. Let us concentrate our discussion only on *meromorphic functions* that are analytical with an exception of a finite number of points called poles. More formally, a meromorphic function $f(z)$ can be represented in a neighborhood of $z = a$ with $z \neq a$ by Laurent series as follows: $f(z) = \Sigma_{n\geq -M} f_n (z-a)^n$ for some integer M. If the above holds with $f_{-M} \neq 0$, then it is said that $f(z)$ has a *pole* of order M at $z = a$. **Cauchy's Integral Theorem** states that for any analytical function $f(z)$,

$$f_n := \left[z^n\right] f(z) = \frac{1}{2\pi i} \oint f(z) \frac{dz}{z^{n+1}} ,$$

and the circle is traversed counterclockwise, where throughout the chapter we write $[z^n]f(z)$ for the coefficient of $f(z)$ at z^n.

An important tool frequently used in the analytic analysis of algorithms is *residue theory.* The residue of $f(z)$ at a point a is the coefficient of $(z-a)^{-1}$ in the expansion of $f(z)$ around a, and it is denoted as $\mathrm{Res}[f(z);\ z = a] = f_{-1}$. There are many simple rules to evaluate residues and the reader can find them in any standard book on complex analysis (e.g., [27]). Actually, the easiest way to compute a residue of a function is to use the `series` commend in MAPLE that produces a series development of a function. The residue is simply the coefficient at $(z-a)^{-1}$. For example, the following session of MAPLE computes series of $f(z) = \Gamma(z)/(1-2^z)$ at $z = 0$ where $\Gamma(z)$ is the Euler gamma function [1]:

```
series(GAMMA(z)/(1-2^z), z=0, 4);
```

$$-\frac{1}{\ln(2)} z^{-2} - \frac{-\gamma - \frac{1}{2}\ln(2)}{\ln(2)} z^{-1} - \frac{-\frac{1}{6}\ln(2)^2 + \frac{1}{12}\pi^2 + \frac{1}{2}\gamma^2 + \frac{1}{4}(2\gamma + \ln(2))\ln(2)}{\ln(2)} + \mathrm{O}(z)$$

From the above we see that $\text{Res}[f(z);\ z=0] = \frac{\gamma}{\log 2} + \frac{1}{2}$.

Residues are very important in evaluating contour integrals. In fact, a well-known theorem in complex analysis, that is, **Cauchy's residue theorem** states that if $f(z)$ is analytic within and on the boundary of C except at a finite number of poles $a_1, a_2, \ldots, a_N$ inside of C having residues $\text{Res}[f(z);\ z = a_1], \ldots, \text{Res}[f(z);\ z = a_N]$, then

$$\oint f(z)dz = 2\pi i \sum_{j=1}^{N} \text{Res}\left[f(z);\ z = a_j\right] ,$$

where the circle is traversed counterclockwise.

14.4 Probabilistic Techniques

In this section we discuss several probabilistic techniques that have been successfully applied to the average case analysis of algorithms. We start with some elementary **inclusion–exclusion** principle known also as **sieve methods**. Then, we present very useful **first** and **second moment methods**. We continue with the **subadditive ergodic theorem** that is quite popular for deducing certain properties of problems on words. Next, we turn our attention to some probabilistic methods of information theory, and in particular we discuss **entropy** and **asymptotic equipartition property**. Finally, we look at some **large deviations** results and **Azuma's type inequality**. In this section, as well in the next one where analytic techniques are discussed, we adopt the following scheme of presentation: First, we describe the method and give a short intuitive derivation. Then, we illustrate it on some nontrivial examples taken from the problems on words discussed in Section 14.2.

Sieve Method and Its Variations

The *inclusion–exclusion principle* is one of the oldest tools in combinatorics, number theory (where this principle is known as *sieve method*), discrete mathematics, and probabilistic analysis. It provides a tool to estimate probability of a union of *not* disjoint events, say $\bigcup_{i=1}^{n} A_i$ where A_i are events for $i = 1, \ldots, n$. Before we plunge into our discussion, let us first show a few examples of problems on words for which an estimation of the probability of a union of events is required.

EXAMPLE 14.1: Depth and Height in a Trie

In "Digital Trees" we discussed tries built over n binary strings $X_1, \ldots, X_n$. We assume that those strings are generated according to the Bernoulli model with one symbol, say "0," occurring with probability p and the other, say "1," with probability $q = 1 - p$. Let C_{ij}, known as *alignment* between ith and jth strings, be defined as the length of the longest string that is a prefix of X_i and X_j. Then, it is easy to see that the mth depth $D_n(m)$ (i.e., length of a path in trie from the root to the external node containing X_m), and the height H_n (i.e., the length of the longest path in a trie) can be expressed as follows:

$$D_n(m) = \max_{1 \le i \ne m \le n} \left\{C_{i,m}\right\} + 1 , \tag{14.1}$$

$$H_n = \max_{1 \le i < j \le n} \left\{C_{ij}\right\} + 1 . \tag{14.2}$$

Certainly, the alignments C_{ij} are dependent random variables even for the Bernoulli model. The above equations expressed the depth and the height as an *order statistic* (i.e., maximum of the sequence $C_{i,j}$ for $i, j = 1, \ldots, n$). We can estimate some probabilities associated with the depth and the height as a union

of properly defined events. Indeed, let $A_{ij} = \{C_{ij} > k\}$ for some k. Then, one finds

$$\mathsf{Pr}\{D_n(m) > k\} = \mathsf{Pr}\left\{\bigcup_{i=1,\neq m}^{n} A_{i,m}\right\}, \tag{14.3}$$

$$\mathsf{Pr}\{H_n > k\} = \mathsf{Pr}\left\{\bigcup_{i\neq j=1}^{n} A_{i,j}\right\}. \tag{14.4}$$

In passing, we should point out that for the shortest common superstring problem (cf. "Shortest Common Superstring") we need to estimate a quantity $M_n(m)$ which is similar to $D_n(m)$ except that C_{im} is defined as the length of the longest string that is a prefix of X_i and suffix of X_m for fixed m. One easily observes that $M_n(m) \stackrel{d}{=} D_n(m)$, that is, these two quantities are equal *in distribution.*

We have just seen that often we need to estimate a probability of union of events. The following formula is known as *inclusion–exclusion formula* (cf. [6])

$$\mathsf{Pr}\left\{\bigcup_{i=1}^{n} A_i\right\} = \sum_{r=1}^{n}(-1)^{r+1}\sum_{|J|=r}\mathsf{Pr}\left\{\bigcap_{j\in J} A_j\right\}. \tag{14.5}$$

The next example illustrates it on the depth on a trie.

EXAMPLE 14.2: Generating Function of the Depth in a Trie

Let us compute the generating function of the depth $D_n := D_n(1)$ for the first string X_1. We start with (14.3), and after some easy algebraic manipulation, (14.5) leads to (cf. [31])

$$\mathsf{Pr}\{D_n > k\} = \mathsf{Pr}\left\{\bigcup_{i=2}^{n}\left[C_{i,1} \geq k\right]\right\} = \sum_{r=1}^{n-1}(-1)^{r+1}\binom{n-1}{r}\mathsf{Pr}\left\{C_{2,1} \geq k, \ldots, C_{r+1,1} \geq k\right\};$$

since the probability $\mathsf{Pr}\{C_{2,1} \geq k, \ldots, C_{r+1,1} \geq k\}$ does not depend on the choice of strings (i.e., it is the same for any r-tuple of strings selected). Moreover, it can be easily explicitly computed. Indeed, we obtain $\mathsf{Pr}\{C_{2,1} \geq k, \ldots, C_{r+1,1} \geq k\} = (p^{r+1} + q^{r+1})^k$, since r independent binary strings must agree on the first k symbols (we recall that p stands for the probability a symbol, say "0," occurrence and $q = 1 - p$). Thus, the generating function $D_n(u) = \mathbf{E}[u^{D_n}] = \Sigma_{k\geq 0}\mathsf{Pr}\{D_n = k\}u^k$ becomes

$$\mathbf{E}\left[u^{D_n}\right] = 1 + \sum_{r=1}^{n-1}(-1)^{r+1}\binom{n-1}{r}\frac{1-u}{1-u\left(p^{r+1}+q^{r+1}\right)}$$

The last formula is a simple consequence of the above, and the following well known fact from the theory of generating function $\mathbf{E}[u^X]$ for a random variable X:

$$\mathbf{E}\left[u^X\right] = \frac{1}{1-u}\sum_{k=0}^{\infty}\mathsf{Pr}\{X \leq k\}\,u^k$$

for $|u| < 1$.

In many real computations, however, one cannot explicitly compute the probability of the events union. Often, one must retreat to inequalities that actually are enough to reach one's goal. The most simple yet still very powerful is the following inequality

$$\mathsf{Pr}\left\{\bigcup_{i=1}^{n} A_i\right\} \leq \sum_{i=1}^{n}\mathsf{Pr}\{A_i\}. \tag{14.6}$$

The latter is an example of a series of inequalities due to Bonferroni which can be formulated as follows: For every even integer $m \geq 0$ we have

$$\begin{aligned}\sum_{j=1}^{m}(-1)^{j-1}\sum_{1\leq t_1<\cdots<t_j\leq n} & \quad \mathsf{Pr}\left\{A_{t_1}\cap\cdots\cap A_{t_j}\right\}\\ &\leq \mathsf{Pr}\left\{\bigcup_{i=1}^{n}A_i\right\}\\ &\leq \sum_{j=1}^{m+1}(-1)^{j-1}\sum_{1\leq t_1<\cdots<t_j\leq n}\mathsf{Pr}\left\{A_{t_1}\cap\cdots\cap A_{t_j}\right\}\ .\end{aligned}$$

In combinatorics (e.g., enumeration problems) and probability the so called *inclusion–exclusion principle* is very popular and had many successes. We formulate it in a form of a theorem whose proof can be found in Bollobás [6].

THEOREM 14.2 **(Inclusion–Exclusion Principle)** *Let $A_1, \ldots, A_n$ be events in a probability space, and let p_k be the probability of exactly k of them to occur. Then:*

$$p_k = \sum_{r=k}^{n}(-1)^{r+k}\binom{r}{k}\sum_{|J|=r}\mathsf{Pr}\left\{\bigcap_{j\in J}A_j\right\}\ .$$

EXAMPLE 14.3: Computing a Distribution Through Its Moments (cf.[6])

Let X be a random variable defined on $\{0, 1, \ldots, n\}$, and let $\mathbf{E}_r[X] = \mathbf{E}X(X-1)\cdots(X-r+1)$ be the rth factorial moment of X. Then

$$\mathsf{Pr}\{X=k\} = \frac{1}{k!}\sum_{r=k}^{n}(-1)^{r+k}\frac{\mathbf{E}_r[X]}{(r-k)!}\ .$$

Indeed, it suffices to set $A_i = \{X \geq i\}$ for all $i = 1, \ldots, n$, and observe that $\Sigma_{|J|=r}\mathsf{Pr}\{\bigcap_{j\in J}A_j\} = \mathbf{E}_r[X]/r!$. Since the event $\{X = k\}$ is equivalent to the event that exactly k of A_i occur, a simple application of Theorem 14.2 proves the announced result.

Inequalities: First and Second Moment Methods

In this subsection, we review some inequalities that play a considerable role in probabilistic analysis of algorithms. In particular, we discuss *first* and *second moment methods.*

We start with a few standard inequalities (cf. [14]):

Markov Inequality: For a nonnegative random variable X and $\varepsilon > 0$ the following holds:

$$\mathsf{Pr}\{X \geq \varepsilon\} \leq \frac{\mathbf{E}[X]}{\varepsilon}\ .$$

Indeed: let $I(A)$ be the indicator function of A (i.e., $I(A) = 1$ if A occurs, and zero otherwise). Then,

$$\mathbf{E}[X] \geq \mathbf{E}\left[XI\left(X \geq \varepsilon\right)\right] \geq \varepsilon\mathbf{E}\left[I\left(X \geq \varepsilon\right)\right] = \varepsilon\mathsf{Pr}\left\{X \geq \varepsilon\right\}\ .$$

Chebyshev's Inequality: If one replaces X by $|X - \mathbf{E}[X]|$ in the Markov inequality, then

$$\mathsf{Pr}\{|X - \mathbf{E}[X]| > \varepsilon\} \leq \frac{\mathbf{Var}[X]}{\varepsilon^2}\ .$$

Schwarz's Inequality (also called Cauchy–Schwarz): Let X and Y be such that $\mathbf{E}[X^2] < \infty$ and $\mathbf{E}[Y^2] < \infty$. Then

$$\mathbf{E}[|XY|]^2 \leq \mathbf{E}[X^2]\mathbf{E}[Y^2] ,$$

where $\mathbf{E}[X]^2 := (\mathbf{E}[X])^2$.

Jensen's Inequality: Let $f(\cdot)$ be a downward convex function, that is, for $\lambda \in (0, 1)$ we have $\lambda f(x) + (1 - \lambda) f(y) \geq f(\lambda x + (1 - \lambda)y)$. Then

$$f(\mathbf{E}[X]) \leq \mathbf{E}[f(X)] .$$

The remainder part of this subsection is devoted to the first and the second moment methods that we illustrate on several examples arising in the analysis of digital trees. The *first moment method* for a nonnegative random variable X states that

$$\mathsf{Pr}\{X > 0\} \leq \mathbf{E}[X] . \tag{14.7}$$

This follows directly from Markov's inequality after setting $\varepsilon = 1$. The above inequality implies also the basic Bonferroni inequality (14.6). Indeed, let A_i $(i = 1, \ldots, n)$ be events, and set $X = I(A_1) + \cdots + I(A_n)$. Inequality (14.6) follows.

In a typical application of (14.7), we expect to show that $\mathbf{E}[X] \to 0$, just $X = 0$ occurs almost always or *with high probability* (whp). We illustrate it in the next example.

EXAMPLE 14.4: Upper Bound on the Height in a Trie

In Example 14.1 we showed that the height H_n of a trie is given by (14.2) or (14.4). Thus, using the first moment method we have

$$\mathsf{Pr}\{H_n \geq k + 1\} \leq \mathsf{Pr}\left\{ \max_{1 \leq i < j \leq n} \{C_{ij}\} \geq k \right\} \leq n^2 \mathsf{Pr}\{C_{ij} \geq k\}$$

for any integer k. From Example 14.2 we know that $\mathsf{Pr}\{C_{ij} \geq k\} = (p^2 + q^2)^k$. Let $P = p^2 + q^2$, $Q = P^{-1}$, and set $k = 2(1 + \varepsilon) \log_Q n$ for any $\varepsilon > 0$. Then, the above implies

$$\mathsf{Pr}\left\{ H_n \geq 2(1 + \varepsilon) \log_Q n + 1 \right\} \leq \frac{n^2}{n^{2(1+\varepsilon)}} = \frac{1}{n^{2\varepsilon}} \to 0 ,$$

thus, $H_n/(2 \log_Q n) \leq 1$ (pr.). Below, in Example 14.5, we will actually prove that $H_n/(2 \log_Q n) = 1$ (pr.) by establishing a matching lower bound.

Let us look now at the *second moment method.* Setting in the Chebyshev inequality $\varepsilon = \mathbf{E}[X]$ we prove that

$$\mathsf{Pr}\{X = 0\} \leq \frac{\mathbf{Var}[X]}{\mathbf{E}[X]^2} .$$

But, one can do better (cf. [3, 10]). Using Schwarz's inequality for a random variable X we obtain the following chain of inequalities

$$\mathbf{E}[X]^2 = \mathbf{E}[I(X \neq 0)X]^2 \leq \mathbf{E}[I(X \neq 0)]\mathbf{E}\left[X^2\right] = \mathsf{Pr}\{I(X \neq 0)\}\mathbf{E}\left[X^2\right] ,$$

which finally implies the second moment inequality

$$\mathsf{Pr}\{X > 0\} \geq \frac{\mathbf{E}[X]^2}{\mathbf{E}[X^2]} . \tag{14.8}$$

Actually, another formulation of this inequality due to Chung and Erdös is quite popular. To derive it, set in (14.8) $X = I(A_1) + \cdots + I(A_n)$ for a sequence of events $A_1, \ldots, A_n$. Noting that $\{X > 0\} = \bigcup_{i=1}^{n} A_i$, we obtain from (14.8) after some algebra

$$\mathsf{Pr}\left\{\bigcup_{i=1}^{n} A_i\right\} \geq \frac{\left(\sum_{i=1}^{n} \mathsf{Pr}\{A_i\}\right)^2}{\sum_{i=1}^{n} \mathsf{Pr}\{A_i\} + \sum_{i \neq j} \mathsf{Pr}\left\{A_i \cap A_j\right\}} \,. \tag{14.9}$$

In a typical application, if we are able to prove that $\mathbf{Var}[X]/\mathbf{E}[X^2] \to 0$, then we can show that $\{X > 0\}$ almost always. The next example — which is a continuation of Example 14.4 — illustrates this point.

EXAMPLE 14.5: Lower Bound for the Height in a Trie

We now prove that $\mathsf{Pr}\{H_n \geq 2(1-\varepsilon)\log_Q n\} \to 1$ for any $\varepsilon > 0$, just completing the proof that $H_n/(2\log_Q n) \to 1$ (pr.). We use the Chung–Erdös formulation, and set $A_{ij} = \{C_{ij} \geq k\}$. Throughout this example, we assume $k = 2(1-\varepsilon)\log_Q n$. Observe that now in (14.9) we must replace the single summation index i by a double summation index (i, j). The following is obvious: $\Sigma_{1 \leq i < j \leq n} \mathsf{Pr}\{A_{ij}\} = \frac{1}{2} n(n-1) P^k$, where $P = p^2 + q^2$. The other sum in (14.9) is a little harder to deal with. We must sum over (i, j), (l, m), and we consider two cases: (i) all indices are different, (ii) $i = l$ (i.e., we have (i, j), (i, m)). In the second case we must consider the probability $\mathsf{Pr}\{C_{ij} \geq k, C_{i,m} \geq k\}$. But, as in Example 14.2, we obtain $\mathsf{Pr}\{C_{ij} \geq k, C_{i,m} \geq k\} = (p^3 + q^3)^k$ since once you choose a symbol in the string X_i you must have the same symbol at the same position in X_j, X_m. In summary,

$$\sum_{(ij),(l,m)} \mathsf{Pr}\left\{C_{ij} \geq k,\ C_{lm} \geq k\right\} \leq \frac{1}{4} n^4 P^{2k} + n^3 \left(p^3 + q^3\right)^k \,.$$

To complete the derivation, it suffices to observe that

$$\left(p^3 + q^3\right)^{\frac{1}{3}} \leq P^{\frac{1}{2}} \,.$$

which is easy to prove by elementary methods (cf. [60]). Then, (14.9) becomes

$$\begin{aligned} \mathsf{Pr}\{H_n \geq k+1\} = \mathsf{Pr}\left\{\bigcup_{i=1}^{n} A_i\right\} &\geq \frac{1}{n^{-2} P^{-k} + 1 + 4\left(p^3 + q^3\right)^k / \left(n P^{2k}\right)} \\ &\geq \frac{1}{1 + n^{-2\varepsilon} + 4/\left(n P^{k/2}\right)} \geq \frac{1}{1 + n^{-2\varepsilon} + 4n^{-\varepsilon}} \to 1 \,. \end{aligned}$$

Thus, we have shown that $H_n/(2\log_Q n) \geq 1$ (pr.), which completes our proof of

$$\lim_{n \to \infty} \mathsf{Pr}\left\{2(1-\varepsilon)\log_Q n \leq H_n \leq 2(1+\varepsilon)\log_Q n\right\} = 1$$

for any $\varepsilon > 0$.

Subadditive Ergodic Theorem

The celebrated *ergodic theorem* of Birkhoff [15] found many useful applications in computer science. It is used habitually during a computer simulation run or whenever one must perform experiments and collect data. However, for probabilistic analysis of algorithms a generalization of this result due to Kingman [36] is more important. We briefly review it here and illustrate on a few examples.

Let us start with the following well known fact attributed to Fekete (cf. [50]). Assume a (deterministic) sequence $\{x_n\}_{n=0}^{\infty}$ satisfies the so called *subadditivity property,* that is,

$$x_{m+n} \le x_n + x_m$$

for all integers $m, n \ge 0$. It is easy to see that then (cf. [14])

$$\lim_{n\to\infty} \frac{x_n}{n} = \inf_{m\ge 1} \frac{x_m}{m} = \alpha$$

for some $\alpha \in [-\infty, \infty)$. Indeed, fix $m \ge 0$, write $n = km + l$ for some $0 \le l \le m$, and observe that by the above subadditivity property

$$x_n \le k x_m + x_l \ .$$

Taking $n \to \infty$ with $n/k \to m$ we finally arrive at $\limsup_{n\to\infty} \frac{x_n}{n} \le \inf_{m\ge 1} \frac{x_m}{m} \le \alpha$ where the last inequality follows from arbitrariness of m. This completes the derivation since $\liminf_{n\to\infty} \frac{x_n}{n} \ge \alpha$ is automatic. One can also see that replacing "$\le$" in the subadditivity property by "$\ge$" (thus, *superadditivity property*) will not change our conclusion except that $\inf_{m\ge 1} \frac{x_m}{m}$ should be replaced by $\sup_{m\ge 1} \frac{x_m}{m}$.

In the early 1970s people started asking whether the above deterministic subadditivity result could be extended to a sequence of random variables. Such an extension would have an impact on many research problems of those days. For example, Chvatal and Sankoff [9] used ingenious tricks to establish the probabilistic behavior of the *Longest Common Subsequence* problem (cf. "String Editing Problem" and below) while we show below that it is a trivial consequence of a stochastic extension of the above subadditivity result. In 1976 Kingman [36] presented the first proof of what later will be called *Subadditivity Ergodic Theorem.* Below, we present an extension of Kingman's result (cf. [50]).

To formulate it properly we must consider a sequence of doubly indexed random variables $X_{m,n}$ with $m \le n$. One can think of it as $X_{m,n} = (X_m, X_{m+1}, \ldots, X_n)$, that is, as a substring of a single-indexed sequence X_n.

THEOREM 14.3 **(Subadditive Ergodic Theorem [36])** (i) *Let $X_{m,n}$ $(m < n)$ be a sequence of nonnegative random variables satisfying the following three properties*

(a) $X_{0,n} \le X_{0,m} + X_{m,n}$ *(subadditivity);*
(b) $X_{m,n}$ *is stationary (i.e., the joint distributions of $X_{m,n}$ are the same as $X_{m+1,n+1}$) and ergodic (cf. [14]);*
(c) $\mathbf{E}[X_{0,1}] < \infty$.

Then,

$$\lim_{n\to\infty} \frac{\mathbf{E}[X_{0,n}]}{n} = \gamma \quad \text{and} \quad \lim_{n\to\infty} \frac{X_{0,n}}{n} = \gamma \quad \text{(a.s.)} \tag{14.10}$$

for some constant γ.
(ii) (**Almost Subadditive Ergodic Theorem**) *If the subadditivity inequality is replaced by*

$$X_{0,n} \le X_{0,m} + X_{m,n} + A_n \tag{14.11}$$

such that $\lim_{n\to\infty} \mathbf{E}[A_n/n] = 0$, then (14.10) holds, too.

We must point out, however, that the above result proves only the existence of a constant γ such that (14.10) holds. It says *nothing* how to compute it, and in fact many ingenious methods have been devised in the past to bound this constant. We discuss it in a more detailed way in the examples below.

EXAMPLE 14.6: String Editing Problem

Let us consider the string editing problem of the subsection "String Editing Problem." To recall, one is interested in estimating the maximum cost $C_{\max}$ of transforming one sequence into another. This problem can be reduced to finding the longest (shortest) path in a special grid graph (cf. Fig. 14.2). Let us assume that the weights W_I, W_D, and W_Q are independently distributed, thus, we adopt the Bernoulli model (B) of "Probabilistic Models of Strings." Then, using the subadditive ergodic theorem it is immediate to see that

$$\lim_{n\to\infty} \frac{C_{\max}}{n} = \lim_{n\to\infty} \frac{EC_{\max}}{n} = \alpha \quad \text{(a.s.)} ,$$

for some constant $\alpha > 0$, provided ℓ/s has a limit as $n\to\infty$. Indeed, let us consider the $\ell \times s$ grid with starting point O and ending point E (cf. Fig. 14.2). Call it Grid(O,E). We also choose an arbitrary point, say A, inside the grid so that we can consider two grids, namely Grid(O,A) and Grid(A,E). Actually, point A splits the edit distance problem into two subproblems with objective functions $C_{\max}(O, A)$ and $C_{\max}(A, E)$. Clearly, $C_{\max}(O, E) \geq C_{\max}(O, A) + C_{\max}(A, E)$. Thus, under our assumption regarding weights, the objective function $C_{\max}$ is superadditive, and direct application of the *Superadditive Ergodic Theorem* proves the result.

Entropy and Its Applications

Entropy and *mutual information* was introduced by Shannon in 1948, and overnight a new field of *information theory* was born. Over the last 50 years information theory underwent many changes, and remarkable progress was achieved. These days entropy and the **Shannon–McMillan–Breiman Theorem** are standard tools of the average case analysis of algorithms. In this subsection, we review some elements of information theory and illustrate its usage to the analysis of algorithms.

Let us start with a simple observation: Consider a binary sequence of symbols of length n, say $(X_1, \ldots, X_n)$, with p denoting the probability of one symbol and $q = 1 - p$ the probability of the other symbol. When $p = q = 1/2$, then $\mathsf{Pr}\{X_1, \ldots, X_n\} = 2^{-n}$, and it does not matter what are the actual values of $X_1, \ldots, X_n$. In general, $\mathsf{Pr}\{X_1, \ldots, X_n\}$ is not the same for all possible values of $X_1, \ldots, X_n$, however, we shall show that a **typical** sequences $(X_1, \ldots, X_n)$ have "asymptotically" the same probability. Indeed, consider $p \neq q$ in the example above. Then, the probability of a typical sequence is approximately equal to (we use here the central limit theorem for i.i.d. sequences):

$$p^{np+O(\sqrt{n})} q^{nq+O(\sqrt{n})} = e^{-n(-p\log p - q\log q)+O(\sqrt{n})} \sim e^{-nh}$$

where $h = -p\log p - q\log q$ is the *entropy* of the underlying Bernoulli model. Thus, a typical sequence X_1^n has asymptotically the same probability equal to e^{-nh}.

To be more precise, let us consider a *stationary and ergodic sequence* $\{X_k\}_{k=1}^{\infty}$, and define $X_m^n = (X_m, X_{m+1}, \ldots, X_n)$ for $m \leq n$ as a substring of $\{X_k\}_{k=1}^{\infty}$. The entropy rate h of $\{X_k\}_{k=1}^{\infty}$ is defined as (cf. [11, 14])

$$h := -\lim_{n\to\infty} \frac{\mathbf{E}\left[\log \mathsf{Pr}\left\{X_1^n\right\}\right]}{n} , \tag{14.12}$$

where one can prove the limit above exists. We must point out that $\mathsf{Pr}\{X_1^n\}$ is a *random variable* since X_1^n is a random sequence!

We show now how to derive the Shannon–McMillan–Breiman Theorem in the case of the Bernoulli model and the mixing model, and later we formulate the theorem in its full generality. Consider first the Bernoulli model, and let $\{X_k\}$ be generated by a Bernoulli source. Thus,

$$-\frac{\log \mathsf{Pr}\left\{X_1^n\right\}}{n} = -\frac{1}{n}\sum_{i=1}^{n} \log \mathsf{Pr}\{X_i\} \to \mathbf{E}\left[-\log \mathsf{Pr}\{X_1\}\right] = h \qquad \text{(a.s.)} ,$$

where the last implication follows from the *Strong Law of Large Numbers* (cf. [14]) applied to the sequence $(-\log \Pr\{X_1\}, \ldots, -\log \Pr\{X_n\})$. One *should* notice a difference between the definition of the entropy (14.12) and the result above. In (14.12) we take the *average* of $\log \Pr\{X_1^n\}$ while in the above we proved that *almost surely* for all but finitely sequences the probability $\Pr\{X_1^n\}$ can be closely approximated by e^{-nh}. For the Bernoulli model, we have already seen it above, but we are aiming at showing that the above conclusion is true for much more general probabilistic models.

As the next step, let us consider the mixing model (MX) (that includes as a special case the Markovian model (M)). For the mixing model the following is true:

$$\Pr\left\{X_1^{n+m}\right\} \leq c \Pr\left\{X_1^n\right\} \Pr\left\{X_{n+1}^{n+m}\right\}$$

for some constant $c > 0$ and any integers $n, m \geq 0$. Taking logarithm we obtain

$$\log \Pr\left\{X_1^{n+m}\right\} \leq \log \Pr\left\{X_1^n\right\} + \log \Pr\left\{X_{n+1}^{n+m}\right\} + \log c$$

which satisfies the subadditivity property (14.11) of the *Subadditive Ergodic Theorem* discussed in "Subadditive Ergodic Theorem." Thus, by (14.10) we have

$$h = -\lim_{n\to\infty} \frac{\log \Pr\left\{X_1^n\right\}}{n} \quad \text{(a.s.)} .$$

Again, the reader should notice the difference between this result and the definition of the entropy.

We are finally ready to state the Shannon–McMillan–Breiman Theorem in its full generality (cf. [14]).

THEOREM 14.4 **(Shannon–McMillan–Breiman)** *For a stationary and ergodic sequence* $\{X_k\}_{k=-\infty}^{\infty}$ *the following holds:*

$$h = -\lim_{n\to\infty} \frac{\log \Pr\left\{X_1^n\right\}}{n} \quad \text{(a.s.)} .$$

where h *is the entropy rate of the process* $\{X_k\}$.

An important conclusion of this result is the so-called **asymptotic equipartition property** (AEP) which basically asserts that asymptotically typical sequences have the same probability approximately equal to e^{-nh}. More precisely, *For a stationary and ergodic sequence* X_1^n, *the state space* Σ^n *can be partitioned into two subsets* $\mathcal{B}_n^\varepsilon$ *("bad set") and* $\mathcal{G}_n^\varepsilon$ *("good set") such that for given* $\varepsilon > 0$ *there is* N_ε *so that for* $n \geq N_\varepsilon$ *we have* $\Pr\{\mathcal{B}_n^\varepsilon\} \leq \varepsilon$, *and* $e^{-nh(1+\varepsilon)} \leq \Pr\{x_1^n\} \leq e^{-nh(1-\varepsilon)}$ *for all* $x_1^n \in \mathcal{G}_n^\varepsilon$.

EXAMPLE 14.7: Shortest Common Superstring or Depth in a Trie/Suffix Tree

For concreteness let us consider the Shortest Common Superstring discussed in the subsection "Shortest Common Superstring," but the same arguments as below can be used to derive the depth in a trie (cf. [48]) or a suffix tree (cf. [54]). Define C_{ij} as the length of the longest suffix of X_i that is equal to the prefix of X_j. Let $M_n(i) = \max_{1\leq j\leq n, j\neq i}\{C_{ij}\}$. We write M_n for a generic random variable distributed as $M_n(i)$ (observe that $M_n \stackrel{d}{=} M_n(i)$ for all i, where $\stackrel{d}{=}$ means "equal in distribution"). We would like to prove that in the mixing model, for any $\varepsilon > 0$,

$$\lim_{n\to\infty} \Pr\left\{(1-\varepsilon)\frac{1}{h}\log n \leq M_n \leq (1+\varepsilon)\frac{1}{h}\log n\right\} = 1$$

provided $\alpha(g) \to 0$ as $g \to \infty$, that is, $M_n/\log n \to h$ (pr.). To prove an upper bound, we take *any fixed* typical sequence $w_k \in \mathcal{G}_k^\varepsilon$ as defined in AEP above, and observe that $\Pr\{M_n \geq k\} \leq n\Pr\{w_k\} + \Pr\{\mathcal{B}_k\}$.

The result follows immediately after substituting $k = (1+\varepsilon)h^{-1}\log n$ and noting that $\mathsf{Pr}\{w_k\} \le e^{nh(1-\varepsilon)}$. For a lower bound, let $w_k \in \mathcal{G}_k^{\varepsilon}$ be any fixed typical sequence with $k = \frac{1}{h}(1-\varepsilon)\log n$. Define Z_k as the number of strings $j \neq i$ such that a prefix of length k is equal to w_k *and* a suffix of length k of the ith string is equal to $w_k \in \mathcal{G}_k^{\varepsilon}$. Since w_k is fixed, the random variables C_{ij} are independent, and hence, by the *second moment method* (cf. "Inequalities: First and Second Moment Method")

$$\mathsf{Pr}\{M_n < k\} = \mathsf{Pr}\{Z_k = 0\} \le \frac{\mathbf{Var}\, Z_k}{(\mathbf{E}Z_k)^2} \le \frac{1}{n\mathsf{Pr}\{w_k\}} = O\left(n^{-\varepsilon^2}\right) ,$$

since $\mathbf{Var}\, Z_k \le n\, P(w_k)$, and this completes the derivation.

In many problems on words another kind of entropy is widely used (cf. [4, 5, 54]). It is called **Rényi entropy** and defined as follows: For $-\infty \le b \le \infty$, the bth *order Rényi entropy* is

$$h_b = \lim_{n\to\infty} \frac{-\log\left(\mathbf{E}\left[\mathsf{Pr}\left\{X_1^n\right\}^{b-1}\right]\right)}{bn} = \lim_{n\to\infty} \frac{-\log\left(\sum_{w\in\Sigma^n}\left(\mathsf{Pr}\{w\}\right)^b\right)^{-1/b}}{n} , \tag{14.13}$$

provided the above limit exists. In particular, by *inequalities on means* we obtain $h_0 = h$ and

$$\begin{aligned} h_{-\infty} &= \lim_{n\to\infty} \frac{\max\left\{-\log \mathsf{Pr}\left\{X_1^n\right\}\ , \mathsf{Pr}\left\{X_1^n\right\} > 0\right\}}{n} , \\ h_{\infty} &= \lim_{n\to\infty} \frac{\min\left\{-\log \mathsf{Pr}\left\{X_1^n\right\}\ , \mathsf{Pr}\left\{X_1^n\right\} > 0\right\}}{n} . \end{aligned}$$

For example, the entropy $h_{-\infty}$ appears in the formulation of the shortest path in digital trees (cf. [48, 54]), the entropy h_{∞} is responsible for the height in PATRICIA tries (cf. [48, 54]), while h_2 determines the height in a trie. Indeed, we claim that in the mixing model the height H_n in a trie behaves probabilistically as $H_n/\log n \to 2/h_2$. To prove it, one should follow the footsteps of our discussion in Examples 14.4 and 14.5 (details can be found in [48, 54]).

Central Limit and Large Deviations Results

Convergence of a sum of independent, identically distributed (i.i.d.) random variables is central to probability theory. In the analysis of algorithms, we mostly deal with *weakly dependent* random variables, but often results from the i.i.d. case can be extended to this new situation by some clever tricks. A more systematic treatment of such cases is usually done through generating functions and complex analysis techniques (cf. [30, 31, 32, 44]), which we briefly discuss in the next section. Hereafter, we concentrate on the i.i.d. case.

Let us consider a sequence $X_1, \ldots, X_n$ of i.i.d. random variables, and let $S_n = X_1 + \cdots + X_n$. Define $\mu := \mathbf{E}[X_1]$ and $\sigma^2 := \mathbf{Var}[X_1]$. We pay particular interest to another random variable, namely

$$s_n := \frac{S_n - n\mu}{\sigma\sqrt{n}}$$

which distribution function we denote as $F_n(x) = \mathsf{Pr}\{s_n \le x\}$. Let also $\Phi(x)$ be the distribution function of the standard normal distribution, that is,

$$\Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-\frac{1}{2}t^2} dt .$$

The **Central Limit Theorem** asserts that $F_n(x) \to \Phi(x)$ for continuity points of $F_n(\cdot)$, provided $\sigma < \infty$ (cf. [14, 15]). A stronger version is due to Berry-Esséen who proved that

$$|F_n(x) - \Phi(x)| \le \frac{2\rho}{\sigma^2\sqrt{n}} \tag{14.14}$$

where $\rho = \mathbf{E}[|X-\mu|^3] < \infty$. Finally, Feller [15] has shown that if centralized moments $\mu_2, \ldots, \mu_r$ exist, then

$$F_n(x) = \Phi(x) - \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2} \sum_{k=3}^{r} n^{-\frac{1}{2}k+1} R_k(x) + O\left(n^{-\frac{1}{2}r+\frac{1}{2}}\right)$$

uniformly in x, where $R_k(x)$ is a polynomial depending only on $\mu_1, \ldots, \mu_r$ but not on n and r.

One should notice from the above, in particular from (14.14), the weakness of central limit results that are able only to assess the probability of *small deviations* from the mean. Indeed, the results above are true for $x = O(1)$ (i.e., for $S_n \in (\mu n - O(\sqrt{n}), \mu n + O(\sqrt{n}))$ due to only a polynomial rate of convergence as shown in (14.14). To see it more clearly, we quote a result from Greene and Knuth [25] who estimated

$$\Pr\{S_n = \mu n + r\} = \frac{1}{\sigma\sqrt{2\pi n}} \exp\left(\frac{-r^2}{2\sigma^2 n}\right)\left(1 - \frac{\kappa_3}{2\sigma^4}\left(\frac{r}{n}\right) + \frac{\kappa_3}{6\sigma^6}\left(\frac{r^3}{n^2}\right)\right) + O\left(n^{-\frac{3}{2}}\right) \qquad (14.15)$$

where κ_3 is the third cumulant of X_1. Observe now that when $r = O(\sqrt{n})$ (which is equivalent to $x = O(1)$ in our previous formulæ) the error term *dominates* the leading term of the above asymptotic, thus, the estimate is quite useless.

From the above discussion, one should conclude that the central limit theorem has limited range of application, and one should expect another law for *large deviations* from the mean, that is, when $x_n \to \infty$ in the above formulæ. The most interesting from the application point of view is the case when $x = O(\sqrt{n})$ (or $r = O(n)$), that is, for $\Pr\{S_n = n(\mu+\delta)\}$ for $\delta \neq 0$. We shall discuss this large deviations behavior next.

Let us first try to "guess" a large deviation behavior of $S_n = X_1 + \cdots X_n$ for i.i.d. random variables. We estimate $\Pr\{S_n \geq an\}$ for $a > 1$ as $n \to \infty$. Observe that (cf. [14])

$$\Pr\{S_{n+m} \geq (n+m)a\} \geq \Pr\{S_m \geq ma,\ S_{n+m} - S_m \geq na\} = \Pr\{S_n \geq na\}\Pr\{S_m \geq ma\}\ ,$$

since S_m and $S_{n+m} - S_m$ are independent. Taking logarithm of the above, and recognizing that $\log \Pr\{S_n \geq an\}$ is a superadditive sequence (cf. "Subadditive Ergodic Theorem"), we obtain

$$\lim_{n\to\infty} \frac{1}{n} \log \Pr\{S_n \geq na\} = -I(a)\ ,$$

where $I(a) \geq 0$. Thus, S_n decays *exponentially* when far away from its mean, not in a Gaussian way as the central limit theorem would predict! Unfortunately, we obtain the above result from the subadditive property which allowed us to conclude the existence of the above limit, but says nothing about $I(a)$.

In order to take the full advantage of the above derivation, we should say something about $I(a)$ and, more importantly, to show that $I(a) > 0$ under some mild conditions. For the latter, let us first assume that the *moment generating function* $M(\lambda) = \mathbf{E}[e^{\lambda X_1}] < \infty$ for some $\lambda > 0$. Let also $\kappa(\lambda) = \log M(\lambda)$ be the *cumulant function* of X_1. Then, by Markov's inequality (cf. "Inequalities: First and Second Moment Methods")

$$e^{\lambda na}\Pr\{S_n \geq na\} = e^{\lambda na}\Pr\left\{e^{\lambda S_n} \geq e^{\lambda na}\right\} \leq \mathbf{E}e^{\lambda S_n}\ .$$

Actually, due to arbitrariness of $\lambda > 0$, we finally arrive at the so-called **Chernoff bound**, that is,

$$\Pr\{S_n \geq na\} \leq \min_{\lambda>0}\left\{e^{-\lambda na}\mathbf{E}\left[e^{\lambda S_n}\right]\right\}\ . \qquad (14.16)$$

We should emphasize that the above bound is true for *dependent* random variables since we only used Markov's inequality applied to S_n.

Returning to the i.i.d. case, we can rewrite the above as

$$\Pr\{S_n \geq na\} \leq \min_{\lambda>0}\left\{\exp(-n(a\lambda - \kappa(\lambda))\right\}\ .$$

But, under mild conditions the above minimization problem is easy to solve. One finds that the minimum is attended at λ_a which satisfies $a = M'(\lambda_a)/M(\lambda_a)$. Thus, we proved that $I(a) \geq a\lambda_a - \log M(\lambda_a)$. A more careful evaluation of the above leads to the following classical large deviations result (cf. [14])

THEOREM 14.5 *Assume $X_1, \ldots, X_n$ are i.i.d. Let $M(\lambda) = \mathbf{E}[e^{\lambda X_1}] < \infty$ for some $\lambda > 0$, the distribution of X_i is not a point mass at μ, and there exists $\lambda_a > 0$ in the domain of the definition of $M(\lambda)$ such that*

$$a = \frac{M'(\lambda_a)}{M(\lambda_a)} .$$

Then

$$\lim_{n\to\infty} \frac{1}{n} \log \mathsf{Pr}\{S_n \geq na\} = -\big(a\lambda_a - \log M(\lambda_a)\big)$$

for $a > \mu$.

A major strengthening of this theorem is due to Gärtner and Ellis (cf. [13]) who extended it to weakly dependent random variables. Let us consider S_n as a sequence of random variables (e.g., $S_n = X_1 + \ldots + X_n$), and let $M_n(\lambda) = \mathbf{E}[e^{\lambda S_n}]$. The following is known (cf. [13, 29]):

THEOREM 14.6 **(Gärtner–Ellis)** *Let*

$$\lim_{n\to\infty} \frac{\log M_n(\lambda)}{n} = c(\lambda)$$

exist and is finite in a subinterval of the real axis. If there exists λ_a such that $c'(\lambda_a)$ is finite and $c'(\lambda_a) = a$, then

$$\lim_{n\to\infty} \frac{1}{n} \log \mathsf{Pr}\{S_n \geq na\} = -(a\lambda_a - c(\lambda_a)) .$$

Let us return again to the i.i.d. case and see if we can strengthen Theorem 14.5 which in its present form gives only a logarithmic limit. We explain our approach on a simple example, following Greene and Knuth [25]. Let us assume that $X_1, \ldots, X_n$ are discrete i.i.d. with common generating function $G(z) = \mathbf{E}[z^X]$. We recall that $[z^m]G(z)$ denote the coefficient at z^m of $G(z)$. In (14.15) we show how to compute such a coefficient at $m = \mu n + O(\sqrt{n})$ of $G^n(z) = Ez^{S_n}$. We observed also that (14.15) cannot be used for large deviations, since the error term was dominating the leading term in such a case. But, one may shift the mean of S_n to a new value such that (14.15) is valid again. Thus, let us define a new random variable $\widetilde{X}$ whose generating function is $\widetilde{G}(z) = \frac{G(z\alpha)}{G(\alpha)}$ where α is a constant that is to be determined. Observe that $\mathbf{E}[\widetilde{X}] = \widetilde{G}'(1) = \alpha G'(\alpha)/G(\alpha)$. Suppose we need large deviations result around $m = n(\mu + \delta)$ where $\delta > 0$. Clearly, (14.15) cannot be applied directly. Now, a proper choice of α can help. Let us select α such that the new $\widetilde{S}_n = \widetilde{X}_1 + \cdots + \widetilde{X}_n$ has mean $m = n(\mu + \delta)$. This results in setting α to be a solution of

$$\frac{\alpha G'(\alpha)}{G(\alpha)} = \frac{m}{n} = \mu + \delta .$$

In addition, we have the following obvious identity

$$\left[z^m\right] G^n(z) = \frac{G^n(\alpha)}{\alpha^m} \left[z^m\right] \left(\frac{G(\alpha z)}{G(\alpha)}\right)^n . \tag{14.17}$$

But, now we can use (14.15) to the right-hand side of the above, since the new random variable $\widetilde{S}_n$ has mean around m.

To illustrate the above technique that is called **shift of mean** we present an example.

EXAMPLE 14.8: Large Deviations by "Shift of Mean" (cf. [25]).

Let S_n be binomially distributed with parameter 1/2, that is, $G^n(z) = ((1+z)/2)^n$. We want to estimate the probability $\mathsf{Pr}\{S_n = n/3\}$, which is far away from its mean ($ES_n = n/2$) and central limit result (14.15) cannot be applied. We apply the shift of mean method, and compute α as

$$\frac{\alpha G'(\alpha)}{G(\alpha)} = \frac{\alpha}{1+\alpha} = \frac{1}{3} ,$$

thus, $\alpha = 1/2$. Using (14.15) we obtain

$$\left[z^{n/3}\right]\left(\frac{2}{3}+\frac{1}{3}z\right)^n = \frac{3}{2\sqrt{\pi n}}\left(1-\frac{7}{24n}\right)+O\left(n^{-5/2}\right) .$$

To derive the result we want (i.e., coefficient at $z^{n/3}$ of $(z/2+1/2)^n$), one must apply (14.17). This finally leads to

$$\left[z^{n/3}\right](z/2+1/2)^n = \left(\frac{3\cdot 2^{1/3}}{4}\right)^n \frac{3}{2\sqrt{\pi n}}\left(1-\frac{7}{24n}+O\left(n^{-2}\right)\right) ,$$

which is a large deviations result (the reader should observe the exponential decay of the above probability).

The last example showed that one may expect a stronger large deviation result than presented in Theorem 14.5. Indeed, under proper mild conditions it can be proved that Theorem 14.5 extends to (cf. [13, 29])

$$\mathsf{Pr}\{S_n \geq na\} \sim \frac{1}{\sqrt{2\pi n}\sigma_a\lambda_a}\exp(-nI(a))$$

where $\sigma_a = M''(\lambda_a)$ with λ_a and $I(a) = a\lambda_a - \log M(\lambda_a)$ is defined in Theorem 14.5.

Finally, we deal with an interesting extension of the above large deviations results initiated by Azuma, and recently significantly extended by Talagrand [56]. These results are known in the literature under the name **Azuma's type inequality** or **method of bounded differences** (cf. [45]). It can be formulated as follows:

THEOREM 14.7 **(Azuma's Type Inequality)** *Let X_i be i.i.d. random variables such that for some function $f(\cdot,\ldots,\cdot)$ the following is true*

$$\left|f(X_1,\ldots,X_i,\ldots,X_n) - f\left(X_1,\ldots,X_i',\ldots,X_n\right)\right| \leq c_i , \tag{14.18}$$

where $c_i < \infty$ are constants, and X_i' has the same distribution as X_i. Then,

$$\mathsf{Pr}\{|f(X_1,\ldots,X_n) - \mathbf{E}[f(X_1,\ldots,X_n)]| \geq t\} \leq 2\exp\left(-2t^2/\sum_{i=1}^n c_i^2\right) \tag{14.19}$$

for some $t > 0$.

We finish this discussion with an application of the Azuma inequality.

EXAMPLE 14.9: Concentration of Mean for the Editing Problem

Let us consider again the editing problem from the subsection "String Editing Problem." The following is true:

$$\mathsf{Pr}\{|C_{\max} - EC_{\max}| > \varepsilon\mathbf{E}[C_{\max}]\} \leq 2\exp\left(-\varepsilon^2\alpha n\right) ,$$

provided all weights are bounded random variables, say $\max\{W_I, W_D, W_Q\} \leq 1$. Indeed, under the Bernoulli model, the X_i are i.i.d. (where $X_i, 1 \leq i \leq n = l+s$, represents symbols of the two underlying sequences), and therefore (14.18) holds with $f(\cdot) = C_{\max}$. More precisely,

$$\left|C_{\max}(X_1, \ldots, X_i, \ldots, X_n) - C_{\max}\left(X_1, \ldots, X_i', \ldots, X_n\right)\right| \leq \max_{1 \leq i \leq n} \{W_{\max}(i)\} ,$$

where $W_{max}(i) = \max\{W_I(i), W_D(i), W_Q(i)\}$. Setting $c_i = 1$ and $t = \varepsilon E C_{\max} = O(n)$ in the Azuma inequality we obtain the desired concentration of mean inequality.

14.5 Analytic Techniques

Analytic analysis of algorithms was initiated by Knuth almost 30 years ago in his *magnum opus* [39, 40, 41], which treated many aspects of fundamental algorithms, seminumerical algorithms, and sorting and searching. A modern introduction to analytic methods can be found in a marvelous book by Sedgewick and Flajolet [49], while advanced analytic techniques are covered in a forthcoming book *Analytical Combinatorics* by Flajolet and Sedgewick [21]. In this section, we only briefly discuss functional equations arising in the analysis of digital trees, complex asymptotics techniques, Mellin transform, and analytic depoissonization.

Recurrences and Functional Equations

Recurrences and functional equations are widely used in computer science. For example, the divide-and-conquer recurrence equations appear in the analysis of searching and sorting algorithms (cf. [41]). Hereafter, we concentrate on recurrences and functional equations that arise in the analysis of digital trees and problems on words.

However, to introduce the reader into the main subject we first consider two well-known functional equations. Let us enumerate the number of *unlabeled binary trees* built over n vertices. Call this number b_n, and let $B(z) = \Sigma_{n=0}^{\infty} b_n z^n$ be its *ordinary generating function.* Since each such a tree is constructed in a recursive manner with left and right subtrees being unlabeled binary trees, we immediately arrive at the following recurrence $b_n = b_0 b_{n-1} + \cdots + b_{n-1} b_0$ for $n \geq 1$ with $b_0 = 1$ by definition. Multiplying by z^n and summing from $n = 1$ to infinity, we obtain $B(z) - 1 = zB^2(z)$ which is a simple functional equation that can be solved to find

$$B(z) = \frac{1 - \sqrt{1 - 4z}}{2z} .$$

To derive the above functional equation, we used a simple fact that the generating function $C(z)$ of the convolution c_n of two sequences, say a_n and b_n (i.e., $c_n = a_0 b_n + a_1 b_{n-1} + \cdots + a_n b_0$), is the product of $A(z)$ and $B(z)$, that is, $C(z) = A(z)B(z)$.

The above functional equation and its solution can be used to obtain an explicit formula on b_n. Indeed, we first recall that $[z^n]B(z)$ denotes the coefficient at z^n of $B(z)$ (i.e., b_n). A standard analysis leads to (cf. [39, 44])

$$b_n = \left[z^n\right] B(z) = \frac{1}{n+1}\binom{2n}{n} ,$$

which is the famous *Catalan number.*

Let us now consider a more challenging example, namely, enumeration of *rooted labeled trees.* Let t_n the number of rooted labeled trees, and $t(z) = \Sigma_{n=0}^{\infty} \frac{t_n}{n!} z^n$ its *exponential generating function.* It is known that $t(z)$ satisfies the following functional equation (cf. [28, 49]) $t(z) = ze^{t(z)}$. To find t_n, we apply *Lagrange's Inversion Formula.* Let $\Phi(u)$ be a formal power series with $[u^0]\Phi(u) \neq 0$, and let $X(z)$ be a solution of $X = z\Phi(X)$. The coefficients of $X(z)$ or in general $\Psi(X(z))$ where Ψ is an arbitrary series can be found

by

$$\begin{aligned} \left[z^n\right] X(z) &= \frac{1}{n}\left[u^{n-1}\right](\Phi(u))^n \ , \\ \left[z^n\right]\Psi(X(z)) &= \frac{1}{n}\left[u^{n-1}\right](\Phi(u))^n\,\Psi'(u) \ . \end{aligned}$$

In particular, an application of the above to $t(z)$ leads to $t_n = n^{n-1}$, and to an interesting formula (which we encounter again in Example 14.14)

$$t(z) = \sum_{n=1}^{\infty} \frac{n^{n-1}}{n!} z^n \ . \tag{14.20}$$

After these introductory remarks, we can now concentrate on certain recurrences that arise in problems on words; in particular in digital trees and shortest common superstring problems. Let x_n be a generic notation for a quantity of interest (e.g., depth, size or path length in a digital tree built over n strings). Given x_0 and x_1, the following three recurrences originate from problems on tries, PATRICIA tries, and digital search trees, respectively (cf. [16, 28, 37, 41, 44, 49, 51, 52, 53]):

$$x_n = a_n + \beta \sum_{k=0}^{n} \binom{n}{k} p^k q^{n-k} \left(x_k + x_{n-k}\right) \ , \quad n \geq 2 \tag{14.21}$$

$$x_n = a_n + \beta \sum_{k=1}^{n-1} \binom{n}{k} p^k q^{n-k} \left(x_k + x_{n-k}\right) - \alpha\left(p^n + q^n\right) x_n \ , \quad n \geq 2 \tag{14.22}$$

$$x_{n+1} = a_n + \beta \sum_{k=0}^{n} \binom{n}{k} p^k q^{n-k} \left(x_k + x_{n-k}\right) \quad n \geq 0 \tag{14.23}$$

where a_n is a known sequence (also called additive term), α and β are some constants, and $p + q = 1$.

To solve this recurrences and to obtain explicit or asymptotic expression for x_n we apply exponential generating function approach. We need to know the following two facts: Let a_n and b_n be sequences with $a(z) = \Sigma_{n=0}^{\infty} \frac{a_n}{n!} z^n$ and $b(z)$ as their exponential generating functions. (Hereafter, we consequently use lower-case letters for exponential generating functions, like $a(z)$, and upper-case letters for ordinary generating functions, like $A(z)$). Then,

- For any integer $h \geq 0$
$$\frac{d^h}{dz^h} a(z) = \sum_{n=0}^{\infty} \frac{a_{n+h}}{n!} z^n \ .$$
- If $c_n = \Sigma_{r=0}^{n} \binom{n}{r} a_r b_{n-r}$, then the exponential generating function $c(z)$ of c_n becomes $c(z) = a(z)b(z)$.

Now, we are ready to attack the above recurrences and show how they can be solved. Let us start with the simplest one, namely (14.21). Multiplying it by z^n, summing up, and taking into account the initial conditions, we obtain

$$x(z) = a(z) + \beta x(zp) e^{zq} + \beta x(zq) e^{zp} + d(z) \ , \tag{14.24}$$

where $d(z) = d_0 + d_1 z$ and d_0 and d_1 depend on the initial condition for $n = 0, 1$. The trick is to introduce the so called **Poisson transform** $\widetilde{X}(z) = x(z)e^{-z}$ which reduces the above functional equation to

$$\widetilde{X}(z) = \widetilde{A}(z) + \beta \widetilde{X}(zp) + \beta \widetilde{X}(z) + d(z)e^{-z} \ . \tag{14.25}$$

Observe that $\widetilde{x}_n$ and x_n are related by $x_n = \Sigma_{k=0}^{n}\binom{n}{k}\widetilde{x}_k$. Using this, and comparing coefficients of $\widetilde{X}(z)$ at z^n we finally obtain

$$x_n = x_0 + n\,(x_1 - x_0) + \sum_{k=2}^{n}(-1)^k\binom{n}{k}\frac{\hat{a}_k + kd_1 - d_0}{1-\beta\left(p^k+q^k\right)}\,, \tag{14.26}$$

where $n![z^n]\widetilde{A}(z) = \widetilde{a}_n := (-1)^n\hat{a}_n$. In fact, $\hat{a}_n$ and a_n form the so called *binomial inverse relations,* i.e.,

$$\hat{a}_n = \sum_{k=0}^{n}\binom{n}{k}(-1)^k a_k\,, \qquad a_n = \sum_{k=0}^{n}\binom{n}{k}(-1)^k\hat{a}_k\,,$$

and $\hat{\hat{a}}_n = a_n$ (cf. [41]).

EXAMPLE 14.10: Average Path Length in a Trie

Let us consider a trie in the Bernoulli model, and estimate the average length, ℓ_n, of the external path length, i.e., $\ell_n = \mathbf{E}[L_n]$ (cf. "Digital Trees"). Clearly, $\ell_0 = \ell_1 = 0$ and for $n \geq 2$

$$\ell_n = n + \sum_{k=0}^{n}\binom{n}{k}p^k q^{n-k}\left(\ell_k + \ell_{n-k}\right)\,.$$

Thus, by (14.26)

$$\ell_n = \sum_{k=2}^{n}(-1)^k\binom{n}{k}\frac{k}{1-p^k-q^k}\,.$$

Below, we shall discuss the asymptotics of ℓ_n (cf. Example 14.15).

Let us now consider recurrence (14.22), which is much more intricate. It has an exact solution only for some special cases (cf. [41, 51, 53]) that we discuss below. We first consider a simplified version of (14.22), namely

$$x_n\left(2^n-2\right) = 2^n a_n + \sum_{k=1}^{n-1}\binom{n}{k}x_k\,.$$

with $x_0 = x_1 = 0$ (for a more general recurrence of this type see [51]). After multiplying by z^n and summing up we arrive at

$$x(z) = \left(e^{z/2}+1\right)x\,(z/2) + a(z) - a_0 \tag{14.27}$$

where $x(z)$ and $a(z)$ are exponential generating functions of x_n and a_n. To solve this recurrence we must observe that after multiplying both sides by $z/(e^z-1)$ and defining

$$\check{X}(z) = x(z)\frac{z}{e^z-1} \tag{14.28}$$

we obtain a new functional equation that is easier to solve, namely

$$\check{X}(z) = \check{X}\,(z/2) + \check{A}(z)\,,$$

where in the above we assume for simplicity $a_0 = 0$. This functional equation is of a similar type as $\widetilde{X}(x)$ considered above. The coefficient $\check{x}_n$ at z^n of $\check{X}(z)$ can also be easily extracted. One must, however, translate coefficients $\check{x}_n$ into the original sequence x_n. In order to accomplish this, let us introduce the Bernoulli polynomials $B_n(x)$ and Bernoulli numbers $B_n = B_n(0)$, that is, $B_n(x)$ is defined as

$$\frac{ze^{tz}}{e^z-1} = \sum_{k=0}^{\infty}B_k(t)\frac{z^k}{k!}\,.$$

Furthermore, we introduce *Bernoulli inverse relations* for a sequence a_n as

$$\check{a}_n = \sum_{k=0}^{n} \binom{n}{k} B_k a_{n-k} \quad \Longleftrightarrow \quad a_n = \sum_{k=0}^{n} \binom{n}{k} \frac{\check{a}_k}{k+1} .$$

One should know that (cf. [41])

$$a_n = \binom{n}{r} q^n \quad \Longleftrightarrow \quad \check{a}_n = \binom{n}{r} q^r B_{n-r}(q)$$

for $0 < q < 1$. For example, for $a_n = \binom{n}{r} q^n$ the above recurrence has a particular simply solution, namely:

$$x_n = \sum_{k=1}^{n} (-1)^k \binom{n}{k} \frac{B_{k+1}(1-q)}{k+1} \frac{1}{2^{k+1}-1} .$$

A general solution to the above recurrence can be found in [51], and it involves $\check{a}_n$.

EXAMPLE 14.11: Unsuccessful Search in PATRICIA

Let us consider the number of trials u_n in an unsuccessful search of a string in a PATRICIA trie constructed over the symmetric Bernoulli model (i.e., $p = q = 1/2$). As in Knuth [41]

$$u_n \left(2^n - 2\right) = 2^n \left(1 - 2^{1-n}\right) + \sum_{k=1}^{n-1} \binom{n}{k} u_k$$

and $u_0 = u_1 = 0$. A simple application of the above derivation leads, after some algebra, to (cf. [53])

$$u_n = 2 - \frac{4}{n+1} + 2\delta_{n0} + \frac{2}{n+1} \sum_{k=2}^{n} \binom{n+1}{k} \frac{B_k}{2^{k-1}-1}$$

where $\delta_{n,k}$ is the Kronecker delta, that is, $\delta_{n,k} = 1$ for $n = k$ and zero otherwise.

We were able to solve the functional equations (14.24) and (14.27) exactly, since we reduce them to a simple functional equation of the form (14.25). In particular, Eq. (14.27) became (14.25), since luckily $e^z - 1 = (e^{z/2} - 1)(e^{z/2} + 1)$, as already pointed out by Knuth [41], but one cannot expect that much luck with other functional equations. Let us consider a general functional equation

$$F(z) = a(z) + b(z) F(\sigma(z)) , \tag{14.29}$$

where $a(z), b(z), \sigma(z)$ are known functions. Formally, iterating this equation we obtain

$$F(z) = \sum_{k=0}^{\infty} a\left(\sigma^{(k)}(z)\right) \prod_{j=0}^{k-1} b\left(\sigma^{(j)}(z)\right) ,$$

where $\sigma^{(k)}(z)$ is the kth iterate of $\sigma(\cdot)$. When applying the above to solve real problems, one must assure the existence of the infinite series involved. In some cases (cf. [19, 38]), we can provide asymptotic solutions to such complicated formulæ by appealing to the Mellin transform which we discuss below in "Mellin Transform and Asymptotics."

Finally, we deal with the recurrence (14.23). Multiplying both sides by $z^n/n!$ and using the above discussed properties of exponential generating functions we obtain for $x(z) = \Sigma_{n \geq 0} x_n \frac{z^n}{n!}$

$$x'(z) = a(z) + x(zp) e^{zq} + x(zq) e^{zp} ,$$

which becomes after the substitution $\widetilde{X}(z) = x(z)e^{-z}$

$$\widetilde{X}'(z) + \widetilde{X}(z) = \widetilde{A}(z) + \widetilde{X}(zp) + \widetilde{X}(zq)\,. \tag{14.30}$$

The above is a differential–functional equation that we did not discuss so far. It can be solved, since a direct translation of coefficients gives $\widetilde{x}_{n+1} + \widetilde{x}_n = \widetilde{a}_n + \widetilde{x}_n(p^n + q^n)$. Fortunately, this is a simple linear recurrence that has an explicit solution. Taking into account $x_n = \Sigma_{k=0}^n \binom{n}{k}\widetilde{x}_k$, we finally obtain

$$x_n = x_0 - \sum_{k=1}^{n}(-1)^k\binom{n}{k}\sum_{i=1}^{k-1}\hat{a}_i\prod_{j=i+1}^{k-1}\left(1 - p^j - q^j\right) = x_0 - \sum_{k=1}^{n}(-1)^k\binom{n}{k}\sum_{i=1}^{k-1}\hat{a}_i\frac{Q_k}{Q_i}\,, \tag{14.31}$$

where $Q_k = \prod_{j=2}^{k}(1 - p^j - q^j)$, and $\hat{a}_n$ is the binomial inverse of a_n as defined above. In passing, we should observe that solutions of the recurrences (14.21), (14.22), and (14.23) have a form of an alternating sum, that is, $x_n = \sum_{k=1}^n (-1)^k\binom{n}{k} f_n$ where f_n has an explicit formula. In "Mellin Transform and Asymptotics," we discuss how to obtain asymptotics of such an alternating sum.

EXAMPLE 14.12: Expected Path Length in a Digital Search Tree

Let ℓ_n be the expected path length in a digital search tree. Then (cf. [21, 41]) for all $n \geq 0$,

$$\ell_{n+1} = n + \sum_{k=1}^{n}\binom{n}{k}p^k q^{n-k}\left(\ell_k + \ell_{n-k}\right)$$

with $\ell_0 = 0$. By (14.31) it has the following solution:

$$\ell_n = \sum_{k=2}^{n}(-1)^k\binom{n}{k}Q_{k-1}$$

where Q_k is defined above.

We were quite lucky when solving the above differential–functional equation, since we could reduce it to a linear recurrence of *first* order. However, this is not any longer true when we consider the so-called b-digital search trees in which one assumes that a node can store up to b strings. Then, the general recurrence (14.23) becomes

$$x_{n+b} = a_n + \beta\sum_{k=0}^{n}\binom{n}{k}p^k q^{n-k}\left(x_k + x_{n-k}\right) \quad n \geq 0,$$

provided $x_0, \ldots, x_{b-1}$ are given. Our previous approach would lead to a linear recurrence of order b that does not possess a nice explicit solution. The "culprit" lies in the fact that the exponential generating function of a sequence $\{x_{n+b}\}_{n=0}^{\infty}$ is the bth derivative of the exponential generating function $x(z)$ of $\{x_n\}_{n=0}^{\infty}$. On the other hand, if one considers *ordinary* generating function $X(z) = \Sigma_{n\geq 0}x_n z^n$, then the sequence $\{x_{n+b}\}_{n=0}^{\infty}$ translates into $z^{-b}(X(z) - x_0 - \cdots - x_{b-1}z^{b-1})$. This observation led Flajolet and Richmond [18] to reconsider the standard approach to the above binomial recurrences, and to introduce ordinary generating function into the play. A careful reader observes, however, that then one must translate into ordinary generating functions sequences such as $s_n = \Sigma_{k=0}^n\binom{n}{k}a_k$ (which were easy under exponential generating functions since they become $a(z)e^z$). But, it is not difficult to see that

$$s_n = \sum_{k=0}^{n}\binom{n}{k}a_k \quad \Longrightarrow \quad S(z) = \frac{1}{1-z}A\left(\frac{z}{1-z}\right)\,.$$

Indeed,

$$\begin{aligned}\frac{1}{1-z}A\left(\frac{z}{1-z}\right) &= \sum_{m=0}^{\infty} a_m z^m \frac{1}{(1-z)^{m+1}} = \sum_{m=0}^{\infty} a_m z_m \sum_{j=0}^{\infty} \binom{m+j}{j} z^j \\ &= \sum_{n=0}^{\infty} z^n \sum_{k=0}^{\infty} \binom{n}{k} a_k \ .\end{aligned}$$

Thus, the above recurrence for $p = q = 1/2$ and any $b \geq 1$ can be translated into ordinary generating functions as

$$\begin{aligned}X(z) &= \frac{1}{1-z}G\left(\frac{z}{1-z}\right) \\ G(z)(1+z)^b &= 2z^b G\,(z/2) + P(z)\ ,\end{aligned}$$

where $P(z)$ is a function of a_n and initial conditions. But, the latter functional equation falls under (14.29) and its solution was already discussed above.

Complex Asymptotics

When analyzing an algorithm we often aim at predicting its rate of growth of time or space complexity for large inputs, n. Precise analysis of algorithms aims at obtaining precise asymptotics and/or full asymptotic expansions of such performance measures. For example, in the previous subsection we studied some parameters of tries (e.g., path length ℓ_n, unsuccessful search u_n, etc.) that depend on input of size n. We observed that these quantities are expressed by some complicated alternating sums (cf. Examples 14.10–14.12). One might be interested in precise rate of growth of these quantities. More precisely, if x_n represents a quantity of interest with input size n, we may look for a simple explicit function a_n (e.g., $a_n = \log n$ or $a_n = \sqrt{n}$) such that $x_n \sim a_n$ (i.e., $\lim_{n\to\infty} x_n/a_n = 1$), or we may be aiming at a very precise asymptotic expansion such as $x_n = a_n^1 + a_n^2 + \cdots + o(a_n^k)$ where for each $1 \leq i \leq k$ we have $a_n^{i+1} = o(a_n^i)$.

The reader is referred to an excellent recent survey by Odlyzko [47] on asymptotic methods. In this subsection, we briefly discuss some elementary facts of asymptotic evaluation, and describe a few useful methods.

Let $A(z) = \Sigma_{n=0}^{\infty} a_n z^n$ be the generating function of a sequence $\{a_n\}_{n=0}^{\infty}$. In the previous subsection, we look at $A(z)$ as a *formal power series.* Now, we ask whether $A(z)$ converges, and what is its region of convergence. It turns out that the radius of convergence for $A(z)$ is responsible for the asymptotic behavior of a_n for large n. Indeed, by *Hadamard's Theorem* [27, 57] we know that radius R of convergence of $A(z)$ (where z is a complex variable) is given by

$$R = \frac{1}{\limsup_{n\to\infty} |a_n|^{1/n}}\ .$$

In other words, for every $\varepsilon > 0$ there exists N such that for $n > N$ we have

$$|a_n| \leq \left(R^{-1} + \varepsilon\right)^n\ ;$$

for infinitely many n we have

$$|a_n| \geq \left(R^{-1} - \varepsilon\right)^n\ .$$

Informally saying, $\frac{1}{n}\log|a_n| \sim 1/R$, or even less formally the exponential growth of a_n is determined by $(1/R)^n$. In summary, singularities of $A(z)$ determine asymptotic behavior of its coefficients for large n. In fact, from *Cauchy's Integral Theorem* (cf. "Review From Complex Analysis") we know that

$$|a_n| \leq \frac{M(r)}{r^n}$$

where $M(r)$ is the maximum value of $|A(z)|$ over a circle of radius $r < R$.

Our goal now is to make a little more formal our discussion above, and deal with multiple singularities. We restrict ourselves to *meromorphic* functions $A(z)$, i.e., ones that are analytic with the exception of a finite number of *poles.* To make our discussion even more concrete we study the following function

$$A(z) = \sum_{j=1}^{r} \frac{a_{-j}}{(z-\rho)^j} + \sum_{j=0}^{\infty} a_j (z-\rho)^j \ .$$

More precisely, we assume that $A(z)$ has the above *Laurent expansion* around a pole ρ of multiplicity r. Let us further assume that the pole ρ is the closest to the origin, that is, $R = |\rho|$ (and there are no more poles on the circle of convergence). In other words, the sum of $A(z)$ which we denote for simplicity as $A_1(z)$, is analytic in the circle $|z| \le |\rho|$, and its possible radius of convergence $R' > |\rho|$. Thus, coefficients a'_n of $A_1(n)$ are bounded by $|a'_n| = O((1/R' + \varepsilon)^n)$ for any $\varepsilon > 0$. Let us now deal with the first part of $A(z)$. Using the fact that $[z^n](1-z)^{-r} = \binom{n+r-1}{r-1}$ for a positive integer r, we obtain

$$\begin{aligned}
\sum_{j=1}^{r} \frac{a_j}{(z-\rho)^j} &= \sum_{j=1}^{r} \frac{a_j (-1)^j}{\rho^j \, (1 - z/\rho)^j} \\
&= \sum_{j=1}^{r} (-1)^j a_j \rho^{-j} \sum_{n=0}^{\infty} \binom{n+j-1}{n} \left(\frac{z}{\rho}\right)^n \\
&= \sum_{n=1}^{\infty} z^n \sum_{j=1}^{r} (-1)^j a_j \binom{n}{j-1} \rho^{-(n+j)} \ .
\end{aligned}$$

In summary, we prove that

$$\left[z^n\right] A(z) = \sum_{j=1}^{r} (-1)^j a_j \binom{n}{j-1} \rho^{-(n+j)} + O\left(\left(1/R' + \varepsilon\right)^n\right)$$

for $R' > \rho$ and any $\varepsilon > 0$.

EXAMPLE 14.13: Frequency of a Given Pattern Occurrence

Let H be a *given* pattern of size m, and consider a random text of length n generated according to the Bernoulli model. An old and well-studied problem of pattern matching (cf. [15]) asks for an estimation of the number O_n of pattern H occurrences in the text. Let $T_r(z) = \Sigma_{n=0}^{\infty} \mathsf{Pr}\{O_n = r\} z^n$ denote the generating function of $\mathsf{Pr}\{O_n = r\}$ for $|z| \le 1$. It can be proved (cf. [24, 26]) that

$$T_r(z) = \frac{z^m P(H) (D(z) + z - 1)^{r-1}}{D^{r+1}(z)} \ ,$$

where $D(z) = P(H) z^m + (1-z) A_H(z)$ and $A(z)$ is the so-called *autocorrelation polynomial* (a polynomial of degree m). It is also easy to see that there exists smallest $\rho > 1$ such that $D(\rho) = 0$. Then, an easy application of the above analysis leads to

$$\mathsf{Pr}\left\{O_n(H) = r\right\} = \sum_{j=1}^{r+1} (-1)^j a_j \binom{n}{j-1} \rho^{-(n+j)} + O\left(\rho_1^{-n}\right)$$

where $\rho_1 > \rho$ and $a_{r+1} = \rho^m P(H) \, (\rho - 1)^{r-1} \left(D'(\rho)\right)^{-r-1}$.

The method just described can be called the method of *subtracted singularities,* and its general description follows: Imagine that we are interested in the asymptotic formula for coefficients a_n of a function $A(z)$, whose circle of convergence is R. Let us also assume that we can find a simpler function, say $\bar{A}(z)$ that has the same singularities as $A(z)$ (e.g., in the example above $\bar{A}(z) = \Sigma_{j=1}^{r} \frac{a_{-j}}{(z-\rho)^j}$). Then, $A_1(z) = A(z) - \bar{A}(z)$ is analytical in a larger disk, of radius $R' > R$, say, and its coefficients are not dominant in an asymptotic sense. To apply this method successfully, we need to develop asymptotics of some known functions (e.g., $(1-z)^\alpha$ for any real α) and establish the so called *transfer theorems* (cf. [17]). This leads us to the so-called *singularity analysis* of Flajolet and Odlyzko [17], which we discuss next.

We start with the observation that $[z^n]A(z) = \rho^n [z^n]A(z/\rho)$, that is, we need only to study singularities at, say, $z = 1$. The next observation deals with asymptotics of $(1-z)^{-\alpha}$. Above, we show how to obtain coefficients at z^n of this function when α is a natural number. Then, the function $(1-z)^{-\alpha}$ has a pole of order α at $z = 1$. However, when $\alpha \neq 1, 2 \ldots$, then the function has an *algebraic singularity* (in fact, it is then a multivalued function). Luckily enough, we can proceed formally as follows:

$$\begin{aligned} \left[z^n\right](1-z)^{-\alpha} &= \binom{n+\alpha-1}{n} = \frac{\Gamma(n+\alpha)}{\Gamma(\alpha)\Gamma(n+1)} \\ &= \frac{n^{\alpha-1}}{\Gamma(\alpha)}\left(1 + \frac{\alpha(\alpha-1)}{2n} + O\left(\frac{1}{n^2}\right)\right), \end{aligned}$$

provided $\alpha \notin \{0, -1, -2, \ldots\}$. In the above, $\Gamma(x) = \int_0^\infty e^{-t}x^{t-1}dx$ is the Euler gamma function (cf. [1, 27]), and the latter asymptotic expansion follows from the Stirling formula. Even more generally, let

$$A(z) = (1-z)^{-\alpha}\left(\frac{1}{z}\log\frac{1}{1-z}\right)^\beta .$$

Then, as shown by Flajolet and Odlyzko [17],

$$a_n = \left[z^n\right]A(z) = \frac{n^{\alpha-1}}{\Gamma(\alpha)}\left(1 + C_1\frac{\beta}{\log n} + C_2\frac{\beta(\beta-1)}{2\log^2 n} + O\left(\frac{1}{\log^3 n}\right)\right), \tag{14.32}$$

provided $\alpha \notin \{0, -1, -2, \ldots\}$, and C_1 and C_2 are constants that can be calculated explicitly.

The most important aspect of the singularity theory comes next: In many instances we do *not* have an explicit expression for the generating function $A(z)$ but only an expansion of $A(z)$ around a singularity. For example, let $A(z) = (1-z)^{-\alpha} + O(B(z))$. In order to pass to coefficients of a_n we need a "transfer theorem" that will allow us to pass to coefficients of $B(z)$ under the "Big Oh" notation. We shall discuss them below.

We need a definition of Δ-analyticity around the singularity $z = 1$:

$$\Delta = \left\{z : |z| < R\,,\, z \neq 1\,,\, \left|\arg(z-1)\right| > \phi\right\}$$

for some $R > 1$ and $0 < \phi < \pi/2$ (i.e., the domain Δ is an extended disk around $z = 1$ with a circular part rooted at $z = 1$ deleted). Then (cf. [17]):

THEOREM 14.8 *Let $A(z)$ be Δ-analytic that satisfies in a neighborhood of $z = 1$ either*

$$A(z) = O\left((1-z)^{-\alpha}\log^\beta(1-z)^{-1}\right)$$

or

$$A(z) = o\left((1-z)^{-\alpha}\log^\beta(1-z)^{-1}\right).$$

Then, either

$$\left[z^n\right] = O\left(n^{\alpha-1}\log^\beta n\right)$$

or

$$[z^n] = o\left(n^{\alpha-1}\log^{\beta} n\right) ,$$

respectively.

A classical example of singularity analysis is the Flajolet and Odlyzko analysis of the height of binary trees (cf. [17]), however, we finish this subsection with a simpler application that quite well illustrates the theory (cf. [55]).

EXAMPLE 14.14: Certain Sums from Coding Theory

In coding theory the following sum is of some interest:

$$S_n = \sum_{i=0}^{n} \binom{n}{i} \left(\frac{i}{n}\right)^i \left(1-\frac{i}{n}\right)^{n-i} .$$

Let $s_n = n^n S_n$. If $s(z)$ denotes the exponential generating function of s_n, then by a simple application of the convolution principle of exponential generating functions we obtain $s(z) = (b(z))^2$ where $b(z) = (1-t(z))^{-1}$ and $t(z)$ is the "tree function" defined in "Recurrences and Functional Equations" (cf. (14.20)). In fact, we already know that this function also satisfies the functional equation $t(z) = ze^{t(z)}$. One observes that $z = e^{-1}$ is the singularity point of $t(z)$, and (cf. [55])

$$\begin{aligned} t(z) - 1 &= -\sqrt{2(1-ez)} + \frac{2}{3}(1-ez) - \frac{11\sqrt{2}}{36}(1-ez)^{3/2} \\ &\quad + \frac{43}{135}(1-ez)^2 + O\left((1-ez)^{5/2}\right) , \\ s(z) &= \frac{1}{2h(z)\left(1+\frac{\sqrt{2}}{3}\sqrt{h(z)}+\frac{11}{36}h(z)+O\left(h^{3/2}(z)\right)\right)^2} \\ &= \frac{1}{2(1-ez)} + \frac{\sqrt{2}}{3\sqrt{(1-ez)}} + \frac{1}{36} + \frac{\sqrt{2}}{540}\sqrt{1-ez} + O(1-ez) . \end{aligned}$$

Thus, an application of the singularity analysis leads finally to the following asymptotic expansion

$$S_n = \sqrt{\frac{n\pi}{2}} + \frac{2}{3} + \frac{\sqrt{2\pi}}{24}\frac{1}{\sqrt{n}} - \frac{4}{135}\frac{1}{n} + O\left(1/n^{3/2}\right) .$$

For more sophisticated examples the reader is referred to [17, 21, 55].

Mellin Transform and Asymptotics

In previous sections, we study functional equations such as (14.25) or more generally (14.30). They can be summarized by the following general functional equation:

$$f^{(b)}(z) = a(z) + \alpha f(zp) + \beta f(zq) , \tag{14.33}$$

where $f^{(b)}(z)$ denotes the bth derivative of $f(z)$, α, β are constants, and $a(z)$ is a known function. An important point to observe is that in the applications described so far the unknown function $f(z)$ was usually a Poisson transform, that is, $\widetilde{f}(z) = \Sigma_{n\geq 0} f_n \frac{z^n}{n!} e^{-z}$. We briefly discuss consequences of this point at the end of this subsection where some elementary *depoissonization* results will be presented. An effective approach to solve asymptotically (either for $z \to 0$ or $z \to \infty$) the above function equation is by the so

called **Mellin transform** which we discuss next. Knuth [41], together with De Bruijn, is responsible for introducing the Mellin transform into the "orbit" of the average case analysis of algorithms; however, it was popularized by Flajolet and his school who applied Mellin transforms to "countably" many problems of analysis of algorithms and analytic combinatorics. We base this subsection mostly on a survey by Flajolet et al. [19].

For a function $f(x)$ on $x \in [0, \infty)$ we define the Mellin transform as

$$\mathcal{M}(f, s) = f^*(s) = \int_0^\infty f(x) x^{s-1} dx \ ,$$

where s is a complex number. For example, observe that from the definition of the Euler gamma function, we have $\Gamma(s) = \mathcal{M}(e^x, s)$. The Mellin transform is a special case of the Laplace transform (set $x = e^t$) or the Fourier transform (set $x = e^{i\omega}$). Therefore, using the inverse Fourier transform, one establishes the inverse Mellin transform (cf. [27]), namely,

$$f(x) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} f^*(s) x^{-s} ds \ ,$$

provided $f(x)$ is piecewise continuous. In the above, the integration is along a vertical line $\Im(s) = c$, and c must belong to the so-called fundamental strip where the Mellin transform exists (see properly (P1) below).

The usefulness of the Mellin transform to the analysis of algorithms is a consequence of a few properties that we discuss in the sequel.

(P1) Fundamental Strip
Let $f(x)$ be a piecewise continuous function on the interval [0,∞) such that

$$f(x) = \begin{cases} O\left(x^\alpha\right) & x \to 0 \\ O\left(x^\beta\right) & x \to \infty \ . \end{cases}$$

Then the Mellin transform of $f(x)$ exists for any complex number s in the **fundamental strip** $-\alpha < \Re(s) < -\beta$, which we will denote $\langle -\alpha; -\beta \rangle$.

(P2) Smallness of Mellin transforms
Let $s = \sigma + it$. By the Riemann–Lebesgue lemma

$$f^*(\sigma + it) = o\left(|t|^{-r}\right) \quad \text{as } t \to \pm\infty$$

provided $f \in \mathcal{C}^r$ where $\mathcal{C}^r$ is the set of functions having continuous r derivatives.

(P3) Basic Functional Properties
The following holds in appropriate fundamental strips:

$$\begin{aligned}
f(\mu x) &\quad \Leftrightarrow \quad \mu^{-s} f^*(s) \quad (\mu > 0) \\
f(x^\rho) &\quad \Leftrightarrow \quad \frac{1}{\rho} f^*(s/\rho) \quad (\rho > 0) \\
\frac{d}{dx} f(x) &\quad \Leftrightarrow \quad -(s-1) f^*(s-1) \\
\int_0^x f(t) dt &\quad \Leftrightarrow \quad -\frac{1}{s} f^*(s+1) \\
f(x) = \sum_{k \geq 0} \lambda_k g(\mu_k x) &\quad \Leftrightarrow \quad f^*(s) = g^*(s) \sum_{k \geq 0} \lambda_k \mu_k^{-s} \quad \text{(Harmonic Sum Rule)}
\end{aligned}$$

(P4) Asymptotics for $x \to 0$ and $x \to \infty$

Let the fundamental strip of $f^*(s)$ be the set of all s such that $-\alpha < \Re(s) < -\beta$ and assume that for $s = \sigma + i\tau$, $f^*(s) = O(|s|^r)$ with $r > 1$ as $|s| \to \infty$. If $f^*(s)$ can be analytically continued to a meromorphic function for $-\beta \le \Re(s) \le M$ with finitely many poles λ_k such that $\Re(\lambda_k) < M$, then as $x \to \infty$,

$$F(x) = -\sum_{\lambda_k \in \mathcal{H}} \operatorname{Res}\left\{F^*(s)x^{-s}, s = \lambda_k\right\} + O\left(x^{-M}\right) \quad x \to \infty$$

where M is as large as we want. (In a similar fashion one can continue the function $f^*(s)$ to the left to get an asymptotic formula for $x \to 0$.)

Sketch of a Proof. Consider the rectangle R with the corners at $c - iA$, $M - iA$, $M + iA$, and $c + iA$. Choose A so that the sides of R do not pass through any singularities of $F^*(s)x^{-s}$. When evaluating

$$\lim_{A\to\infty}\int_R = \lim_{A\to\infty}\left(\int_{c-iA}^{c+iA} + \int_{c+iA}^{M+iA} + \int_{M+iA}^{M-iA} + \int_{M-iA}^{c-iA}\right),$$

the second and fourth integrals contribute very little, since $F^*(s)$ is small for s with a large imaginary part by property (P2). The contribution of the fourth integral is computed as follows:

$$\left|\int_{M+i\infty}^{M-i\infty} F^*(s)x^{-s}ds\right| = \left|\int_{\infty}^{-\infty} F^*(M+it)x^{-M-it}dt\right| \le \left|x^{-M}\right| \int_{\infty}^{-\infty} \left|F^*(M+it)\right| \left|x^{-it}\right| dt\,.$$

But the last integrand decreases exponentially as $|t| \to \infty$, thus, giving a contribution of $O(x^{-M})$. Finally, using Cauchy's residue theorem and taking into account the negative direction of R, we have

$$-\sum_{\lambda_k \in \mathcal{H}} Res\left\{F^*(s)x^{-s}, s = \lambda_k\right\} = \frac{1}{2i\pi}\int_{c-i\infty}^{c+i\infty} F^*(s)x^{-s}ds + O\left(x^{-M}\right),$$

which proves the desired result.

Specifically, the above implies that if the above smallness condition on $f^*(s)$ is satisfied for $-\beta < \Re(s) \le M$, $(M > 0)$, then

$$f^*(s) = \sum_{k=0}^{K} \frac{d_k}{(s-b)^{k+1}}\,, \tag{14.34}$$

leads to

$$f(x) = -\sum_{k=0}^{K} \frac{d_k}{k!}x^{-b}(-\log x)^k + O\left(x^{-M}\right) \quad x \to \infty\,. \tag{14.35}$$

In a similar fashion, if for $-M < \Re(s) < -\alpha$ the smallness condition of $f^*(s)$ holds and

$$f^*(s) = \sum_{k=0}^{K} \frac{d_k}{(s-b)^{k+1}}\,, \tag{14.36}$$

then

$$f(x) = \sum_{k=0}^{K} \frac{d_k}{k!}x^{-b}(-\log x)^k + O\left(x^{M}\right) \quad x \to 0\,. \tag{14.37}$$

(P5) Mellin Transform in The Complex Plane (cf. [19, 33])

If $f(z)$ is analytic in a cone $\theta_1 \le \arg(z) \le \theta_2$ with $\theta_1 < 0 < \theta_2$, then the Mellin transform $f^*(s)$ can be defined by replacing the path of the integration $[0, \infty[$ by any curve starting at $z = 0$ and going to ∞

inside the cone, and it is identical with the real transform $f^*(s)$ of $f(z) = F(z)\Big|_{z\in\mathbb{R}}$. In particular, if $f^*(s)$ fulfills an asymptotic expansion such as (14.34) or (14.36), then (14.35) or (14.37) for $f(z)$ holds in $z\to\infty$ and $z \to 0$ in the cone, respectively.

Let us now apply Mellin transforms to some problems studies above. For example, consider a trie for which the functional equation (14.25) becomes

$$\widetilde{X}(z) = \widetilde{A}(z) + \widetilde{X}(zp) + \widetilde{X}(zq) ,$$

where $p + q = 1$ and $\widetilde{A}(z)$ is the Poisson transform of a known function. Thanks to property (P3) the Mellin transform translates the above functional equation to an algebraic one which can be immediately solved, resulting in

$$X^*(s) = \frac{A^*(s)}{1 - p^{-s} - q^{-s}} ,$$

provided there exists a fundamental strip for $X^*(s)$ where also $A^*(s)$ is well defined. Now, due to property (P4) we can easily compute asymptotics of $\widetilde{X}(z)$ as $z \to \infty$ in a cone. More formally, we obtain asymptotics for z real, say x, and then either analytically continue our results or apply property (P5) which basically says that there is a cone in which the asymptotic results for real x can be extended to a complex z. Examples of usage of this technique can be found in [21, 28, 30, 32, 33, 38, 41, 44].

This is a good plan to attack problems as the above; however, one must translate asymptotics of the Poisson transform $\widetilde{X}(z)$ into the original sequence, say x_n. One would like to have $x_n \sim \widetilde{X}(n)$, but this is not true in general (e.g., take $x_n = (-1)^n$). To assure the above asymptotic equivalence, we briefly discuss the so called **depoissonization** [30, 32, 33]. We cite below only one result that found many applications in the analysis of algorithms (cf. [32]).

THEOREM 14.9 *Let $\tilde{X}(z) = \Sigma_{n\geq 0} x_n \frac{z^n}{n!} e^{-z}$ be the Poisson transform of a sequence x_n that is assumed to be an entire function of z. We postulate that in a cone S_θ ($\theta < \pi/2$) the following two conditions simultaneously hold for some real numbers A, B, $R > 0$, β, and $\alpha < 1$:*

(I) *For $z \in S_\theta$*

$$|z| > R \quad \Rightarrow \quad \left|\widetilde{X}(z)\right| \leq B|z|^\beta \Psi(|z|) ,$$

where $\Psi(x)$ is a slowly varying function, that is, such that for fixed t $\lim_{x\to\infty} \frac{\Psi(tx)}{\Psi(x)} = 1$ (e.g., $\Psi(x) = \log^d x$ for some $d > 0$);

(O) *For $z \notin S_\theta$*

$$|z| > R \quad \Rightarrow \quad \left|\widetilde{X}(z)e^z\right| \leq A \exp(\alpha|z|) .$$

Then,

$$x_n = \widetilde{X}(n) + O\left(n^{\beta-1}\Psi(n)\right) \tag{14.38}$$

or more precisely:

$$x_n = \widetilde{X}(n) - \frac{1}{2}\widetilde{X}''(n) + O\left(n^{\beta-2}\Psi(n)\right) .$$

where $\widetilde{X}''(n)$ is the second derivative of $\widetilde{X}(z)$ at $z = n$.

The verification of conditions (I) and (O) is usually not too difficult, and can be accomplished directly on the functional equation at hand through the so called *increasing domains* method discussed in [32].

Finally, we should say that there is an easier approach to deal with a majority of functional equations of type (14.25). As we pointed out, such equations possess solutions that can be represented as alternating sums (cf. (14.26) and Examples 14.10–14.12). Let us consider a general alternating sum

$$S_n = \sum_{k=m}^{n} (-1)^k \binom{n}{k} f_k$$

where f_k is a known, but otherwise, general sequence. The following two equivalent approaches (cf. [41, 52]) use complex integration (the second one is actually a Mellin-like approach) to simplify the computations of asymptotics of S_n for $n \to \infty$ (cf. [39, 52]).

THEOREM 14.10 **(Rice's Formula)** (i) *Let $f(s)$ be an analytical continuation of $f(k) = f_k$ that contains the half line $[m, \infty)$. Then,*

$$S_n := \sum_{k=m}^{n} (-1)^k \binom{n}{k} f_k = \frac{(-1)^n}{2\pi i} \int_C f(s) \frac{n!}{s(s-1)\cdots(s-n)} ds$$

where C is a positively enclosed curve that encircles $[m, n]$ and does not include any of the integers $0, 1, \ldots, m-1$.
(ii) Let $f(s)$ be analytic left to the vertical line $(\frac{1}{2} - m - i\infty, \frac{1}{2} - m + i\infty)$ with subexponential growth at infinity, then

$$\begin{aligned} S_n &= \frac{1}{2\pi i} \int_{\frac{1}{2}-m-i\infty}^{\frac{1}{2}-m+i\infty} f(-z) B(N+1, z) dz \\ &= \frac{1}{2\pi i} \int_{\frac{1}{2}-m-i\infty}^{\frac{1}{2}-m+i\infty} f(-z) n^{-z} \Gamma(z) \\ &\quad \left(1 - \frac{z(z+1)}{2n} + \frac{z(1+z)}{24n^2}(3(1+z)^2 + z - 1) + O\left(n^{-3}\right)\right) dz \end{aligned}$$

where $B(x, y) = \Gamma(x)\Gamma(y)/\Gamma(x+y)$ is the Beta function.

The precise growth condition for $f(z)$ of part (ii) can be found in [52].

EXAMPLE 14.15: Asymptotics of Some Alternating Sums

In Examples 14.10–14.12 we deal with alternating sums of the following general type:

$$S_n(r) = \sum_{k=2}^{n} (-1)^k \binom{n}{k} \binom{k}{r} \frac{1}{p^{-k} - q^{-k}} ,$$

where $p + q = 1$. We now use Theorem 14.10 to obtain asymptotics of S_n as n becomes large and r is fixed. To simplify our computation we use part (ii) of the above theorem, which leads to

$$S_n(r) = \frac{1}{2\pi i} \frac{(-1)^n}{r!} \int_{\frac{1}{2}-[2-r]^+-i\infty}^{\frac{1}{2}-[2-r]^+ + i\infty} n^{r-z} \Gamma(z) \frac{1}{1 - p^{r-z} - q^{r-z}} dz + e_n .$$

$x^+ = \max\{0, x\}$, where e_n is an error term that we discuss later. The above integral should remind the reader of the integral appearing in the inverse Mellin transform. Thus, we can estimate it using a similar approach. First of all, we observe that the function under the integral has infinitely many poles satisfying

$$1 = p^{r-z} + q^{r-z} .$$

It can be proved (cf. [32]) that these poles, say z_k for $k = 0, \pm 1, \ldots$, lie on a line $\Re(z) = r - 1$ provided $\log p / \log q$ is rational, which we assume to hold. Thus, we can write $z_k = r - 1 + i y_k$ where $y_0 = 0$ and otherwise a real number for $k \neq 0$. Observe also that the line at $\Re(z) = r - 1$ lies *right* to the line of integration $(\frac{1}{2} - [2-r]^+ - i\infty, \frac{1}{2} - [2-r]^+ + i\infty)$. To take advantages of the Cauchy residue theorem, we consider a big rectangle with left side being the line of integration, the right size position at $\Re(z) = M$

(where M is a large number), and bottom and top side position at $\Im(z) = \pm A$, say. We further observe that the right side contributes only $O(n^{r-M})$ due to the factor n^{r-M} in the integral. Both bottom and top sides contribute negligible amounts too, since the gamma function decays exponentially fast with the increase of imaginary part (i.e., when $A \to \infty$). In summary, the integral is equal to a circular integral (around the rectangle) plus a negligible part $O(n^{r-M})$. But, then by Cuachy's residue theorem the latter integral is equal to minus the sum of all residues at z_k, that is,

$$S_n(r) = -\sum_{k-\infty}^{\infty} \operatorname{Res}\left(\frac{n^{r-z}\Gamma(z)}{1-p^{r-z}-q^{r-z}},\ z = z_k\right) + O\left(n^{r-M}\right) .$$

We can compute the residues using MAPLE (as shown in "Review From Complex Analysis"). Equivalently, for $k = 0$ (the main contribution to the asymptotics comes from $z_0 = r - 1$) we can use the following expansions around $w = z - z_0$:

$$\begin{aligned} n^{r-z} &= n\left(1 - w\ln n + O\left(w^2\right)\right) , \\ \left(1 - p^{r-z} - q^{r-z}\right)^{-1} &= -w^{-1}h^{-1} + \frac{1}{2}h_2h^{-2} + O(w) , \\ \Gamma(z) &= (-1)^{r+1}\left(w^{-1} - \gamma + \delta_{r,0}\right) + O(w) \quad r = 0, 1 \end{aligned}$$

where $h = -p\ln p - q\ln q$, $h_2 = p\ln^2 p + q\ln^2 q$, and $\gamma = 0.577215\ldots$ is the Euler constant and $\delta_{r,0}$ is the Kronecker symbol. Considering in addition the residues coming from z_k for $k \neq 0$ we finally arrive at

$$S_n(r) = \begin{cases} \frac{1}{h}n\left(\ln n + \gamma - \delta_{r,0} + \frac{1}{2}h_2\right) + (-1)^r n P_r(n) + e_n & r = 0, 1 \\ n\frac{(-1)^r}{r(r-1)h} + (-1)^r n P_r(n) + e_n & r \geq 2 \end{cases}$$

where the error term can be computed easily to be $e_n = O(1)$ (using the arguments as above and observing that the error term has a similar integral representation but with term n^{-1} in front of it). In the above $P_r(n)$ is a contribution from z_k for $k \neq 0$, and it is a fluctuating function with small amplitude. For example, when $p = q = 1/2$, then

$$P_r(n) = \frac{1}{\ln 2}\sum_{k\neq 0}\Gamma\left(r + 2\pi ik/\log 2\right)\exp\left(-2\pi ik\log_2 n\right)$$

is a periodic function of $\log x$ with period 1, mean 0 and amplitude $\leq 10^{-6}$ for $r = 0, 1$.

14.6 Research Issues and Summary

In this chapter we presented a brief overview of probabilistic and analytic methods of the average-case analysis of algorithms. Among probabilistic methods we discussed the inclusion–exclusion principle, first and second moments methods, subadditive ergodic theorem, entropy and asymptotic equipartition property, central limit theorems, large deviations, and Azuma's type inequality. Analytic tools discussed in this chapter are recurrences, functional equations, complex asymptotics, Mellin transform, and analytic depoissonization. These techniques were illustrated in examples that arose in the design and analysis of algorithms on words.

We can trace back probabilistic techniques to the 1960 famous paper of Erdös and Rènyi "On the Evolution of Random Graphs." The analytic approach "was born" in 1963 when Knuth analyzed successfully the average numbers of probes in the linear hashing. Since then we have witnessed an increasing interest in the average-case analysis and design of algorithms, possibly due to the high success rate of randomized

algorithms for computational geometry, scientific visualization, molecular biology, etc. We now see the emergence of combinatorial and asymptotic methods that permit us to classify data structures into broad categories that are susceptible to a unified treatment. Probabilistic methods that have been so successful in the study of random graphs and hard combinatorial optimization problems also play an important role in the field. These developments have two important consequences for the analysis of algorithms: it becomes possible to predict average-case behavior under more *general* probabilistic models, at the same time it becomes possible to analyze much more structurally *complex* algorithms.

14.7 Defining Terms

Asymptotic equipartition property: A set of all strings of a given length can be partitioned into a set of "bad states" of a low probability, and a set of "good states" such that every string in the latter set has approximately the same probability.

Digital trees: Trees that store digital information (e.g., strings, keys, etc.). There are several types of digital trees, namely: **tries**, **PATRICIA tries**, **digital search trees**, and **suffix trees**.

Edit distance: The smallest number of insertions/deletions/substitutions required to change one string onto another.

Inclusion–exclusion principle: A rule that allows to compute the probability of *exactly r* occurrences of events $A_1, A_2, \ldots, A_n$.

Large deviations: When away by more than the standard deviation from the mean, apply the large deviation principle!

Meromorphic function: A function that is analytic, except for a finite number of poles (at which the function ceases to be defined).

Poissonization and depoissonization: When a deterministic input is replaced by a Poisson process, then the new model is called the Poisson model. After finding a solution to the Poisson model, one must interpret it in terms of the original problem, i.e., depoissonize the Poisson model.

Probabilistic models: Underlying probabilistic models that determine the input distribution (e.g., of generated strings). We discussed the **Bernoulli model,** the **Markovian model,** and the **mixing model**.

Rice's method: A method of complex asymptotics that can handle certain alternating sums arising in the analysis of algorithms.

Shortest common superstring: A shortest possible string that contains as substrings a number of given strings.

Singularity analysis: A complex asymptotic technique for determining the asymptotics of certain algebraic functions.

Subadditive ergodic theorem: If a stationary and ergodic process satisfies the subadditive inequality, then it grows almost surely linearly in time.

Acknowledgment

The author thanks his colleagues P. Jacquet, J. Kieffer, G. Louchard, H. Prodinger, and K. Park for reading earlier versions of this chapter, and for comments that led to improvements in the presentation.

Further Information

In this chapter we illustrated probabilistic techniques on examples from "stringology," that is, problems on words. Probabilistic methods found applications in many other facets of computer science, namely, random graphs (cf. [3, 22]), computational geometry (cf. [46]), combinatorial algorithms (cf. [10, 34, 50]), molecular biology (cf. [60]), and so forth. Probabilistic methods are useful in the design of randomized algorithms that make random choices during their executions. The reader interested in these algorithms is referred to [35, 46]. Analytic techniques are discussed in Knuth [39, 40, 41], recent book of Sedgewick and Flajolet [49], and in a forthcoming new book by the same authors [21].

Finally, a homepage of **Analysis of Algorithms** was recently created. The interested reader is invited to visit `http://pauillac.inria.fr/algo/AofA/index.html`.

Randomized Algorithms

Rajeev Motwani[1]
Stanford University

Prabhakar Raghavan
IBM Almaden Research Center

15.1 Introduction

A **randomized algorithm** is one that makes random choices during its execution. The behavior of such an algorithm may thus, be random even on a fixed input. The design and analysis of a randomized algorithm focuses on establishing that it is likely to behave "well" on *every* input; the likelihood in such a statement depends only on the probabilistic choices made by the algorithm during execution and not on any assumptions about the input. It is especially important to distinguish a randomized algorithm from the *average-case analysis* of algorithms, where one analyzes an algorithm assuming that its input is drawn from a fixed probability distribution. With a randomized algorithm, in contrast, no assumption is made about the input.

Two benefits of randomized algorithms have made them popular: simplicity and efficiency. For many applications, a randomized algorithm is the simplest algorithm available, or the fastest, or both. Below we make these notions concrete through a number of illustrative examples. We assume that the reader has

[1]Supported by an Alfred P. Sloan Research Fellowship, an IBM Faculty Partnership Award, an ARO MURI Grant DAAH04-96-1-0007, and NSF Young Investigator Award CCR-9357849, with matching funds from IBM, Schlumberger Foundation, Shell Foundation, and Xerox Corporation.

had undergraduate courses in algorithms and complexity, and in probability theory. A comprehensive source for randomized algorithms is the book by the authors [24]. The articles by Karp [17], Maffioli, Speranza, and Vercellis [21] and Welsh [44] are good surveys of randomized algorithms. The book by Mulmuley [25] focuses on randomized geometric algorithms.

Throughout this chapter we assume the RAM model of computation, in which we have a machine that can perform the following operations involving registers and main memory: input–output operations, memory–register transfers, indirect addressing, branching and arithmetic operations. Each register or memory location may hold an integer which can be accessed as a unit, but an algorithm has no access to the representation of the number. The arithmetic instructions permitted are $+, -, \times, /$. In addition, an algorithm can compare two numbers, and evaluate the square root of a positive number. In this article $\mathbf{E}[X]$ will denote the expectation of a random variable X, and $\mathbf{Pr}[A]$ will denote the probability of an event A.

15.2 Sorting and Selection by Random Sampling

Some of the earliest randomized algorithms included algorithms for sorting a set S of numbers, and the related problem of finding the kth smallest element in S. The main idea behind these algorithms is the use of *random sampling:* a randomly chosen member of S is unlikely to be one of its largest or smallest elements; rather, it is likely to be "near the middle." Extending this intuition suggests that a random sample of elements from S is likely to be spread "roughly uniformly" in S. We now describe randomized algorithms for sorting and selection based on these ideas.

Algorithm RQS:

Input: A set of numbers S.

Output: The elements of S sorted in increasing order.

1. Choose an element y uniformly at random from S: every element in S has equal probability of being chosen.

2. By comparing each element of S with y, determine the set S_1 of elements smaller than y and the set S_2 of elements larger than y.

3. Recursively sort S_1 and S_2. Output the sorted version of S_1, followed by y, and then the sorted version of S_2.

Algorithm **RQS** is an example of a *randomized algorithm* — an algorithm that makes random choices during execution. It is inspired by the **Quicksort** algorithm due to Hoare [12], and described in [24]. We assume that the random choice in Step 1 can be made in unit time. What can we prove about the running time of **RQS**?

We now analyze the *expected* number of comparisons in an execution of **RQS.** Comparisons are performed in Step 2, in which we compare a randomly chosen element to the remaining elements. For $1 \leq i \leq n$, let $S_{(i)}$ denote the element of *rank* i (the ith smallest element) in the set S. Define the random variable X_{ij} to assume the value 1 if $S_{(i)}$ and $S_{(j)}$ are compared in an execution, and the value 0 otherwise. Thus, the total number of comparisons is $\Sigma_{i=1}^{n} \Sigma_{j>i} X_{ij}$. By linearity of expectation the expected number of comparisons is

$$\mathbf{E}\left[\sum_{i=1}^{n}\sum_{j>i} X_{ij}\right] = \sum_{i=1}^{n}\sum_{j>i} \mathbf{E}\left[X_{ij}\right] . \tag{15.1}$$

Let p_{ij} denote the probability that $S_{(i)}$ and $S_{(j)}$ are compared during an execution. Then

$$\mathbf{E}\left[X_{ij}\right] = p_{ij} \times 1 + \left(1 - p_{ij}\right) \times 0 = p_{ij} \; . \tag{15.2}$$

To compute p_{ij} we view the execution of **RQS** as a binary tree T each node of which is labeled with a distinct element of S. The root of the tree is labeled with the element y chosen in Step 1, the left subtree of y contains the elements in S_1, and the right subtree of y contains the elements in S_2. The structures of the two subtrees are determined recursively by the executions of **RQS** on S_1 and S_2. The root y is compared to the elements in the two subtrees, but no comparison is performed between an element of the left subtree and an element of the right subtree. Thus, there is a comparison between $S_{(i)}$ and $S_{(j)}$ if and only if one of these elements is an ancestor of the other.

Consider the permutation π obtained by visiting the nodes of T in increasing order of the level numbers, and in a left-to-right order within each level; recall that the ith level of the tree is the set of all nodes at distance exactly i from the root. The following two observation lead to the determination of p_{ij}.

1. There is a comparison between $S_{(i)}$ and $S_{(j)}$ if and only if $S_{(i)}$ or $S_{(j)}$ occurs earlier in the permutation π than any element $S_{(\ell)}$ such that $i < \ell < j$. To see this, let $S_{(k)}$ be the earliest in π from among all elements of rank between i and j. If $k \notin \{i, j\}$, then $S_{(i)}$ will belong to the left subtree of $S_{(k)}$ while $S_{(j)}$ will belong to the right subtree of $S_{(k)}$, implying that there is no comparison between $S_{(i)}$ and $S_{(j)}$. Conversely, when $k \in \{i, j\}$, there is an ancestor-descendant relationship between $S_{(i)}$ and $S_{(j)}$, implying that the two elements are compared by **RQS.**
2. Any of the elements $S_{(i)}, S_{(i+1)}, \ldots, S_{(j)}$ is equally likely to be the first of these elements to be chosen as a partitioning element and hence, to appear first in π. Thus, the probability that this first element is either $S_{(i)}$ or $S_{(j)}$ is exactly $2/(j - i + 1)$.

It follows that $p_{ij} = 2/(j - i + 1)$. By (15.1) and (15.2), the expected number of comparisons is given by

$$\begin{aligned} \sum_{i=1}^{n} \sum_{j>i} p_{ij} &= \sum_{i=1}^{n} \sum_{j>i} \frac{2}{j - i + 1} \\ &\leq \sum_{i=1}^{n-1} \sum_{k=1}^{n-i} \frac{2}{k+1} \\ &\leq 2 \sum_{i=1}^{n} \sum_{k=1}^{n} \frac{1}{k} \; . \end{aligned}$$

It follows that the expected number of comparisons is bounded above by $2nH_n$, where H_n is the *nth harmonic number,* defined by $H_n = \Sigma_{k=1}^{n} 1/k$.

THEOREM 15.1 *The expected number of comparisons in an execution of* **RQS** *is at most* $2nH_n$.

Now $H_n = \ln n + \Theta(1)$, so that the expected running time of **RQS** is $\mathrm{O}\left(n \log n\right)$. Note that this expected running time *holds for every input.* It is an expectation that depends only on the random choices made by the algorithm, and *not* on any assumptions about the distribution of the input.

Randomized Selection

We now consider the use of random sampling for the problem of selecting the kth smallest element in a set S of n elements drawn from a totally ordered universe. We assume that the elements of S are all distinct,

although it is not very hard to modify the following analysis to allow for multisets. Let $r_S(t)$ denote the rank of an element t (the kth smallest element has rank k) and recall that $S_{(i)}$ denotes the ith smallest element of S. Thus, we seek to identify $S_{(k)}$. We extend the use of this notation to subsets of S as well. The following algorithm is adapted from one due to Floyd and Rivest [9].

Algorithm LazySelect:

Input: A set S of n elements from a totally ordered universe, and an integer k in $[1, n]$.

Output: The kth smallest element of S, $S_{(k)}$.

1. Pick $n^{3/4}$ elements from S, chosen independently and uniformly at random with replacement; call this multiset of elements R.

2. Sort R in $O(n^{3/4} \log n)$ steps using any optimal sorting algorithm.

3. Let $x = kn^{-1/4}$. For $\ell = \max\{\lfloor x - \sqrt{n} \rfloor, 1\}$ and $h = \min\{\lceil x + \sqrt{n} \rceil, n^{3/4}\}$, let $a = R_{(\ell)}$ and $b = R_{(h)}$. By comparing a and b to every element of S, determine $r_S(a)$ and $r_S(b)$.

4. **if** $k < n^{1/4}$, let $P = \{y \in S \mid y \leq b\}$ and $r = k$;
else if $k > n - n^{1/4}$, let $P = \{y \in S \mid y \geq a\}$ and $r = k - r_S(a) + 1$;
else if $k \in [n^{1/4}, n - n^{1/4}]$, let $P = \{y \in S \mid a \leq y \leq b\}$ and $r = k - r_S(a) + 1$;
Check whether $S_{(k)} \in P$ *and* $|P| \leq 4n^{3/4} + 2$. If not, repeat Steps 1–3 until such a set P is found.

5. By sorting P in $O(|P| \log |P|)$ steps, identify P_r, which is $S_{(k)}$.

Figure 15.1 illustrates Step 3, where small elements are at the left end of the picture and large ones to the right. Determining (in Step 4) whether $S_{(k)} \in P$ is easy, since we know the ranks $r_S(a)$ and $r_S(b)$ and we compare either or both of these to k, depending on which of the three **if** statements in Step 4 we execute. The sorting in Step 5 can be performed in $O(n^{3/4} \log n)$ steps.

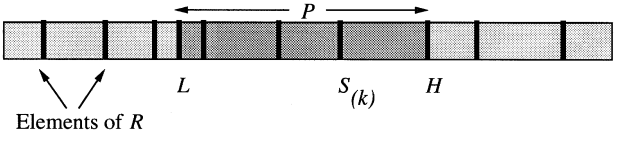

FIGURE 15.1 The **LazySelect** algorithm.

Thus, the idea of the algorithm is to identify two elements a and b in S such that both of the following statements hold with high probability:

1. The element $S_{(k)}$ that we seek is in P, the set of elements between a and b;
2. The set P of elements is not very large, so that we can sort P inexpensively in Step 5.

As in the analysis of **RQS** we measure the running time of **LazySelect** in terms of the number of comparisons performed by it. The following theorem is established using the *Chebyshev bound* from elementary probability theory; a full proof may be found in [24].

THEOREM 15.2 *With probability* $1 - O(n^{-1/4})$, **LazySelect** *finds* $S_{(k)}$ *on the first pass through Steps 1–5, and thus, performs only* $2n + o(n)$ *comparisons.*

This adds to the significance of **LazySelect:** the best known deterministic selection algorithms use $3n$ comparisons in the worst case, and are quite complicated to implement.

15.3 A Simple Min-Cut Algorithm

Two events $\mathcal{E}_1$ and $\mathcal{E}_2$ are said to be *independent* if the probability that they both occur is given by

$$\mathbf{Pr}\left[\mathcal{E}_1 \cap \mathcal{E}_2\right] = \mathbf{Pr}\left[\mathcal{E}_1\right] \times \mathbf{Pr}\left[\mathcal{E}_2\right] \ . \tag{15.3}$$

More generally when $\mathcal{E}_1$ and $\mathcal{E}_2$ are not necessarily independent,

$$\mathbf{Pr}\left[\mathcal{E}_1 \cap \mathcal{E}_2\right] = \mathbf{Pr}\left[\mathcal{E}_1 \mid \mathcal{E}_2\right] \times \mathbf{Pr}\left[\mathcal{E}_2\right] = \mathbf{Pr}\left[\mathcal{E}_2 \mid \mathcal{E}_1\right] \times \mathbf{Pr}\left[\mathcal{E}_1\right] \ , \tag{15.4}$$

where $\mathbf{Pr}\left[\mathcal{E}_1 \mid \mathcal{E}_2\right]$ denotes the *conditional probability* of $\mathcal{E}_1$ given $\mathcal{E}_2$. When a collection of events is not independent, the probability of their intersection is given by the following generalization of (15.4):

$$\mathbf{Pr}\left[\cap_{i=1}^{k}\mathcal{E}_i\right] = \mathbf{Pr}\left[\mathcal{E}_1\right] \times \mathbf{Pr}\left[\mathcal{E}_2 \mid \mathcal{E}_1\right] \times \mathbf{Pr}\left[\mathcal{E}_3 \mid \mathcal{E}_1 \cap \mathcal{E}_2\right] \cdots \mathbf{Pr}\left[\mathcal{E}_k \mid \cap_{i=1}^{k-1}\mathcal{E}_i\right] \ . \tag{15.5}$$

Let G be a connected, undirected multigraph with n vertices. A *multigraph* may contain multiple edges between any pair of vertices. A *cut* in G is a set of edges whose removal results in G being broken into two or more components. A *min-cut* is a cut of minimum cardinality. We now study a simple algorithm due to Karger [14] for finding a min-cut of a graph.

We repeat the following step: pick an edge uniformly at random and merge the two vertices at its end points. If as a result there are several edges between some pairs of (newly formed) vertices, retain them all. Remove edges between vertices that are merged, so that there are never any self-loops. This process of merging the two end-points of an edge into a single vertex is called the *contraction* of that edge. With each contraction, the number of vertices of G decreases by one. Note that as long as at least two vertices remain, an edge contraction does not reduce the min-cut size in G. The algorithm continues the contraction process until only two vertices remain; at this point, the set of edges between these two vertices is a cut in G and is output as a candidate min-cut. What is the probability that this algorithm finds a min-cut?

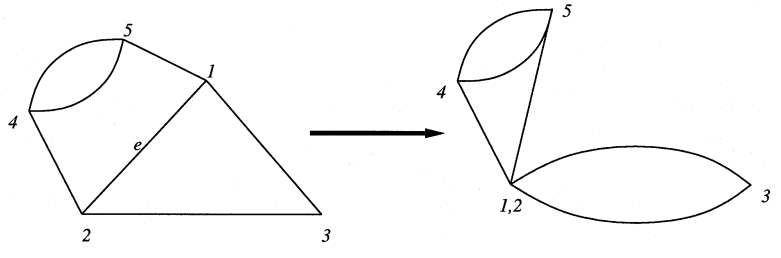

FIGURE 15.2 A step in the min-cut algorithm; the effect of contracting edge $e = (1, 2)$ is shown.

DEFINITION 15.1 For any vertex v in a multigraph G, the *neighborhood* of G, denoted $\Gamma(v)$, is the set of vertices of G that are adjacent to v. The *degree* of v, denoted $d(v)$, is the number of edges incident on v. For a set S of vertices of G, the neighborhood of S, denoted $\Gamma(S)$, is the union of the neighborhoods of the constituent vertices.

Note that $d(v)$ is the same as the cardinality of $\Gamma(v)$ when there are no self-loops or multiple edges between v and any of its neighbors.

Let k be the min-cut size and let C be a particular min-cut with k edges. Clearly G has at least $kn/2$ edges (otherwise there would be a vertex of degree less than k, and its incident edges would be a min-cut of size less than k). We bound from below the probability that no edge of C is ever contracted during an execution of the algorithm, so that the edges surviving till the end are exactly the edges in C.

For $1 \leq i \leq n-2$, let $\mathcal{E}_i$ denote the event of *not* picking an edge of C at the ith step. The probability that the edge randomly chosen in the first step is in C is at most $k/(nk/2) = 2/n$, so that $\mathbf{Pr}[\mathcal{E}_1] \geq 1 - 2/n$. Conditioned on the occurrence of $\mathcal{E}_1$, there are at least $k(n-1)/2$ edges during the second step so that $\mathbf{Pr}[\mathcal{E}_2 \mid \mathcal{E}_1] \geq 1 - 2/(n-1)$. Extending this calculation, $\mathbf{Pr}\left[\mathcal{E}_i \mid \cap_{j=1}^{i-1}\mathcal{E}_j\right] \geq 1 - 2/(n-i+1)$. We now invoke (15.5) to obtain

$$\mathbf{Pr}\left[\cap_{i=1}^{n-2}\mathcal{E}_i\right] \geq \prod_{i=1}^{n-2}\left(1 - \frac{2}{n-i+1}\right) = \frac{2}{n(n-1)}\,.$$

Our algorithm may err in declaring the cut it outputs to be a min-cut. But the probability of discovering a particular min-cut (which may in fact be the unique min-cut in G) is larger than $2/n^2$, so the probability of error is at most $1 - 2/n^2$. Repeating the above algorithm $n^2/2$ times making independent random choices each time, the probability that a min-cut is not found in any of the $n^2/2$ attempts is [by (15.3)] at most

$$\left(1 - \frac{2}{n^2}\right)^{n^2/2} < 1/e\,.$$

By this process of repetition, we have managed to reduce the probability of failure from $1 - 2/n^2$ to less than $1/e$. Further executions of the algorithm will make the failure probability arbitrarily small (the only consideration being that repetitions increase the running time). Note the extreme simplicity of this randomized min-cut algorithm. In contrast, most **deterministic algorithms** for this problem are based on network flow and are considerably more complicated.

Classification of Randomized Algorithms

The randomized sorting algorithm and the min-cut algorithm exemplify two different types of randomized algorithms. The sorting algorithm *always* gives the correct solution. The only variation from one run to another is its running time, whose distribution we study. Such an algorithm is called a **Las Vegas algorithm.**

In contrast, the min-cut algorithm may sometimes produce a solution that is incorrect. However, we prove that the probability of such an error is bounded. Such an algorithm is called a **Monte Carlo algorithm.** In Section 15.3 we observed a useful property of a Monte Carlo algorithm: if the algorithm is run repeatedly with independent random choices each time, the failure probability can be made arbitrarily small, at the expense of running time. In some randomized algorithms both the running time and the quality of the solution are random variables; sometimes these are also referred to as Monte Carlo algorithms. The reader is referred to [24] for a detailed discussion of these issues.

15.4 Foiling an Adversary

A common paradigm in the design of randomized algorithms is that of *foiling an adversary.* Whereas an adversary might succeed in defeating a deterministic algorithm with a carefully constructed "bad" input, it is difficult for an adversary to defeat a deterministic algorithm in this fashion. Due to the random choices made by the randomized algorithm the adversary cannot, while constructing the input, predict the precise

behavior of the algorithm. An alternative view of this process is to think of the randomized algorithm as first picking a series of random numbers which it then uses in the course of execution as needed. In this view, we may think of the random numbers chosen at the start as "selecting" one of a family of deterministic algorithms. In other words a randomized algorithm can be thought of as a probability distribution on deterministic algorithms. We illustrate these ideas in the setting of AND-OR *tree evaluation*; the following algorithm is due to Snir [38].

For our purposes an AND-OR tree is a rooted complete binary tree in which internal nodes at even distance from the root are labeled AND and internal nodes at odd distance are labeled OR. Associated with each leaf is a Boolean *value.* The *evaluation* of the game tree is the following process. Each leaf *returns* the value associated with it. Each OR node returns the Boolean OR of the values returned by its children, and each AND node returns the Boolean AND of the values returned by its children. At each step an evaluation algorithm chooses a leaf and reads its value. We do not charge the algorithm for any other computation. We study the number of such steps taken by an algorithm for evaluating an AND-OR tree, the worst case being taken over all assignments of Boolean values to the leaves.

Let T_k denote an AND-OR tree in which every leaf is at distance $2k$ from the root. Thus, any root-to-leaf path passes through k AND nodes (including the root itself) and k OR nodes, and there are 2^{2k} leaves. An algorithm begins by specifying a leaf whose value is to be read at the first step. Thereafter, it specifies such a leaf at each step, based on the values it has read on previous steps. In a deterministic algorithm, the choice of the next leaf to be read is a deterministic function of the values at the leaves read so far. For a randomized algorithm, this choice may be randomized. It is not hard to show that for any deterministic evaluation algorithm, there is an instance of T_k that forces the algorithm to read the values on all 2^{2k} leaves.

We now give a simple randomized algorithm and study the expected number of leaves it reads on any instance of T_k. The algorithm is motivated by the following simple observation. Consider a single AND node with two leaves. If the node were to return 0, at least one of the leaves must contain 0. A deterministic algorithm inspects the leaves in a fixed order, and an adversary can therefore always "hide" the 0 at the second of the two leaves inspected by the algorithm. Reading the leaves in a random order foils this strategy. With probability $1/2$, the algorithm chooses the hidden 0 on the first step, so its expected number of steps is $3/2$, which is better than the worst case for any deterministic algorithm. Similarly, in the case of an OR node, if it were to return a 1 then a randomized order of examining the leaves will reduce the expected number of steps to $3/2$. We now extend this intuition and specify the complete algorithm.

To evaluate an AND node v, the algorithm chooses one of its children (a subtree rooted at an OR node) at random and evaluates it by recursively invoking the algorithm. If 1 is returned by the subtree, the algorithm proceeds to evaluate the other child (again by recursive application). If 0 is returned, the algorithm returns 0 for v. To evaluate an OR node, the procedure is the same with the roles of 0 and 1 interchanged. We establish by induction on k that the expected cost of evaluating any instance of T_k is at most 3^k.

The basis ($k = 0$) is trivial. Assume now that the expected cost of evaluating any instance of T_{k-1} is at most 3^{k-1}. Consider first a tree T whose root is an OR node, each of whose children is the root of a copy of T_{k-1}. If the root of T were to evaluate to 1, at least one of its children returns 1. With probability $1/2$ this child is chosen first, incurring (by the inductive hypothesis) an expected cost of at most 3^{k-1} in evaluating T. With probability $1/2$ both subtrees are evaluated, incurring a net cost of at most $2 \times 3^{k-1}$. Thus, the expected cost of determining the value of T is

$$\leq \frac{1}{2} \times 3^{k-1} + \frac{1}{2} \times 2 \times 3^{k-1} = \frac{3}{2} \times 3^{k-1} . \tag{15.6}$$

If on the other hand the OR were to evaluate to 0 both children must be evaluated, incurring a cost of at most $2 \times 3^{k-1}$.

Consider next the root of the tree T_k, an AND node. If it evaluates to 1, then both its subtrees rooted at OR nodes return 1. By the discussion in the previous paragraph and by linearity of expectation, the expected cost of evaluating T_k to 1 is at most $2 \times (3/2) \times 3^{k-1} = 3^k$. On the other hand, if the instance

of T_k evaluates to 0, at least one of its subtrees rooted at OR nodes returns 0. With probability 1/2 it is chosen first, and so the expected cost of evaluating T_k is at most

$$2 \times 3^{k-1} + \frac{1}{2} \times \frac{3}{2} \times 3^{k-1} \leq 3^k \ .$$

THEOREM 15.3 *Given any instance of T_k, the expected number of steps for the above randomized algorithm is at most 3^k.*

Since $n = 4^k$ the expected running time of our randomized algorithm is $n^{\log_4 3}$, which we bound by $n^{0.793}$. Thus, the expected number of steps is smaller than the worst case for any deterministic algorithm. Note that this is a Las Vegas algorithm and always produces the correct answer.

15.5 The Minimax Principle and Lower Bounds

The randomized algorithm of the preceding section has an expected running time of $n^{0.793}$ on any uniform binary AND-OR tree with n leaves. Can we establish that *no randomized algorithm* can have a lower expected running time? We first introduce a standard technique due to Yao [45] for proving such lower bounds. This technique applies only to algorithms that terminate in finite time on all inputs and sequences of random choices.

The crux of the technique is to relate the running times of randomized algorithms for a problem to the running times of *deterministic* algorithms for the problem *when faced with randomly chosen inputs.* Consider a problem where the number of distinct inputs of a fixed size is finite, as is the number of distinct (deterministic, terminating, and always correct) algorithms for solving that problem. Let us define the **distributional complexity** of the problem at hand as the expected running time of the best deterministic algorithm for the worst distribution on the inputs. Thus, we envision an adversary choosing a probability distribution on the set of possible inputs, and study the best deterministic algorithm for this distribution. Let $\boldsymbol{p}$ denote a probability distribution on the set $\mathcal{I}$ of inputs. Let the random variable $C(I_{\boldsymbol{p}}, A)$ denote the running time of deterministic algorithm $A \in \mathcal{A}$ on an input chosen according to $\boldsymbol{p}$. Viewing a randomized algorithm as a probability distribution $\boldsymbol{q}$ on the set $\mathcal{A}$ of deterministic algorithms, we let the random variable $C(I, A_{\boldsymbol{q}})$ denote the running time of this randomized algorithm on the worst-case input.

PROPOSITION 15.1 **(Yao's Minimax Principle):** For all distributions $\boldsymbol{p}$ over $\mathcal{I}$ and $\boldsymbol{q}$ over $\mathcal{A}$,

$$\min_{A \in \mathcal{A}} \mathbf{E}\left[C(I_{\boldsymbol{p}}, A)\right] \leq \max_{I \in \mathcal{I}} \mathbf{E}\left[C(I, A_{\boldsymbol{q}})\right] \ .$$

In other words, the expected running time of the optimal deterministic algorithm for an arbitrarily chosen input distribution $\boldsymbol{p}$ is a lower bound on the expected running time of the optimal (Las Vegas) randomized algorithm for Π. Thus, to prove a lower bound on the **randomized complexity** it suffices to choose any distribution $\boldsymbol{p}$ on the input and prove a lower bound on the expected running time of deterministic algorithms for that distribution. The power of this technique lies in the flexibility in the choice of $\boldsymbol{p}$ and, more importantly, the reduction to a lower bound on deterministic algorithms. It is important to remember that the deterministic algorithm "knows" the chosen distribution $\boldsymbol{p}$.

The above discussion dealt only with lower bounds on the performance of Las Vegas algorithms. We briefly discuss Monte Carlo algorithms with error probability $\epsilon \in [0, 1/2]$. Let us define the distributional complexity with error ϵ, denoted $\min_{A \in \mathcal{A}} \mathbf{E}[C_\epsilon(I_{\boldsymbol{p}}, A)]$, to be the minimum expected running time of any deterministic algorithm that errs with probability at most ϵ under the input distribution $\boldsymbol{p}$. Similarly, we denote by $\max_{I \in \mathcal{I}} \mathbf{E}[C_\epsilon(I, A_{\boldsymbol{q}})]$ the expected running time (under the worst input) of any randomized

algorithm that errs with probability at most ϵ (again, the randomized algorithm is viewed as a probability distribution $\boldsymbol{q}$ on deterministic algorithms). Analogous to Proposition 15.1, we then have the following:

PROPOSITION 15.2 For all distributions $\boldsymbol{p}$ over $\mathcal{I}$ and $\boldsymbol{q}$ over $\mathcal{A}$ and any $\epsilon \in [0, 1/2]$,

$$\frac{1}{2}\left(\min_{A\in\mathcal{A}} \mathbf{E}\left[C_{2\epsilon}\left(I_{\boldsymbol{p}}, A\right)\right]\right) \leq \max_{I\in\mathcal{I}} \mathbf{E}\left[C_{\epsilon}\left(I, A_{\boldsymbol{q}}\right)\right] .$$

Lower Bound for Game Tree Evaluation

We now apply Yao's Minimax Principle to the AND-OR tree evaluation problem. A randomized algorithm for AND-OR tree evaluation can be viewed as a probability distribution over deterministic algorithms, because the length of the computation as well as the number of choices at each step are both finite. We may imagine that all of these coins are tossed before the beginning of the execution.

The tree T_k is equivalent to a balanced binary tree all of whose leaves are at distance $2k$ from the root, and all of whose internal nodes compute the NOR function: a node returns the value 1 if both inputs are 0, and 0 otherwise. We proceed with the analysis of this tree of NORs of depth $2k$.

Let $p = (3 - \sqrt{5})/2$; each leaf of the tree is independently set to 1 with probability p. If each input to a NOR node is independently 1 with probability p, its output is 1 with probability

$$\left(\frac{\sqrt{5}-1}{2}\right)^2 = \frac{3-\sqrt{5}}{2} = p .$$

Thus, the value of every node of the NOR tree is 1 with probability p, and the value of a node is independent of the values of all the other nodes on the same level. Consider a deterministic algorithm that is evaluating a tree furnished with such random inputs; let v be a node of the tree whose value the algorithm is trying to determine. Intuitively, the algorithm should determine the value of one child of v before inspecting any leaf of the other subtree. An alternative view of this process is that the deterministic algorithm should inspect leaves visited in a depth-first search of the tree, except of course that it ceases to visit subtrees of a node v when the value of v has been determined. Let us call such an algorithm a *depth-first pruning* algorithm, referring to the order of traversal and the fact that subtrees that supply no additional information are "pruned" away without being inspected. The following result is due to Tarsi [40].

PROPOSITION 15.3 Let T be a NOR tree each of whose leaves is independently set to 1 with probability q for a fixed value $q \in [0, 1]$. Let $W(T)$ denote the minimum, over all deterministic algorithms, of the expected number of steps to evaluate T. Then, there is a depth-first pruning algorithm whose expected number of steps to evaluate T is $W(T)$.

Proposition 15.3 tells us that for the purposes of our lower bound, we may restrict our attention to depth-first pruning algorithms. Let $W(h)$ be the expected number of leaves inspected by a depth-first pruning algorithm in determining the value of a node at distance h from the leaves, when each leaf is independently set to 1 with probability $(3 - \sqrt{5})/2)$. Clearly

$$W(h) = W(h-1) + (1-p) \times W(h-1) ,$$

where the first term represents the work done in evaluating one of the subtrees of the node, and the second term represents the work done in evaluating the other subtree (which will be necessary if the first subtree returns the value 0, an event occurring with probability $1 - p$). Letting h be $\log_2 n$, and solving, we get $W(h) \geq n^{0.694}$.

THEOREM 15.4 *The expected running time of any randomized algorithm that always evaluates an instance of T_k correctly is at least $n^{0.694}$, where $n = 2^{2k}$ is the number of leaves.*

Why is our lower bound of $n^{0.694}$ less than the upper bound of $n^{0.793}$ that follows from Theorem 15.3? The reason is that we have not chosen the best possible probability distribution for the values of the leaves. Indeed, in the NOR tree if both inputs to a node are 1, no reasonable algorithm will read leaves of both subtrees of that node. Thus, to prove the best lower bound we have to choose a distribution on the inputs that precludes the event that both inputs to a node will be 1; in other words, the values of the inputs are chosen at random but not independently. This stronger (and considerably harder) analysis can in fact be used to show that the algorithm of Section 15.4 is optimal; the reader is referred to the paper of Saks and Wigderson [33] for details.

15.6 Randomized Data Structures

Recent research into data structures has strongly emphasized the use of randomized techniques to achieve increased efficiency without sacrificing simplicity of implementation. An illustrative example is the randomized data structure for dynamic dictionaries called *skip list* that is due to Pugh [27].

The dynamic dictionary problem is that of maintaining a set of keys X drawn from a totally ordered universe so as to provide efficient support of the following operations: $\mathsf{find}(q, X)$ — decide whether the query key q belongs to X and return the information associated with this key if it does indeed belong to X; $\mathsf{insert}(q, X)$ — insert the key q into the set X, unless it is already present in X; $\mathsf{delete}(q, X)$ — delete the key q from X, unless it is absent from X. The standard approach for solving this problem involves the use of a binary search tree and gives worst-case time per operation that is $O(\log n)$, where n is the size of X at the time the operation is performed. Unfortunately, achieving this time bound requires the use of complex rebalancing strategies to ensure that the search tree remains "balanced," i.e., has depth $O(\log n)$. Not only does rebalancing require more effort in terms of implementation, it also leads to significant overheads in the running time (at least in terms of the constant factors subsumed by the big-oh notation). The skip list data structure is a rather pleasant alternative that overcomes both these shortcomings.

Before getting into the details of randomized skip lists, we will develop some of the key ideas without the use of randomization. Suppose we have a totally ordered data set $X = \{x_1 < x_2 < \cdots < x_n\}$. A *gradation* of X is a sequence of nested subsets (called *levels*)

$$X_r \subseteq X_{r-1} \subseteq \cdots \subseteq X_2 \subseteq X_1$$

such that $X_r = \emptyset$ and $X_1 = X$. Given an ordered set X and a gradation for it, the level of any element $x \in X$ is defined as

$$L(x) = \max \{i \mid x \in X_i\} \ ,$$

that is, $L(x)$ is the largest index i such that x belongs to the ith level of the gradation. In what follows, we will assume that two special elements $-\infty$ and $+\infty$ belong to each of the levels, where $-\infty$ is smaller than all elements in X and $+\infty$ is larger than all elements in X.

We now define an ordered list data structure with respect to a gradation of the set X. The first level, X_1, is represented as an ordered linked list, and each node x in this list has a stack of $L(x) - 1$ additional nodes directly above it. Finally, we obtain the skip list with respect to the gradation of X by introducing horizontal and vertical pointers between these nodes as illustrated in Fig. 15.3. The skip list in Fig. 15.3 corresponds to a gradation of the data set $X = \{1, 3, 4, 7, 9\}$ consisting of the following 6 levels:

$$\begin{aligned} X_6 &= \emptyset \\ X_5 &= \{3\} \\ X_4 &= \{3, 4\} \end{aligned}$$

$$
\begin{aligned}
X_3 &= \{3, 4, 9\} \\
X_2 &= \{3, 4, 7, 9\} \\
X_1 &= \{1, 3, 4, 7, 9\}
\end{aligned}
$$

Observe that starting at the ith node from the bottom in the left-most column of nodes, and traversing the horizontal pointers in order yields a set of nodes corresponding to the elements of the ith level X_i.

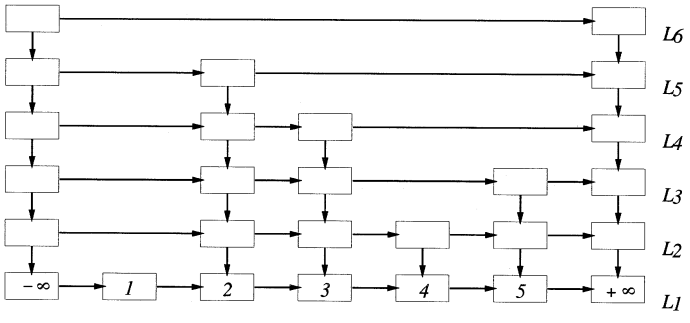

FIGURE 15.3 A skip list.

Additionally, we will view each level i as defining a set of *intervals* each of which is defined as the set of elements of X spanned by a horizontal pointer at level i. The sequence of levels X_i can be viewed as successively coarser partitions of X. In Fig. 15.3, the levels determine the following partitions of X into a intervals.

$$
\begin{aligned}
X_6 &= [-\infty, +\infty] \\
X_5 &= [-\infty, 3] \cup [3, +\infty] \\
X_4 &= [-\infty, 3] \cup [3, 4] \cup [4, +\infty] \\
X_3 &= [-\infty, 3] \cup [3, 4] \cup [4, 9] \cup [9, +\infty] \\
X_2 &= [-\infty, 3] \cup [3, 4] \cup [4, 7] \cup [7, 9] \cup [9, +\infty] \\
X_1 &= [-\infty, 1] \cup [1, 3] \cup [3, 4] \cup [4, 7] \cup [7, 9] \cup [9, +\infty]
\end{aligned}
$$

An alternate view of the skip list is in terms of a tree defined by the interval partition structure, as illustrated in Fig. 15.4 for the example above. In this tree, each node corresponds to an interval, and the intervals at a given level are represented by nodes at the corresponding level of the tree. When an interval J at level $i + 1$ is a superset of an interval I at level i, then the corresponding node J has the node I as a child in this tree. Let $C(I)$ denote the number of children in the tree of a node corresponding to the interval I, i.e., it is the number of intervals from the previous level that are subintervals of I. Note that the tree is not necessarily binary since the value of $C(I)$ is arbitrary. We can view the skip list as a threaded version of this tree, where each thread is a sequence of (horizontal) pointers linking together the nodes at a level into an ordered list. In Fig. 15.4, the broken lines indicate the threads, and the full lines are the actual tree pointers.

Finally, we need some notation concerning the membership of an element x in the intervals defined above, where x is not necessarily a member of X. For each possible x, let $I_j(x)$ be the interval at level j containing x. In the degenerate case where x lies on the boundary between two intervals, we assign it to the leftmost such interval. Observe that the nested sequence of intervals containing y,

$$
I_r(y) \subseteq I_{r-1}(y) \subseteq \cdots \subseteq I_1(y) \,,
$$

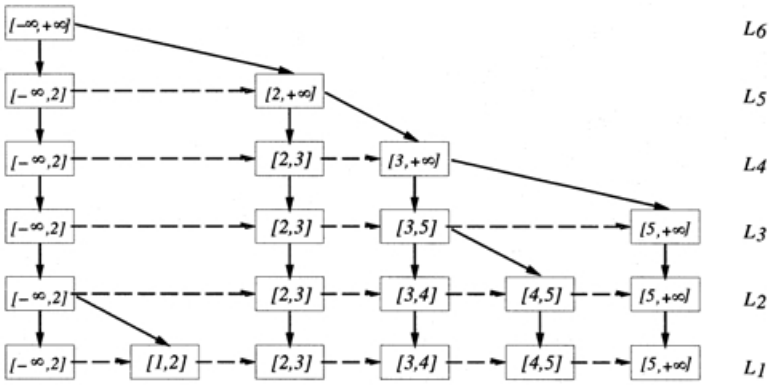

FIGURE 15.4 Tree representation of a skip list.

corresponds to a root-leaf path in the tree corresponding to the skip list.

It remains to specify the choice of the gradation that determines the structure of a skip list. This is precisely where we introduce randomization into the structure of a skip list. The idea is to define a random gradation. Our analysis will show that with high probability, the search tree corresponding to a random skip list is "balanced," and then the dictionary operations can be efficiently implemented.

We define the *random gradation* for X as follows: given level X_i, the next level X_{i+1} is determined by independently choosing to retain each element $x \in X_i$ with probability $1/2$. The random selection process begins with $X_1 = X$ and terminates when for the first time the resulting level is empty. Alternatively, we may view the choice of the gradation as follows: for each $x \in X$, choose the level $L(x)$ independently from the geometric distribution with parameter $p = 1/2$ and place x in the levels $X_1, \ldots, X_{L(x)}$. We define r to be one more than the maximum of these level numbers. Such a random level is chosen for every element of X upon its insertion and remains fixed until its deletion.

We omit the proof of the following theorem bounding the space complexity of a randomized skip list. The proof is a simple exercise, and it is recommended that the reader verify this to gain some insight into the behavior of this data structure.

THEOREM 15.5 *A random skip list for a set X of size n has expected space requirement $O(n)$.*

We will go into more details about the time complexity of this data structure. The following lemma underlies the running time analysis.

LEMMA 15.1 The number of levels r in a random gradation of a set X of size n has expected value $\mathbf{E}[r] = O(\log n)$. Further, $r = O(\log n)$ with high probability.

PROOF We will prove the high probability result; the bound on the expected value follows immediately from this. Recall that the level numbers $L(x)$ for $x \in X$ are i.i.d. (independent and identically distributed) random variables distributed geometrically with parameter $p = 1/2$; notationally, we will denote these random variables by $Z_1, \ldots, Z_n$. Now, the total number of levels in the skip list can be determined as

$$r = 1 + \max_{x \in X} L(x) = 1 + \max_{1 \le i \le n} Z_i \ ,$$

that is, as one more than the maximum of n i.i.d. geometric random variables.

For such geometric random variables with parameter p, it is easy to verify that for any positive real t, $\mathbf{Pr}[Z_i > t] \leq (1-p)^t$. It follows that

$$\mathbf{Pr}\left[\max_i Z_i > t\right] \leq n(1-p)^t = \frac{n}{2^t} ,$$

since $p = 1/2$ in this case. For any $\alpha > 1$, setting $t = \alpha \log n$, we obtain that

$$\mathbf{Pr}\left[r > \alpha \log n\right] \leq \frac{1}{n^{\alpha-1}} .$$

We can now infer that the tree representing the skip list has height $\mathsf{O}(\log n)$ with high probability. To show that the overall search time in a skip list is similarly bounded, we must first specify an efficient implementation of the find operation. We present the implementation of the dictionary operations in terms of the tree representation; it is fairly easy to translate this back into the skip list representation.

To implement $\mathsf{find}(y, X)$, we must walk down the path

$$I_r(y) \subseteq I_{r-1}(y) \subseteq \cdots \subseteq I_1(y) .$$

For this, at level j, starting at the node $I_j(y)$, we use the vertical pointer to descend to the leftmost child of the current interval; then, via the horizontal pointers, we move rightwards till the node $I_j(y)$ is reached. Note that it is easily determined whether y belongs to a given interval, or to an interval to its right. Further, in the skip list, the vertical pointers allow access only to the leftmost child of an interval, and therefore we must use the horizontal pointers to scan its children.

To determine the expected cost of a $\mathsf{find}(y, X)$ operation, we must take into account both the number of levels and the number of intervals/nodes scanned at each level. Clearly, at level j, the number of nodes visited is no more than the number of children of $I_{j+1}(y)$. It follows that the cost of find can be bounded by

$$\mathsf{O}\left(\sum_{j=1}^{r} \left(1 + C\left(I_j(y)\right)\right)\right) .$$

The following lemma shows that this quantity has expectation bounded by $\mathsf{O}(\log n)$.

LEMMA 15.2 For any y, let $I_r(y), \ldots, I_1(y)$ be the search path followed by $\mathsf{find}(y, X)$ in a random skip list for a set X of size n. Then,

$$\mathbf{E}\left[\sum_{j=1}^{r} \left(1 + C(I_j(y))\right)\right] = \mathsf{O}(\log n) .$$

PROOF We begin by showing that for any interval I in a random skip list, $\mathbf{E}[C(I)] = \mathsf{O}(1)$. By Lemma 15.1, we are guaranteed that $r = \mathsf{O}(\log n)$ with high probability, and so we will obtain the desired bound. It is important to note that we really do need the high probability bound on Lemma 15.1, since it is incorrect to multiply the expectation of r with that of $1 + C(I)$ (the two random variables need not be independent). However, in the approach we will use, since $r > \alpha \log n$ with probability at most $1/n^{\alpha-1}$ and $\Sigma_j(1 + C(I_j(y))) = \mathsf{O}(n)$, it can be argued that the case $r > \alpha \log n$ does not contribute significantly to the expectation of $\Sigma_j C(I_j(y))$.

To show that the expected number of children of an interval J at level i is bounded by a constant, we will show that the expected number of siblings of J (children of its parent) is bounded by a constant; in

fact, we will only bound the number of right siblings since the argument for the number of left siblings is identical. Let the intervals to the right of J be the following:

$$J_1 = [x_1, x_2]\,;\, J_2 = [x_2, x_3]\,;\, \ldots;\, J_k = [x_k, +\infty]\ .$$

Since these intervals exist at level i, each of the elements $x_1, \ldots, x_k$ belong to X_i. If J has s right siblings, then it must be the case that $x_1, \ldots, x_s \notin X_{i+1}$, and $x_{s+1} \in X_{i+1}$. The latter event occurs with probability $1/2^{s+1}$ since each element of X_i is independently chosen to be in X_{i+1} with probability $1/2$. Clearly, the number of right siblings of J can be viewed as a random variable that is geometrically distributed with parameter $1/2$. It follows that the expected number of right siblings of J is at most 2.

Consider now the implementation of the insert and delete operations. In implementing the operation insert(y, X), we assume that a random level $L(y)$ is chosen for y as described earlier. If $L(y) > r$, then we start by creating new levels from $r + 1$ to $L(y)$ and then redefine r to be $L(y)$. This requires $O(1)$ time per level, since the new levels are all empty prior to the insertion of y. Next we perform find(y, X) and determine the search path $I_r(y)$, ..., $I_1(y)$, where r is updated to its new value if necessary. Given this search path, the insertion can be accomplished in time $\mathsf{O}(L(y))$ by splitting around y the intervals $I_1(y), \ldots, I_{L(y)}(y)$ and updating the pointers as appropriate. The delete operation is the converse of the insert operation; it involves performing find(y, X) followed by collapsing the intervals that have y as an end-point. Both operations incur cost that is the cost of a find operation and additional cost proportional to $L(y)$. By Lemmas 15.1 and 15.2, we obtain the following theorem.

THEOREM 15.6 *In a random skip list for a set X of size n, the operations* find, insert, *and* delete *can be performed in expected time* $\mathsf{O}(\log n)$.

15.7 Random Reordering and Linear Programming

The *linear programming problem* is a particularly notable example of the two main benefits of randomization — simplicity and speed. We now describe a simple algorithm for linear programming based on a paradigm for randomized algorithms known as *random reordering.* For many problems it is possible to design natural algorithms based on the following idea. Suppose that the input consists of n elements. Given any subset of these n elements, there is a solution to the partial problem defined by these elements. If we start with the empty set and add the n elements of the input one at a time, maintaining a partial solution after each addition, we will obtain a solution to the entire problem when all the elements have been added. The usual difficulty with this approach is that the running time of the algorithm depends heavily on the order in which the input elements are added; for any fixed ordering, it is generally possible to force this algorithm to behave badly. The key idea behind random reordering is to *add the elements in a random order.* This simple device often avoids the pathological behavior that results from using a fixed order.

The linear programming problem is to find the extremum of a linear objective function of d real variables subject to a set H of n constraints that are linear functions of these variables. The intersection of the n half-spaces defined by the constraints is a polyhedron in d-dimensional space (which may be empty, or possibly unbounded). We refer to this polyhedron as the *feasible region.* Without loss of generality [34] we assume that the feasible region is nonempty and bounded. (Note that we are not assuming that we can *test* an arbitrary polyhedron for nonemptiness or boundedness; this is known to be equivalent to solving a linear program.) For a set of constraints S, let $\mathcal{B}(S)$ denote the optimum of the linear program defined by S; we seek $\mathcal{B}(S)$.

Consider the following algorithm due to Seidel [36]: add the n constraints in random order, one at a time. After adding each constraint, determine the optimum subject to the constraints added so far. This algorithm may also be viewed in the following "backwards" manner, which will prove useful in the sequel.

Algorithm SLP:

Input: A set of constraints H, and the dimension d.

Output: The optimum $\mathcal{B}(H)$.

0. If there are only d constraints, output $\mathcal{B}(H) = H$.

1. Pick a random constraint $h \in H$;
Recursively find $\mathcal{B}(H \backslash \{h\})$.

2.1. if $\mathcal{B}(H \backslash \{h\})$ does not violate h, output $\mathcal{B}(H \backslash \{h\})$ to be the optimum $\mathcal{B}(H)$.

2.2. else project all the constraints of $H \backslash \{h\}$ onto h and recursively solve this new linear programming problem of one lower dimension.

The idea of the algorithm is simple. Either h (the constraint chosen randomly in Step 1) is redundant (in which case we execute Step 2.1), or it is not. In the latter case, we know that the vertex formed by $\mathcal{B}(H)$ must lie on the hyperplane bounding h. In this case, we project all the constraints of $H \backslash \{h\}$ onto h and solve this new linear programming problem (which has dimension $d - 1$).

The optimum $\mathcal{B}(H)$ is defined by d constraints. At the top level of recursion, the probability that a random constraint h violates $\mathcal{B}(H \backslash \{h\})$ is at most d/n. Let $T(n, d)$ denote an upper bound on the expected running time of the algorithm for any problem with n constraints in d dimensions. Then, we may write

$$T(n, d) \leq T(n-1, d) + O(d) + \frac{d}{n} \left[O(dn) + T(n-1, d-1) \right] . \tag{15.7}$$

In (15.7), the first term on the right denotes the cost of recursively solving the linear program defined by the constraints in $H \backslash \{h\}$. The second accounts for the cost of checking whether h violates $\mathcal{B}(H \backslash \{h\})$. With probability d/n it does, and this is captured by the bracketed expression, whose first term counts the cost of projecting all the constraints onto h. The second counts the cost of (recursively) solving the projected problem, which has one fewer constraint and dimension. The following theorem may be verified by substitution, and proved by induction.

THEOREM 15.7 *There is a constant b such that the recurrence (15.7) satisfies the solution* $T(n, d) \leq bnd!$.

In contrast if the choice in Step 1 of **SLP** were not random, the recurrence (15.7) would be

$$T(n, d) \leq T(n-1, d) + O(d) + O(dn) + T(n-1, d-1) , \tag{15.8}$$

whose solution contains a term that grows quadratically in n.

15.8 Algebraic Methods and Randomized Fingerprints

Some of the most notable randomized results in theoretical computer science, particularly in complexity theory, have involved a nontrivial combination of randomization and algebraic methods. In this section we describe a fundamental randomization technique based on algebraic ideas. This is the randomized fingerprinting technique, originally due to Freivalds [10], for the verification of identities involving matrices, polynomials, and integers. We also describe how this generalizes to the so-called Schwartz–Zippel

technique for identities involving multivariate polynomials (independently due to Schwartz [35] and Zippel [46]; see also DeMillo and Lipton [6]). Finally, following Lovász [20], we apply the technique to the problem of detecting the existence of perfect matchings in graphs.

The *fingerprinting* technique has the following general form. Suppose we wish to decide the equality of two elements x and y drawn from some "large" universe U. Assuming any reasonable model of computation, this problem has a deterministic complexity $\Omega(\log |U|)$. Allowing randomization, an alternative approach is to choose a random function from U into a smaller space V such that with high probability x and y are identical if and only if their images in V are identical. These images of x and y are said to be their *fingerprints*, and the equality of fingerprints can be verified in time $O(\log |V|)$. Of course, for any fingerprint function the average number of elements of U mapped to an element of V is $|U|/|V|$; so, it would appear impossible to find good fingerprint functions that work for arbitrary or worst-case choices of x and y. However, as we will show below, when the identity-checking is only required to be correct for x and y chosen from a small subspace S of U, particularly a subspace with some algebraic structure, it is possible to choose good fingerprint functions without any *a priori* knowledge of the subspace, provided the size of V is chosen to be comparable to the size of S.

Throughout this section we will be working over some unspecified field $\mathcal{F}$. Since the randomization will involve uniform sampling from a finite subset of the field, we do not even need to specify whether the field is finite or not. The reader may find it helpful in the infinite case to assume that $\mathcal{F}$ is the field $\mathcal{Q}$ of rational numbers, and in the finite case to assume that $\mathcal{F}$ is $\mathcal{Z}_p$, the field of integers modulo some prime number p.

Freivalds' Technique and Matrix Product Verification

We begin by describing a fingerprinting technique for verifying matrix product identities. Currently, the fastest algorithm for matrix multiplication (due to Coppersmith and Winograd [5]) has running time $O(n^{2.376})$, improving significantly on the obvious $O(n^3)$ time algorithm; however, the fast matrix multiplication algorithm has the disadvantage of being extremely complicated. Suppose we have an implementation of the fast matrix multiplication algorithm and, given its complex nature, are unsure of its correctness. Since program verification appears to be an intractable problem, we consider the more reasonable goal of verifying the correctness of the output produced by executing the algorithm on specific inputs. (This notion of verifying programs on specific inputs is the basic tenet of the theory of *program checking* recently formulated by Blum and Kannan [4].) More concretely, suppose we are given three $n \times n$ matrices $\boldsymbol{X}$, $\boldsymbol{Y}$, and $\boldsymbol{Z}$ over a field $\mathcal{F}$, and would like to verify that $\boldsymbol{XY} = \boldsymbol{Z}$. Clearly, it does not make sense to use simpler but slower matrix multiplication algorithm for the verification, as that would defeat the whole purpose of using the fast algorithm in the first place. Observe that, in fact, there is no need to recompute $\boldsymbol{Z}$; rather, we are merely required to verify that the product of $\boldsymbol{X}$ and $\boldsymbol{Y}$ is indeed equal to $\boldsymbol{Z}$. Freivalds' technique gives an elegant solution that leads to an $O(n^2)$ time randomized algorithm with bounded error probability.

The idea is to first pick a random vector $\boldsymbol{r} \in \{0, 1\}^n$, i.e., each component of $\boldsymbol{r}$ is chosen independently and uniformly at random from the set $\{0, 1\}$ consisting of the additive and multiplicative identities of the field $\mathcal{F}$. Then, in $O(n^2)$ time, we can compute $\boldsymbol{y} = \boldsymbol{Yr}$, $\boldsymbol{x} = \boldsymbol{Xy} = \boldsymbol{XYr}$, and $\boldsymbol{z} = \boldsymbol{Zr}$. We would like to claim that the identity $\boldsymbol{XY} = \boldsymbol{Z}$ can be verified by merely checking that $\boldsymbol{x} = \boldsymbol{z}$. Quite clearly, if $\boldsymbol{XY} = \boldsymbol{Z}$ then $\boldsymbol{x} = \boldsymbol{z}$; unfortunately, the converse is not true in general. However, given the random choice of $\boldsymbol{r}$, we can show that for $\boldsymbol{XY} \neq \boldsymbol{Z}$, the probability that $\boldsymbol{x} \neq \boldsymbol{z}$ is at least $1/2$. Observe that the fingerprinting algorithm errs only if $\boldsymbol{XY} \neq \boldsymbol{Z}$ but $\boldsymbol{x}$ and $\boldsymbol{z}$ turn out to be equal, and this has a bounded probability.

THEOREM 15.8 *Let $\boldsymbol{X}$, $\boldsymbol{Y}$, and $\boldsymbol{Z}$ be $n \times n$ matrices over some field $\mathcal{F}$ such that $\boldsymbol{XY} \neq \boldsymbol{Z}$; further, let $\boldsymbol{r}$ be chosen uniformly at random from $\{0, 1\}^n$ and define $\boldsymbol{x} = \boldsymbol{XYr}$ and $\boldsymbol{z} = \boldsymbol{Zr}$. Then,*

$$\mathbf{Pr}[\boldsymbol{x} = \boldsymbol{z}] \leq 1/2 .$$

PROOF Define $\boldsymbol{W} = \boldsymbol{XY} - \boldsymbol{Z}$ and observe that $\boldsymbol{W}$ is not the all-zeroes matrix. Since $\boldsymbol{Wr} = \boldsymbol{XYr} - \boldsymbol{Zr} = \boldsymbol{x} - \boldsymbol{z}$, the event $\boldsymbol{x} = \boldsymbol{z}$ is equivalent to the event that $\boldsymbol{Wr} = 0$. Assume, without loss of generality, that the first row of $\boldsymbol{W}$ has a nonzero entry and that the nonzero entries in that row precede all the zero entries. Define the vector $\boldsymbol{w}$ as the first row of $\boldsymbol{W}$, and assume that the first $k > 0$ entries in $\boldsymbol{w}$ are nonzero. Since the first component of $\boldsymbol{Wr}$ is $\boldsymbol{w}^T\boldsymbol{r}$, giving an upper bound on the probability that the inner product of $\boldsymbol{w}$ and $\boldsymbol{r}$ is zero will give an upper bound on the probability that $\boldsymbol{x} = \boldsymbol{z}$.

Observe that $\boldsymbol{w}^T\boldsymbol{r} = 0$ if and only if

$$r_1 = \frac{-\sum_{i=2}^{k} w_i r_i}{w_1} . \tag{15.9}$$

Suppose that while choosing the random vector $\boldsymbol{r}$, we choose $r_2, \ldots, r_n$ before choosing r_1. After the values for $r_2, \ldots, r_n$ have been chosen, the right-hand side of (15.9) is fixed at some value $v \in \mathcal{F}$. If $v \notin \{0, 1\}$, then r_1 will never equal v; conversely, if $v \in \{0, 1\}$, then the probability that $r_1 = v$ is $1/2$. Thus, the probability that $\boldsymbol{w}^T\boldsymbol{r} = 0$ is at most $1/2$, implying the desired result.

We have reduced the matrix multiplication verification problem to that of verifying the equality of two vectors. The reduction itself can be performed in $O(n^2)$ time and the vector equality can be checked in $O(n)$ time, giving an overall running time of $O(n^2)$ for this Monte Carlo procedure. The error probability can be reduced to $1/2^k$ via k independent iterations of the Monte Carlo algorithm. Note that there was nothing magical about choosing the components of the random vector $\boldsymbol{r}$ from $\{0, 1\}$, since any two distinct elements of $\mathcal{F}$ would have done equally well. This suggests an alternative approach toward reducing the error probability, as follows: each component of $\boldsymbol{r}$ is chosen independently and uniformly at random from some subset $\mathcal{S}$ of the field $\mathcal{F}$; then, it is easily verified that the error probability is no more than $1/|\mathcal{S}|$.

Finally, note that Freivalds' technique can be applied to the verification of any matrix identity $\boldsymbol{A} = \boldsymbol{B}$. Of course, given $\boldsymbol{A}$ and $\boldsymbol{B}$, just comparing their entries takes only $O(n^2)$ time. But there are many situations where, just as in the case of matrix product verification, computing $\boldsymbol{A}$ explicitly is either too expensive or possibly even impossible, whereas computing $\boldsymbol{Ar}$ is easy. The random fingerprint technique is an elegant solution in such settings.

Extension to Identities of Polynomials

The fingerprinting technique due to Freivalds is fairly general and can be applied to many different versions of the identity verification problem. We now show that it can be easily extended to identity verification for symbolic polynomials, where two polynomials $P_1(x)$ and $P_2(x)$ are deemed identical if they have identical coefficients for corresponding powers of x. Verifying integer or string equality is a special case since we can represent any string of length n as a polynomial of degree n by using the kth element in the string to determine the coefficient of the kth power of a symbolic variable.

Consider first the polynomial product verification problem: given three polynomials $P_1(x)$, $P_2(x)$, $P_3(x) \in \mathcal{F}[x]$, we are required to verify that $P_1(x) \times P_2(x) = P_3(x)$. We will assume that $P_1(x)$ and $P_2(x)$ are of degree at most n, implying that $P_3(x)$ has degree at most $2n$. Note that degree n polynomials can be multiplied in $O(n \log n)$ time via fast Fourier transforms, and that the evaluation of a polynomial can be done in $O(n)$ time.

The randomized algorithm we present for polynomial product verification is similar to the algorithm for matrix product verification. It first fixes a set $\mathcal{S} \subseteq \mathcal{F}$ of size at least $2n + 1$ and chooses $r \in \mathcal{S}$ uniformly at random. Then, after evaluating $P_1(r)$, $P_2(r)$ and $P_3(r)$ in $O(n)$ time, the algorithm declares the identity $P_1(x)P_2(x) = P_3(x)$ to be correct if and only if $P_1(r)P_2(r) = P_3(r)$. The algorithm makes an error only in the case where the polynomial identity is false but the value of the three polynomials at r indicates otherwise. We will show that the error event has a bounded probability.

Consider the degree $2n$ polynomial $Q(x) = P_1(x)P_2(x) - P_3(x)$. The polynomial $Q(x)$ is said to be *identically zero,* denoted by $Q(x) \equiv 0$, if each of its coefficients equals zero. Clearly, the polynomial

identity $P_1(x)P_2(x) = P_3(x)$ holds if and only if $Q(x) \equiv 0$. We need to establish that if $Q(x) \not\equiv 0$, then with high probability $Q(r) = P_1(r)P_2(r) - P_3(r) \neq 0$. By elementary algebra we know that $Q(x)$ has at most $2n$ distinct roots. It follows that unless $Q(x) \equiv 0$, not more that $2n$ different choices of $r \in \mathcal{S}$ will cause $Q(r)$ to evaluate to 0. Therefore, the error probability is at most $2n/|\mathcal{S}|$. The probability of error can be reduced either by using independent iterations of this algorithm, or by choosing a larger set $\mathcal{S}$. Of course, when $\mathcal{F}$ is an infinite field (e.g., the reals), the error probability can be made 0 by choosing r uniformly from the entire field $\mathcal{F}$; however, that requires an infinite number of random bits!

Note that we could also use a deterministic version of this algorithm where each choice of $r \in \mathcal{S}$ is tried once. But this involves $2n + 1$ different evaluations of each polynomial, and the best known algorithm for multiple evaluations needs $\Theta(n\log^2 n)$ time, which is more than the $\mathsf{O}(n \log n)$ time requirement for actually performing a multiplication of the polynomials $P_1(x)$ and $P_2(x)$.

This verification technique is easily extended to a generic procedure for testing any polynomial identity of the form $P_1(x) = P_2(x)$ by converting it into the identity $Q(x) = P_1(x) - P_2(x) \equiv 0$. Of course, when P_1 and P_2 are explicitly provided, the identity can be deterministically verified in $\mathsf{O}(n)$ time by comparing corresponding coefficients. Our randomized technique will take just as long to merely evaluate $P_1(x)$ and $P_2(x)$ at a random value. However, as in the case of verifying matrix identities, the randomized algorithm is quite useful in situations where the polynomials are implicitly specified, e.g., when we only have a "black box" for computing the polynomials with no information about their coefficients, or when they are provided in a form where computing the actual coefficients is expensive. An example of the latter situation is provided by the following problem concerning the determinant of a symbolic matrix. In fact, the determinant problem will require a technique for the verification of polynomial identities of *multivariate* polynomials that we will discuss shortly.

Consider an $n \times n$ matrix $\boldsymbol{M}$. Recall that the determinant of the matrix $\boldsymbol{M}$ is defined as follows:

$$\det(\boldsymbol{M}) = \sum_{\pi \in \mathcal{S}_n} \operatorname{sgn}(\pi) \prod_{i=1}^{n} M_{i,\pi(i)} \,, \tag{15.10}$$

where $\mathcal{S}_n$ is the symmetric group of permutations of order n, and $\operatorname{sgn}(\pi)$ is the sign of a permutation π. (The sign function is defined to be $\operatorname{sgn}(\pi) = (-1)^t$, where t is the number of pairwise exchanges required to convert the identity permutation into π.) Although the determinant is defined as a summation with $n!$ terms, it is easily evaluated in polynomial time provided that the matrix entries M_{ij} are explicitly specified. Consider the Vandermonde matrix $\boldsymbol{M}(x_1, \ldots, x_n)$ which is defined in terms of the indeterminates $x_1, \ldots, x_n$ such that $M_{ij} = x_i^{j-1}$, i.e.,

$$\boldsymbol{M} = \begin{pmatrix} 1 & x_1 & x_1^2 & \ldots & x_1^{n-1} \\ 1 & x_2 & x_2^2 & \ldots & x_2^{n-1} \\ & & & \cdot & \\ & & & \cdot & \\ & & & \cdot & \\ 1 & x_n & x_n^2 & \ldots & x_n^{n-1} \end{pmatrix} .$$

It is known that for the Vandermonde matrix, $\det(\boldsymbol{M}) = \prod_{i<j}(x_i - x_j)$. Consider the problem of verifying this identity without actually devising a formal proof. Computing the determinant of a symbolic matrix is infeasible as it requires dealing with a summation over $n!$ terms. However, we can formulate the identity verification problem as the problem of verifying that the polynomial $Q(x_1, \ldots, x_n) = \det(\boldsymbol{M}) - \prod_{i<j}(x_i - x_j)$ is identically zero. Based on our discussion of Freivalds' technique, it is natural to consider the substitution of random values for each x_i. Since the determinant can be computed in polynomial time for any specific assignment of values to the symbolic variables $x_1, \ldots, x_n$, it is easy to evaluate the polynomial Q for random values of the variables. The only issue is that of bounding the error probability for this randomized test.

We now extend the analysis of Freivalds' technique for univariate polynomials to the multivariate case. But first, note that in a multivariate polynomial $Q(x_1, \ldots, x_n)$, the degree of a term is the sum of the exponents of the variable powers that define it, and the total degree of Q is the maximum over all terms of the degrees of the terms.

THEOREM 15.9 *Let $Q(x_1, \ldots, x_n) \in \mathcal{F}[x_1, \ldots, x_n]$ be a multivariate polynomial of total degree m. Let $\mathcal{S}$ be a finite subset of the field $\mathcal{F}$, and let $r_1, \ldots, r_n$ be chosen uniformly and independently from $\mathcal{S}$. Then,*

$$\mathbf{Pr}\left[Q(r_1, \ldots, r_n) = 0 \mid Q(x_1, \ldots, x_n) \not\equiv 0\right] \leq \frac{m}{|\mathcal{S}|} .$$

PROOF We will proceed by induction on the number of variables n. The basis of the induction is the case $n = 1$, which reduces to verifying the theorem for a univariate polynomial $Q(x_1)$ of degree m. But we have already seen for $Q(x_1) \not\equiv 0$, the probability that $Q(r_1) = 0$ is at most $m/|\mathcal{S}|$, taking care of the basis.

We now assume that the induction hypothesis holds for multivariate polynomials with at most $n - 1$ variables, where $n > 1$. In the polynomial $Q(x_1, \ldots, x_n)$ we can factor out the variable x_1 and thereby express Q as

$$Q(x_1, \ldots, x_n) = \sum_{i=0}^{k} x_1^i P_i(x_2, \ldots, x_n) ,$$

where $k \leq m$ is the largest exponent of x_1 in Q. Given our choice of k, the coefficient $P_k(x_2, \ldots, x_n)$ of x_1^k cannot be identically zero. Note that the total degree of P_k is at most $m - k$. Thus, by the induction hypothesis, we conclude that the probability that $P_k(r_2, \ldots, r_n) = 0$ is at most $(m - k)/|\mathcal{S}|$.

Consider now the case where $P_k(r_2, \ldots, r_n)$ is indeed not equal to 0. We define the following univariate polynomial over x_1 by substituting the random values for the other variables in Q:

$$q(x_1) = Q(x_1, r_2, r_3, \ldots, r_n) = \sum_{i=0}^{k} x_1^i P_i(r_2, \ldots, r_n) .$$

Quite clearly, the resulting polynomial $q(x_1)$ has degree k and is not identically zero (since the coefficient of x_1^k is assumed to be nonzero). As in the basis case, we conclude that the probability that $q(r_1) = Q(r_1, r_2, \ldots, r_n)$ evaluates to 0 is bounded by $k/|\mathcal{S}|$.

By the preceding arguments, we have established the following two inequalities:

$$\begin{aligned} \mathbf{Pr}\left[P_k(r_2, \ldots, r_n) = 0\right] &\leq \frac{m-k}{|\mathcal{S}|} ; \\ \mathbf{Pr}\left[Q(r_1, r_2, \ldots, r_n) = 0 \mid P_k(r_2, \ldots, r_n) \neq 0\right] &\leq \frac{k}{|\mathcal{S}|} . \end{aligned}$$

Using the elementary observation that for any two events $\mathcal{E}_1$ and $\mathcal{E}_2$, $\mathbf{Pr}[\mathcal{E}_1] \leq \mathbf{Pr}[\mathcal{E}_1 \mid \overline{\mathcal{E}}_2] + \mathbf{Pr}[\mathcal{E}_2]$, we obtain that the probability that $Q(r_1, r_2, \ldots, r_n) = 0$ is no more than the sum of the two probabilities on the right-hand side of the two obtained inequalities, which is $m/|\mathcal{S}|$. This implies the desired result.

This randomized verification procedure has one serious drawback: when working over large (or possibly infinite) fields, the evaluation of the polynomials could involve large intermediate values, leading to inefficient implementation. One approach to dealing with this problem in the case of integers is to perform all computations modulo some small random prime number; it can be shown that this does not have any adverse effect on the error probability.

Detecting Perfect Matchings in Graphs

We close by giving a surprising application of the techniques from the preceding section. Let $G(U, V, E)$ be a bipartite graph with two independent sets of vertices $U = \{u_1, \ldots, u_n\}$ and $V = \{v_1, \ldots, v_n\}$, and edges E that have one end-point in each of U and V. We define a matching n G as a collection of edges $M \subseteq E$ such that each vertex is an end-point of at most one edge in M; further, a perfect matching is defined to be a matching of size n, i.e., where each vertex occurs as an end-point of exactly one edge in M. Any perfect matching M may be put into a 1-to-1 correspondence with the permutations in $\mathcal{S}_n$, where the matching corresponding to a permutation $\pi \in \mathcal{S}_n$ is given by the collection of edges $\{(u_i, v_{\pi(i)}) \mid 1 \leq i \leq n\}$. We now relate the matchings of the graph to the determinant of a matrix obtained from the graph.

THEOREM 15.10 *For any bipartite graph $G(U, V, E)$, define a corresponding $n \times n$ matrix $\boldsymbol{A}$ as follows:*

$$A_{ij} = \begin{cases} x_{ij} & (u_i, v_j) \in E \\ 0 & (u_i, v_j) \notin E \end{cases} .$$

Let the multivariate polynomial $Q(x_{11}, x_{12}, \ldots, x_{nn})$ denote the determinant $\det(\boldsymbol{A})$. *Then, G has a perfect matching if and only if $Q \not\equiv 0$.*

PROOF We may express the determinant of $\boldsymbol{A}$ as follows:

$$\det(\boldsymbol{A}) = \sum_{\pi \in \mathcal{S}_n} \operatorname{sgn}(\pi) A_{1,\pi(1)} A_{2,\pi(2)} \cdots A_{n,\pi(n)} .$$

Note that there cannot be any cancellation of the terms in the summation since each indeterminate x_{ij} occurs at most once in $\boldsymbol{A}$. Thus, the determinant is not identically zero if and only if there exists some permutation π for which the corresponding term in the summation is nonzero. Clearly, the term corresponding to a permutation π is non zero if and only if $A_{i,\pi(i)} \neq 0$ for each i, $1 \leq i \leq n$; this is equivalent to the presence in G of the perfect matching corresponding to π.

The matrix of indeterminates is sometimes referred to as the *Edmonds matrix* of a bipartite graph. The above result can be extended to the case of non-bipartite graphs, and the corresponding matrix of indeterminates is called the Tutte matrix. Tutte [41] first pointed out the close connection between matchings in graphs and matrix determinants; the simpler relation between bipartite matchings and matrix determinants was given by Edmonds [7].

We can turn the above result into a simple randomized procedure for testing the existence of perfect matchings in a bipartite graph (due to Lovász [20]): using the algorithm from Section "Extension to Identities of Polynomials," determine whether the determinant is identically zero or not. The running time of this procedure is dominated by the cost of computing a determinant, which is essentially the same as the time required to multiply two matrices. Of course, there are algorithms for *constructing* a maximum matching in a graph with m edges and n vertices in time $O(m\sqrt{n})$ (see Hopcroft and Karp [13], Micali and Vazirani [22, 43], and Feder and Motwani [8]). Unfortunately, the time required to compute the determinant exceeds $m\sqrt{n}$ for small m, and so the benefit in using this randomized *decision* procedure appears marginal at best. However, this technique was extended by Rabin and Vazirani [30, 31] to obtain simple algorithms for the actual *construction* of maximum matchings; although their randomized algorithms for matchings are simple and elegant, they are still slower than the deterministic $O(m\sqrt{n})$ time algorithms known earlier. Perhaps more significantly, this randomized decision procedure proved to be an essential ingredient in devising fast *parallel* algorithms for computing maximum matchings [18, 26].

15.9 Research Issues and Summary

Perhaps the most important research issue in the area of randomized algorithms is to prove or disprove that are problems solvable in polynomial time by either Las Vegas or Monte Carlo algorithms, but cannot be solved in polynomial time by any deterministic algorithm. Another important direction for future work is to devise high quality pseudo-random number generators, which take a small seed of truly random bits and stretch it into a much longer string that can be used as the random string to fuel randomized algorithms.

15.10 Defining Terms

Deterministic algorithm: An algorithm whose execution is completely determined by its input.

Distributional complexity: The expected running time of the best possible deterministic algorithm over the worst possible probability distribution on the inputs.

Las Vegas algorithm: A randomized algorithm that always produces correct results, with the only variation from one run to another being in its running time.

Monte Carlo algorithm: A randomized algorithm that may produce incorrect results, but with bounded error probability.

Randomized algorithm: An algorithm that makes random choices during the course of its execution.

Randomized complexity: The expected running time of the best possible randomized algorithm over the worst input.

Further Information

In this section we give pointers to a plethora of randomized algorithms not covered here. The reader should also note that the examples above are but a (random!) sample of the many randomized algorithms for each of the problems considered. These algorithms have been chosen to illustrate the main ideas behind randomized algorithms, rather than to represent the state of the art for these problems. The reader interested in other algorithms for these problems is referred to the book by Motwani and Raghavan [24].

Randomized algorithms also find application in a number of other areas: in load-balancing [42], approximation algorithms and combinatorial optimization [11, 16, 23], graph algorithms [1, 15], data structures [2], counting and enumeration [37], parallel algorithms [18, 19], distributed algorithms [29], geometric algorithms [25], online algorithms [3, 32], and number-theoretic algorithms [28, 39]. The reader interested in these applications may consult these articles or the book by Motwani and Raghavan [24].

16.1 Introduction

The title's subject is the algorithmic approach to algebra: arithmetic with numbers, polynomials, matrices, differential polynomials, such as $y'' + (1/2 + x^4/4)y$, truncated series, and algebraic sets, i.e., quantified expressions such as $\exists x \in \mathbb{R}: x^4 + p \cdot x + q = 0$, which describes a subset of the two-dimensional space with

coordinates p and q for which the given quartic equation has a real root. Algorithms that manipulate such objects are the backbone of modern symbolic mathematics software such as the Maple and Mathematica systems, to name but two among many useful systems. This chapter restricts itself to algorithms in four areas: linear algebra, root finding for univariate polynomials, solution of systems of nonlinear algebraic equations, and polynomial factorization (see Section 16.5 on some pointers to the vast further material on algebraic algorithms and "Some Computations Related to Matrix Multiplication" and [118] on further applications to the graph and combinatorial computations).

16.2 Matrix Computations and Approximation of Polynomial Zeros

This section covers several major algebraic and numerical problems of scientific and engineering computing that are usually solved numerically, with rounding-off or chopping the input and computed values to a fixed number of bits that fit the computer precision (Sections 16.3 and 16.4 are devoted to some fundamental infinite precision symbolic computations, and in "Rational Matrix Computations, Computations in Finite Fields, and Semirings" we comment on the infinite precision techniques for some matrix computations). We also study approximation of polynomial zeros, which is an important, fundamental, and very popular subject, too. In our presentation, we will very briefly list the major subtopics of our huge subject and will give some pointers to the bibliography. We will include brief coverage of the topics of the algorithm design and analysis, regarding the complexity of matrix computation and of approximating polynomial zeros. The reader may find further material on these subjects and further references in the survey articles [112, 115, 116, 124] and in the books [12, 13, 36, 62, 64, 68, 140, 145].

Products of Vectors and Matrices, Convolution of Vectors

An $m \times n$ matrix $A = [\ a_{i,j}\ ,\ i = 0, 1, \ldots, m-1;\ j = 0, 1, \ldots, n-1\ ]$ is a 2-dimensional array, whose (i, j)-entry is $[A]_{i,j} = a_{i,j}$. A is a column vector of dimension m if $n = 1$ and is a row vector of dimension n if $m = 1$. Transposition, hereafter, indicated by the superscript T, transforms a row vector $\vec{v}^{\,T} = [\ v_0, \ldots, v_{n-1}\ ]$ into a column vector $\vec{v} = [\ v_0, \ldots, v_{n-1}\ ]^T$.

For two vectors, $\vec{u} = [\ u_0, \ldots, u_{m-1}]^T$ and $\vec{v} = [\ v_0, \ldots, v_{n-1}\ ]^T$, their *outer product* is an $m \times n$ matrix,

$$W = \vec{u}\vec{v}^{\,T} = \left[w_{i,j}\ ,\ i = 0, \ldots, m-1; j = 0, \ldots, n-1\right]\ ,$$

where $w_{i,j} = u_i\ v_j$, for all i and j, and their *convolution* vector is said to equal

$$\vec{w} = \vec{u} \circ \vec{v} = [w_0, \ldots, w_{m+n-2}]^T\ ,\quad w_k = \sum_{i=0}^{k} u_i v_{k-i}\ ,$$

where $u_i = v_j = 0$, for $i \geq m,\ j \geq n$; in fact, $\vec{w}$ is the coefficient vector of the product of 2 polynomials,

$$u(x) = \sum_{i=0}^{m-1} u_i x^i \quad \text{and} \quad v(x) = \sum_{i=0}^{n-1} v_i x^i\ ,$$

having coefficient vectors $\vec{u}$ and $\vec{v}$, respectively.

If $m = n$, then the scalar value

$$\vec{v}^{\,T}\ \vec{u} = \vec{u}^{\,T}\ \vec{v} = u_0v_0 + u_1v_1 + \cdots + u_{n-1}v_{n-1} = \sum_{i=0}^{n-1} u_i v_i$$

is called the *inner* (*dot,* or *scalar*) *product* of $\vec{u}$ and $\vec{v}$.

The straightforward algorithms compute the inner and outer products of $\vec{u}$ and $\vec{v}$ and their convolution vector by using $2n-1$, mn, and $mn+(m-1)(n-1) = 2mn-m-n+1$ arithmetic operations (hereafter, referred to as **ops**), respectively. By counting the ops involved, we estimate the arithmetic cost of the computations. This is a realistic measure for the computational complexity if the precision of computing is within the range of the computer precision. In practical numerical computations with rounding-off, the latter requirement is usually stated in terms of *conditioning of the computational problem* and *numerical stability of algorithms* [62, 68, 145], and [12, ch. 3]. A more universal and computer independent measure is given by the number of Boolean (bit) operations involved into the computations, which grows with the growth of both ops number and precision of computing.

The above upper bounds on the numbers of ops for computing the inner and outer products are sharp, that is, cannot be decreased, for the general pair of the input vectors $\vec{u}$ and $\vec{v}$, whereas (see, e.g., [12]) one may apply the *fast Fourier transform* (FFT) (see Chapter 17) in order to compute the convolution vector $\vec{u} \circ \vec{v}$ much faster, for larger m and n; namely, it suffices to use $4.5K \log K + 2K$ ops, for $K = 2^k$, $k = \lceil \log(m+n-1) \rceil$. (Here and hereafter, all logarithms are binary unless specified otherwise.)

If $A = [a_{i,j}]$ and $B = [b_{j,k}]$ are $m \times n$ and $n \times p$ matrices, respectively, and $\vec{v} = [v_k]$ is a p-dimensional vector, then the straightforward algorithms compute the vector

$$\vec{w} = B\vec{v} = [\, w_0, \ldots, w_{n-1} \,]^T, \qquad w_i = \sum_{j=0}^{p-1} b_{i,j} v_j, \quad i = 0, \ldots, n-1,$$

by using $(2p-1)n$ ops (sharp bound), and compute the *matrix product*

$$AB = \left[w_{i,k},\ i = 0, \ldots, m-1;\ k = 0, \ldots, p-1 \right]$$

by using $2mnp - mp$ ops, which is $2n^3 - n^2$ if $m = n = p$. The latter upper bound is not sharp: the subroutines for $n \times n$ matrix multiplication on some modern computers, such as CRAY and Connection Machines, rely on algorithms using $O(n^{2.81})$ ops [62]. Such algorithms rely on representing an $n \times n$ matrix A, for $n = 2^s$, as a 2×2 block matrix,

$$A = \begin{bmatrix} A_{0,0} & A_{0,1} \\ A_{1,0} & A_{1,1} \end{bmatrix},$$

where the blocks $A_{i,j}$, $i, j = 0, 1$, are $(n/2) \times (n/2)$ matrices. Multiplication of a pair of such 2×2 block matrices is reduced to 7 multiplications of $(n/2) \times (n/2)$ matrices represented as linear combinations of the input blocks and to 15 or 18 matrix additions/subtractions. For block multiplications, one applies the same algorithm recursively, until arriving at matrices of a small size. More involved technically advanced but nonpractical algorithms decrease the exponent from 2.81 below 2.376 [12, 13, 32].

If all the input entries and components are bounded integers having short binary representation, each of the above operations with vectors and matrices can be reduced to a single multiplication of 2 longer integers, by means of the techniques of *binary segmentation* (cf. [113, Sect. 40]; [115, 117], or [12, Examples 3.9.1–3.9.3]). The Boolean cost of the computations does not decrease much or even at all, but the techniques may be practically useful if the 2 longer integers still fit the computer precision.

For an $n \times n$ matrix B and an n-dimensional vector $\vec{v}$, one frequently needs to compute the vectors $B^i \vec{v}$, $i = 1, 2, \ldots, k-1$, which define *Krylov sequence* or *Krylov matrix*

$$\left[B^i \vec{v},\ i = 0, 1, \ldots, k-1 \right],$$

[62, 64]. The straightforward sequential algorithm takes on $(2n-1)n(k-1)$ ops, which is order n^3 if k is of order n. An alternative algorithm (most effective for parallel computation) first computes the matrix powers

$$B^2, B^4, B^8, \ldots, B^{2^s}, \qquad s = \lceil \log k \rceil - 1,$$

and then, the products of $n \times n$ matrices B^{2^i} by $n \times 2^i$ matrices, for $i = 0, 1, \ldots, s$:

$$\begin{aligned} & B \quad v\,, \\ & B^2 \quad [\, v,\ Bv\,] = \left[\, B^2v,\ B^3v\,\right], \\ & B^4 \quad \left[\, v,\ Bv,\ B^2v,\ B^3v\,\right] = \left[\, B^4v,\ B^5v,\ B^6v,\ B^7v\,\right], \\ & \vdots \end{aligned}$$

The last step completes the evaluation of the Krylov sequence, which amounts to $2s + 1$ matrix multiplications, and, therefore, can be performed (in theory) in $O(n^{2.376} \log k)$ ops, for $k = n$ [32].

Some Computations Related to Matrix Multiplication

Several fundamental matrix computations can be ultimately reduced to relatively few (that is, to a constant number, or, say, to $O(\log n)$) $n \times n$ matrix multiplications. The list of such computations includes the evaluation of the **determinant,** $det\ A$, of an $n \times n$ matrix A; its *inverse* A^{-1} (where A is nonsingular, that is, where $det\ A \neq 0$); the coefficients of its **characteristic polynomial,** $c_A(x) = det(xI - A)$, x denoting a scalar variable and I being the $n \times n$ identity matrix, which has ones on its diagonal and zeros elsewhere; its *minimal polynomial,* $m_A(x)$; its *rank,* rank A; the solution vector $\vec{x} = A^{-1}\,\vec{v}$ to a nonsingular *linear system of equations,* $A\,\vec{x} = \vec{v}$; various *orthogonal* and *triangular factorizations* of A, and a submatrix of A having the maximal rank, as well as some fundamental *computations with singular matrices.* Furthermore, similar reductions to matrix multiplication have been obtained for some apparently quite distant computational problems, including some major problems of combinatorial and graph computations such as Boolean matrix multiplication and computing the transitive closure of a graph [1], computing all pair shortest distances in graphs [12, p. 222], and pattern recognition. Consequently, all these operations can be performed by using (theoretically) $O(n^{2.376})$ ops (cf. [12, chap. 2]). One of the basic ideas is to represent the input matrix A as a block matrix and, operating with its blocks (rather than with its entries), to apply fast matrix multiplication algorithms. In particular, suppose that all the square northwestern blocks of A (called leading principal submatrices) are nonsingular. (This assumption holds for a large and practically important class of matrices, it also can be achieved by means of symmetrization of A or by randomization). Then one may compute det A and A^{-1} by factoring A as a 2×2 block matrix,

$$A = \begin{bmatrix} I & O \\ A_{1,0}A_{0,0}^{-1} & I \end{bmatrix} \begin{bmatrix} A_{0,0} & O \\ O & S \end{bmatrix} \begin{bmatrix} I & A_{0,0}^{-1}A_{0,1} \\ O & I \end{bmatrix},$$

$S = A_{1,1} - A_{1,0}A_{0,0}^{-1}A_{0,1}$, I and O denoting the identity and null matrices, respectively, and then recursively factorizing $A_{0,0}$ and S (see, e.g.,[12, sect. 2.2]). This is very close to recursive 2×2 block version of Gaussian elimination (cf. "Gaussian Elimination Algorithm"). Many of such block matrix algorithms are practically important for parallel computations (see "Parallel Matrix Computations"). On the other hand, however, due to various other considerations (accounting, in particular, for the overhead constants hidden in the $''O''$ notation, for the memory space requirements, and particularly, for numerical stability problems), these computations are, in practice, based either on the straightforward algorithm for matrix multiplication or on other methods allowing order n^3 arithmetic operations (cf. [62]).

In the next 3 sections, we will more closely consider the solution of a linear system of equations, $A\,\vec{v} = \vec{b}$, which is the most frequent operation in practice of scientific and engineering computing and is highly important theoretically. We will partition the known solution methods depending on whether the coefficient matrix A is *dense and unstructured, sparse,* or *dense and structured.* We will omit the study of singular (in particular, over- and underdetermined) linear systems, their least-squares solution, and various computations with singular matrices, referring the reader to [12, 62, 117]. Also, we refer the reader

to [42] (and references therein) on the major subject of solving sparse linear systems of equations in finite fields.

Gaussian Elimination Algorithm

The solution of a nonsingular (lower or upper) triangular linear system $A\ \vec{x} = \vec{v}$ only involves about n^2 ops. For example [117], let $n = 3$,

$$\begin{aligned} x_1 + 2x_2 - x_3 &= 3\,, \\ -2x_2 - 2x_3 &= -10\,, \\ -6x_3 &= -18\,. \end{aligned}$$

Compute $x_3 = 3$ from the last equation, substitute into the previous ones, and arrive at a triangular system of $n - 1 = 2$ equations. In $n - 1$ (in our case, in 2) such recursive substitution steps, we compute the solution.

The triangular case is itself important; furthermore, every nonsingular linear system is reduced to 2 triangular ones by means of *forward elimination* of the variables, which essentially amounts to computing the PLU-factorization of the input matrix A, that is, to computing 2 lower triangular matrices L and U^T (where L has unit values on its diagonal) and a permutation matrix P such that $A = PLU$. (A permutation matrix P is filled with zeros and ones and has exactly one nonzero entry in each row and in each column; in particular, this implies that $P^T = P^{-1}$. $P\ \vec{u}$ has the same components as $\vec{u}$ but written in a distinct (fixed) order, for any vector $\vec{u}$.) As soon as the latter factorization is available, we may compute $\vec{x} = A^{-1}\ \vec{v}$ by solving 2 triangular systems, that is, at first, $L\ \vec{y} = P^T\ \vec{v}$, in $\vec{y}$, and then $U\ \vec{x} = \vec{y}$, in $\vec{x}$. Computing the factorization (elimination stage) is more costly than the subsequent *back substitution stage,* the latter involving about $2n^2$ ops. Gaussian elimination algorithm involves about $2n^3/3$ ops and some comparisons, required in order to ensure appropriate *pivoting*, also called *elimination ordering.* Pivoting enables us to avoid divisions by small values. Otherwise, we would have needed a higher precision of computing, thus, facing numerical stability problems. Theoretically, one may employ fast matrix multiplication and compute the matrices P, L, and U in $O(n^{2.376})$ ops [1] (and then compute the vectors $\vec{y}$ and $\vec{x}$ in $O(n^2)$ ops). Pivoting can be dropped for some important classes of linear systems, notably, for *positive definite* and for *diagonally dominant* systems ([62, 115, 117], or [12]).

We refer the reader to [62, p. 82–83] or [117, p. 794] on sensitivity of the solution to the input and round-off errors in numerical computing. The output errors grow with the **condition number** of A, represented by $||A||\ ||A^{-1}||$ for a fixed matrix norm or by the ratio of maximum and minimum singular values of A. Except for ill-conditioned linear systems $A\ \vec{x} = \vec{v}$, having very large condition numbers, a rough initial approximation to the solution can be rapidly refined (cf. [62]) via the *iterative improvement algorithm,* as soon as we know P and rough approximations to the matrices L and U of the PLU factorization of A. Then, b correct bits of each output value can be computed in $O(b + n)n^2$ ops as $b \to \infty$.

Sparse Linear Systems. Direct and Iterative Solution Algorithms

A matrix is sparse if it is filled mostly with zeros, say, if its all nonzero entries lie on 3 or 5 of its diagonals; it can be stored economically if the disposition of its nonzero entries has a certain structure. Such matrices arise in many important applications, in particular, to solving partial and ordinary differential equations (PDEs and ODEs). Then, memory space and computation time can be dramatically decreased (say, from order n^2 to order $n \log n$ words of memory and from n^3 to $n^{3/2}$ or $n \log n$ ops) by using some special data structures and special solution methods. The methods are either direct, that is, are modifications of Gaussian elimination with some special policies of elimination ordering that preserve sparsity during the computation (notably, *Markowitz rule* and *nested dissection* [58, 61, 98, 118]), or various iterative algorithms. The latter ones usually rely either on computing Krylov sequences [64] or on multilevel or

multigrid techniques [53, 104, 126], specialized for solving linear systems that arise from discretization of PDEs. *Banded linear systems* have $n \times n$ coefficient matrices $A = [a_{i,j}]$ where $a_{i,j} = 0$ if $i - j > g$ or $j - i > h$, for $g + h$ being much less than n. For such systems, the nested dissection is known under the name of *block cyclic reduction* and is highly effective, but [128] gives some alternative algorithms too. Some special techniques for parallel computation of Krylov sequences for sparse and other special matrices A can be found in [119]; according to these techniques, Krylov sequence is recovered from the solution of the associated linear system $(I - A)\,\vec{x} = \vec{v}$, which is solved fast in the case of a special matrix A.

Dense and Structured Matrices and Linear Systems

Many dense $n \times n$ matrices are defined by $O(n)$, say, by less than $2n$, parameters and can be multiplied by a vector by using $O(n \log n)$ or $O(n \log^2 n)$ ops. Such matrices arise in numerous applications (to signal and image processing, coding, algebraic computation, PDEs, integral equations, particle simulation, Markov chains, and many others). An important example is given by $n \times n$ *Toeplitz matrices* $T = [t_{i,j}]$, $t_{i,j} = t_{i+1,j+1}$ for $i,\ j = 0, 1, \ldots, n-2$. Such a matrix can be represented by $2n - 1$ entries of its first row and first column or by $2n - 1$ entries of its first and last columns. The product $T\,\vec{v}$ is defined by vector convolution, and its computation uses $O(n \log n)$ ops. Other major examples are given by *Hankel matrices* (obtained by reflecting the row or column sets of Toeplitz matrices), *circulant* (which are a subclass of Toeplitz matrices), *Bézout, Sylvester, Vandermonde,* and *Cauchy* matrices. The known solution algorithms for linear systems with such dense structured coefficient matrices use from order $n \log n$ to order $n \log^2 n$ ops. These properties and algorithms are extended via associating some linear operators of displacement and scaling to some more general classes of matrices and linear systems. (See Chapter 17 in this volume for details and further bibliography.)

Parallel Matrix Computations

Algorithms for matrix multiplication are particularly suitable for parallel implementation; one may exploit natural association of processors to rows and/or columns of matrices or to their blocks, particularly, in the implementation of matrix multiplication on loosely coupled multiprocessors (cf. [62, 130]). In particular, the straightforward algorithm for $n \times n$ matrix multiplication uses $2n^2$ fetches of input data and n^2 writings into the memory, for $2n^3 - n^2$ ops, that is, in block matrix algorithms, the slow data manipulation operations are relatively few (versus the more numerous but faster ops). This motivates special attention to and rapid progress in devising effective practical parallel algorithms for block matrix computations (see "Further Information"). The theoretical complexity of parallel computations is usually measured by the computational and communication time and the number of processors involved; decreasing all these parameters, we face a trade-off; the product of time and processor bounds (called potential work of parallel algorithms) cannot usually be made substantially smaller than the sequential time bound for the solution. This follows because, according to a variant of *Brent's scheduling principle,* a single processor can simulate the work of s processors in time $O(s)$. The usual goal of designing a parallel algorithm is in decreasing its parallel time bound (ideally, to a constant, logarithmic or polylogarithmic level, relative to n) and keeping its work bound at the level of the record sequential time bound for the same computational problem (within constant, logarithmic, or at worst polylog factors). This goal has been easily achieved for matrix and vector multiplications, but turned out to be nontrivial for linear system solving, inversion, and some other related computational problems. The recent solution for general matrices [79, 80] relies on computation of a Krylov sequence and the coefficients of the minimum polynomial of a matrix, by using randomization and auxiliary computations with **structured matrices** (see the details in [12, 122]).

Rational Matrix Computations, Computations in Finite Fields, and Semirings

Rational algebraic computations with matrices are performed for a rational input given with no errors, and the computations are also performed with no errors. The precision of computing can be bounded by reducing the computations modulo one or several fixed primes or prime powers. At the end, the exact output values $z = p/q$ are recovered from $z \; mod \; M$ (if M is sufficiently large relative to p and q) by using the continued fraction approximation algorithm, which is the Euclidean algorithm applied to integers (cf. [115, 116], and [12, Sect. 3 of ch. 3]). If the output z is known to be an integer lying between $-m$ and m and if $M > 2m$, then z is recovered from $z \bmod M$ as follows:

$$z = \begin{cases} z \bmod M & \text{if} \quad z \bmod M < m \\ -M + z \bmod M & \text{otherwise} . \end{cases}$$

The reduction modulo a prime p may turn a nonsingular matrix A and a nonsingular linear system $A\vec{x} = \vec{v}$ into singular ones, but this is proved to occur only with a low probability for a random choice of the prime p in a fixed sufficiently large interval (see [12, Sect. 9 of ch. 4]). To compute the output values z modulo M for a large M, one may first compute them modulo several relatively prime integers $m_1, m_2, \ldots, m_k$ having no common divisors and such that $m_1 m_2 \ldots m_k = M$ and then easily recover $z \bmod M$ by means of the Chinese remainder algorithm. For matrix and polynomial computations, there is an effective alternative technique of *p-adic* (*Newton–Hensel*) *lifting* (cf. [12, Sect. 3 of ch. 3]), which is particularly powerful for computations with dense structured matrices, since it preserves the structure of a matrix. We refer the reader to [6] and [56] on some special techniques that enable one to control the growth of all intermediate values computed in the process of performing rational Gaussian elimination, with no round-off and no reduction modulo an integer. The highly important topic of randomized solution of linear systems of equations in finite fields is covered in [42], which also contains further bibliography. [63] and [118] describe some applications of matrix computations on semirings (with no divisions and subtractions allowed) to graph and combinatorial computations.

Matrix Eigenvalues and Singular Values Problems

The matrix eigenvalue problem is one of the major problems of matrix computation: given an $n \times n$ matrix A, one seeks the maximum k and a $k \times k$ diagonal matrix Λ and an $n \times k$ matrix V of full rank k such that

$$A \; V = V \Lambda \; . \tag{16.1}$$

The diagonal entries of Λ are called the *eigenvalues* of A; the entry (i, i) of Λ is associated with the ith column of V, called an *eigenvector* of A. The eigenvalues of an $n \times n$ matrix A coincide with the zeros of the characteristic polynomial

$$c_A(x) = \det(\, xI - A \,) \; .$$

If this polynomial has n distinct zeros, then $k = n$, and V of (16.1) is a nonsingular $n \times n$ matrix. The Toeplitz matrix $A = I + Z$, $Z = (z_{i,j})$, $z_{i,j} = 0$ unless $j = i + 1$, $z_{i,i+1} = 1$, is an example of a matrix for which $k = 1$, so that the matrix V degenerates to a vector.

In principle, one may compute the coefficients of $c_A(x)$, the characteristic polynomial of A, and then approximate its zeros (see the next section) in order to approximate the eigenvalues of A. Given the eigenvalues, the corresponding eigenvectors can be recovered by means of the inverse power iteration [62, 145]. Practically, the computation of the eigenvalues via the computation of the coefficients of $c_A(x)$ is not recommended, due to arising numerical stability problems [145], and most frequently, the eigenvalues and eigenvectors of a general (unsymmetric) matrix are approximated by means of the *QR algorithm* [62, 145]. Before application of this algorithm, the matrix A is simplified by transforming it into the more special (*lower Hessenberg*) *form*, $H = [h_{i,j}]$, $h_{i,j} = 0$ if $i - j > 1$, by a *similarity transformation,*

$$H = UAU^H \; , \tag{16.2}$$

where $U = [u_{i,j}]$ is a unitary matrix, $U^H U = I$, $U^H = [\overline{u}_{j,i}]$ is the Hermitian transpose of U, $\overline{z}$ denoting the complex conjugate of z; $U^H = U^T$ if U is a real matrix [62]. Similarity transformation into Hessenberg form is a *rational transformation* of a matrix into a special *canonical form, Smith* and *Hermite forms* are two other most important representatives of canonical forms [56, 60, 76].

The eigenvalue problem is *symmetric,* if the matrix A is real symmetric,

$$A^T = \left[a_{j,i}\right] = A = \left[a_{i,j}\right] ,$$

or complex Hermitian,

$$A^H = \left[\overline{a}_{j,i}\right] = A = \left[a_{i,j}\right] .$$

The symmetric eigenvalue problem is simpler: the matrix V of (16.1) is a nonsingular $n \times n$ matrix, and all the eigenvalues are real and little sensitive to small input perturbations of A [62, 129]. Furthermore, the Hessenberg matrix H of (16.2) becomes symmetric tridiagonal (cf. [62] or [12, Sect. 2.3]). For such a matrix H, application of the QR algorithm is dramatically simplified; moreover, two competitive algorithms are also widely used, that is, the *bisection* [129] (a slightly slower but very robust algorithm) and the *divide-and-conquer* method [34, 62]. The latter method has a modification [11] that only uses $O(n \log^2 n(\log n + \log^2 b))$ arithmetic operations in order to compute all the eigenvalues of an $n \times n$ symmetric tridiagonal matrix A within the output error bound $2^{-b}||A||$, where $||A|| \leq n \max |a_{i,j}|$.

A natural generalization of the eigenproblem (16.1) is to the *generalized eigenproblem.* Given a pair A, B of matrices, the generalized eigenvalue Λ and the generalized eigenvector V satisfy

$$A\ V = B\ V\Lambda\ .$$

The solution algorithm should not compute matrix $B^{-1}A$ explicitly, so as to avoid problems of numerical stability.

Another important extension of the symmetric eigenvalue problem is *singular value decomposition* (SVD) of a (generally unsymmetric and, possibly, rectangular) matrix A: $A = U\Sigma\ V^T$, where U and V are unitary matrices, $U^H U = V^H V = I$, and Σ is a diagonal (generally rectangular) matrix, filled with zeros, except for its diagonal, filled with (positive) singular values of A and, possibly, with zeros. The SVD is widely used in the study of numerical stability of matrix computations and in numerical treatment of singular and ill-conditioned (close to singular) matrices. It is a basic tool, for instance, in the study of approximate polynomial GCD [33, 49].

Approximating Polynomial Zeros

Solution of an nth degree polynomial equation,

$$p(x) = \sum_{i=0}^{n} p_i\ x^i = 0\ , \qquad p_n \neq 0$$

(where one may assume that $p_{n-1} = 0$; this can be achieved via shifting the variable x), is a classical problem that has greatly influenced the development of mathematics throughout the centuries [124]. The problem remains highly important for the theory and practice of present day computing, and dozens of new algorithms for its approximate solution appear every year. Among the existent implementations of such algorithms, the practical heuristic champions in efficiency (in terms of computer time and memory space used, according to the results of many experiments) are various modifications of *Newton's iteration,* $z(i+1) = z(i) - a(i)p(z(i))/p'(z(i))$, $a(i)$ being the step-size parameter [101], *Laguerre's method* [54, 66], and the randomized *Jenkins–Traub algorithm* [69] (all three for approximating a single zero z of $p(x)$), which can be extended to approximating other zeros by means of deflation of the input polynomial via its

numerical division by $x - z$. For simultaneous approximation of all the zeros of $p(x)$, one may apply the Durand–Kerner algorithm, which is defined by the following recurrence:

$$z_j(l+1) = z_j(l) - \frac{p\left(z_j(l)\right)}{p_n \prod_{i \neq j}\left(z_j(l) - z_i(l)\right)}, \quad j = 1, \ldots, n, \quad l = 1, 2, \ldots . \tag{16.3}$$

Here, the most customary choice (see [13] for some effective alternatives) for the n initial approximations $z_j(0)$ to the n zeros of

$$p(x) = p_n \prod_{j=1}^{n}\left(x - z_j\right)$$

is given by $z_j(0) = Z\, exp(2\pi\sqrt{-1}/n)$, $j = 1, \ldots, n$, Z exceeding (by some fixed factor $t > 1$) $\max_j |z_j|$; for instance, one may set

$$Z = 2\,t \max_{i<n} |p_i/p_n| . \tag{16.4}$$

For a fixed l and for all j, the computation according to (16.3) is simple, only involving order n^2 ops, (or even $O(n \log^2 n)$ ops with deteriorated numerical stability [13]). Furthermore, according to the results of many experiments, the iteration (16.3) rapidly converges to the solution, though no theory confirms or explains these results. Similar is the situation with various modifications of this algorithm, which are now even more popular than the original algorithms. The reader is referred to [13, 105, 116], and [124] on many of these algorithms, some implementation issues, and further extensive bibliography.

Neither of the algorithms (cited above) supports any reasonable good estimates for the computational complexity of approximating polynomial zeros for the worst case inputs, but such estimates have been achieved based on algorithms of two other groups. One such group is given by the modern modifications and improvements (due to [114, 120, 132]) of *Weyl's quadtree construction* of 1924. In this approach, an initial square S, containing all the zeros of $p(x)$ is recursively partitioned into 4 congruent subsquares; say, $S = \{ x , | Im\, x | < Z, | Re\, x | < Z \}$ for Z of (16.4). In the center of each of them, a proximity test is applied that estimates the distance from this center to the closest zero of $p(x)$. If such a distance exceeds one half of the diagonal length, then the subsquare contains no zeros of $p(x)$ and is discarded. When this process ensures a strong isolation from each other for the components formed by the remaining squares, then certain extensions of Newton's iteration [120, 132] or some iterative techniques based on numerical integration [114] are applied and very rapidly converge to the desired approximations to the zeros of $p(x)$, within the error bound $2^{-b}Z$ for Z of (16.4). As a result, the algorithms of [114, 120] solve the entire problem of approximating (within $2^{-b}Z$) all the zeros of $p(x)$ at the overall cost of performing $O(\,(n^2 \log n)\ \log(bn)\,)$ ops (cf. [13]).

The second group is given by the *divide-and-conquer algorithms.* They first compute a sufficiently wide annulus A, which is free of the zeros of $p(x)$ and contains comparable numbers of such zeros (that is, the same numbers up to a fixed constant factor) in its exterior and its interior. Then the 2 factors of $p(x)$ are numerically computed, that is, $F(x)$, having all its zeros in the interior of the annulus, and $G(x) = p(x)/F(x)$, having no zeros there. The same process is recursively repeated for $F(x)$ and $G(x)$ until factorization of $p(x)$ into the product of linear factors is computed numerically. From this factorization, approximations to all the zeros of $p(x)$ are obtained. The algorithms of [121] based on this approach only require $O(n \log(bn)\ (\log n)^2)$ ops in order to approximate all the n zeros of $p(x)$ within $2^{-b}Z$ for Z of (16.4). (Note that this is a quite sharp bound: at least n ops are necessary in order to output n distinct values.)

The computations for the polynomial zero problem are ill-conditioned, that is, they generally require a high precision for the worst case input polynomials in order to ensure a required output precision, no matter which algorithm is applied for the solution. Consider, for instance, the polynomial $(x - \frac{6}{7})^n$ and perturb its x-free coefficient by 2^{-bn}. Observe the resulting jumps of the zero $x = 6/7$ by 2^{-b}, and observe similar jumps if the coefficients p_i are perturbed by $2^{(i-n)b}$ for $i = 1, 2, \ldots, n-1$. Therefore, to ensure

the output precision of b bits, we need an input precision of at least $(n-i)b$ bits for each coefficient p_i, $i = 0, 1, \ldots, n-1$. Consequently, for the worst case input polynomial $p(x)$, any solution algorithm needs at least about by factor n increase of the precision of the input and of computing, versus the output precision.

Numerically unstable algorithms may require even a higher input and computation precision, but inspection shows that this is not the case for the algorithms of [13, 114, 120, 121, 132].

16.3 Systems of Nonlinear Equations

Given a system $P = \{p_1(x_1, \ldots, x_n),\ p_2(x_1, \ldots, x_n), \ldots, p_r(x_1, \ldots, x_n)\}$ of nonlinear polynomials with rational coefficients (each $p_i(x_1, \ldots, x_n)$ is said to be an element of $\mathbb{Q}[x_1, \ldots, x_n]$, the ring of polynomials in $x_1, \ldots, x_n$ over the field of rational numbers), the n-tuple of complex numbers $(a_1, \ldots, a_n)$ is a solution of the system if $f_i(a_1, \ldots, a_n) = 0$ for each i with $1 \leq i \leq r$. In this section, we explore the problem of exactly solving a system of nonlinear equations over the field $\mathbb{Q}$. We also indicate how an initial phase of exact algebraic computation leads to certain numerical methods that approximate the solutions; the interaction of symbolic and numeric computation is currently an active domain of research [47]. We provide an overview and cite references to different symbolic techniques used for solving systems of algebraic (polynomial) equations. In particular, we describe methods involving *resultant* and *Gröbner basis* computations.

The *Sylvester resultant method* is the technique most frequently utilized for determining a common zero of two polynomial equations in one variable [88]. However, using the Sylvester method successively to solve a system of multivariate polynomials proves to be inefficient. Successive resultant techniques, in general, lack efficiency as a result of their sensitivity to the ordering of the variables [85]. It is more efficient to eliminate all variables together from a set of polynomials, thus, leading to the notion of the *multivariate resultant.* The three most commonly used multivariate resultant formulations are the *Dixon* [40, 86], *Macaulay* [21, 23, 99], and *sparse resultant formulations* [22, 139].

The theory of Gröbner bases provides powerful tools for performing computations in multivariate polynomial rings. Formulating the problem of solving systems of polynomial equations in terms of polynomial ideals, we will see that a Gröbner basis can be computed from the input polynomial set, thus, allowing for a form of back substitution in order to compute the common roots.

Although not discussed, it should be noted that the *characteristic set algorithm* can be utilized for polynomial system solving. Ritt [133] introduced the concept of a characteristic set as a tool for studying solutions of algebraic differential equations. In 1984, Wu [147] in search of an effective method for automatic theorem proving, converted Ritt's method to ordinary polynomial rings. Given the before mentioned system P, the characteristic set algorithm transforms P into a triangular form, such that the set of common zeros of P is equivalent to the set of roots of the triangular system [85].

Throughout this exposition we will also see that these techniques used to solve nonlinear equations can be applied to other problems as well, such as computer-aided design and automatic geometric theorem proving.

The Sylvester Resultant

The question of whether two polynomials $f(x),\ g(x) \in \mathbb{Q}[x]$,

$$\begin{aligned} f(x) &= f_n x^n + f_{n-1} x^{n-1} + \ldots + f_1 x + f_0\,, \\ g(x) &= g_m x^m + g_{m-1} x^{m-1} + \ldots + g_1 x + g_0\,, \end{aligned}$$

have a common root leads to a condition that has to be satisfied by the coefficients of both f and g. Using a derivation of this condition due to Euler, the *Sylvester matrix* of f and g (which is of order $m+n$) can

be formulated. The vanishing of the determinant of the Sylvester matrix, known as the *Sylvester resultant,* is a necessary and sufficient condition for f and g to have common roots [88].

As a running example let us consider the following system in two variables provided by Lazard [94]:

$$\begin{aligned} f &= x^2 + xy + 2x \quad + y - 1 = 0\,, \\ g &= x^2 \quad + 3x - y^2 + 2y - 1 = 0\,. \end{aligned}$$

The Sylvester resultant can be used as a tool for eliminating several variables from a set of equations [85]. Without loss of generality, the roots of the Sylvester resultant of f and g treated as polynomials in y, whose coefficients are polynomials in x, are the x-coordinates of the common zeros of f and g. More specifically, the Sylvester resultant of the Lazard system with respect to y is given by the following determinant:

$$\det\left(\begin{bmatrix} x+1 & x^2+2x-1 & 0 \\ 0 & x+1 & x^2+2x-1 \\ -1 & 2 & x^2+3x-1 \end{bmatrix}\right) = -x^3 - 2x^2 + 3x\,.$$

An alternative matrix formulation named after Bézout yields the same determinant. This formulation is discussed below in the context of multivariate polynomials, in "Resultants of Multivariate Systems."

The roots of the Sylvester resultant of f and g are $\{-3, 0, 1\}$. For each x value, one can substitute the x value back into the original polynomials yielding the solutions $(-3, 1)$, $(0, 1)$, $(1, -1)$.

The method just outlined can be extended recursively, using *polynomial GCD computations,* to a larger set of multivariate polynomials in $\mathbb{Q}[x_1, \ldots, x_n]$. This technique, however, is impractical for eliminating many variables, due to an explosive growth of the degrees of the polynomials generated in each elimination step.

The Sylvester formulations has led to a *subresultant theory,* developed simultaneously by G.E. Collins and W.S. Brown and J. Traub. The subresultant theory produced an efficient algorithm for computing polynomial GCDs and their resultants, while controlling intermediate expression swell [15, 31, 88].

It should be noted that by adopting an implicit representation for symbolic objects, the intermediate expression swell introduced in many symbolic computations can be palliated. Recently, polynomial GCD algorithms have been developed that use implicit representations and thus, avoid the computationally costly content and primitive part computations needed in those GCD algorithms for polynomials in explicit representation [38, 71, 83].

Resultants of Multivariate Systems

The solvability of a set of nonlinear multivariate polynomials can be determined by the vanishing of a generalization of the Sylvester resultant of two polynomials in a single variable. We examine two generalizations, namely, the classical and the sparse resultants. The *classical resultant* of a system of n homogeneous polynomials in n variables vanishes exactly when there exists a common solution in *projective* space [85, 141]. The *sparse resultant* characterizes solvability over a smaller space which coincides with affine space under certain genericity conditions [57, 139]. The main algorithmic question, then, is to construct a matrix whose determinant is the resultant or a nontrivial multiple of it.

Due to the special structure of the Sylvester matrix, Bézout developed a method for computing the resultant as a determinant of order $\mathrm{Max}(m, n)$ during the eighteenth century. Cayley [29] reformulated Bézout's method leading to Dixon's [40] extension to the bivariate case. Dixon's method can be generalized to a set

$$\{p_1\,(x_1, \ldots, x_n)\,,\, p_2\,(x_1, \ldots, x_n)\,, \ldots,\, p_{n+1}\,(x_1, \ldots, x_n)\}$$

of $n + 1$ generic n-degree polynomials in n variables [87]. The vanishing of the determinant of the Dixon matrix is a necessary and sufficient condition for the polynomials to have a nontrivial projective common

zero, and also a necessary condition for the existence of an affine common zero. The Dixon formulation gives the resultant up to a multiple, and hence, in the affine case it may happen that the vanishing of the Dixon determinant does not necessarily indicate that the equations in question have a common root. A nontrivial multiple, known as the *projection operator,* can be extracted via a method based on so-called *rank subdeterminant computation* (RSC) [87]. It should be noted that the RSC method can also be applied to the Macaulay and sparse resultant formulations as is detailed below. A more general and simpler method for extracting a projection operator from the Dixon matrix is discussed in [28, thm. 3.3.4]. This article, along with [43], explain the correlation between residue theory and the Dixon matrix, which yields an alternative method for studying and approximating all common solutions.

In 1916, Macaulay [99] constructed a matrix whose determinant is a multiple of the classical resultant for n homogeneous polynomials in n variables. The Macaulay matrix simultaneously generalizes the Sylvester matrix and the coefficient matrix of a system of linear equations [85]. As the Dixon formulation, the Macaulay determinant is a multiple of the resultant. Macaulay, however, proved that a certain minor of his matrix divides the matrix determinant so as to yield the exact resultant in the case of generic homogeneous polynomials. Canny [21] has invented a general method that perturbs any polynomial system and extracts a nontrivial projection operator.

Using recent results pertaining to sparse polynomial systems [57, 139], a matrix formula for computing the sparse resultant of $n+1$ polynomials in n variables was given by Canny and Emiris [22] and consequently improved in [25, 48]. The determinant of the sparse resultant matrix, like the Macaulay and Dixon matrices, only yields a projection operation, not the exact resultant.

Here, sparsity means that only certain monomials in each of the $n + 1$ polynomials have nonzero coefficients. Sparsity is measured in geometric terms, namely, by the *Newton polytope* of the polynomial, which is the convex hull of the exponent vectors corresponding to nonzero coefficients. The *mixed volume* of the Newton polytopes of n polynomials in n variables is defined as a certain integer-valued function that bounds the number of affine common roots of these polynomials, according to a theorem of [10]. This remarkable theorem is the cornerstone of sparse elimination. The mixed volume bound is significantly smaller than the classical Bézout bound for polynomials with small Newton polytopes. Since these bounds also determine the degree of the sparse and classical resultants, respectively, the latter has larger degree for sparse polynomials.

Polynomial System Solving by Using Resultants

Suppose we are asked to find the common zeros of a set of n polynomials in n variables $\{p_1(x_1, \ldots, x_n), p_2(x_1, \ldots, x_n), \ldots, p_n(x_1, \ldots, x_n)\}$. By augmenting the polynomial set by a generic linear polynomial [21, 24, 85], one can construct the *u-resultant* of a given system of polynomials. The u-resultant is named after the vector of indeterminates u, traditionally used to represent the generic coefficients of the additional linear polynomial. The u-resultant factors into linear factors over the complex numbers, providing the common zeros of the given polynomials equations. The u-resultant method takes advantage of the properties of the multivariate resultant, and hence, can be constructed using either Dixon's, Macaulay's, or sparse formulations. An alternative approach, where we *hide* a variable in the coefficient field, instead of adding a polynomial, is discussed in [46, 102].

Consider the previous example augmented by a generic linear form:

$$\begin{aligned} f_1 &= x^2 + xy + 2x \quad + y - 1 = 0\,, \\ f_2 &= x^2 \quad + 3x - y^2 + 2y - 1 = 0\,, \\ f_l &= \qquad ux \qquad + vy + w = 0\,. \end{aligned}$$

As described in Canny, Kaltofen and Lakshman [23], the following matrix M corresponds to the

Macaulay u-resultant of the above system of polynomials, with z being the homogenizing variable:

$$M = \begin{bmatrix} 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 & u & 0 & 0 & 0 \\ 2 & 0 & 1 & 3 & 0 & 1 & 0 & u & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 & 0 & v & 0 & 0 & 0 \\ 1 & 2 & 1 & 2 & 3 & 0 & w & v & u & 0 \\ -1 & 0 & 2 & -1 & 0 & 3 & 0 & w & 0 & u \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 2 & -1 & 0 & 0 & v & 0 \\ 0 & -1 & 1 & 0 & -1 & 2 & 0 & 0 & w & v \\ 0 & 0 & -1 & 0 & 0 & -1 & 0 & 0 & 0 & w \end{bmatrix}.$$

It should be noted that

$$\det(M) = (u - v + w)(-3u + v + w)(v + w)(u - v)$$

corresponds to the affine solutions $(1, -1)$, $(-3, 1)$, $(0, 1)$, and one solution at infinity.

Resultants may also be applied to reduce polynomial system solving to a regular or generalized eigenproblem (cf. "Matrix Eigenvalues and Singular Values Problems"), thus, transforming the nonlinear question to a problem in linear algebra. This is a classical technique that enables us to approximate all solutions (cf. [3, 24, 28, 46]). For demonstration, consider the previous system and its resultant matrix M. The matrix rows are indexed by the following row vector of monomials in the eliminated variables:

$$\vec{v} = \left[x^3, x^2y, x^2, xy^2, xy, x, y^3, y^2, y, 1\right].$$

Vector $\vec{v}M$ expresses the polynomials indexing the columns of M, which are multiples of the three input polynomials by various monomials. Let us specialize variables u and v to random values. Then the matrix M contains a single variable w and is denoted $M(w)$. Solving the linear system $\vec{v}M(w) = \vec{0}$ in vector $\vec{v}$ and in scalar w is a generalized eigenproblem, since $M(w)$ can be represented as $M_0 + wM_1$, where M_0 and M_1 have numeric entries. If, moreover, M_1 is invertible, we arrive at the following eigenproblem:

$$\vec{v}\,(M_0 + wM_1) = \vec{0} \Longleftrightarrow \vec{v}\left(-M_1^{-1}M_0 - wI\right) = \vec{0} \Longleftrightarrow \vec{v}\left(-M_1^{-1}M_0\right) = w\vec{v}\,.$$

For every solution (a, b) of the original system, there is a vector $\vec{v}$ among the computed eigenvectors, which we evaluate at $x = a,\ y = b$ and from which the solution can be recovered by means of division (cf. [46]). As for the eigenvalues, they correspond to the values of w at the solutions.

Recently, the structure of various resultant matrices has been studied, continuing work in [23]. By exploiting the quasi-Toeplitz or quasi-Hankel structure of such matrices, it is possible to accelerate their construction, the computation of the resultant itself, and the approximation of the system's solutions [44, 108].

An empirical comparison of the detailed resultant formulations can be found in [86, 102]. The multivariate resultant formulations have been used for diverse applications such as *algebraic and geometric reasoning* [28, 87, 102], *computer-aided design* [89, 138], *robot kinematics* [45, 102], computing *molecular conformations* [45, 103] and for *implicitization and finding base points* [30, 102].

Gröbner Bases

Solving systems of nonlinear equations can be formulated in terms of polynomial ideals [7, 56, 146]. Let us first establish some terminology.

The ideal generated by a system of polynomial equations $p_1, \ldots, p_r$ over $\mathbb{Q}[x_1, \ldots, x_n]$ is the set of all linear combinations

$$(p_1, \ldots, p_r) = \{h_1 p_1 + \ldots + h_r p_r \mid h_1, \ldots, h_r \in \mathbb{Q}[x_1, \ldots, x_n]\} .$$

The algebraic variety of $p_1, \ldots, p_r \in \mathbb{Q}[x_1, \ldots, x_n]$ is the set of their common zeros,

$$V(p_1, \ldots, p_r) = \left\{(a_1, \ldots, a_n) \in \mathbb{C}^n \mid f_1(a_1, \ldots, a_n) = \ldots = f_r(a_1, \ldots, a_n) = 0\right\} .$$

A version of the *Hilbert Nullstellensatz* states that

$$V(p_1, \ldots, p_r) = \text{the empty set } \emptyset \Longleftrightarrow 1 \in (p_1, \ldots, p_r) \text{ over } \mathbb{Q}[x_1, \ldots, x_n] ,$$

which relates the solvability of polynomial systems to the ideal membership problem.

A term $t = x_1^{e_1} x_2^{e_2} \ldots x_n^{e_n}$ of a polynomial is a product of powers with $\deg(t) = e_1 + e_2 + \cdots + e_n$. In order to add needed structure to the polynomial ring we will require that the terms in a polynomial be ordered in an admissible fashion [56, 85]. Two of the most common admissible orderings are the **lexicographic order** ($\prec_l$), where terms are ordered as in a dictionary, and the **degree order** ($\prec_d$), where terms are first compared by their degrees with equal degree terms compared lexicographically. A variation to the lexicographic order is the *reverse lexicographic order,* where the lexicographic order is reversed [35, p. 96].

It is this above mentioned structure that permits a type of simplification known as polynomial reduction. Much like a polynomial remainder process, the process of polynomial reduction involves subtracting a multiple of one polynomial from another to obtain a smaller degree result [7, 56, 85, 146].

A polynomial g is said to be reducible with respect to a set $P = \{p_1, \ldots, p_r\}$ of polynomials if it can be reduced by one or more polynomials in P. When g is no longer reducible by the polynomials in P, we say that g is *reduced* or is *a normal form* with respect to P.

For an arbitrary set of basis polynomials, it is possible that different reduction sequences applied to a given polynomial g could reduce to different normal forms. A basis $G \subseteq \mathbb{Q}[x_1, \ldots, x_n]$ is a *Gröbner basis* if and only if every polynomial in $\mathbb{Q}[x_1, \ldots, x_n]$ has a unique normal form with respect to G. Bruno Buchberger [16, 17, 18, 19] showed that every basis for an ideal $(p_1, \ldots, p_r)$ in $\mathbb{Q}[x_1, \ldots, x_n]$ can be converted into a Gröbner basis $\{p_1^*, \ldots, p_s^*\} = GB(p_1, \ldots, p_r)$, concomitantly designing an algorithm that transforms an arbitrary ideal basis into a Gröbner basis. Another characteristic of Gröbner bases is that by using the above mentioned reduction process we have

$$g \in (p_1 \ldots, p_r) \Longleftrightarrow \left(g \bmod p_1^*, \ldots, p_s^*\right) = 0 .$$

Further, by using the Nullstellensatz it can be shown that $p_1 \ldots, p_r$ viewed as a system of algebraic equations is solvable if and only if $1 \notin GB(p_1, \ldots, p_r)$.

Depending on which admissible term ordering is used in the Gröbner bases construction, an ideal can have different Gröbner bases. However, an ideal cannot have different (reduced) Gröbner bases for the same term ordering.

Any system of polynomial equations can be solved using a lexicographic Gröbner basis for the ideal generated by the given polynomials. It has been observed, however, that Gröbner bases, more specifically lexicographic Gröbner bases, are hard to compute [7, 56, 93, 146]. In the case of zero-dimensional ideals, those whose varieties have only isolated points, Faugère et al. [50] outlined a change of basis algorithm which can be utilized for solving zero-dimensional systems of equations. In the zero-dimensional case, one computes a Gröbner basis for the ideal generated by a system of polynomials under a degree ordering. The so-called *change of basis algorithm* can then be applied to the degree ordered Gröbner basis to obtain a Gröbner basis under a lexicographic ordering.

Turning to Lazard's example in form of a polynomial basis,

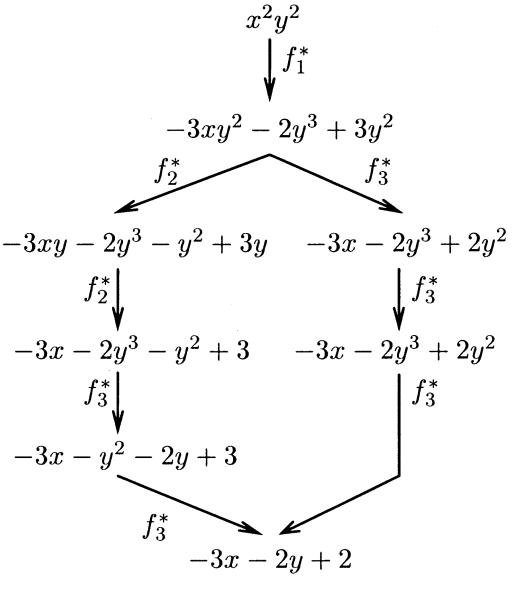
$$\begin{array}{lllllll} f_1 & = & x^2 & +xy & +2x & +y & -1 , \\ f_2 & = & x^2 & & +3x & -y^2 & +2y & -1 , \end{array}$$

one obtains (under lexicographical ordering with $x \prec_l y$) a Gröbner basis in which the variables are triangularized such that the finitely many solutions can be computed via back substitution:

$$\begin{array}{lcccccc} f_1^* & = & x^2 & & +3x & +2y & -2\,, \\ f_2^* & = & & xy & -x & -y & +1\,, \\ f_3^* & = & & & y^2 & & -1\,. \end{array}$$

It should be noted that the final univariate polynomial is of minimal degree and the polynomials used in the back substitution will have degree no larger than the number of roots.

As an example of the process of polynomial reduction with respect to a Gröbner basis, the following demonstrates two possible reduction sequences to the same normal form. The polynomial x^2y^2 is reduced with respect to the previously computed Gröbner basis $\{f_1^*, f_2^*, f_3^*\} = GB(f_1, f_2)$ along the following two distinct reduction paths, both yielding $-3x - 2y + 2$ as the normal form.



There is a strong connection between lexicographic Gröbner bases and the previously mentioned resultant techniques. For some types of input polynomials, the computation of a reduced system via resultants might be much faster than the computation of a lexicographic Gröbner basis. A good comparison between the Gröbner computations and the different resultant formulations can be found in [86, 102].

In a survey article, Buchberger [18] detailed how Gröbner bases can be used as a tool for many polynomial ideal theoretic operations. Other applications of Gröbner basis computations include automatic geometric theorem proving [84, 147], multivariate polynomial factorization and GCD computations [59], and polynomial interpolation [91, 92].

16.4 Polynomial Factorization

The problem of factoring polynomials is a fundamental task in symbolic algebra. An example in one's early mathematical education is the factorization $x^2 - y^2 = (x + y) \cdot (x - y)$, which in algebraic terms is a factorization of a polynomial in two variables with integer coefficients. Technology has advanced to a state where most polynomial factorization problems are doable on a computer, in particular, with any of the

popular mathematical software, such as the Mathematica or Maple systems. For instance, the factorization of the determinant of a 6×6 symmetric Toeplitz matrix over the integers is computed in Maple as

```
>readlib(showtime):
>showtime():
O1 := T := linalg[toeplitz]([a,b,c,d,e,f]);
```

$$T := \begin{bmatrix} a & b & c & d & e & f \\ b & a & b & c & d & e \\ c & b & a & b & c & d \\ d & c & b & a & b & c \\ e & d & c & b & a & b \\ f & e & d & c & b & a \end{bmatrix}$$

```
time 0.03 words 7701
O2 := factor(linalg[det](T));
```

$$\begin{aligned} -(&2dca - 2bce + 2c^2a - a^3 - da^2 + 2d^2c + d^2a + b^3 + 2abc - 2c^2b \\ &+ d^3 + 2ab^2 - 2dcb - 2cb^2 - 2ec^2 + 2eb^2 + 2fcb + 2bae \\ &+ b^2f + c^2f + be^2 - ba^2 - fdb - fda - fa^2 - fba + e^2a - 2db^2 \\ &+ dc^2 - 2deb - 2dec - dba)(2dca - 2bce - 2c^2a + a^3 \\ &- da^2 - 2d^2c - d^2a + b^3 + 2abc - 2c^2b + d^3 - 2ab^2 + 2dcb \\ &+ 2cb^2 + 2ec^2 - 2eb^2 - 2fcb + 2bae + b^2f + c^2f + be^2 - ba^2 \\ &- fdb + fda - fa^2 + fba - e^2a - 2db^2 + dc^2 + 2deb - 2dec \\ &+ dba) \end{aligned}$$

```
time 27.30 words 857700
```

Clearly, the Toeplitz determinant factorization requires more than tricks from high school algebra. Indeed, the development of modern algorithms for the polynomial factorization problem is one of the great successes of the discipline of symbolic mathematical computation. Kaltofen has surveyed the algorithms until 1992 in [70, 73, 74], mostly from a computer science perspective. In this article we shall focus on the applications of the known fast methods to problems in science and engineering. For a more extensive set of references, please refer to Kaltofen's survey articles.

Polynomials in a Single Variable Over a Finite Field

At the first glance, the problem of factoring an integer polynomial modulo a prime number appears to be very similar to the problem of factoring an integer represented in a prime radix. That is simply not so. The factorization of the polynomial $x^{511} - 1$ can be done modulo 2 on a computer in a matter of milliseconds, while the factorization of the integer $2^{511} - 1$ into its integer factors is a computational challenge. For those interested, the largest prime factors of $2^{511} - 1$ have 57 and 67 decimals digits, respectively, which makes a tough but not undoable 123 digit product for the number field sieve factorizer [97]. Irreducible factors of polynomials modulo 2 are needed to construct finite fields. For example, the factor $x^9 + x^4 + 1$ of $x^{511} - 1$ leads to a model of the finite field with 2^9 elements, GF(2^9), by simply computing with the polynomial remainders modulo $x^9 + x^4 + 1$ as the elements. Such irreducible polynomials are used for setting up error-correcting codes, for instance, the BCH codes [100]. Berlekamp's [8, 9] pioneering work on factoring polynomials over a finite field by linear algebra is done with this motivation. The linear

algebra tools that Berlekamp used seem to have been introduced to the subject as early as in 1937 by Petr (cf. [134]).

Today, factoring algorithms for univariate polynomials over finite fields form the innermost subalgorithm to lifting-based algorithms for factoring polynomials in one [148] and many [109] variables over the integers. When Maple computed the factorization of the above Toeplitz determinant, it began with factoring a univariate polynomial modulo a prime integer. The case when the prime integer is very large has lead to a significant development in computer science itself. As it turns out, by selecting random residues the expected performance of the algorithms can be speeded up exponentially [9, 131]. Randomization is now an important tool for designing efficient algorithms and has proliferated to many fields of computer science. Paradoxically, the random elements are produced by a congruential random number generator, and the actual computer implementations are quite deterministic, which leads some computer scientists to believe that random bits can be eliminated in general at no exponential slow-down. Nonetheless, for the polynomial factoring problem modulo a large prime, no fast methods are known to-date that would work without this "probabilistic" approach.

One can measure the computing time of selected algorithms in terms of n, the degree of the input polynomial, and p, the cardinality of the field. When counting arithmetic operations modulo p (including reciprocals), the best known algorithms are quite recent. Berlekamp's 1970 method performs $O(n^{\omega} + n^{1+o(1)} \log p)$ residue operations. Here and below, ω denotes the exponent implied by the used linear system solver, i.e., $\omega = 3$ when classical methods are used, and $\omega = 2.376$ when asymptotically fast (though impractical) matrix multiplication is assumed. The correction term $o(1)$ accounts for the $\log n$ factors derived from the FFT-based fast polynomial multiplication and remaindering algorithms. An approach in the spirit of Berlekamp's but possibly more practical for $p = 2$ has recently been discovered by Niederreiter [110]. A very different technique by Cantor and Zassenhaus [27] first separates factors of different degrees and then splits the resulting polynomials of equal degree factors. It has $O(n^{2+o(1)} \log p)$ complexity and is the basis for the following two methods. Algorithms by von zur Gathen and Shoup [142] have running time $O(n^{2+o(1)} + n^{1+o(1)} \log p)$ and those by Kaltofen and Shoup [81] have running time $O(n^{1.815} \log p)$, the latter with fast matrix multiplication. The techniques of von zur Gathen and Shoup have recently been applied to speed the case $p = 2^k$ for large k in terms of fixed precision (bit) operations [82].

For n and p simultaneously large, a variant of the method by Kaltofen and Shoup [81] that uses classical linear algebra and runs in $O(n^{2.5} + n^{1+o(1)} \log p)$ residue operations is the current champion among the practical algorithms. With it Shoup, using his own fast polynomial arithmetic package [136], has factored a random-like polynomial of degree 2048 modulo a 2048-bit prime number in about 12 days on a Sparc-10 computer using 68 Mbyte of main memory. For even larger n, but smaller p, parallelization helps, and Kaltofen and Lobo [77] could factor a polynomial of degree $n = 15001$ modulo $p = 127$ in about 6 days on 8 computers that are rated at 86.1 MIPS. To date, the largest polynomial factored modulo 2 is a random polynomial of degree 262143; this was accomplished by von zur Gathen and Gerhard [143]. They employ Cantor's fast polynomial multiplication algorithm based on additive transforms [26].

Polynomials in a Single Variable over Fields of Characteristic Zero

As mentioned before, generally usable methods for factoring univariate polynomials over the rational numbers begin with the Hensel lifting techniques introduced by Zassenhaus [148]. The input polynomial is first factored modulo a suitable prime integer p, and then the factorization is lifted to one modulo p^k for an exponent k of sufficient size to accommodate all possible integer coefficients that any factors of the polynomial might have. The lifting approach is fast in practice, but there are hard-to-factor polynomials on which it runs an exponential time in the degree of the input. This slowdown is due to so-called parasitic modular factors. The polynomial $x^4 + 1$, for example, factors modulo all prime integers but is irreducible over the integers: it is the cyclotomic equation for 8th roots of unity. The products of all subsets of modular

factors are candidates for integer factors, and irreducible integer polynomials with exponentially many such subsets exist [78].

The elimination of the exponential bottleneck by giving a polynomial-time solution to the integer polynomial factoring problem, due to Lenstra et al. [95], is considered a major result in computer science algorithm design. The key ingredient to their solution is the construction of integer relations to real or complex numbers. For the simple demonstration of this idea, consider the polynomial

$$x^4 + 2x^3 - 6x^2 - 4x + 8 \,.$$

A root of this polynomial is $\alpha \approx 1.236067977$, and $\alpha^2 \approx 1.527864045$. We note that $2\alpha + \alpha^2 \approx 4.000000000$, hence, $x^2 + 2x - 4$ is a factor. The main difficulty is to efficiently compute the integer linear relation with relatively small coefficients for the high precision big-float approximations of the powers of a root. Lenstra et al. solve this diophantine optimization problem by means of their now famous lattice reduction procedure, which is somewhat reminiscent of the ellipsoid method for linear programming.

The determination of linear integer relations among a set of real or complex numbers is a useful task in science in general. Very recently, some stunning identities could be produced by this method, including the following formula for π [5]:

$$\pi = \sum_{n=0}^{\infty} \frac{1}{16^n} \left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6} \right) .$$

Even more surprising, the lattice reduction algorithm can prove that no linear integer relation with integers smaller than a chosen parameter exists among the real or complex numbers. There is an efficient alternative to the lattice reduction algorithm, originally due to Ferguson and Forcade [52] and recently improved by Ferguson and Bailey [51].

The complexity of factoring an integer polynomial of degree n with coefficients of no more than l bits is thus, a polynomial in n and l. From a theoretical point of view, an algorithm with a low estimate is by Miller [106] and has a running time of $O(n^{5+o(1)}l^{1+o(1)} + n^{4+o(1)}l^{2+o(1)})$ bit-operations. It is expected that the relation-finding methods will become usable in practice on hard-to-factor polynomials in the near future. If the hard-to-factor input polynomial is irreducible, an alternate approach can be used to prove its irreducibility. One finds an integer evaluation point at which the integral value of the polynomial has a large prime factor, and the irreducibility follows by mathematical theorems. Monagan [107] has proven large hard-to-factor polynomials irreducible in this way, which would be hopeless by the lifting algorithm.

Coefficient fields other than finite fields and the rational numbers are of interest. Computing the factorizations of univariate polynomials over the complex numbers is the root finding problem described earlier in "Approximating Polynomial Zeros." When the coefficient field has an extra variable, such as the field of fractions of polynomials ("rational functions") the problem reduces, by an old theorem of C.F. Gauss, to factoring multivariate polynomials, which we discuss below. When the coefficient field is the field of Laurent series in t with a finite segment of negative powers,

$$\frac{c_{-k}}{t^k} + \frac{c_{-k+1}}{t^{k-1}} + \cdots + \frac{c_{-1}}{t} + c_0 + c_1 t + c_2 t^2 + \cdots, \quad \text{where } k \geq 0 \,,$$

fast methods appeal to the theory of Puiseux series, which constitute the domain of algebraic functions [144].

Polynomials in Two Variables

Factoring bivariate polynomials by reduction to univariate factorization via homomorphic projection and subsequent lifting can be done similarly to the univariate algorithm [109]. The second variable y takes the role of the prime integer p and $f(x, y) \bmod y = f(x, 0)$. Lifting is possible only if $f(x, 0)$ had

no multiple root. Provided that $f(x, y)$ has no multiple factor, which can be insured by a simple GCD computation, the squarefreeness of $f(x, 0)$ can be obtained by variable translation $\hat{y} = y + a$, where a is an easy-to-find constant in the coefficient field. For certain domains, such as the rational numbers, any irreducible multivariate polynomial $h(x, y)$ can be mapped to an irreducible univariate polynomial $h(x, b)$ for some constant b. This is the important *Hilbert irreducibility theorem,* whose consequence is that the combinatorial explosion observed in the univariate lifting algorithm is, in practice, unlikely. However, the magnitude and probabilistic distribution of good points b is not completely analyzed.

For so-called non-Hilbertian coefficient fields good reduction is not possible. An important such field are the complex numbers. Clearly, all $f(x, b)$ completely split into linear factors, while $f(x, y)$ may be irreducible over the complex numbers. An example for an irreducible polynomial is $f(x, y) = x^2 - y^3$. Polynomials that remain irreducible over the complex numbers are called absolutely irreducible. An additional problem is the determination of the algebraic extension of the ground field in which the absolutely irreducible factors can be expressed. In the example

$$x^6 - 2x^3y^2 + y^4 - 2x^3 = \left(x^3 - \sqrt{2}x - y^2\right) \cdot \left(x^3 + \sqrt{2}x - y^2\right) ,$$

the needed extension field is $\mathbb{Q}(\sqrt{2})$. The relation-finding approach proves successful for this problem. The root is computed as a Taylor series in y, and the integrality of the linear relation for the powers of the series means that the multipliers are polynomials in y of bounded degree. Several algorithms of polynomial-time complexity and pointers to the literature are found in [75].

Bivariate polynomials constitute implicit representations of algebraic curves. It is an important operation in geometric modeling to convert from implicit to parametric representation. For example, the circle

$$x^2 + y^2 - 1 = 0$$

has the rational parameterization

$$x = \frac{2t}{1 + t^2}, \quad y = \frac{1 - t^2}{1 + t^2}, \quad \text{where } -\infty \le t \le \infty .$$

Algorithms are known that can find such rational parameterizations provided that they exist [135]. It is crucial that the inputs to these algorithms are absolutely irreducible polynomials.

Polynomials in Many Variables

Polynomials in many variables, such as the symmetric Toeplitz determinant exhibited above, are rarely given explicitly, due to the fact that the number of possible terms grows exponentially in the number of variables: there can be as many as $\binom{n+v}{n} \ge 2^{\min\{n,v\}}$ terms in a polynomial of degree n with v variables. Even the factors may be dense in canonical representation, but could be sparse in another basis: for instance, the polynomial

$$(x_1 - 1)\,(x_2 - 2) \cdots (x_v - v) + 1$$

has only 2 terms in the "shifted basis," while it has 2^v terms in the power basis, i.e., in expanded format.

Randomized algorithms are available that can efficiently compute a factor of an implicitly given polynomial, say, a matrix determinant, and even can find a shifted basis with respect to which a factor would be sparse, provided, of course, that such a shift exists. The approach is by manipulating polynomials in so-called black box representations [83]: a black box is an object that takes as input a value for each variable, and then produces the value of the polynomial it represents at the specified point. In the Toeplitz example the representation of the determinant could be the Gaussian elimination program which computes it. We note that the size of the polynomial in this case would be nearly constant, only the variable names and the dimension need to be stored. The factorization algorithm then outputs procedures which

will evaluate all irreducible factors at an arbitrary point (supplied as the input). These procedures make calls to the black box given as input to the factorization algorithm in order to evaluate them at certain points, which are derived from the point at which the procedures computing the values of the factors are probed. It is, of course, assumed that subsequent calls evaluate one and the same factor and not associates that are scalar multiples of one another. The algorithm by Kaltofen and Trager [83] finds procedures that with a controllably high probability evaluate the factors correctly. Randomization is needed to avoid parasitic factorizations of homomorphic images that provide some static data for the factor boxes and cannot be avoided without mathematical conjecture. The procedures that evaluate the individual factors are deterministic.

Factors constructed as black box programs are much more space efficient than those represented in other formats, for example, the straight-line program format [72]. More importantly, once the black box representation for the factors is found, sparse representations can be rapidly computed by any of the new sparse interpolation algorithms. See [65] for the latest method allowing shifted bases and pointers to the literature of other methods, including ones for the standard power bases.

The black box representation of polynomials is normally not supported by commercial computer algebra systems such as Axiom, Maple, or Mathematica. Díaz and Kaltofen have developed the FOXBOX system in C++ that makes black box methodology available to users of such systems [37, 39]. They have computed a factor over the rationals of the determinant of a generic 13 by 13 symmetric Toepitz matrix, which has 4982 nonzero terms, in 15 hours and 25 minutes on a single processor of a Sun Ultra 2 computer.

16.5 Research Issues and Summary

Section 16.3 of this chapter has briefly reviewed polynomial system solving based on resultant matrices as well as Gröbner bases. Both approaches are currently active, especially in applications dealing with small and medium-size systems. Handling the nongeneric cases, including multiple roots and nonisolated solutions, is probably the most crucial issue today in relation to resultants. An interesting practical question is to delimit those cases where each of the two methods and their different variants is preferable.

16.6 Defining Terms

Characteristic polynomial: A polynomial associated with a square matrix, the determinant of the matrix when a single variable is subtracted to its diagonal entries. The roots of the characteristic polynomial are the eigenvalues of the matrix.

Condition number: A scalar derived from a matrix that measures its relative nearness to a singular matrix. Very close to singular means a large condition number, in which case numeric inversion becomes an ill-conditioned problem.

Degree order: An order on the terms in a multivariate polynomial; for two variables x and y with $x \prec y$ the ascending chain of terms is $1 \prec x \prec y \prec x^2 \prec xy \prec y^2 \cdots$.

Determinant: A polynomial in the entries of a square matrix with the property that its value is nonzero if and only if the matrix is invertible.

Lexicographic order: An order on the terms in a multivariate polynomial; for two variables x and y with $x \prec y$ the ascending chain of terms is $1 \prec x \prec x^2 \prec \cdots \prec y \prec xy \prec x^2y \cdots \prec y^2 \prec xy^2 \cdots$.

Matrix eigenvector: A column vector v such that, given square matrix A, $Av = \lambda v$, where λ is the matrix eigenvalue corresponding to v. A generalized eigenvector v is such that, given square matrices A, B, it satisfies $Av = \lambda Bv$. Both definitions extend to a row vector which premultiplies the corresponding matrix.

Ops: Arithmetic operations, i.e., additions, subtractions, multiplications, or divisions; as in **flops,** i.e., floating point operations.

Singularity: A square matrix is singular if there is a nonzero second matrix such that the product of the two is the zero matrix. Singular matrices do not have inverses.

Sparse matrix: A matrix where many of the entries are zero.

Structured matrix: A matrix where each entry can be derived by a formula depending on few parameters. For instance, the Hilbert matrix has $1/(i + j - 1)$ as the entry in row i and column j.

Further Information

The books [1, 4, 12, 13, 14, 20, 35, 56, 88, 146, 149] provide a much broader introduction to the general subject and further bibliography. There are well-known libraries and packages of subroutines for the most popular numerical matrix computations, in particular, [41] for solving linear systems of equations, [137] and [55] for approximating matrix eigenvalues, and [2] for both of the two latter computational problems. There is a comprehensive treatment of numerical matrix computations [62], with extensive bibliography, and there are several more specialized books on them [58, 64, 68, 129, 140, 145] as well as many survey articles [67, 111, 117] and thousands of research articles. Two journals are currently dedicated to the subject, the *Journal of Symbolic Computation* by Academic Press, London and *Applicable Algebra in Engineering, Communication and Computing* by Springer-Verlag. The annual *International Symposium on Symbolic and Algebraic Computation* is what we consider the flagship conference of the research community.

Special (more efficient) parallel algorithms have been devised for special classes of matrices, such as sparse [118, 127], banded [128], and dense structured [12, 122]. We also refer to [125] on simple but surprisingly effective extension of Brent's principle for improving the processor and work efficiency of parallel matrix algorithms (with applications to path computations in graphs) and to [62, 67, 111] on practical parallel algorithms for matrix computations.

17.1 Introduction

The subject of this chapter lies in the area of theoretical computer science, though it borrows certain results from computational mathematics, and is fundamental to the theory and practice of signal and image processing and scientific and engineering computing.

A central theme is to bridge the gap between polynomial arithmetic on the one hand, and integer arithmetic and matrix computations on the other. This is the premise of applying the **fast Fourier transform (FFT)** on a wide range of problems, yielding the fastest known algorithms for performing the basic arithmetic operations on integers, polynomials, and dense structured matrices. For instance, this chapter shows different ways of multiplying two univariate polynomials fast. This means that, instead of the classical method that requires a quadratic number of multiplications and additions between constants, we consider algorithms with significantly lower complexity in terms of the polynomial degrees. In particular, we detail an FFT-based approach, which requires a quasi-linear number of operations. Another example

[1]This material is based on work supported in part by the European Union under ESPRIT FRISCO project LTR 21.024 (first author), by the National Science Foundation, under Grant nos. CCR-9020690 and CCR-9625344 (second author), and by PSC CUNY Award nos. 666327 and 667340 (second author).

is a popular and very efficient method for performing arithmetic on modern computers over rationals of arbitrary size.

We state the complexity bounds under the random access machine (RAM) model of computation [1]. Typically, a unit cost is assigned to addition, subtraction, multiplication, and division between real numbers, as well as to reading or writing into a memory location; this is the *arithmetic* model. In estimating the complexity of integer operations, we shall assign different costs to these basic operations, depending on the bit size of the involved parameters; this is the *Boolean* or *bit* model. The distinction between the two models shall be explicit or obvious from the context.

Section 17.2 examines the fundamental transforms between vectors, in particular, the discrete Fourier transform, its inverse, vector convolution, its extensions to wrapped convolutions, and the sine and cosine transforms. The basic algorithm for computing these transforms is the fast Fourier transform (FFT), which is discussed in some detail and then applied to these problems.

Section 17.3 applies these results to some fundamental operations on univariate polynomials and shows the correlations between the main vector transforms and polynomial arithmetic. These results are carried over to the integers, then extended to the polynomials in several variables.

Section 17.4 examines structured matrices defined by significantly fewer elements than the full matrix size, typically, a linear function of the matrix dimension, instead of quadratic. Furthermore, we perform all the fundamental computations with such structured matrices in time quasi linear in the matrix dimension, which is a dramatic improvement over the quadratic or higher complexity estimates for the complexity of the same computations with arbitrary matrices. Such an improvement relies on exploiting correlations among structured matrices, fast polynomial arithmetic, and FFT. Lastly, we examine some transformations among different classes of structured matrices and between computations with such matrices and some other major algebraic computational problems. Although this is a mere glimpse at the numerous applications of structured matrices, we hope to illustrate the richness of the subject.

We practically omit the *lower bound* topics, referring the reader to [14, 19, 62] on some nontrivial results. The reader always may apply the obvious information lower bounds: since each arithmetic and each Boolean operand has two operations and one output, there must always be at least $\max\{O, I/2\}$ operations, where O and I are the sizes of the output and input, respectively. We also omit certain generalizations of Fourier transforms that are of some interest in theoretical computer science; see, for instance, [19]. There are several important applications of FFT in engineering, such as signal and image processing and solving PDEs (see the end of "The Discrete Fourier Transform and Its Inverse" and the introduction of Section 17.4), which could not be covered in a chapter of the present size.

We try to cite books, surveys, or comprehensive articles, rather than the publications that first contained a certain result. There is a tacit understanding that the interested reader will look into the bibliography of the cited references, in which the historical development is outlined.

Hereafter, log stands for $\log_2$ unless specified otherwise.

17.2 Some Fundamental Transforms

The transforms discussed here can be thought of as mappings that transform a given vector to another vector. They are fundamental because a variety of interesting and general problems can be solved by means of these transforms. More importantly, polynomial and integer arithmetic can be reduced to application of such transforms, and this reduction yields algorithms supporting the record estimates for the asymptotic computational complexity (see Section 17.3).

"The Discrete Fourier Transform and Its Inverse" defines the **discrete Fourier transform (DFT)** and some closely related transforms, and outlines the main algorithm for solving DFT, namely, the fast Fourier transform (FFT). The record complexity bounds for polynomial arithmetic, including multiplication, division, transformation under a shift of the variable, evaluation, **interpolation,** and approximating polynomial zeros, are based on FFT. The FFT and fast polynomial algorithms are the basis for many

other fast polynomial computations, performed both numerically and symbolically. "Vector Convolution" studies vector convolution and shows its equivalence to DFT and also to generalized DFT. "Sine and Cosine Transforms" recalls the sine, cosine, and some other transforms.

Abundant further material and bibliography on transforms and convolution can be found in [10, 12, 13, 16, 27, 34, 35, 81, 89].

The Discrete Fourier Transform and Its Inverse

The **discrete Fourier transform (DFT)** of the coefficient vector $\mathbf{p} = [p_0, \ldots, p_n]^T$ of a polynomial

$$p(x) = p_0 + p_1 x + \cdots + p_n x^n \tag{17.1}$$

is the vector $[p(1), \ldots, p(\omega^{K-1})]^T$, where ω is a primitive Kth root of 1, so that $\{1, \omega, \omega^2, \ldots, \omega^{K-1}\}$ is the set of all the Kth roots of 1 and $K = 2^k = n+1$, for a natural k. For simplicity, the reader may assume the study of DFT in the complex field but it can be extended to other fields, rings, and even groups, where the Kth roots of 1 are defined [21, 27, 29, 38]. The problem of computing the DFT is solved by applying the **fast Fourier transform (FFT)** algorithm, which is an important example of *recursive* algorithms based on the **divide-and-conquer** method. The FFT algorithm can be traced back at least to [83] and, to some extent, even to a work of K.F. Gauss of 1805, though its introduction in modern times has been credited to [31] (see [1, 12, 14, 62, 92] for details). To derive FFT, write

$$p(x) = q\left(x^2\right) + xs\left(x^2\right) = q(y) + xs(y)\,,$$

where $y = x^2$, $q(y) = p_0 + p_2 y + \cdots + p_{n-1} y^{(n-1)/2}$, $s(y) = p_1 + p_3 y + \cdots + p_n y^{(n-1)/2}$, and the polynomials $q(y)$ and $s(y)$ have degree at most $(n-1)/2$. To evaluate $p(x)$ at $x = \omega^h$ for $h = 0, 1, \ldots, n$, we first compute $q(y)$ and $s(y)$ at $y = (\omega^2)^h$ and then $q(\omega^{2h}) + xs(\omega^{2h})$ at $x = \omega^h$. There exist only $K/2$ distinct values among all the integer powers of ω^2, since ω^2 is a $(K/2)$-nd root of 1. Half of the multiplications of ω^h by $s(\omega^{2h})$ can be saved because $\omega^i = -\omega^{i+K/2}$ for all i. By applying this method recursively, we arrive at the overall complexity bound of $1.5\ K \log K$ arithmetic operations, hereafter referred to as **ops.** Note that the old classical algorithm uses $2n^2$ ops to compute DFT, not including the cost of computing the roots of 1.

For demonstration, we describe FFT over the field of complex numbers for polynomial

$$p(x) = 3x^3 + 2x^2 - x + 5\,.$$

Here, $K = 4$, and the 4th roots of unity are $1, \omega = \sqrt{-1}, \omega^2 = -1$, and $\omega^3 = -\omega$. We write

$$p(x) = \left(5 + 2x^2\right) + x\left(-1 + 3x^2\right) = q(y) + xs(y), \qquad y = x^2\,.$$

At the cost of performing 2 multiplications (by 1 and ω) and 4 additions/subtractions, this reduces DFT for $p(x)$ to the evaluation of $q(y)$ and $s(y)$ at the points 1 and $\omega^2 = -1$. We compute $q(1), q(\omega^2), s(1)$, and $s(\omega^2)$, by using 2 multiplications (of the values 2 and 3 by 1) and 4 additions/subtractions: $5+2,\ 5-2,\ -1+3,\ -1-3$. Overall, 4 multiplications and 8 additions were required, which is indeed bounded by $1.5\ K\ \log K = 12$.

In actual computations, we may use complex approximations to $\omega^i = \exp(2\pi i\sqrt{-1}/K),\ i = 0, \ldots, K-1$ [62]. In computations where all the p_i are integers, we may perform the computations over the ring Z_m of integers modulo an appropriate natural m or use other special techniques (cf. [91] and [12, Sect. 1.7]). For appropriate choices of m, the desired Kth roots of 1 are readily available in Z_m (see [1, p. 265–269], [14, p. 86–87], or [12, Sect. 3.3]). Performing FFT over finite fields or rings is also required in several applications, for instance, integer multiplication (see [12, ch. 1]).

The **inverse discrete Fourier transform (IDFT)** of a vector $\mathbf{r}$ of polynomial values $r_h = p(\omega^h),\ h = 0, 1, \cdots, K-1$, on a set of all the Kth roots of 1 is the coefficient vector $\mathbf{p} = [p_0, \cdots, p_n]^T$ of $p(x)$. Computing DFT and IDFT is a special case of the more general problems of multipoint polynomial **evaluation** and **interpolation** ("Evaluation, Interpolation, and Chinese Remainder Computations"), whose equivalence to **structured matrix** computations is analyzed in "Vandermonde and Cauchy (generalized Hilbert) Matrices."

The IDFT can be computed in at most $K + 1.5K \log K$ ops by means of applying the *inverse FFT* algorithm, which is again a divide-and-conquer procedure, reminiscent of FFT (see [12, p. 12]). Alternatively, we may reduce DFT and IDFT to each other and to matrix computations, based on the following vector equation: $\Omega\mathbf{p} = \mathbf{r}/\sqrt{K}$. Here, $\Omega = [\omega^{ij}/\sqrt{K}]$ is the *Fourier matrix*, $\mathbf{p} = [p_j]$ is the input vector of DFT, and $\mathbf{r} = [r_i]$, $i, j = 0, 1, \ldots, n$, where $\mathbf{r}/\sqrt{K}$ is the output vector $[p(\omega^h)]$ of DFT. It follows that $\Omega^{-1} = [\omega^{-ij}/\sqrt{K}]$ and $\mathbf{p} = \Omega^{-1}\mathbf{r}/\sqrt{K} = [\omega^{-ij}]\mathbf{r}/K$. Since ω^{-1} is a Kth root of 1, the latter matrix-by-vector product can be computed by means of an FFT; it will remain to divide the resulting vector by K to complete the computation of the IDFT.

The problem of computing the *generalized DFT* at any number K of points is defined as follows: Given a value w, having the reciprocal w^{-1} but not necessarily being any root of 1, and a vector $\mathbf{p} = (p_0, p_1, \ldots, p_{K-1})$, compute the vector $\mathbf{r}$ of the generalized DFT, $\mathbf{r} = (r_h)$, $r_h = \Sigma_{j=0}^{K-1} p_j w^{hj}$ for $h = 0, 1, \ldots, K-1$.

In "Vector Convolution," we will obtain the complexity bound of $O(K \log K)$ ops for computing generalized DFT for any K, by reducing the problem to computing vector convolution, defined in "Vector Convolution" and shown to be equivalent to the generalized DFT.

By using a variable shift ("Multiplication, Division, and Variable Shift") and scaling of the variable, we may extend the solution to the generalized DFT so as to evaluate $p(x)$ on the set $\{ah^{2i} + fh^i + g, i = 0, 1, \ldots, n-1\}$ for any fixed 4-tuple of constants (a, f, g, h), by using $O(n \log n)$ ops [2].

Then again, the bound $O(n \log n)$ is a dramatic improvement of the classical algorithms for IDFT and generalized DFT, which require order of n^2 ops. In practice of computations, DFT and IDFT are frequently computed on $K \geq 10,000$ or even $K \geq 100,000$ points, so the practical impact of FFT has been immense. There are several issues related to efficient implementation of FFT, as well as further techniques for reducing the complexity of computing the DFT and IDFT for specific smaller K, even though these algorithms do not decrease the asymptotic complexity estimates [8, 89, 91]. There exist public domain codes implementing FFT freely accessible via netlib [3, 4, 43, 87], and certain libraries of arbitrary-precision integer arithmetic [4, 7, 45] use FFT.

Some comments are in order on conditioning and numerical stability. It is fortunate that the DFT is a well-conditioned problem and that FFT is a numerically stable algorithm if we consider both input and output as vectors and measure the errors in terms of vector norms. More formally, let $\mathbf{x}$ and $\mathbf{y}$ be a pair of K-dimensional complex vectors, for $K = 2^k$, such that $\mathbf{y} = DFT(\mathbf{x})$ is the DFT of $\mathbf{x}$, let $FFT(\mathbf{x})$ denote the vector computed by applying the matrix version of the FFT algorithm described above and by using floating point arithmetic with d bits, $d \geq 10$, and let $e_K(x)$ express the error vector of dimension K. Then, according to [12, prop. 3.4.1], we have

$$\begin{aligned} FFT(x) &= DFT(x + e_K(x))\,; \\ ||e_K(x)|| &\leq \left(\left(1 + \rho\, 2^{-d}\right)^k - 1\right) ||x||,\ 0 < \rho < 4.83\,, \end{aligned}$$

where $||\cdot|| = ||\cdot||_2$ denotes the Euclidean norm. Moreover,

$$||e_K(x)|| \leq (5k)\, 2^{-d} ||x|| \quad \text{for any} \quad K \leq 2^{2^{d-6}}\,.$$

It immediately follows ([12, cor. 3.4.1]) that

$$||FFT(x) - DFT(x)|| \le 5\sqrt{K}(\log K)2^{-d}||x|| ,$$

if $K < 2^{2^{d-6}}$.

Similar results hold for IDFT and certain other computational problems reducible to computing DFT. In particular, we may apply FFT with a relatively low precision when we compute the product of two polynomials with integer coefficients (see "Vector Convolution"), and then rounding off still gives us the output with no error. On the other hand, polynomial division and computing the greatest common divisor (GCD) and the zeros of polynomials (see "Multiplication, Division, and Variable Shift" and "GCD, LCM, and Padé Approximation" and Chapter 16) are generally ill-conditioned problems [12, 52, 62].

The application of FFT to the computation of the continuous Fourier transform is central to several engineering and numerical applications [44]. More specifically, there are important applications to digital filters, image restoration, and numerical solution of PDEs, which are not developed here; see, for instance, [24].

Vector Convolution

Another fundamental problem equivalent to computing the DFT, as well as the generalized DFT, is the computation of the **convolution,** as well as the positive and/or negative *wrapped convolution,* of 2 vectors $u = (u_i)$ and $v = (v_i)$. Given the values $u_0, v_0, u_1, v_1, \ldots, u_n, v_n$, we seek the coefficients w_i, w_i^+ and/or w_i^- of the polynomials

$$\begin{aligned} w(x) &= \sum_{i=0}^{2n} w_i x^i, \quad w^+(x) = \sum_{i=0}^{n} w_i^+ x^i, \quad w_i^-(x) = \sum_{i=0}^{n} w_i^- x^i , \\ w_i^+ &= w_i + \hat{w}_i, \quad w_i^- = w_i - \hat{w}_i , \\ w_i &= \sum_{j=0}^{i} u_j v_{i-j}, \quad \hat{w}_i = w_{n+1+i} = \sum_{j=i+1}^{n} u_j v_{n+1+i-j}, \quad i = 0, 1, \ldots, n, \quad \hat{w}_n = 0 . \end{aligned}$$

In fact, $w(x) = u(x)v(x)$, *so that the coefficient vector of the product of 2 polynomials is the convolution* of their coefficient vectors, $w^+(x) = w(x) \bmod (x^{n+1}-1)$, $w^-(x) = w(x) \bmod (x^{n+1}+1)$, $u(x) = \Sigma_{j=0}^{n} u_j x^j$, $v(x) = \Sigma_{j=0}^{n} v_j x^j$.

We will reduce this problem essentially to the solution of a few DFT problems. Let $n+1 = K = 2^k$ for a natural k, for otherwise, we may pad $u(x)$ and $v(x)$ with l zero leading coefficients each, for $l < n$, so as to bring the degree values to the form $K - 1 = 2^k - 1$, $k = \lceil \log_2 n \rceil$. By applying Toom's evaluation–interpolation techniques [88], we may evaluate at first $u(x)$ and $v(x)$ at the $(2K)$-th roots of 1 (2 FFTs), then multiply the $2K$ computed values pairwise, which gives us the values of $w(x)$ at the $(2K)$-th roots of 1, and then obtain the coefficients of $w(x)$ (via IDFT) at the overall cost of $9K \log K + 2K$ ops. By reducing $w(x)$ modulo $(x^{n+1} \pm 1)$, we may also obtain $w^+(x)$ and $w^-(x)$.

Let us compute w^+ by performing two DFTs and an IDFT at Kth roots of 1. Consider the values of $w^+(x)$ at ω^h, where ω is a primitive $(n+1)$-st root of unity and $h = 0, \ldots, n$. Applying $\hat{w}_n = 0$, we have

$$w^+\left(\omega^h\right) = \sum_{i=0}^{n} \left(w_i + \hat{w}_i\right) \omega^{ih} = \sum_{i=0}^{n} \omega^{ih} \sum_{j=0}^{i} u_j v_{i-j} + \sum_{i=0}^{n-1} \omega^{ih} \sum_{j=i+1}^{n} u_j v_{n+1+i-j} .$$

Since $\omega^{n+1} = 1$, the second summand can be written as follows:

$$\left(\omega^{n+1}\right)^h \sum_{i=0}^{n-1} \omega^{ih} \sum_{j=i+1}^{n} u_j v_{n+1+i-j} = \sum_{i=n+1}^{2n} \omega^{ih} \sum_{j=0}^{i} u_j v_{i-j} ,$$

where the second summand is simplified by the fact that $u_j = v_j = 0$ for $j < 0$. Let $w(x)$ be the product polynomial $u(x)v(x)$. Then $w^+(\omega^h) = w(\omega^h), \quad h = 0, \ldots, n$, and we may recover $\omega^+(x)$, by means of Toom's technique, at the cost of 3 FFTs, each on the set of $(n+1)$-st roots of 1. Therefore, computing the positive wrapped convolution has complexity of $4.5K \log K + K$ ops.

A similar argument applies to the negative wrapped convolution. Let ψ be a $(2n+2)$-nd primitive root of unity and let ω and h be as above. Then $w^-(x) = u(x)v(x)$, for $x = \psi\omega^h$, since $x^{n+1} = -1$, and it suffices to use 3 FFTs, each on $n+1$ points $\psi\omega^h$, at the overall cost $4.5K \log K + K$.

Conversely, let us reduce the generalized DFT problem to convolution. We seek

$$r_h = \sum_{j=0}^{K-1} p_j \omega^{hj} = \omega^{-h^2/2} \sum_{j=0}^{K-1} p_j \omega^{(j+h)^2/2} \omega^{-j^2/2}, \quad \text{for } h = 0, \ldots, K-1 .$$

Let $w_i = r_h \omega^{h^2/2}$, $v_{i-j} = \omega^{(j+h)^2/2}$, and $u_j = p_j \omega^{-j^2/2}$, for $i = K-1, \ldots, 2K-2$ and $j = 0, \ldots, K-1$. Essentially, we change indices by setting $i = 2K-2-h$. The undefined values of u_j are zero; in particular, $u_j = 0$ for $j \geq K$. Then,

$$w_i = \sum_{j=0}^{K-1} u_j v_{i-j} + \sum_{j=K}^{i} u_j v_{i-j}, \qquad i = K-1, \ldots, 2K-2 ,$$

which is a part of the convolution problem $w_i = \Sigma_{j=0}^{i} u_j v_{i-j}$, where $i = 0, \ldots, 2K-2$ and $u_s = v_s = 0$ for $s \geq K$. Hence, the generalized DFT can be reduced to two wrapped convolutions, followed by $2K$ multiplications for computing the u_j and recovering r_h from w_i. Therefore, the *asymptotic complexity of generalized DFT* is $O(K \log K)$, *the same as for DFT and (wrapped) convolutions.*

More generally, $4.5K \log K + 2K$ ops suffice for computing the **convolution of two vectors** of lengths $m+1$ and $n+1$, respectively, which is the coefficient vector of the product of two polynomials of degrees at most m and n with given coefficient vectors, where $K = 2^k$ and $k = \lceil \log(m+n+1) \rceil$. The problem and the solution are immediately extended to multiplication of several polynomials [12].

For smaller m and n, the convolution and the associated polynomial product can be alternatively computed by means of the straightforward (classical) algorithm that uses $(m+1)(n+1)$ multiplications and $(m+1)(n+1) - m - n - 1$ additions.

For moderate m and n, $m \leq n$, one may prefer the alternative algorithm of [61], where we assume for simplicity that n is a power of 2 and rely on the recursive application of the following equations:

$$\begin{aligned} u(x)v(x) &= \left(u_0(x) + x^{n/2} u_1(x)\right)\left(v_0(x) + x^{n/2} v_1(x)\right) \\ &= u_0(x)v_0(x)\left(1 - x^{n/2}\right) + (u_1(x) + u_0(x))\,(v_1(x) + v_0(x))\,x^{n/2} \\ &\quad + u_1(x)v_1(x)\left(x^n - x^{n/2}\right) . \end{aligned} \tag{17.2}$$

The algorithm uses $O(n^{\log 3})$ ops, where $\log 3 = 1.5849\ldots$, and has a small overhead constant.

Sine and Cosine Transforms

Besides FFT, other related transforms widely used in signal processing include *sine, cosine, Hartley,* and *wavelet* transforms. Given a vector $\mathbf{y} = [y_1, \ldots, y_n]$, its sine transform can be defined as the vector $\mathbf{x} = [x_1, \ldots, x_n]$, where

$$x_i = \sum_{j=1}^{n} y_j \sin \frac{\pi i j}{n+1}, \quad i = 1, \ldots, n ,$$

or, equivalently, $\mathbf{x} = \sqrt{\frac{n+1}{2}}Sy$, where $S = [\sqrt{\frac{2}{n+1}} \sin \frac{\pi ij}{n+1}]$, $i, j = 1, \ldots, n$, $S^T = S^{-1} = S$. The cosine transform of vector $[y_j]$ can be defined analogously by substituting sine by cosine. For further variants of sine and cosine transforms see [56, 81].

The sine and cosine transforms can be performed in $O(n \log n)$ ops by means of FFT [56].

An important application of the sine transform is in computations with the matrix algebra τ, introduced in [9]; further applications can be found in [53]. This algebra consists of all the $n \times n$ matrices $A = [a_{ij}]$, such that

$$\begin{aligned} a_{i,j-1} + a_{i,j+1} &= a_{i-1,j} + a_{i+1,j}, \quad i, j = 0, 1, \ldots, n-1\,; \\ a_{i,j} &= 0 \text{ if } i \in \{-1, n\}, \text{ or } j \in \{-1, n\}\,. \end{aligned}$$

Then A is also denoted $\tau(a)$, where a is vector $[a_{0,0}, a_{1,0}, \ldots, a_{n-1,0}]$, i.e., the first column of A. Several properties of this matrix algebra, including its connection to Chebyshev-like polynomials, are discussed in [12, ch. 2].

For any matrices $A \in \tau$ and S defined above, $SAS = D$ is a diagonal matrix with nonzero entries $d_1, \ldots, d_n$, given by $d_i = (Sa)_i / (\sqrt{2/(n+1)} \sin \frac{\pi i}{n+1})$, where a denotes the first column of matrix A. Furthermore, given two vectors u, v, each having n components, the following vectors can be computed in $O(n \log n)$ ops, by means of a constant number of sine transforms: $\tau(u)v$, the first column of $\tau(u)\tau(v)$, and $\tau(u)^{-1}v$, if the matrix $\tau(u)$ is nonsingular. The matrix algebra τ is important in the analysis of the spectral properties of band Toeplitz matrices and the computation of their tensor rank, as well as in solving Toeplitz and block Toeplitz linear systems (see "Circulant, Toeplitz, and Hankel Matrices").

The reader is referred to [10, 86] on wavelet and Hartley transforms.

17.3 Fast Polynomial and Integer Arithmetic

Computations with integers and polynomials, in one or more variables, is of fundamental importance in computational mathematics and computer science. Such operations lie at the core of every computer algebra system. In this section, we focus on univariate polynomials and show some extensions to integer arithmetic and multivariate polynomials. The connection between vector manipulation, on the one hand, and univariate polynomial and integer arithmetic, on the other hand, relies on representing a polynomial or an integer by a vector of coefficients or digits, respectively. A large number of problems in science and engineering can be solely expressed in terms of polynomials. In addition, polynomials serve as the basis for the study of more complex structures, such as rational functions, algebraic functions, power series and transcendental functions.

The first theme of this section is to apply the transforms seen so far in order to yield the record asymptotic upper bounds on the complexity of several fundamental operations with univariate polynomials. In exploiting the power of FFT, we are implicitly assuming that the polynomials are dense; in other words, most of their coefficients are nonzero and, therefore, it makes sense to represent them by the vector of their coefficients. Different representations of sparse polynomials (for instance, by the straight-line programs for their evaluation) and different complexity measures (for instance, in terms of the output size) can be found in [1, 17, 57, 92].

In particular, we cover polynomial multiplication, division, evaluation and interpolation, as well as further extensions of these basic operations. Our study shows that all of these problems have the same asymptotic complexity within a logarithmic factor, which is due to their correlation to DFT, IDFT, and vector convolution.

Some algorithms for manipulating univariate polynomials can be adapted to performing the analogous operation over the integers and vice versa (see "Integer Arithmetic").

Lastly, "Multivariate Polynomials" examines the case of polynomials in more than one indeterminates.

Multiplication, Division, and Variable Shift

Multiplication of univariate polynomials is an important and fundamental operation, to which all other important operations can be ultimately reduced. This section also studies division of polynomials with remainder and computing the reciprocal of a polynomial. We show that both of these operations, as well as the transformation of a polynomial under a shift of the variable, have the same asymptotic complexity as multiplication. The "linear" operations of addition, subtraction, and multiplication by a constant for degree n polynomials can be performed in $n + 1$ ops.

Polynomial *multiplication* is the problem of computing the coefficients $w_i = \Sigma_{j=0}^{i} u_j v_{i-j}$, $i = 0, 1, \ldots, m + n$, of the polynomial $w(x) = u(x)v(x)$ provided that we are given the coefficients of a pair of polynomials $u(x)$ and $v(x)$,

$$u(x) = \sum_{i=0}^{m-1} u_i x^i, \quad v(x) = \sum_{i=0}^{n-1} v_i x^i ,$$

and that $u_j = 0$, for $j > m$, $v_k = 0$, for $k > n$. We have already solved this problem, in $O(K \log K)$ ops, for $K = m + n$, in "Vector Convolution" as the problem of computing the convolution of 2 vectors.

Given polynomials $u(x)$ and $v(x)$ of degrees m and n, respectively, polynomial *division* with a *remainder* is the computation of the coefficients of the unique pair of polynomials $q(x) = \Sigma_{g=0}^{m-n} q_g x^g$ (quotient) and $r(x) = \Sigma_{h=0}^{n-1} r_h x^h$ (remainder) such that

$$u(x) = q(x)v(x) + r(x), \quad \deg r(x) < n .$$

$r(x)$ is also called the **residue** of $u(x)$ modulo $v(x)$ and is denoted $u(x) \bmod v(x)$.

A related problem is the computation of the *reciprocal* of a polynomial. Given a natural n and a polynomial $u(x)$, $u(0) \neq 0$, compute the first n coefficients of the formal power series $w(x)$ such that $w(x)u(x) = 1$ or, equivalently, compute $w(x) \bmod x^n$. Both problems of polynomial division and computation of the reciprocal can be reduced to polynomial multiplication [1, 12, 14] and solved in $O(n \log n)$ ops.

Another reduction of polynomial division to FFT is direct, by means of Toom's techniques of evaluation-interpolation with no reduction to polynomial multiplication. This is easily done where it is known that $r(x) \equiv 0$, but in [76] such a reduction to FFT has been elaborated for parallel approximate division of any pair of polynomials.

So far, we have assumed computations in the fields that support $O(n \log n)$ reduction to FFT. For an arbitrary ring of constants with unity, only the reduction to FFT in $O(n \log n \log \log n)$ is supported, so that the cited complexity estimates for these operations with polynomials are multiplied by an $O(\log \log n)$ factor, thus, yielding an $O(n \log n \log \log n)$ overall bound [21]. Over any ring of constants, however, multiplication, division, and the reciprocal computation have complexities related by constant factors, since each of them can be solved by means of a *constant number* of applications of any one of the others [12]. Hereafter, we will write $M(n)$ to denote the asymptotic arithmetic complexity of solving these problems, where n is the degree of the input polynomials.

Shifting the variable, also known as a **Taylor shift,** is the problem of computing the coefficients $q_0(\Delta)$, $q_1(\Delta), \ldots, q_n(\Delta)$ of the polynomial

$$q(y) = p(y + \Delta) = \sum_{h=0}^{n} p_h (y + \Delta)^h = \sum_{g=0}^{n} q_g(\Delta) y^g ,$$

given a scalar Δ and the coefficients $p_0, p_1, \ldots, p_n$ of a polynomial $p(x)$. This problem is solved in $O(M(n))$ ops [2, 12].

The practical impact of using FFT and the fast convolution algorithm in computer algebra, however, is more limited than one may suspect, for several reasons. In many cases, the application of the fast

convolution algorithm requires special care in order to contract the resulting growth of the precision needed in order to represent the auxiliary parameters [39]. In addition to the classical algorithms, supporting the bound $M(n) = O(n^2)$, and one of [61], supporting the bound $M(n) = O(n^{\log 3})$, strong competitors to FFT and fast convolution are the algorithms based on the techniques of binary segmentation (see Chapter 16), which is effective for computations in finite fields and in other cases where the input parameters are represented by short binary integers.

Evaluation, Interpolation, and Chinese Remainder Computations

Historically, the first topic in the algebraic computational complexity theory is the evaluation of a polynomial at a single point. Given the coefficients of a polynomial

$$p(x) = p_0 + p_1 x + \cdots + p_n x^n ,$$

compute its value at a point x_0. Newton's optimal solution, known as Horner's rule, is based on the decomposition

$$p(x_0) = (\cdots((p_n x_0 + p_{n-1})x_0 + p_{n-2})x_0 + \cdots + p_1)x_0 + p_0$$

and uses n multiplications and n additions [1, 14, 62], though about 50% of multiplications can be saved if we allow to precondition the coefficients and if we count only operations depending on x [62].

More generally, given the coefficients p_i of a polynomial $p(x)$, one may need to evaluate $p(x)$ on a fixed set of points $\{x_0, \ldots, x_{K-1}\}$. The problem can be reduced to K applications of Horner's rule and solved in $2Kn$ ops. Alternative reduction to polynomial multiplications and divisions yields an $O(M(m)\log m)$ algorithm, where $m = \max\{n, K\}$. The cost turns into $O(m\log^2 m)$ provided that $M(m) = O(m\log m)$, where polynomial arithmetic is implemented based on FFT. We will show the two stages of this approach referring to [1, 12, 14] for further details.

Assume that $K \le 2^k \le n+1$. Note that $p(x_i) = p(x) \bmod (x - x_i)$, $i = 0, \ldots, K-1$. The first stage is based on the *fan-in method.* Successively compute the polynomials $m_i^{(j)} = m_{2i}^{(j-1)} m_{2i+1}^{(j-1)}$, for $i = 0, \ldots, \frac{K}{2^j} - 1$ and $j = 1, \ldots, k-1$, starting with the given moduli $m_i^{(0)} = x - x_i$ for all i. The degree of $m_i^{(j)}$ in x is 2^j, so that for a fixed j and given the $m_i^{(j-1)}$, we compute all $m_i^{(j)}$ in $2^{k-j}M(2^j)$ ops.

The second stage is called the *fan-out method* and is another instance of the divide-and-conquer approach. Since $m_0^{(k-1)} = \prod_{i=0}^{K/2-1} m_i$ and $m_1^{(k-1)} = \prod_{i=K/2}^{K-1} m_i$, we have

$$p(x) \bmod (x - x_i) = \left(p(x) \bmod m_0^{(k-1)}\right) \bmod (x - x_i), \ i = 0, \ldots, K/2 - 1, \quad \text{and}$$
$$p(x) \bmod (x - x_i) = \left(p(x) \bmod m_1^{(k-1)}\right) \bmod (x - x_i), \ i = K/2, \ldots, K - 1.$$

Thus, we have reduced the evaluation of $p(x)$ to the evaluation of two polynomials of roughly half degree, by means of two polynomial divisions. This stage continues recursively and has the same asymptotic complexity as the fan-in stage, since polynomial division and multiplication have the same asymptotic complexity.

The overall complexity is $O(M(n)\log K)$. The algorithm can be adapted to the case $K > n+1$ with complexity $O((K/n)M(n)\log K)$. Hence, the bound $O(M(m)\log m)$, stated earlier, for $m = \max\{n, K\}$, which grows to $O(m^{\log 3}\log m)$, $\log 3 = 1.5849\ldots$, if, instead of FFT, we apply the method of [61] for polynomial multiplication.

In short, *evaluation on a set of points reduces to multiplications,* which can be implemented based on DFT. The computation of the latter is, obviously, a special case of the evaluation problem. Thus, all basic problems seen so far can be *reduced to any one of them,* at most with a polylogarithmic asymptotic overhead.

This is also the case with *interpolation* to a function by a polynomial, which is the inverse of the polynomial evaluation problem and is stated as follows: Given two sets of values,

$$\left\{x_i \ : \quad i = 0, \ldots, n; \quad x_i \neq x_j \text{ for } i \neq j\right\} \ , \quad \{r_i \ : i = 0, \ldots, n\} \ ,$$

evaluate the coefficients $p_0, p_1, \ldots, p_n$ of the polynomial $p(x)$ of Eq. (17.1) satisfying $p(x_i) = r_i, i = 0, 1, \ldots, n$. The problem always has a unique solution, which the classical interpolation algorithms compute in $O(n^2)$ ops [30, 48]. However, by using FFT, $O(n \log^2 n)$ ops suffice. This bound is optimal up to the factor $O(\log n)$ [14, 19, 62].

The fast algorithm [12, 40] uses the Lagrange interpolation formula:

$$p(x) = L(x) \sum_{i=0}^{n} \frac{r_i}{L'(x_i)\,(x - x_i)}, \qquad \text{where} \qquad L(x) = \prod_{i=0}^{n} (x - x_i) \ , \tag{17.3}$$

$L'(x_i) = \prod_{k=1,\ k\neq i}^{n} (x_i - x_k)$ for $i = 0, 1, \ldots, n$, and $L'(x)$ is the formal derivative of $L(x)$. Interpolation then reduces to application of, at first, the fan-in method to computing the polynomials $L(x)$ and $L'(x)$, secondly, the evaluation algorithm to finding the values $L'(x_i)$ for all i, and, thirdly, polynomial multiplications to obtain $p(x)$ from (17.3). The overall cost is $O(M(n) \log n)$, where $M(n) = O(n \log n)$ is used.

A generalization of interpolation is the *Chinese remainder* problem. Here, we shall examine its univariate polynomial version, though its name comes from its application to the integers (cf. "Integer Arithmetic"), by Chinese mathematicians in the 2nd century A.D. or even earlier [62]. Let us be given the coefficients of $2h$ polynomials $m_i(x), r_i(x), \ i = 1, \ldots, h$, where $\deg m_i(x) > \deg r_i(x)$ and where the polynomials $m_i(x)$ are pairwise relatively prime, that is, pairwise have only constant common divisors or, equivalently, $\gcd(m_i, m_j) = 1$ when $i \neq j$. Then, we are asked to compute the unique polynomial $p(x) = p(x) \bmod \prod_{i=1}^{h} m_i(x)$, such that $r_i(x) = p(x) \bmod m_i(x), i = 1, \ldots, h$. When every $m_i(x)$ is of the form $x - x_i$, we come back to the interpolation problem.

The Chinese remainder theorem states that there always exists a unique solution to this problem. The importance of this theorem cannot be overestimated, since it allows us to reduce computation with a high-degree polynomial to similar computations with several smaller-degree polynomials, namely, to computations modulo each $m_i(x)$. Then the **Chinese remainder algorithm** combines the results modulo each $m_i(x)$ so as to yield $p(x)$.

There are two approaches to recovering $p(x) = p(x) \bmod \prod_{i=1}^{h} m_i(x)$ from given $r_i(x)$ and $m_i(x)$, $i = 1, \cdots, h$. The first uses essentially Lagrange's interpolation formula, simply by generalizing the polynomial values in formula (17.3) to polynomial remainders. The second approach is named after Newton and is incremental, in the sense that successive steps compute $p_{k-1}(x) = p(x) \bmod \prod_{i=1}^{k} m_i(x)$, for $k = 1, 2, \ldots, h$, where the last step gives the final result:

$$p_k(x) = p_{k-1}(x) + \Big(\big(r_k(x) - p_{k-1}(x)\big)\, s_k(x) \bmod m_k(x)\Big) \prod_{i=1}^{k-1} m_i(x) \ ,$$

$$\text{where } \ s_k(x) \prod_{i=1}^{k-1} m_i(x) \bmod m_k(x) = 1, \quad k = 1, 2, \ldots, h, \quad p_h(x) = p(x) \ .$$

Let $N = \sum_{i=1}^{h} d_i, \ d_i = \deg m_i(x)$. Then the overall complexity of computing $p_h(x) = p(x)$ by this algorithm is $O(M(N)h + \Sigma_{i=1}^{h} M(d_i) \log d_i)$, which, based on FFT, turns into $O(Nh \log N)$.

Further details can be found in [1, 12, 14, 17, 62, 92].

GCD, LCM, and Padé Approximation

In this section, we will study the computation of the **greatest common divisor (GCD)** and the **least common multiple (LCM) of two polynomials**, and we will list some of their numerous applications to polynomial and rational computations.

The classical solution method is the Euclidean algorithm, which is a major general tool for many algebraic and numerical computations. Despite its ancient origins, the problem of computing greatest common divisors, with its numerous facets, is still an active area of research.

Given the coefficients of two polynomials

$$u(x) = \sum_{i=0}^{m} u_i x^i, \ v(x) = \sum_{j=0}^{n} v_j x^j, \ m \geq n \geq 0, \ u_m v_n \neq 0 \, ,$$

their greatest common divisor, denoted $\gcd(u(x), v(x))$, is a common divisor of $u(x)$ and $v(x)$ having the highest degree in x. The GCD of $u(x)$ and $v(x)$ is unique up to within constant factors, or it can be assumed monic, and then it is unique. For example,

$$\gcd\left(x^5 + x^4 + x^3 + x^2 + x + 1, x^4 - 2x^3 + 3x^2 - x - 7\right) = x + 1 \, ,$$

because $x + 1$ divides both polynomials and they have no common divisor of degree greater than or equal to two.

Algorithm 17.1 (Euclid's). *Set* $u_0(x) = u(x), \ v_0(x) = v(x)$. *Compute*

$$\begin{aligned} u_{i+1}(x) &= v_i(x) \, , \\ v_{i+1}(x) &= u_i(x) \bmod v_i(x) = u_i(x) - q_{i+1}(x) v_i(x), \ i = 0, 1, \ldots, \ell - 1 \, , \end{aligned} \tag{17.4}$$

where $q_{i+1}(x)$ is the quotient polynomial, and ℓ is such that $v_\ell(x) = 0$. At the end of this process, $u_\ell(x) = \gcd(u(x), v(x))$.

The correctness of the algorithm can be deduced from the following equation:

$$\gcd\left(u_i(x), v_i(x)\right) = \gcd\left(u_{i+1}(x), v_{i+1}(x)\right) \, ,$$

which holds for all i. Euclid's algorithm only involves arithmetic operations, so that the output coefficients of the GCD are rational functions in the input coefficients. Assuming that $m = n$, the algorithm involves $O(n^2)$ ops, but using a matrix representation of the recurrence and the fan-in method yields an $O(M(n) \log n)$ bound [12].

The sequence $v_1(x), v_2(x), \ldots, v_l(x)$ is called a *polynomial remainder sequence.* It can be generalized to the sequence of remainder polynomials obtained if the division step (17.4) is substituted by

$$a_{i+1} v_{i+1}(x) = b_i u_i(x) \bmod v_i(x) = b_i u_i(x) - q_{i+1}(x) v_i(x), \ i = 0, 1, \ldots, \ell - 1 \, ,$$

where the a_{i+1} and b_i, for $i = 0, \ldots, \ell - 1$, are scalars. When all scalars are units we recover the original equation. The polynomial *pseudo-remainder sequence* is obtained by setting $a_{i+1} = 1$ and $b_i = c_i^{d_i}$, for $i = 0, \ldots, \ell - 1$, where c_i is the leading coefficient of $v_i(x)$ and $d_i = \deg u_i(x) - \deg v_i(x) + 1$. There exists the third remainder sequence, called the *subresultant* sequence, which is closely related to the Sylvester resultant (see Chapter 16). These variations aim at palliating the swell of the intermediate coefficients. For details, consult [1, 12, 17, 33, 57, 92].

A closely related problem is the least common multiple (LCM) computation. Given the coefficients of the two polynomials $u(x)$ and $v(x)$, compute the coefficients of $\operatorname{lcm}(u(x), v(x))$, that is, of a common

multiple of $u(x)$ and $v(x)$ having the minimum degree. In the previous example, the LCM is $x^8 - 2x^7 + 4x^6 - 3x^5 - 3x^4 - 3x^3 - 4x^2 - x - 7$. Given $u(x)$, $v(x)$, and their GCD, we may immediately compute

$$\operatorname{lcm}(u(x), v(x)) = \frac{u(x)v(x)}{\gcd(u(x), v(x))} .$$

The cited references for the GCD problem also present alternative algorithms for the LCM; the best asymptotic complexity bound is $O(M(n)\log n)$, if $n \geq m$.

In the (m, n) *Padé approximation* problem, we are given two natural numbers m and n and the first $N + 1 = m + n + 1$ Taylor coefficients of an analytic function $V(x)$ decomposed at $x = 0$, and we are seeking two polynomials $R(x)$ and $T(x)$ satisfying the relations

$$R(x) - T(x)V(x) = 0 \bmod x^{N+1} , \ N = m + n, \ \deg T(x) \leq n, \ \deg R(x) \leq m .$$

This is actually a special case of Hermite's interpolation problem (cf. [12] on both subjects). Its complexity is $O(M(N)\log N)$ ops. An alternative solution of [15] relying on Toeplitz computations (discussed in "Circulant, Toeplitz, and Hankel Matrices") requires $O(N\log^3 N)$ ops but leads to a faster parallel algorithm [12].

A well-known application of Padé approximation is to computing the *minimum span for a linear recurrence,* also known as the *Berlekamp–Massey* problem and having important applications to algebraic coding theory, sparse polynomial interpolation, and parallel matrix computations [6, 12, 49, 59, 92]. Given a natural s and $2s$ numbers $v_0, \ldots, v_{2s-1}$, compute the minimum natural $n \leq s$ and n numbers $t_0, \ldots, t_{n-1}$ such that $v_i = t_{n-1}v_{i-1} + \cdots + t_0 v_{i-n}$, for $i = n, n + 1, \ldots, 2s - 1$. Its solution can be obtained by extending the solution of Padé approximation problem and requires $O(M(s)\log s)$ ops [6, 15, 75].

Integer Arithmetic

This section carries over the results seen so far for univariate polynomials to the domain of integers. The basic premise of this correlation, which goes in both directions, is that any binary integer can be thought of as a polynomial with coefficients in {0, 1}. For instance, the binary representation of 24 is 11000, which corresponds to the univariate polynomial $u(x) = x^4 + x^3$, which has degree 4 and the coefficient vector [1, 1, 0, 0, 0]. One difference is that operating with integers we must take care of the carry bits.

As a result, the algorithms for some basic operations on univariate polynomials can be applied to the integers and vice versa, and in many cases the complexity estimates do not change significantly when we shift from arithmetic operations with polynomials to binary operations with integers [1, 12]. This is illustrated below for the multiplication and GCD algorithms. This section also emphasizes the role of Chinese remaindering, which, as we mentioned already, has been historically introduced in the context of integers but also applies to polynomials. Likewise, the algorithms of "Multiplication, Division, and Variable Shift" for polynomial multiplication can be applied to integer multiplication modulo $2^N + 1$, whose complexity we denote $\mu(N)$. Assume that for a given pair of N-bit integers u and v,

$$u = \sum_{i=0}^{N-1} u_i 2^i , \quad v = \sum_{i=0}^{N-1} v_i 2^i , \quad u_i, v_i \in \{0, 1\} ,$$

we seek the integer uv. The classical algorithm has complexity $O(N^2)$. [61] recursively apply the equation

$$uv = U_0V_0\left(1 - 2^{N-1}\right) + (U_1 + U_0)(V_1 + V_0)\,2^{N-1} + U_1V_1\left(2^{2N-2} - 2^{N-1}\right) ,$$

where $u = U_0 + 2^{N-1}U_1$ and $v = V_0 + 2^{N-1}V_1$; see Eq. (17.2). This algorithm uses $O(N^{\log 3})$ Boolean operations, where $\log 3 = 1.5849\ldots$, and has a small overhead constant. The evaluation–interpolation

idea demonstrated for polynomial multiplication enable us to reduce the complexity to $O(N^{1+\epsilon})$ for any positive ϵ. Finally, by exploiting fast convolution by means of FFT over finite rings of constants, Schönhage and Strassen reduced the asymptotic complexity bound to $O(N \log N \log\log N)$; see [84, 85], [1, p. 270–274], or [12, p. 78–79]. Only the (obvious) information lower estimate of order N is known for $\mu(N)$.

In practice, the Schönhage–Strassen algorithm is used only for very large N, for instance, in applications to polynomial root-finding, because the overhead constant is considerable. At present, the algorithms used in practice otherwise are either the classical method or the one of [61]. Recently, however, in addition to the two latter algorithms, the algorithm of [85] has been implemented on modern computers [7, 45].

Integer division is the problem where, given two positive integers u, v with the bit sizes n, m, respectively, we seek the unique pair of integers q, r for which $u = qv + r$, where $0 \leq r < v$. The classical algorithm has Boolean complexity $O(mn)$, whereas the fast multiplication algorithm yields the $O(\mu(m))$ bound [1, 14, 62]. The asymptotic complexity of integer multiplication and division is actually the same [1, 12].

Given two **integers** u and v, their **greatest common divisor (GCD)** is the largest integer that divides both u and v, and their **least common multiple (LCM)** is the smallest integer that is divisible by both u and v. For instance, $\gcd(16, 24) = 8$, whereas $\mathrm{lcm}(16, 24) = 48$. The Euclidean algorithm was the historically first algorithm for integer GCD. The GCD of a pair of positive integers less than 2^n can be computed in $O(\mu(n) \log n) = O(n \log^2 n \log\log n)$ Boolean ops, where $\mu(n)$ denotes the Boolean complexity of multiplying two integers modulo $2^n + 1$ [1, 12, 50, 62].

Likewise, historically, the Chinese remainder algorithm has been first devised for integers. Given the **integer residues** r_i with respect to fixed integer moduli m_i, for $i = 0, 1, \ldots, k$, where $\gcd(m_i, m_j) = 1$ for $i \neq j$, we seek an integer $p = p \bmod \prod_{i=0}^{k} m_i$ such that $r_i = p \bmod m_i$ for all i. The Chinese remainder theorem states that such an integer p exists and is unique. The Boolean complexity of computing such an integer p is $O(\mu(N) \log N)$ ops, where $N = \Sigma_i \lceil \log m_i \rceil$.

An important application of the Chinese remainder theorem is in reducing the bulk of an arbitrary-precision integer computation to computations with fixed-precision integers. We map the input integers into their residues moduli m_i, then perform the computation in the finite field or ring of integers modulo m_i for each i, and, finally, use the Chinese remainder algorithm in order to compute the exact answer (see [36] for extensions).

The above technique of modular arithmetic is one of the most efficient methods for conducting integer (as well as rational) arithmetic on modern computers. Typically, the moduli used are primes that fit in a computer word. The implementation of the Chinese remainder algorithm relies either on an extension of Lagrange's formula (17.3) or on Newton's incremental approach (cf. "Evaluation, Interpolation, and Chinese Remainder Computations"). For a comprehensive discussion as well as other alternatives, see [1, 12, 14, 17, 62, 92].

Multivariate Polynomials

Polynomials in several variables generalize the univariate case, which we have examined so far. Multivariate polynomials appear in a wide variety of scientific and engineering applications (see Chapter 16 of this handbook). This section outlines some basic results regarding multiplication, evaluation and interpolation of multivariate polynomials over arbitrary rings of constants.

Just as we did in the univariate case, we do not consider in depth the question of representation, but assume that polynomials are represented by a coefficient vector indexed by the corresponding monomials in some order. Other operations, such as addition, subtraction, taking integer powers and division, as well as the various representations are treated extensively in [17, 92].

A polynomial in n variables is of the form

$$p(x_1, \ldots, x_n) = \sum_{i_1, \ldots, i_n} p_{i_1, i_2, \ldots, i_n} x_1^{i_1} x_2^{i_2} \ldots x_n^{i_n} ,$$

where the coefficients correspond to distinct monomials. Recall that the degree of p in x_j is the maximum i_j for which $p_{i_1, i_2, \ldots, i_n} \neq 0$, the total degree of a monomial $x_1^{i_1} x_2^{i_2} \cdots x_n^{i_n}$ is $i_1 + \cdots + i_n$, and the total degree of the polynomial p is the maximum total degree of any monomial. If d is the maximum degree in any variable, then the total number of terms is $O(d^n)$. A polynomial most of whose coefficients are nonzero is called *dense*.

To compute the product of two such polynomials, we may reduce the problem to the univariate case by means of Kronecker's substitution:

$$x_1 = y , \quad x_{k+1} = y^{D_1 \ldots D_k} , \quad k = 1, \ldots, n-1 .$$

Here, $D_j = 2d_j + 1$ exceeds the degree in x_j of the product polynomial provided that both input polynomials have degrees at most d_j in x_j, $j = 1, 2, \ldots, n$. Once the univariate product is computed, we may recover the product polynomial in the n variables x_i by inverting the Kronecker map. This method yields the complexity bound $O(N \log N \log\log N)$, where $N = \prod_{i=1}^{n} D_i$.

A certain improvement for polynomials with a large number of variables in [73] relies on the evaluation–interpolation method and (over any field of constants) yields complexity bound

$$O\left(N \log N \log\log D\right) = O\left(n D^n \log D \log\log D\right) , \tag{17.5}$$

where $D = \max\{D_1, \ldots, D_n\}$, $N = D^n$, and the number of terms is of order D^n.

Another algorithm for dense polynomials is due to [20], also relies on the evaluation–interpolation scheme, but only applies over fields of characteristic 0. The algorithm supports, for a product polynomial with at most T terms, each of a total degree at most T, the complexity bound $O(M(T) \log T) = O(T \log^2 T \log\log T)$, which is inferior to the estimate (17.5) under the bound D on the degree of each variable but superior under the bound T on the total number of terms.

Alternatively, we may extend the algorithm of [61], having complexity $O(D^{n \log 3})$.

Evaluation and interpolation of dense multivariate polynomials may use points on a grid (or lattice) in which each variable is assigned the values in a fixed set. Let $E(d)$ and $I(d)$ denote, respectively, the complexity of evaluating and interpolating a univariate polynomial of degree bounded by $(d-1)/2$ on d points. Then, for grids of d_j values for each variable x_j, the complexity of evaluation and interpolation of a multivariate polynomial is $d^{n-1} E(d)$ and $n d^{n-1} I(d)$, respectively, where $d = \max\{d_1, d_2, \ldots, d_n\}$. By applying FFT, we yield the bounds $O(d^n \log^2 d)$ and $O(n d^n \log^2 d)$, for evaluation and interpolation, respectively. For dense polynomials, these bounds are satisfactory. The approach of [20] adapts the algorithm of [5] and also relies on solving a transposed Vandermonde system fast. It yields the bounds

$$O\left(T \log T \log\log T \log t\right) \qquad \text{and} \qquad O\left(T \log^2 T \log\log T\right)$$

for evaluation and interpolation, respectively, over fields of characteristic zero, where t is the actual number of nonzero terms and T is an upper bound on the number of input terms. Alternatively, we can use the total degree of the product polynomial to estimate T, which is typically the case when this technique is applied to multiplication.

With multivariate polynomials, sparsity considerations become more important. Typically, the critical computation is interpolation. On the other hand, evaluation depends strongly on the form in which the polynomial is expressed and which is often a **determinant** formula [64]. In addition to multiplication, computing the GCD can also be reduced to interpolation [92]. So, in the rest of this section, we concentrate on sparse multivariate interpolation.

There are two main approaches with different advantages and drawbacks. One approach is Zippel's randomized algorithm. Its merit is that it does not require a bound on the number of nonzero terms as input but requires a bound d on the degree in each variable. The computation involves Vandermonde matrices (cf. "Vandermonde and Cauchy (generalized Hilbert) Matrices"), and its complexity is $O^*(nd^2t)$, where t denotes the number of nonzero terms of the input polynomial, and $O^*(\cdot)$ indicates that some polylogarithmic factors may have been omitted. There exists a deterministic version of this algorithm with higher, but still polynomial, complexity. For further information, see [49, 58, 92].

Another, historically the first, approach is due to [5]. The algorithm of [5] does not need any degree bounds, but uses a bound on the actual number of terms t, on which both the algorithm and its estimates complexity, $O^*(ndt)$, depend. The algorithm applies to fields of characteristic equal to zero or to a very large positive integer. It proceeds by finding the exponents of the nonzero monomials which is reduced to the solution of the Berlekamp–Massey problem (cf. "GCD, LCM, and Padé Approximation"). Then, at the cost $O^*(ndt)$, the algorithm computes the corresponding coefficients, by exploiting the structure of Toeplitz and Vandermonde matrices [5, 58].

17.4 Structured Matrices

Matrices with special structure are encountered in several applications to problems in sciences and engineering. These matrices have several repeated entries or entries that satisfy certain relations. More formally, an $n \times n$ **structured matrix** is typically defined by $O(n)$ entries, say by less than $2n$ entries, instead of the n^2 entries required in order to specify a general matrix. Moreover, structured matrices can typically be multiplied by a vector in $O(n \log n)$ or $O(n \log^2 n)$ ops, instead of $2n^2 - n$ ops, required for a general matrix. Structured matrices arise in numerous applications such as control, signal and image processing, coding, a variety of algebraic computations, solution of PDEs, integral equations, singular integrals, conformal mappings, particle simulation, and Markov chains [24, 66]. In addition, several fundamental parallel computations with general matrices can be effectively reduced to computations with structured matrices [12].

This section focuses on computations with dense structured matrices, including Vandermonde, generalized Hilbert or Cauchy, circulant, Toeplitz, Hankel, and Bézout matrices. Computations with matrices of these classes are strongly related to computations with polynomials, thus, enabling us to employ FFT in order to arrive at a dramatic acceleration of the algorithms versus the case of general matrices. For example, solving a nonsingular linear system of n equations with a structured matrix of coefficients takes $O(n \log^2 n)$ or $O(n \log n)$ ops. Furthermore, a substantial improvement of parallel computations with general matrices can be obtained based on their reduction to computations with dense structured matrices and polynomials.

We refer the reader to [12] for information about other important classes of structured matrices, for instance, Frobenius (companion) matrices.

Hereafter, $(A)_{i,j}$ denotes the (i, j)-th entry of a matrix A.

Vandermonde and Cauchy (generalized Hilbert) Matrices

This section defines two important classes of structured matrices and demonstrates the improvement (versus general matrices) in the running time of basic matrix operations when this structure is exploited, based on correlation to computations with polynomials and FFT.

An $m \times n$ *Vandermonde* matrix V has its entries $(V)_{i,j} = v_i^j$ for $i = 0, 1, \ldots, m$, $j = 0, 1, \ldots, n$. If $m = n$, then V has the determinant

$$\det V = \prod_{0 \le i < k \le n} (v_k - v_i) \ . \tag{17.6}$$

Clearly, a square Vandermonde matrix is nonsingular if and only if $v_i \neq v_k$ for $i \neq k$.

For example, for $m = 1$ and $n = 3$ we have

$$V = \begin{pmatrix} 1 & v_0 & v_0^2 & v_0^3 \\ 1 & v_1 & v_1^2 & v_1^3 \end{pmatrix}.$$

Some authors call V^T, rather than V, a Vandermonde matrix. A *generalized Vandermonde* matrix G (cf. [92]) is defined by $(G)_{i,j} = v_i^{e_j}$, $i = 0, \ldots, m$, $j = 0, \ldots, n$, for some sequence $0 \leq e_0 < e_1 < \cdots < e_{n-1}$ of integers.

An important example of a Vandermonde matrix is given by the matrix $\sqrt{K}\Omega$, which is the scaled *Fourier matrix* $\Omega = (\omega^{ij}/\sqrt{K})$, $K = n + 1$, associated to the DFT and the inverse DFT, where ω is a primitive nth root of 1. Different FFT algorithms correspond to different factorizations of the matrix ω; see [89] and [12, Sect. 3.4].

Multiplication of a Vandermonde matrix $V = (v_i^j)$ by a vector $\mathbf{p}$ is equivalent to the evaluation at the points $v_0, \cdots, v_m$ of the polynomial with the coefficient vector $\mathbf{p}$. The solution of a linear system $V\mathbf{x} = \mathbf{v}$, where $\mathbf{x}$ and $\mathbf{v}$ are vectors and V is a nonsingular square Vandermonde matrix, is equivalent to interpolating from the vector $\mathbf{v}$ of the polynomial values at the points $v_0, \cdots, v_m$ to the coefficient vector $\mathbf{x}$. Due to the algorithms of "Evaluation, Interpolation, and Chinese Remainder Computations," both of these operations with Vandermonde matrices can be performed in $O((m + n)\log^2(m + n))$ ops, which is a dramatic decrease versus the case of a general $m \times n$ matrix. On the other hand, the estimated parallel complexity of these operations with general matrices can be decreased based on their reduction to operations with other structured matrices (see "Correlations among Structured Matrices"), and the Vandermonde–polynomial correlations have also been exploited in the reverse direction, in order to improve the known methods for polynomial evaluation and interpolation [77, 79].

The same operations with V^T can be performed in $O(n \log^2 n)$ ops, where V is an $n \times n$ Vandermonde matrix (see Algorithm 17.2 in "Circulant, Toeplitz, and Hankel Matrices"). The same bound also holds for computing the absolute value $|\det V|$. The speed of performing all these computations relies on their reduction to basic polynomial operations and, ultimately, to FFT. Straightforward computation of the determinant of an $n \times n$ Vandermonde matrix V requires $O(n^2)$ ops, based on Eq. (17.6), but for a real matrix V [47] also determines the sign of $\det V$, by means of ordering $v_0, \cdots, v_n$ and then using $O(n \log n)$ comparisons.

The next class of structured matrices is named after Cauchy. An $m \times n$ *Cauchy matrix* C is defined by two vectors $\mathbf{s} = [s_i]$ and $\mathbf{t} = [t_j]$, such that $s_i \neq t_j$ for $i = 0, \ldots, m - 1$, $j = 0, 1, \ldots, n - 1$, and $(C)_{ij} = 1/(t_i - s_j)$. For instance, if $m = 2$, $n = 3$, then

$$C = \begin{pmatrix} (t_0 - s_0)^{-1} & (t_0 - s_1)^{-1} & (t_0 - s_2)^{-1} \\ (t_1 - s_0)^{-1} & (t_1 - s_1)^{-1} & (t_1 - s_2)^{-1} \end{pmatrix}.$$

Cauchy matrices generalize *Hilbert matrices* $(C)_{i,j} = 1/(i + j + 1)$ and are sometimes called *generalized Hilbert matrices.* On the other hand, Cauchy matrices form a special subclass of *Loewner matrices* [41, 42], that is, matrices B such that $(B)_{i,j} = (u_i - v_j)/(s_i - t_j)$.

Both (post)multiplication of a Cauchy matrix by a vector and solution (for vector $\mathbf{x}$) of the equation $C\mathbf{x} = \mathbf{v}$, where C is a square and nonsingular Cauchy matrix and $\mathbf{v}$ is a vector, reduce to polynomial evaluation and interpolation and take $O((m + n)\log^2(m + n))$ ops, due to application of FFT. The algorithm of [82] approximates the product Cv at the cost $c_\epsilon(m+n)\log(m+n)$ ops where c_ϵ depends on the approximation error ϵ and the minimum distance $\min_{i,j} |t_i - s_j|$. Some typical applications of Cauchy matrices include the study of integral equations, conformal mappings, and singular integrals [67, 82] (see also "Correlation among Structured Matrices").

Circulant, Toeplitz, and Hankel Matrices

Toeplitz matrices and matrices closely related to them are among the most used structured matrices.

T is a *Toeplitz matrix* if $(T)_{i,j} = (T)_{i+k,j+k}$, for all positive k, that is, if all the entries of T are invariant in their shifts in the diagonal direction. T is completely defined by its first row and its first column. For example, below we display a 4×3 Toeplitz matrix specified by the coefficients of polynomial $v(x) = v_2x^2 + v_1x + v_0$ in such a way as to express the multiplication of polynomials $u(x) = u_2x^2 + u_1x + u_0$ and $v(x)$ as (post)multiplication of the matrix by the column vector of the coefficients of $u(x)$.

$$\begin{pmatrix} v_2 & 0 & 0 \\ v_1 & v_2 & 0 \\ v_0 & v_1 & v_2 \\ 0 & v_0 & v_1 \\ 0 & 0 & v_0 \end{pmatrix} \begin{pmatrix} u_2 \\ u_1 \\ u_0 \end{pmatrix} = \begin{pmatrix} v_2u_2 \\ v_1u_2 + v_2u_1 \\ v_0u_2 + v_1u_1 + v_2u_0 \\ v_0u_1 + v_1u_0 \\ v_0u_0 \end{pmatrix}. \tag{17.7}$$

In general, in this way, Toeplitz matrices of such a form express polynomial multiplication and, hence, vector convolution. Furthermore, a general Toeplitz matrix T can be embedded into a matrix of a such form as its middle block of rows. Then the product of T by a vector can be immediately extracted from the associated polynomial product (convolution).

H is a *Hankel matrix* if $(H)_{i,j} = (H)_{i-k,j+k}$, that is, if all the entries of H are invariant in their shifts in the antidiagonal direction. H is completely defined by its first row and its last column. For example, a 4×3 Hankel matrix is

$$H = \begin{pmatrix} v_0 & v_1 & v_2 & v_3 \\ v_1 & v_2 & v_3 & v_4 \\ v_2 & v_3 & v_4 & v_5 \end{pmatrix}.$$

The correlation of Hankel and Toeplitz matrices is formalized by introducing the *reversion matrix.*

$$J = J^{-1} = \begin{pmatrix} 0 & 0 & \cdots & 1 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 1 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \end{pmatrix}. \tag{17.8}$$

Then TJ and JT are Hankel matrices for any Toeplitz matrix T, whereas HJ and JH are Toeplitz matrices for any Hankel matrix H. Consequently, computations with Hankel matrices can be reduced to computations with Toeplitz matrices, and vice versa. Hereafter, we will focus on the Toeplitz class.

$C_f = C_f(v)$, for a vector $v = [v_0, \ldots, v_{m-1}]^T$ and for a scalar f, is an *f-circulant* $m \times n$ matrix if $(C_f)_{i,j} = v_{i-j \bmod m}$ for $i \geq j$; $(C_f)_{i,j} = f v_{i-j \bmod m}$ for $i < j$. For example, for $m = n = 4$ we have

$$C_f(v) = \begin{pmatrix} v_0 & fv_3 & fv_2 & fv_1 \\ v_1 & v_0 & fv_3 & fv_2 \\ v_2 & v_1 & v_0 & fv_3 \\ v_3 & v_2 & v_1 & v_0 \end{pmatrix}.$$

$1-$circulant and $(-1)-$circulant matrices are called *circulant* and *anticirculant,* respectively. For any f, an f-circulant matrix is a special Toeplitz matrix, completely defined by its first column v and by the scalar f. It is possible to embed an $m \times n$ Toeplitz matrix into an $m \times (m + n - 1)$ circulant matrix. Therefore, certain operations on the former matrix, such as multiplication by a vector, can be reduced to multiplication of a circulant matrix by a vector.

Circulant matrix manipulation is fast due to FFT and the following well-known result:

THEOREM 17.1 [28, 32] *Let C_f be an $n \times n$ f-circulant matrix, with complex $f \neq 0$, and let c_f^T denote its first row. Let Ω be the $n \times n$ Fourier matrix, $(\Omega)_{i,j} = \omega^{ij}/\sqrt{n}$, $i, j = 0, 1, \ldots, n-1$, where ω is a*

primitive n-th root of unity, $(\Omega^H)_{i,j} = \omega^{-ij}/\sqrt{n}$, *and* $\Omega^H\Omega = I$. *Let* $D_f = diag(1, g, g^2, \ldots, g^{n-1})$, $g^n = f$, *and let D be another diagonal matrix with entries given by the vector* $\sqrt{n}\,\Omega D_f c_f$. *Then*

$$\Omega D_f C_f D_f^{-1} \Omega^H = D, \quad \textit{or, equivalently,} \quad C_f = D_f^{-1}\Omega^H D \Omega D_f \ .$$

This immediately implies that multiplication of an $n \times n$ f-circulant matrix by a vector reduces to vector convolution, which can be implemented by three DFTs on n elements and thus, has complexity $O(n \log n)$. Consequently, multiplication of an $m \times n$ Toeplitz matrix by a vector takes $O((m+n)\log(m+n))$ ops, and similarly for a Hankel matrix. Such an alternative reduction of Tv to convolution is slightly more effective because the total size of FFTs involved is smaller. Conversely, computing the DFT of an n-vector, for a prime n, reduces to multiplying a vector by an $(n-1) \times (n-1)$ circulant matrix [91].

For a nonsingular $n \times n$ Toeplitz matrix, the solution of a linear system $Tx = b$ has been extensively studied (see [12] and the references therein). Different algorithms have different advantages with respect to running time and numerical stability, the record time-complexity bound being $O(n \log^2 n)$ and based on reductions to FFT. If the field of constants does not support FFT, then the alternative construction of [21] gives us all stated time bounds multiplied by $O(\log\log(m+n))$.

Given a square Toeplitz matrix T, the problem of computing its determinant and the coefficients of its characteristic polynomial both reduce to a sequence of multiplications of this matrix T by vectors. This technique is effective for any matrix that can be multiplied by a vector at a low computational cost; it has been introduced in [90] and is based on the computation of the associated *Krylov sequence* (see Chapter 16 of this handbook). If the field of constants supports FFT, then the complexity of both operations is $O(n^2 \log n)$. To compute only the absolute value of the determinant, $O(n \log^2 n)$ ops suffice; moreover, if an $n \times n$ Toeplitz matrix is strongly nonsingular, its determinant is computed in $O(n \log^2 n)$ ops [12].

The inverse of a Toeplitz or Hankel matrix generally contains roughly $n^2/2$ distinct entries. There exist asymptotically optimal algorithms that compute the inverse in $O(n^2)$ ops, as well as slightly slower algorithms having better numerical stability (see [12] and the references therein). A major result in this area is the following theorem extending one of Gohberg and Semencul (see [12, 15, 51] for this fundamental result and its variants).

THEOREM 17.2 *Let T be a nonsingular* $n \times n$ *Toeplitz matrix,* $(T)_{i,j} = t_{i-j}$, $i, j = 0, 1, \ldots, n-1$; $t = [s, t_{1-n}, t_{2-n}, \ldots, t_{-1}]^T$, *for any fixed scalar s;* $x = [x_0, \ldots, x_{n-1}]^T = T^{-1}t$; $v = [-1, x_{n-1}, \ldots, x_1]^T$; $y = [y_0, \ldots, y_{n-1}]^T = T^{-1}[1, 0, \ldots, 0]^T$; $u = [0, y_{n-1}, \ldots, y_1]^T$. *For a given* $n \times 1$ *vector a, matrix* $L(a)$ *is an* $n \times n$ *lower triangular Toeplitz matrix whose first column is a. Then* $T^{-1} = L(x)L^T(u) - L(y)L^T(v)$.

In the special cases of a lower (upper) triangular Toeplitz or f-circulant matrix, the inverse is again a lower (upper) triangular Toeplitz or f-circulant matrix, respectively, and can be computed in $O(n \log n)$ ops.

Generally, the product of two Toeplitz matrices is not a Toeplitz matrix but is in the generalized class of Toeplitz-like matrices, to be introduced in "Correlations among Structured Matrices."

The classes of *block Toeplitz* and *block Hankel matrices* generalize Toeplitz and Hankel matrices, respectively. These are Toeplitz or Hankel matrices whose entries are matrices themselves. A $p \times q$ block Toeplitz (Hankel) matrix with blocks of size $r \times s$ can be turned into an $r \times s$ block matrix with $p \times q$ Toeplitz (Hankel) blocks and vice versa, by a sequence of row and column permutations.

Another class of structured matrices are *banded* matrices, where all nonzero entries are concentrated on a relatively small number of diagonals. Banded Toeplitz matrices are important in several applications [12, Sect. 2.11]. The sine transform enables us to simplify computations with such matrices. For instance, it is possible to embed a symmetric $(2k+1)$-diagonal $n \times n$ Toeplitz matrix T into an $(n+2\lfloor k/2 \rfloor) \times (n+2\lfloor k/2 \rfloor)$ matrix of the τ algebra, defined in "Sine and Cosine Transforms." Here is an example with $k = 2$ and $n = 4$:

Embedding the matrix

$$T = \begin{pmatrix} a_0 & a_1 & a_2 & 0 \\ a_1 & a_0 & a_1 & a_2 \\ a_2 & a_1 & a_0 & a_1 \\ 0 & a_2 & a_1 & a_0 \end{pmatrix} \quad \text{yields} \quad \begin{pmatrix} a_0 - a_2 & a_1 & a_2 & 0 & 0 & 0 \\ a_1 & a_0 & a_1 & a_2 & 0 & 0 \\ a_2 & a_1 & a_0 & a_1 & a_2 & 0 \\ 0 & a_2 & a_1 & a_0 & a_1 & a_2 \\ 0 & 0 & a_2 & a_1 & a_0 & a_1 \\ 0 & 0 & 0 & a_2 & a_1 & a_0 - a_2 \end{pmatrix} \in \tau \ . \tag{17.9}$$

This property allows us to reduce the solution of a band Toeplitz linear system to performing the sine transform and to solving a $k \times k$ linear system [9].

Block Toeplitz and block Hankel matrices, block matrices with Toeplitz and Hankel blocks, banded Toeplitz matrices, and several other classes of Toeplitz-like and Hankel-like matrices, including proper Toeplitz and f-circulant matrices, naturally arise in numerous applications, in particular, to control, signal processing, systems theory, solution of PDEs, and algebraic computations. A simple example is a Sylvester matrix S, which is a 2×1 block matrix with Toeplitz blocks. It can be multiplied with a vector in quasi-linear time. Hence, the Krylov sequence associated with S can be computed in quasi-quadratic time, which yields fast algorithms for determinant computation, inversion, etc. Similarly, the structure of various multivariate resultant matrices leads to an acceleration of their construction, of computing the resultant itself, and of approximating the solutions of a polynomial system of equations (see Chapter 16 of this handbook). On these and other computations with structured matrices, see [12, 23, 25, 37, 51, 65, 82] and references therein.

To conclude this section, we recall an algorithm of [20] for a linear system $V^T \mathbf{x} = \mathbf{w}$. An alternative and simpler approach would be to reduce this question to one on V by applying Tellegen's theorem; see [19, thm. 13.20]. Still, we recall below some interesting techniques from [20]. Matrix V^T is an $n \times n$ transposed Vandermonde matrix, such that $(V)_{i,j} = v_i^j$, for $i, j = 0, \ldots, n-1$, and $\mathbf{w}$ is a given column vector. The problem is reduced to computing the vector $\mathbf{w}^T V^{-1}$, $\mathbf{w}^T \left(V^T V\right)^{-1} V^T$. Observe that

$$\left(V^T V\right)_{i,j} = \sum_{k=0}^{n-1} v_k^{i+j}, \qquad i, j = 0, \ldots, n-1 \ ,$$

so that $V^T V$ is a Hankel matrix. Consider the values v_i as the roots of the (monic) polynomial $p(x) = \Sigma_{i=0}^{n-1} p_i x^i = \prod_{i=0}^{n-1} (x - v_k)$, $p_{n-1} = 1$, and compute all $2n-1$ distinct entries of $V^T V$, that is, $s_j = \Sigma_{i=0}^{n-1} v_i^j$, $j = 0, \ldots, 2n-2$, as the first $2n-1$ power sums of the roots $v_0, \ldots, v_{n-1}$.

Formally, we solve a linear system $V^T \mathbf{x} = \mathbf{w}$ as follows:

Algorithm 17.2

1. Compute the coefficients $p_0, \ldots, p_{n-2}$ of the above monic polynomial $p(x)$ by the fan-in method used in polynomial evaluation (cf. "Evaluation, Interpolation, and Chinese Remainder Computations"). This requires $O(n \log^2 n)$ ops. Write $p_{n-1} = 1$.

2. Compute the $s_0, \ldots, s_{2n-2}$ by solving in $O(n \log n)$ ops the lower triangular Toeplitz system of Newton's identities,

$$\begin{pmatrix} 1 & & & & & \\ p_{n-1} & \ddots & & & O & \\ \vdots & \ddots & \ddots & & & \\ p_0 & & \ddots & \ddots & & \\ & \ddots & & \ddots & \ddots & \\ O & & p_0 & \ldots & p_{n-1} & 1 \end{pmatrix} \begin{pmatrix} s_0 \\ \\ \vdots \\ \\ s_{2n-2} \end{pmatrix} = \begin{pmatrix} -p_{n-1} \\ -2p_{n-2} \\ \vdots \\ -np_0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} ,$$

3. Compute the vector $\mathbf{y} = (V^T V)^{-1}\mathbf{w}$ *by solving the Hankel linear system* $(V^T V)\mathbf{y} = \mathbf{w}$. *This requires* $O(n \log^2 n)$ *ops.*

4. Compute and output the desired vector $\mathbf{x} = V\mathbf{y} = (V^T)^{-1}\mathbf{w}$. *Due to the results of "Vandermonde and Cauchy (generalized Hilbert) Matrices," this step is equivalent to polynomial evaluation and uses* $O(n \log^2 n)$ *ops.*

In summary, the multiplication of V^T by a vector takes $O(n \log^2 n)$ ops, and the same complexity bound holds for solving a linear system defined by the transpose of a Vandermonde matrix.

Algorithm 17.2 has been applied in [20] to multivariate polynomial multiplication (cf. "Multivariate Polynomials").

Bézout Matrices

Bézout matrices are structured matrices arising in several fundamental algebraic operations. In particular, they play a central role in studying the solutions of a system of two univariate polynomials and the GCD of two univariate polynomials, especially, when Boolean complexity and numerical stability issues become critical. Moreover, this study can be generalized to the solution of a system of several multivariate polynomial equations. This section introduces Bézout's matrices, demonstrates their structure and correlations to structured matrices studied above, and discusses some applications and computational complexity issues.

Consider two polynomials, $u(x) = \Sigma_{i=0}^{n} u_i x^i$ and $v(x) = \Sigma_{i=0}^{m} v_i x^i$, of degrees n and m, respectively, where $m \leq n$. The expression

$$\frac{u(z)v(w) - v(z)u(w)}{z - w} = \sum_{i,j=0}^{n-1} b_{i,j} z^i w^j \tag{17.10}$$

is easily verified to be a polynomial in w and z. This polynomial is called the generating function of the $n \times n$ *Bézout matrix* B or, simply, *Bezoutian* of $u(x)$ and $v(x)$, with $(B)_{i,j} = b_{i,j}$. The polynomial of (17.10) is sometimes also called the Bezoutian of $u(x)$ and $v(x)$.

By definition, $B(u, v) = -B(v, u)$. Observe, as particular cases, that

$$B(u, 1) = \begin{pmatrix} u_1 & \dots & u_n \\ \vdots & \ddots & \\ u_n & & O \end{pmatrix}, \qquad B\left(u, x^n\right) = -\begin{pmatrix} O & & u_0 \\ & \ddots & \vdots \\ u_0 & \dots & u_{n-1} \end{pmatrix}$$

are triangular Hankel matrices. It has been proven that $B(u, v)$, for general $u(x)$ and $v(x)$, can be written in terms of matrices of this form (see, for instance, [63]):

$$B(u, v) = B(v, 1)JB\left(u, x^n\right) - B(u, 1)JB\left(v, x^n\right), \tag{17.11}$$

where J is the reversion matrix of (17.8).

There is a deeper connection of Bezoutians to Hankel matrices [12, Sect. 2.9]. Given univariate polynomials $u(x)$, $v(x)$, of respective degrees n, m, where $n > m$, consider the infinite sequence of values $h_0, h_1, \dots$, in the coefficient field of $u(x)$, $v(x)$, known as the *Markov parameters* and defined as follows:

$$\frac{v\left(x^{-1}\right)}{xu\left(x^{-1}\right)} = \sum_{i=0}^{\infty} h_i x^i \quad \text{or, equivalently,} \quad \frac{v(x)}{u(x)} = \sum_{i=0}^{\infty} h_i x^{-i-1}.$$

The Markov parameters generate an $n \times n$ Hankel matrix $H(u, v)$ such that $(H)_{i,j} = h_{i+j}$ for $i, j = 0, 1, \dots, n-1$. Given $u(x)$, $v(x)$, the entries of $H(u, v)$ are computed by solving a lower triangular Toeplitz system of $2n-1$ equations in $O(n \log n)$ ops. These equations are obtained by truncating the first formal power series above and expressing polynomial multiplication by a Toeplitz matrix as in Eq. (17.7).

If $u(x)$ and $v(x)$ are relatively prime, then $H(u, v)$ is nonsingular. Moreover, for any nonsingular $n \times n$ Hankel matrix H, there exists a pair of relatively prime polynomials $u(x)$, $v(x)$, of degrees n and $m < n$, respectively, such that $u(x)$ is monic and $H = H(u, v)$. Matrix $H(u, v)$, for polynomials $u(x)$ and $v(x)$ whose degrees m and n satisfy $n > m$, is related to the Bezoutian $B(u, v)$ of the same polynomials by

$$B(u, v) = B(u, 1)H(u, v)B(u, 1) \quad \text{and} \quad B(u, w)H(u, v) = I_n ,$$

where $w(x)$ is a univariate polynomial of degree less than n and such that $w(x)v(x) = 1 \bmod u(x)$ and where I_n is the $n \times n$ identity matrix. The second expression states, in words, that the inverse of any nonsingular Hankel matrix is a Bezoutian. This expression, together with Eq. (17.11), extends the Gohberg–Semencul formula and Theorem 17.2 to Hankel matrices.

An important application of these results is to compute the polynomial GCD [12]. Assume that $u(x)$, $v(x)$ are monic and their degrees satisfy $m < n$. Let $k \geq 1$ be such that the degree of $\gcd(u(x), v(x))$ in x is $n - k$. Then $\operatorname{rank}(H(u, v)) = k$, $\det H_k \neq 0$, where H_k is the $k \times k$ leading principal submatrix of $H(u, v)$. Moreover, if $H_{k+1}\mathbf{w} = 0$, $\mathbf{w} = [w_0, \ldots, w_k]$, $w_k = 1$, then

$$u(x) = \gcd(u(x), v(x)) \sum_{i=0}^{k} w_i x^i .$$

This result yields an algorithm for the GCD using $O(n^2 \log n)$ ops and supporting the record parallel complexity. In addition, this algorithm is quite stable numerically (since the Bezoutian entries have bounded moduli) and supports the record Boolean complexity estimates for computing the GCD of a pair of polynomials defined over the integers or rationals.

Bezoutians have been studied in classical elimination theory (starting with univariate polynomials and then extended to the multivariate case), in stability theory, as well as in computing the reduction of a general matrix to the tridiagonal form. The reader may consult [12, ch. 2], for a comprehensive introduction, and [22, 41, 52, 63] for further information.

Correlations among Structured Matrices

In this section we extend effective algorithms for Toeplitz matrix computations to computations with more general classes of dense structured matrices. In this way, we will unify efficient computations with various dense structured matrices. This approach has further extensions to computations with polynomials, rational functions, and general matrices. In particular, we apply certain shifts and scaling operators to the matrices in order to represent in a simpler and more convenient form.

The main tool are linear operators F that map an $m \times n$ structured matrix A into the product of two matrices $F(A) = GH^T$, where G is $m \times d$ and H is $n \times d$ matrices for a smaller d. Then $r = rank(F(A))$, the rank of the matrix $F(A)$, is called the *F-rank* of A, and the pair of the matrices G and H is called an *F-generator* of A of *length* d.

For the structured matrices seen so far, there exist linear operators F such that the F-generators of A have constant length. Moreover, A can be efficiently expressed via the generators. Thus, an $m \times n$ matrix $F(A)$ with its generator (G, H) of length r can be represented by using only $(m + n)r$, rather than mn, words of storage space. Furthermore, we shall see that to compute the vector $A\mathbf{v}$, for a given pair of matrices G, H, satisfying $F(A) = GH^T$, and for a vector $\mathbf{v}$, we only need $O((m + n)r \log^h(m + n))$ ops, for $h = 1$ or $h = 2$, rather than $(2n - 1)m$ ops. Now, for a given dense structured matrix A, we look for an operator F that transforms A into a low rank matrix, from which we could easily recover the original matrix. Then we may take all the advantages of operating with low rank matrices, even though the structured input matrix may have the full rank. Below we provide some further specifications; more details are found in [12, 47, 55], including a discussion on the powerful theorems that relate the F-rank of a nonsingular matrix and that of its inverse.

Let $Z = Z_k$ be the following $k \times k$ square *down-shift matrix,*

$$Z = \begin{pmatrix} 0 & \dots & & \dots & 0 \\ 1 & 0 & & & \vdots \\ 0 & \ddots & \ddots & & \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & \dots & \dots & 1 & 0 \end{pmatrix}.$$

We generalize the class of Toeplitz matrices to the class of *Toeplitz-like* $m \times n$ matrices A, whose F-rank is bounded from above by a fixed constant independent of m and n, where F is one of the two following operators F_+ or F_-:

$$F_+(A) = F_{Z,Z^T}(A) = A - Z_m A Z_n^T, \quad F_-(A) = F_{Z^T,Z}(A) = A - Z_m^T A Z_n .$$

$F(A) = A - PAQ$ and $F(A) = PA - QA$, for a pair of fixed matrices P, Q, are typical forms of linear operators defining various classes of structured matrices.

Due to the shifting properties of multiplications by Z and Z^T, the operators F_+, F_- turn into zero all the entries of a Toeplitz matrix A, except for the first row and column under F_+ and for the last row and column under F_-, which are invariant in the transition from A to $F(A)$. The above F-generators, for $F = F_+$ and $F = F_-$, have lengths at most 2 for Toeplitz matrices. The length only increases to $p + q$ for $p \times q$ block matrices with Toeplitz blocks. For these operators, it is possible to recover a matrix A from $F(A)$. Therefore, in the Toeplitz case, we may shift to operating with $F(A)$, and thus, save computational resources of time and space. For instance, we may compute the product Av for arbitrary vector v in time $O(nr \log n)$, where r is the rank of $F(A)$, which is typically much smaller than n.

For a concrete illustration, take matrix $A = T$ of Example (17.9). Then we have

$$F_+(A) = \begin{pmatrix} a_0 & a_1 & a_2 & 0 \\ a_1 & 0 & 0 & 0 \\ a_2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} a_0 & 1 \\ a_1 & 0 \\ a_2 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & a_1 & a_2 & 0 \end{pmatrix},$$

where the rank and length of $F(A)$ is 2. In the above notation $F_+(A) = GH$, and let g_i, h_i be the respective column vectors of G, H, for $i = 1, 2$. Then, $F_+(A) = \Sigma_{i=1}^2 g_i h_i^T$. The important property is that A can be expressed as a sum of d products of triangular Toeplitz matrices. Here, $A = \Sigma_{i=1}^2 L(g_i) L^T(h_i)$, where for any $1 \times n$ vector v, $L(v)$ is a lower triangular $n \times n$ Toeplitz matrix, with v being its first column. This kind of representation using $F_+(A)$, $F_-(A)$ is possible for any matrix A. A small number of products $L(g_i)L^T(h_i)$ in the sum characterizes matrices with Toeplitz-like structure, and then we yield efficient ways for several basic operations, including vector multiplication and the recovery of A from its F-image, for the various F such as $F = F_+$ and $F = F_-$.

Analogously, A is said to be *Hankel-like* if the F-rank does not exceed a fixed constant under one of the following two operators:

$$F_{Z,Z}(A) = A - Z_m A Z_n, \quad F_{Z^T,Z^T}(A) = A - Z_m^T A Z_n^T ,$$

and the stated properties of Toeplitz-like matrices can be extended.

A further generalization is to Toeplitz-like plus Hankel-like matrices, expressed as the sum of a Toeplitz-like matrix and a Hankel-like matrix. This class includes both Toeplitz-like and Hankel-like matrices. Suppose that such a pair of $n \times n$ matrices is given by their F-generators with a constant F-length. The F-generator of their product can be computed in $O(n \log n)$ ops by using FFT. At the computational cost $O(n^2 \log n)$, we can compute the inverse and the characteristic polynomial and solve a linear system $Tx = b$ of an $n \times n$ Toeplitz-like plus Hankel-like matrix T. This complexity bound is record and

nearly optimal (up to a logarithmic factor) for the inverse and characteristic polynomial, even in the class of Toeplitz matrices, and the approach yields the record parallel complexity bounds also for solving a Toeplitz-like plus Hankel-like linear system of equations [11, 12, 69]. Sequential algorithms for Toeplitz-like plus Hankel-like linear systems cost $O(n \log^2 n)$ ops (see [12]). There are also several effective iterative algorithms for Toeplitz and other structured linear systems (see [70, 71, 72, 78, 80]), and the reader is also referred to [11, 12, 69, 72] on some other basic properties of Toeplitz-like and Toeplitz-like plus Hankel-like matrices.

Let $D(\mathbf{v}) = D_n(\mathbf{v}) = diag(v_0, v_1, \ldots, v_{n-1})$ where $\mathbf{v}$ is the vector $[v_0, v_1, \ldots, v_{n-1}]^T$ and let us extend the class of Cauchy (or generalized Hilbert) matrices as follows: an $m \times n$ matrix C is said to be *Cauchy (Hilbert)-like* if the F-rank of C is bounded by a constant independent of m and n, F is the operator

$$F_{\mathbf{s},\mathbf{t}}(C) = D_m(\mathbf{s})C - CD_n(\mathbf{t}) ,$$

and $\mathbf{s}$ and $\mathbf{t}$ denote a pair of m- and n-dimensional vectors, respectively.

By definition, a Loewner matrix is Cauchy (Hilbert)-like.

An operator of the Cauchy type is represented by a nonsingular matrix if and only if every entry of $\mathbf{s}$ is distinct from all entries of $\mathbf{t}$. For the Cauchy matrix C with $(C)_{i,j} = \frac{1}{s_i - t_j}$, this operator gives us $F_{\mathbf{s},\mathbf{t}}(C) = \mathbf{e}\mathbf{e}^T$, where $\mathbf{e} = [1, \ldots, 1]^T$. We refer the reader to [12] on further study of the matrices of this class.

The class of $m \times n$ *Vandermonde-like* matrices is formed by the matrices having a constant F-rank, where F is defined by any of the following matrix equations:

$$\begin{aligned} F_{\mathbf{v},Z}(V) &= D_m(\mathbf{v})V - VZ_n, \quad F_{\mathbf{v},Z^T}(V) = D_m(\mathbf{v})V - VZ_n^T , \\ F_{Z,\mathbf{v}}(V) &= VD_n(\mathbf{v}) - Z_mV, \quad F_{Z^T,\mathbf{v}}(V) = VD_n(\mathbf{v}) - Z_m^TV . \end{aligned}$$

If $m = n$ and V is defined by an n-dimensional vector $\mathbf{v}$, then

$$F_{\mathbf{v},Z}(V) = \begin{pmatrix} 0 & \cdots & 0 & v_0^n \\ \vdots & & \vdots & \vdots \\ 0 & \cdots & 0 & v_{n-1}^n \end{pmatrix} = D^n(\mathbf{v})\,\mathbf{e}\,[0, \ldots, 0, 1] .$$

Both Cauchy-like and Vandermonde-like matrices can be recovered from their respective images under the operators specified here.

We conclude this section by following [68] in order to demonstrate how associating the operators unifies the treatment of dense structured matrices, revealing some important but hidden correlations among various classes of such matrices (such correlations have been already demonstrated when we solved a transposed Vandermonde linear system in "Circulant, Toeplitz, and Hankel Matrices"). The first basic idea is that several operations can be applied to the generators without explicitly constructing the matrices. Addition and subtraction, for the operators examined, satisfy

$$F(A \pm B) = F(A) \pm F(B) ,$$

and the F-generator of the sum or difference is the union of the other two generators.

For multiplication, we may rely on a result of [68], generalizing a result of [26], which allows us to compute a generator of the product in terms of the generators of the two given matrices. Let K, L, M, and N be four fixed matrices, $\Delta = LM - I$, I be the identity matrix, and let $F_{(P,Q)}$ be an operator defined by the equation $F_{(P,Q)}(A) = A - PAQ$, for any matrices P, Q, and A. Then

$$F_{(K,N)}(AB) = F_{(K,L)}(A)B + KALF_{(M,N)}(B) + KA(LM - I)BN .$$

Let r=rank $F_{(K,N)}(AB)$, r_1 = rank $F_{(K,L)}(A)$, and r_2 = rank $F_{(M,N)}(B)$. It follows that $r \leq$ rank $(LM - I) + r_1 + r_2$.

Based on this result, [68] extends the algorithms for structured matrices seen so far to matrices with similar structures. For instance, specialize L and M as follows:

$$L = Z,\ M = Z^T, \quad \text{or} \quad L = Z^T,\ M = Z\,,$$

where Z is the down-shift matrix defined above. If we require all three operators be of Hankel and/or Toeplitz type, then K and N are implicitly defined. If all matrices are of size $n \times n$ and the length of F-generator of A, B is d_1, d_2, respectively, then an F-generator for AB of a length at most $d_1 + d_2 + 1$ can be computed in $O(n(d_1 + d_2)^2 \log(n(d_1 + d_2)))$ ops. Moreover, the rank of $LM - I$ for both specializations is 1, so the F-rank of the product is bounded by $1 + r_1 + r_2$. This implies that the product of two Toeplitz- or Hankel-like matrices is again Toeplitz- or Hankel-like, with F-rank bounded as in the second to last line of the following table from [68] and [12, Sect. 2.12].

Different specializations of matrices K, L, M, and N imply the rest of the entries in the table. We write HT, C, and V, for the classes of Hankel-like plus Toeplitz-like, Cauchy-like, and Vandermonde-like matrices, respectively.

A	B	AB	F-rank of AB
HT	V	V	$r \le r_1 + r_2 + 1$
V	V	C	$r \le r_1 + r_2 + 1$
V	V	HT	$r \le r_1 + r_2$
C	V	V	$r \le r_1 + r_2$
HT	HT	HT	$r \le r_1 + r_2 + 1$
C	C	C	$r \le r_1 + r_2 + 1$

By using these transitions, we may reduce the original computational problem to other problems for which we have effective algorithms. For instance, suppose that, given an $F_{\mathbf{s},\mathbf{t}}$-generator for a Cauchy-like matrix A, with $\mathbf{s},\mathbf{t}$ vectors, we wish to compute its determinant and its inverse, when the latter exists. We may choose B to be the Vandermonde matrix defined by the inverse entries of $\mathbf{t}$ and compute an F-generator for AB. Then the matrix AB is Vandermonde-like, with rank bounded as in the fourth line of the table above. Now, $\det A = \det(AB)/\det B$ and $A^{-1} = B(AB)^{-1}$, so we have reduced the original problems to a sequence of operations on Vandermonde-like matrices.

After the transformations displayed in the above table have been established in [68], some of them have been further simplified, due to the following result of [46]:

THEOREM 17.3 *$C = \Omega T D_{2n} \Omega^{-1}$ is a Cauchy-like matrix, having a r-generator $G^* = \Omega G$, $H^* = \Omega D(w) H$, for $F = F_{D_n, D_{-n}} = F(D_n, D_{-n})$, that is,*

$$F_{D_n, D_{-n}} C = D_n C - C D_{-n} = G^* \left(H^*\right)^T\,,$$

provided that T is a Toeplitz-like matrix with an F-generator G, H for $F = F_{Z_1, Z_{-1}} = F(Z_1, Z_{-1})$,

$$F_{Z_1, Z_{-1}} T = Z_1 T - T Z_{-1} = G H^T\,,$$

$D_k = diag(1, w_k, w_k^2, \ldots, w_k^{n-1})$, $w_k = exp(2\pi\sqrt{-1}/k)$, and $\Omega = 1/\sqrt{n}(w_n^{ij})$ is a Fourier matrix, $\Omega^{-1} = 1/\sqrt{n}(w_n^{-ij})$, $i, j = 0, 1, \ldots, n-1$.

Due to this result, the transformation from any Toeplitz-like matrix into a Cauchy-like matrix is immediately reduced to FFT, which leads to effective practical algorithms for Toeplitz-like linear systems [46]. Another example of applications of this kind is the fast algorithms for polynomial evaluation and interpolation based on manipulation with structured matrices of the classes HT, V, and C [77, 79].

Additional bibliography on the material of this section can be found in [12].

17.5 Research Issues and Summary

We have reviewed the known highly effective algorithms for the discrete Fourier transform (DFT) and its inverse, as well as for some related transforms, all of them based on the celebrated fast Fourier transform (FFT) algorithm. We have shown immediate application of FFT to computing convolution of vectors (polynomial products), which is a fundamental operation of computer algebra and signal processing. We have also demonstrated further applications to other basic operations with integers, univariate and multivariate polynomials and power series, as well as to the fundamental computations with circulant, Toeplitz, Hankel, Vandermonde, Cauchy (generalized Hilbert), and Bézout matrices, as well as to other structured matrices related to the above classes of matrices via the associated linear operators. We exemplified some major techniques establishing such relations and other major basic techniques for extending the power of FFT to numerous other computational problems, and we supplied pointers to further bibliography. Some of these techniques are quite recent, and further research is very promising, in particular, via the study of structured matrices and polynomial systems of equations [20, 37, 65]. New practical and theoretical research directions have emerged recently related to the numerical implementation of FFT, leading to interesting algebraic techniques [18] and certain finite group applications [29, 38].

17.6 Defining Terms

Chinese remainder algorithm: The algorithm recovering a unique integer (or polynomial) p modulo M from the h residues of p modulo pairwise relatively prime integers (or, respectively, polynomials) $m_1, \cdots, m_h$, where M is the product $m_1 \cdots m_h$. (The **residue** of p modulo m is the remainder of the division of p by m.)

Convolution of two vectors: A vector that contains the coefficients of the product of two polynomials whose coefficients make up the given vectors. The positive and negative wrapped convolutions are the coefficient vectors of the two polynomials obtained via reduction of the polynomial product by $x^n + 1$ and $x^n - 1$, respectively.

Determinant (of an $n \times n$ matrix): A polynomial of degree n in the entries of the matrix with the property of being invariant in the elementary transformations of a matrix used in Gaussian elimination; the determinant of the product of matrices is the product of their determinants; the determinant of a triangular matrix is the product of its diagonal entries; the determinant of any matrix is nonzero if and only if the matrix is invertible (nonsingular).

Discrete Fourier transform (DFT): The vector of the values of a given polynomial at the set of all the Kth roots of unity. **The inverse discrete Fourier transform (IDFT)** of a vector **v:** The vector of the coefficients of a polynomial whose values at the Kth roots of 1 form a given vector **v.**

Divide-and-conquer: A general algorithmic method of dividing a given problem into two (or more) subproblems of smaller sizes that are easier to solve, then synthesizing the overall solution from the solutions to the subproblems.

Fast Fourier transform (FFT): An algorithm that uses $1.5K \log K$ ops in order to compute the DFT at the Kth roots of 1, where $K = 2^k$, for a natural k. It also computes the IDFT in $K + 1.5K \log K$ ops.

Greatest common divisor (GCD) of 2 or several integers (or polynomials): The largest positive integer (or a polynomial of the largest degree) that divides both or all of the input integers (or polynomials).

Interpolation: The computation of the coefficients of a polynomial in one or more variables, given its values at a set of points. The inverse problem is the **evaluation** of a given polynomial **on a set of points.**

Least common multiple (LCM) of 2 or several integers (or polynomials): The smallest positive integer (or a polynomial of the smallest degree) divisible by both or by all of the input integers (or polynomials).

Ops: Arithmetic operations, i.e., additions, subtractions, multiplications, or divisions.

Structured matrix: A matrix whose each entry can be derived by a formula depending on a few parameters. For instance, the Hilbert matrix has $\frac{1}{i+j-1}$ as the entry in row i and column j.

Taylor shift of the variable: Recovery of the coefficient vector of a polynomial after a linear substitution of its variable, $y = x + \Delta$ for x, where Δ is a fixed shift value.

Further Information

The main research journals in this area are *Computers and Mathematics (with Applications), Journal of the ACM, Journal of Symbolic Computation, Linear Algebra and Its Applications, Mathematics of Computation, SIAM Journal of Computing, SIAM Journal of Matrix Analysis and Applications,* and *Theoretical Computer Science.* New implementations are reported in the *ACM Transactions on Mathematical Software.*

The main annual conferences in this area are the "ACM-SIGSAM International Symposium on Symbolic and Algebraic Computation," the "ACM Symposium on Theory of Computing," the "ACM-SIAM Symposium on Discrete Algorithms," the "European Symposium on Algorithms," the "IEEE Symposium on Foundations of Computer Science," and the "Symposium on Parallel Algorithms and Architectures."

The following books contain general information on the topics of this chapter [1, 12, 14, 17, 62, 92], where the last three present the state of the art, and [12] also points to an extensive list of applications. Some references on transforms and convolution have been listed at the beginning of Section 17.2.

Parallel computation is an important subject, which we have barely touched. We refer the interested reader to [12, 54, 70].

Multidimensional Data Structures[1]

Hanan Samet
University of Maryland

18.1 Introduction

The representation of **multidimensional data** is an important issue in applications in diverse fields that include database management systems, computer graphics, computer vision, computational geometry, image processing, geographic information systems (GIS), pattern recognition, VLSI design, and others. The most common definition of multidimensional data is a collection of points in a higher dimensional space. These points can represent locations and objects in space as well as more general records. As an example of a record, consider an employee record that has attributes corresponding to the employee's name, address, sex, age, height, weight, and social security number. Such records arise in database management systems and can be treated as points in, for this example, a seven-dimensional space (i.e., there is one dimension for each attribute), albeit the different dimensions have different type units (i.e., name and address are strings of characters, sex is binary; while age, height, weight, and social security number are numbers).

When multidimensional data corresponds to locational data, we have the additional property that all of the attributes have the same unit, which is distance in space. In this case, we can combine the attributes and pose queries that involve proximity. For example, we may wish to find the closest city to Chicago within the two-dimensional space from which the locations of the cities are drawn. Another query seeks to find all cities within 50 miles of Chicago. In contrast, such queries are not very meaningful when the attributes do not have the same type. For example, it is not customary to seek the person with age–weight combination closest to John Jones, as we do not have a commonly accepted unit of year-pounds (year-kilograms) or

Supported by the National Science Foundation under grant IRI-9712715.

definition thereof. It should be clear that we are not speaking of queries involving Boolean combinations of the different attributes (e.g., range queries), which are quite common.

When multidimensional data spans a continuous physical space (i.e., an infinite collection of locations), the issues become more interesting. In particular, we are no longer just interested in the locations of objects but, we are also interested in the space that they occupy (i.e., their extent). Some example objects include lines (e.g., roads, rivers), regions (e.g., lakes, counties, buildings, crop maps, polygons, polyhedra), rectangles, and surfaces. The objects may be disjoint or could even overlap. One way to deal with such data is to store it explicitly by parametrizing it and thereby reduce it to a point in a higher dimensional space. For example, a line in two-dimensional space can be represented by the coordinate values of its endpoints (i.e., a pair of x and a pair of y coordinate values) and then stored as a point in a four-dimensional space. Thus, in effect, we have constructed a transformation (i.e., mapping) from a two-dimensional space (i.e., the space from which the lines are drawn) to a four-dimensional space (i.e., the space containing the representative point corresponding to the line).

The transformation approach is fine if we are just interested in retrieving the data. It is appropriate for queries about the objects (e.g., determining all lines that pass through a given point or that share an endpoint, etc.) and the immediate space that they occupy. However, the drawback of the transformation approach is that it ignores the geometry inherent in the data (e.g., the fact that a line passes through a particular region) and its relationship to the space in which it is embedded.

For example, suppose that we want to detect if two lines are near each other, or, alternatively, to find the nearest line to a given line. This is difficult to do in the four-dimensional space, regardless of how the data in it is organized, since proximity in the two-dimensional space from which the lines are drawn is not necessarily preserved in the four-dimensional space. In other words, although the two lines may be very close to each other, the Euclidean distance between their representative points may be quite large.

Of course, we could overcome these problems by projecting the lines back to the original space from which they were drawn, but in such a case, we may ask what was the point of using the transformation in the first place? In other words, at the least, the representation that we choose for the data should allow us to perform operations on the data. Thus, we need special representations for spatial multidimensional data other than point representations. One solution is to use data structures that are based on spatial occupancy.

Spatial occupancy methods decompose the space from which the spatial data is drawn (e.g., the two-dimensional space containing the lines) into regions called *buckets.* They are also commonly known as **bucketing methods.** Traditional bucketing methods such as the grid file [45], BANG file [22], LSD trees [27], buddy trees [55], etc. have been designed for multidimensional point data that need not be locational. In the case of spatial data, these methods have usually been applied to the transformed data (i.e., the representative points). In contrast, we discuss their application to the actual objects in the space from which the objects are drawn (i.e., two dimensions in the case of a collection of line segments).

In this chapter, we explore a number of different representations of multidimensional data bearing the above issues in mind. In the case of point data, we examine representations of both locational and nonlocational data, as well as combinations of the two. While we cannot give exhaustive details of all of the data structures, we try to explain the intuition behind their development as well as to give literature pointers to where more information can be found. Many of these representations are described in greater detail in [50, 51], including an extensive bibliography. Our approach is primarily a descriptive one. Most of our examples are of two-dimensional spatial data, although we do touch briefly on three-dimensional data.

At times, we discuss bounds on execution time and space requirements. Nevertheless, this information is presented in an inconsistent manner. The problem is that such analyses are very difficult to perform for many of the data structures that we present. This is especially true for the data structures that are based on spatial occupancy (e.g., **quadtree** and **R-tree** variants). In particular, such methods have good observable average-case behavior but may have very bad worst cases which may only arise rarely in practice. Their analysis is beyond the scope of this chapter and usually we do not say anything about it. Nevertheless,

these representations find frequent use in applications where their behavior is deemed acceptable, and is often found to be better than that of solutions whose theoretical behavior would appear to be superior. The problem is primarily attributed to the presence of large constant factors which are usually ignored in the *big O* and Ω analyses [38].

The rest of this chapter is organized as follows. Section 18.2 reviews a number of representations of point data of arbitrary dimensionality. Section 18.3 describes bucketing methods that organize collections of spatial objects (as well as multidimensional point data) by aggregating their bounding rectangles. Sections 18.2 and 18.3 are applicable to both spatial and nonspatial data, although all the examples that we present are of spatial data. Section 18.4 focuses on representations of region data, while Section 18.5 discusses a subcase of region data, which consists of collections of rectangles. Section 18.6 deals with curvilinear data, which also includes polygonal subdivisions and collections of line segments. Section 18.7 contains a summary and a brief indication of some research issues. Section 18.8 reviews some of the definitions of the terms used in this chapter. Note that although our examples are primarily from a two-dimensional space, the representations are applicable to higher dimensional spaces as well.

18.2 Point Data

Our discussion assumes that there is one record per data point, and that each record contains several attributes or keys (also frequently called fields, dimensions, coordinates, and axes). In order to facilitate retrieval of a record based on some of its attribute values, we also assume the existence of an ordering for the range of values of each of these attributes. In the case of locational attributes, such an ordering is quite obvious as the values of these attributes are numbers. In the case of alphanumeric attributes, the ordering is usually based on the alphabetic sequence of the characters making up the attribute value. Other data such as color could be ordered by the characters making up the name of the color or possibly the color's wavelength. It should be clear that finding an ordering for the range of values of an attribute is generally not an issue; the real issue is what ordering to use!

The representation that is ultimately chosen for the data depends, in part, on answers to the following questions:

1. What operations are to be performed on the data?
2. Should we organize the data or the embedding space from which the data is drawn?
3. Is the database static or dynamic (i.e., can the number of data points grow and shrink at will)?
4. Can we assume that the volume of data is sufficiently small so that it can all fit in core, or should we make provisions for accessing disk-resident data?

Disk-resident data implies grouping the data (either the underlying space based on the volume — that is, the amount — of the data it contains or the points, hopefully, by the proximity of their values) into sets (termed *buckets*) corresponding to physical storage units (i.e., pages). This leads to questions about their size, and how they are to be accessed.

1. Do we require a constant time to retrieve a record from a file or is a logarithmic function of the number of records in the file adequate? This is equivalent to asking if the access is via a directory in the form of an array (i.e., direct access) or a tree?
2. How large can the directories be allowed to grow before it is better to rebuild them?
3. How should the buckets be laid out on the disk?

Clearly, these questions are complex and we cannot address them all here. Some are answered in other sections. In this section, we focus primarily on dynamic data with an emphasis on two dimensions (i.e., attributes) and concentrate on the following queries:

1. Point queries — that is, if a particular point is present.

2. Range queries.
3. Boolean combinations of 1 and 2.

Most of the representations that we describe can be extended easily to higher dimensions, although some like the priority search tree are basically for two-dimensional data. Our discussion and examples are based on the fact that all of the attributes are locational or numeric and that they have the same range, although all of the representations can also be used to handle nonlocational and nonnumeric attributes. When discussing behavior in the general case, we assume a data set of N points and d attributes.

The simplest way to store point data is in a sequential list. Accesses to the list can be sped up by forming sorted lists for the various attributes which are known as *inverted lists* (e.g., [37]). There is one list for each attribute. This enables pruning the search with respect to the value of one of the attributes. In order to facilitate random access, the lists can be implemented using range trees [10].

It should be clear that the inverted list is not particularly useful for range searches. The problem is that it can only speed up the search for one of the attributes (termed the *primary* attribute). A number of solutions have been proposed. These solutions can be decomposed into two classes. One class of solutions enhances the range tree corresponding to the inverted list to include information about the remaining attributes in its internal nodes. This is the basis of the multidimensional range tree and variants of the priority search tree [15, 41] that are discussed at the end of this section.

The second class of solutions is more widely used and is exemplified by the *fixed-grid* method [9, 37]. It partitions the space from which the data is drawn into rectangular cells by overlaying it with a grid. Each grid cell c contains a pointer to another structure (e.g., a list) which contains the set of points that lie in c. Associated with the grid is an access structure to enable the determination of the grid cell associated with a particular point p. This access structure acts like a directory and is usually in the form of a d-dimensional array with one entry per grid cell or a tree with one leaf node per grid cell.

There are two ways to build a fixed grid. We can either subdivide the space into equal-sized intervals along each of the attributes (resulting in congruent grid cells) or place the subdivision lines at arbitrary positions that are dependent on the underlying data. In essence, the distinction is between organizing the data to be stored and organizing the embedding space from which the data is drawn [45]. In particular, when the grid cells are congruent (i.e., equal-sized when all of the attributes are locational with the same range and termed a *uniform grid*), use of an array access structure is quite simple and has the desirable property that the grid cell associated with point p can be determined in constant time. Moreover, in this case, if the width of each grid cell is twice the search radius for a rectangular range query, then the average search time is $O(F \cdot 2^d)$ where F is the number of points that have been found [11]. Figure 18.1 is an example of a uniform-grid representation for a search radius equal to 10 (i.e., a square of size 20×20[2]).

Use of an array access structure when the grid cells are not congruent requires us to have a way of keeping track of their size so that we can determine the entry of the array access structure corresponding to the grid cell associated with point p. One way to do this is to make use of what are termed *linear scales,* which indicate the positions of the grid lines (or partitioning hyperplanes in $d > 2$ dimensions). Given a point p, we determine the grid cell in which p lies by finding the "coordinate values" of the appropriate grid cell. The linear scales are usually implemented as one-dimensional trees containing ranges of values.

The use of an array access structure is fine as long as the data is static. When the data is dynamic, it is likely that some of the grid cells become too full while other grid cells are empty. This means that we need to rebuild the grid (i.e., further partition the grid or reposition the grid partition lines or hyperplanes) so that the various grid cells are not too full. However, this creates many more empty grid cells as a result

[2]Note that although the data consists of three attributes, one of which is nonlocational (i.e., name) and two of which are locational (i.e., the coordinate values), retrieval is only on the basis of the locational attribute values. Thus, there is no ordering on the name, and, therefore, we treat this example as two-dimensional locational data.

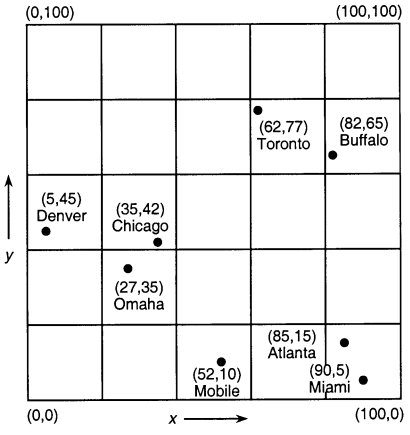

FIGURE 18.1 Uniform-grid representation corresponding to a set of points with a search radius of 20.

of repartitioning the grid (i.e., empty grid cells are split into more empty grid cells). In this case, we have two alternatives. The first is to assign an ordering to all the grid cells and to impose a tree access structure on the elements of the ordering that correspond to nonempty grid cells. The effect of this alternative is analogous to using a mapping from d dimensions to one dimension and then applying one of the one-dimensional access structures such as a B-tree, balanced binary tree, etc., to the result of the mapping. There are a number of possible mappings including row, Morton (i.e., bit interleaving or bit interlacing), and Peano–Hilbert (e.g.,[51])[3]. This alternative is applicable regardless of whether or not the grid cells are congruent. Of course, if the grid cells are not congruent, then we must also record their size in the element of the access structure.

The second alternative is to merge spatially adjacent empty grid cells into larger empty grid cells, while splitting grid cells that are too full, thereby making the grid adaptive. Again, the result is that we can no longer make use of an array access structure to retrieve the grid cell that contains query point p. Instead, we make use of a tree access structure in the form of a k-ary tree where k is usually 2^d. Thus, what we have done is marry a k-ary tree with the fixed-grid method. This is the basis of the point quadtree [17] and the PR quadtree [46, 51] which are multidimensional generalizations of binary trees.

The difference between the point quadtree and the PR quadtree is the same as the difference between *trees* and *tries* [20], respectively. The binary search tree [37] is an example of the former since the boundaries of different regions in the search space are determined by the data being stored. Address computation methods such as radix searching [37] (also known as digital searching) are examples of the latter, since region boundaries are chosen from among locations that are fixed regardless of the content of the data set. The process is usually a recursive halving process in one dimension, recursive quartering in two dimensions, etc., and is known as **regular decomposition.**

In two dimensions, a point quadtree is just a two-dimensional binary search tree. The first point that is inserted serves as the root, while the second point is inserted into the relevant quadrant of the tree rooted at the first point. Clearly, the shape of the tree depends on the order in which the points were inserted. For example, Fig. 18.2 is the point quadtree corresponding to the data of Fig. 18.1 inserted in the order `Chicago`, `Mobile`, `Toronto`, `Buffalo`, `Denver`, `Omaha`, `Atlanta`, and `Miami`.

In two dimensions, the PR quadtree is based on a recursive decomposition of the underlying space into four congruent (usually square in the case of locational attributes) cells until each cell contains no more

[3]These mappings have been investigated primarily for purely locational multidimensional point data. They cannot be applied directly to the key values for nonlocational point data.

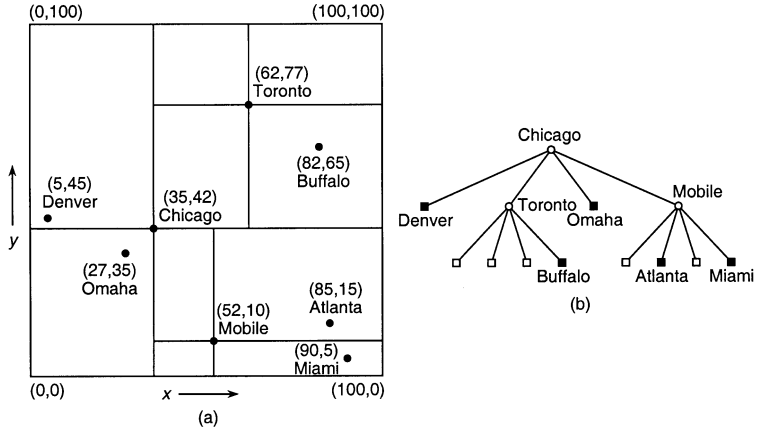

FIGURE 18.2 A point quadtree and the records it represents corresponding to Fig.18.1: (a) the resulting partition of space, and (b) the tree representation.

than one point. For example, Fig. 18.3 is the PR quadtree corresponding to the data of Fig. 18.1. The shape of the PR quadtree is independent of the order in which data points are inserted into it. The disadvantage of the PR quadtree is that the maximum level of decomposition depends on the minimum separation between two points. In particular, if two points are very close, then the decomposition can be very deep. This can be overcome by viewing the blocks or nodes as buckets with capacity c and only decomposing a block when it contains more than c points.

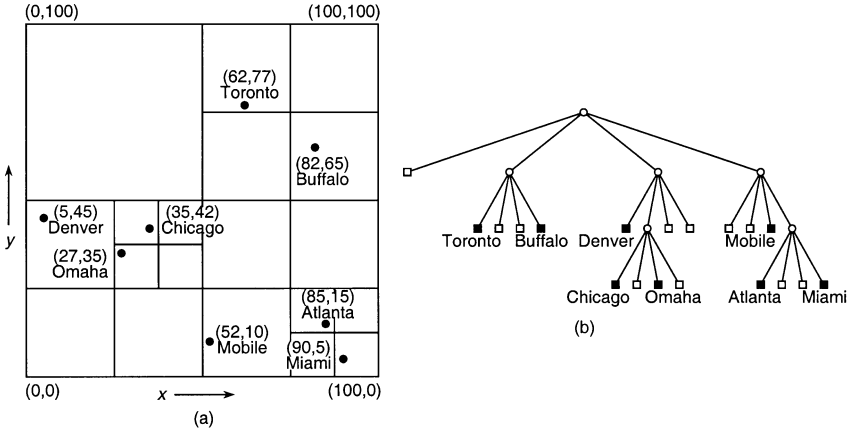

FIGURE 18.3 A PR quadtree and the records it represents corresponding to Fig.18.1: (a) the resulting partition of space, and (b) the tree representation.

As the dimensionality of the space increases, each level of decomposition of the quadtree results in many new cells as the fanout value of the tree is high (i.e., 2^d). This is alleviated by making use of a **k-d tree** [7]. The k-d tree is a binary tree where at each level of the tree, we subdivide along a different attribute so that, assuming d locational attributes, if the first split is along the x axis, then after d levels, we cycle back and again split along the x axis. It is applicable to both the point quadtree and the PR quadtree (in which case we have a *PR k-d tree,* or a **bintree** in the case of region data).

At times, in the dynamic situation, the data volume becomes so large that a tree access structure is inefficient. In particular, the grid cells can become so numerous that they cannot all fit into memory, thereby causing them to be grouped into sets (termed *buckets*) corresponding to physical storage units (i.e., pages) in secondary storage. The problem is that, depending on the implementation of the tree access structure, each time we must follow a pointer, we may need to make a disk access. This has led to a return to the use of an array access structure. The difference from the array used with the static fixed-grid method described earlier is that the array access structure (termed *grid directory*) may be so large (e.g., when d gets large) that it resides on disk as well, and the fact that the structure of the grid directory can be changed as the data volume grows or contracts. Each grid cell (i.e., an element of the grid directory) contains the address of a bucket (i.e., page) that contains the points associated with the grid cell. Notice that a bucket can correspond to more than one grid cell. Thus, any page can be accessed by two disk operations: one to access the grid cell and one more to access the actual bucket.

This results in *EXCELL* [59] when the grid cells are congruent (i.e., equal-sized for locational data), and *grid file* [45] when the grid cells need not be congruent. The difference between these methods is most evident when a grid partition is necessary (i.e., when a bucket becomes too full and the bucket is not shared among several grid cells). In particular, a grid partition in the grid file only splits one interval in two, thereby resulting in the insertion of a $(d-1)$-dimensional cross section. On the other hand, a grid partition in EXCELL means that all intervals must be split in two, thereby doubling the size of the grid directory.

Fixed-grids, quadtrees, k-d trees, grid file, EXCELL, as well as other hierarchical representations are good for range searching as they make it easy to implement the query. A typical query is one that seeks all cities within 80 miles of St. Louis, or, more generally, within 80 miles of the latitude position of St. Louis and within 80 miles of the longitude position of St. Louis.[4] In particular, these structures act as pruning devices on the amount of search that will be performed as many points will not be examined since their containing cells lie outside the query range. These representations are generally very easy to implement and have good expected execution times, although they are quite difficult to analyze from a mathematical standpoint. However, their worst cases, despite being rare, can be quite bad. These worst cases can be avoided by making use of variants of range trees [10] and priority search trees [41]. They are applicable to both locational and nonlocational attributes, although our presentation assumes that all the attributes are locational.

A one-dimensional range tree is a balanced binary search tree where the data points are stored in the leaf nodes and the leaf nodes are linked in sorted order by use of a doubly-linked list. A range search for $[L : R]$ is performed by searching the tree for the node with the smallest value that is $\geq L$, and then following the links until reaching a leaf node with a value greater than R. For N points, this process takes $O(\log_2 N + F)$ time and uses $O(N)$ storage. F is the number of points found.

A two-dimensional range tree is a binary tree of binary trees. It is formed in the following manner. First, sort all of the points along one of the attributes, say x, and store them in the leaf nodes of a balanced binary search tree, say T. With each non-leaf node of T, say I, associate a one-dimensional range tree, say T_I, of the points in the subtree rooted at I where now these points are sorted along the other attribute, say y. The range tree also can be adapted easily to handle d-dimensional data. In such a case, for N points, a d-dimensional range search takes $O(\log_2^d N + F)$ time, where F is the number of points found. The d-dimensional range tree uses $O(N \cdot \log_2^{d-1} N)$ storage.

The *priority search tree* is a related data structure that is designed for solving queries involving semi-infinite ranges in two-dimensional space. A typical query has a range of the form $([L_x : R_x], [L_y : \infty])$.

[4]The difference between these two formulations of the query is that the former admits a circular search region, while the latter admits a rectangular search region. In particular, the latter formulation is applicable to both locational and non-locational attributes, while the former is only applicable to locational attributes.

For example, Fig. 18.4 is the priority search tree for the data of Fig. 18.1. It is built as follows. Assume that no two data points have the same x coordinate value. Sort all the points along the x coordinate value and store them in the leaf nodes of a balanced binary search tree (a range tree in our formulation), say T. We proceed from the root node toward the leaf nodes. With each node I of T, associate the point in the subtree rooted at I with the maximum value for its y coordinate that has not already been stored at a shallower depth in the tree. If such a point does not exist, then leave the node empty. For N points, this structure uses $O(N)$ storage.

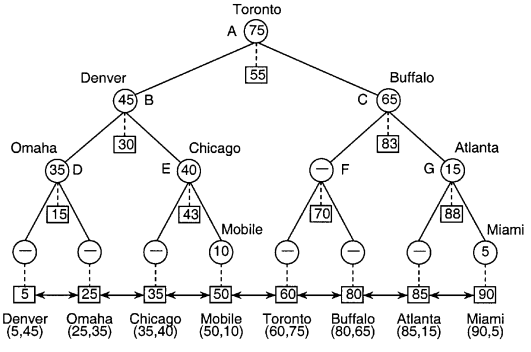

FIGURE 18.4 Priority search tree for the data of Fig.18.1. Each leaf node contains the value of its x coordinate in a square box. Each nonleaf node contains the appropriate x coordinate midrange value in a box using a link drawn with a broken line. Circular boxes indicate the value of the y coordinate of the point in the corresponding subtree with the maximum value for its y coordinate that has not already been associated with a node at a shallower depth in the tree.

It is not easy to perform a two-dimensional range query of the form $([L_x : R_x], [L_y : R_y])$ with a priority search tree. The problem is that only the values of the x coordinates are sorted. In other words, given a leaf node C that stores point (x_C, y_C), we know that the values of the x coordinates of all nodes to the left of C are smaller than x_C and the values of all those to the right of C are greater than x_C. On the other hand, with respect to the values of the y coordinates, we only know that all nodes below non-leaf node D with value y_D have values less than or equal to y_D; the y coordinate values associated with the remaining nodes in the tree that are not ancestors of D may be larger or smaller than y_D. This is not surprising, because a priority search tree is really a variant of a range tree in x and a heap (i.e., priority queue) [37] in y.

A heap enables finding the maximum (minimum) value in $O(1)$ time. Thus, it is easy to perform a semi-infinite range query of the form $([L_x : R_x], [L_y : \infty])$, as all we need do is descend the priority search tree and stop as soon as we encounter a y coordinate value that is less than L_y. For N points, performing a semi-infinite range query in this way takes $O(\log_2 N + F)$ time, where F is the number of points found.

The priority search tree is used as the basis of the *range priority tree* [15] to reduce the order of execution time of a two-dimensional range query to $O(\log_2 N + F)$ time (but still using $O(N \cdot \log_2 N)$ storage). Define an *inverse priority search tree* to be a priority search tree S such that with each node of S, say I, we associate the point in the subtree rooted at I with the minimum (instead of the maximum!) value for its y coordinate that has not already been stored at a shallower depth in the tree. The range priority tree is a balanced binary search tree (i.e., a range tree), say T, where all the data points are stored in the leaf nodes and are sorted by their y coordinate values. With each non-leaf node of T, say I, which is a left son of its father, we store a priority search tree of the points in the subtree rooted at I. With each non-leaf node of T, say I, which is a right son of its father we store an inverse priority search tree of the points in the subtree rooted at I. For N points, the range priority tree uses $O(N \cdot \log_2 N)$ storage.

Performing a range query for $([L_x : R_x], [L_y : R_y])$ using a range priority tree is done in the following manner. We descend the tree looking for the nearest common ancestor of L_y and R_y, say Q. The values of the y coordinates of all points in the left son of Q are less than R_y. We want to retrieve just the ones that are greater than or equal to L_y. We can obtain them with the semi-infinite range query $([L_x : R_x], [L_y : \infty])$. This can be done by using the priority tree associated with the left son of Q. Similarly, the values of the y coordinates of all points in the right son of Q are greater than L_y. We want to retrieve just the ones that are less than or equal to R_y. We can obtain them with the semi-infinite range query $([L_x : R_x], [-\infty : R_y])$. This can be done by using the inverse priority search tree associated with the right son of Q. Thus, for N points the range query takes $O(\log_2 N + F)$ time, where F is the number of points found.

18.3 Bucketing Methods

There are four principal approaches to decomposing the space from which the records are drawn. They are applicable regardless of whether the attributes are locational or nonlocational, although our discussion assumes that they are locational and that the records correspond to spatial objects. One approach makes use of an object hierarchy. It propagates the space occupied by the objects up the hierarchy with the identity of the propagated objects being implicit to the hierarchy. In particular, associated with each object is an object description (e.g., for region data, it is the set of locations in space corresponding to the cells that make up the object). Actually, since this information may be rather voluminous, it is often the case that an approximation of the space occupied by the object is propagated up the hierarchy rather than the collection of individual cells that are spanned by the object. For spatial data, the approximation is usually the minimum bounding rectangle for the object, while for nonspatial data it is simply the hyperrectangle whose sides have lengths equal to the ranges of the values of the attributes. Therefore, associated with each element in the hierarchy is a bounding rectangle corresponding to the union of the bounding rectangles associated with the elements immediately below it.

The R-tree (e.g., [6, 26]) is an example of an object hierarchy that finds use especially in database applications. The number of objects or bounding rectangles that are aggregated in each node is permitted to range between $m \leq \lceil M/2 \rceil$ and M. The root node in an R-tree has at least two entries unless it is a leaf node, in which case it has just one entry corresponding to the bounding rectangle of an object. The R-tree is usually built as the objects are encountered rather than waiting until all objects have been input. The hierarchy is implemented as a tree structure with grouping being based, in part, on proximity of the objects or bounding rectangles.

For example, consider the collection of line segment objects given in Fig. 18.5 shown embedded in a 4×4 grid. Figure 18.6(a) is an example R-tree for this collection with $m = 2$ and $M = 3$. Figure 18.6(b) shows the spatial extent of the bounding rectangles of the nodes in Fig. 18.6(a), with heavy lines denoting the bounding rectangles corresponding to the leaf nodes, and broken lines denoting the bounding rectangles corresponding to the subtrees rooted at the nonleaf nodes. Note that the R-tree is not unique. Its structure depends heavily on the order in which the individual objects were inserted into (and possibly deleted from) the tree.

Given that each R-tree node can contain a varying number of objects or bounding rectangles, it is not surprising that the R-tree was inspired by the B-tree [12]. Therefore, nodes are viewed as analogous to disk pages. Thus, the parameters defining the tree (i.e., m and M) are chosen so that a small number of nodes is visited during a spatial query (i.e., point and range queries), which means that m and M are usually quite large. The actual implementation of the R-tree is really a B^+-tree [12] as the objects are restricted to the leaf nodes.

The efficiency of the R-tree for search operations depends on its ability to distinguish between occupied space and unoccupied space (i.e., coverage), and to prevent a node from being examined needlessly due to a false overlap with other nodes. In other words, we want to minimize coverage and overlap. These goals

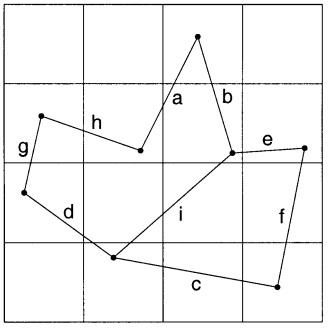

FIGURE 18.5 Example collection of line segments embedded in a 4×4 grid.

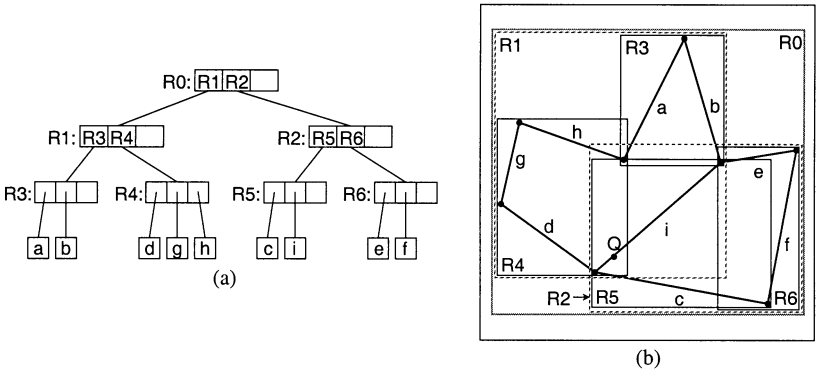

FIGURE 18.6 (a) R-tree for the collection of line segments with $m = 2$ and $M = 3$, in Fig.18.5, and (b) the spatial extents of the bounding rectangles. Notice that the leaf nodes in the index also store bounding rectangles, although this is only shown for the nonleaf nodes.

guide the initial R-tree creation process as well, subject to the previously mentioned constraint that the R-tree is usually built as the objects are encountered rather than waiting until all objects have been input.

The drawback of the R-tree (and any representation based on an object hierarchy) is that it does not result in a disjoint decomposition of space. The problem is that an object is only associated with one bounding rectangle (e.g., line segment `i` in Fig. 18.6 is associated with bounding rectangle `R5`, yet it passes through `R1`, `R2`, `R4`, and `R5`, as well as through `R0` as do all the line segments). In the worst case, this means that when we wish to determine which object (e.g., an intersecting line in a collection of line segment objects, or a containing rectangle in a collection of rectangle objects) is associated with a particular point in the two-dimensional space from which the objects are drawn, we may have to search the entire collection. For example, in Fig. 18.6, when searching for the line segment that passes through point Q, we need to examine bounding rectangles `R0`, `R1`, `R4`, `R2`, and `R5`, rather than just `R0`, `R2`, and `R5`.

This drawback can be overcome by using one of three other approaches that are based on a decomposition of space into disjoint cells. Their common property is that the objects are decomposed into disjoint subobjects such that each of the subobjects is associated with a different cell. They differ in the degree of regularity imposed by their underlying decomposition rules, and by the way in which the cells are aggregated into buckets.

The price paid for the disjointness is that in order to determine the area covered by a particular object, we have to retrieve all the cells that it occupies. This price is also paid when we want to delete an object. Fortunately, deletion is not so common in such applications. A related costly consequence of disjointness is that when we wish to determine all the objects that occur in a particular region, we often need to retrieve some of the objects more than once. This is particularly troublesome when the result of the operation serves as input to another operation via composition of functions. For example, suppose we wish to

compute the perimeter of all the objects in a given region. Clearly, each object's perimeter should only be computed once. Eliminating the duplicates is a serious issue (see [1] for a discussion of how to deal with this problem for a collection of line segment objects, and [2] for a collection of rectangle objects).

The first method based on disjointness partitions the embedding space into disjoint subspaces, and hence, the individual objects into subobjects, so that each subspace consists of disjoint subobjects. The subspaces are then aggregated and grouped in another structure, such as a B-tree, so that all subsequent groupings are disjoint at each level of the structure. The result is termed a k-d-B-tree [49]. The R^+-tree [56, 58] is a modification of the k-d-B-tree where at each level we replace the subspace by the minimum bounding rectangle of the subobjects or subtrees that it contains. The cell tree [25] is based on the same principle as the R^+-tree except that the collections of objects are bounded by minimum convex polyhedra instead of minimum bounding rectangles.

The R^+-tree (as well as the other related representations) is motivated by a desire to avoid overlap among the bounding rectangles. Each object is associated with all the bounding rectangles that it intersects. All bounding rectangles in the tree (with the exception of the bounding rectangles for the objects at the leaf nodes) are nonoverlapping.[5] The result is that there may be several paths starting at the root to the same object. This may lead to an increase in the height of the tree. However, retrieval time is sped up.

Figure 18.7 is an example of one possible R^+-tree for the collection of line segments in Fig. 18.5. This particular tree is of order (2,3) although in general it is not possible to guarantee that all nodes will always have a minimum of 2 entries. In particular, the expected B-tree performance guarantees are not valid (i.e., pages are not guaranteed to be m/M full) unless we are willing to perform very complicated record insertion and deletion procedures. Notice that line segment objects `c`, `h`, and `i` appear in two different nodes. Of course, other variants are possible since the R^+-tree is not unique.

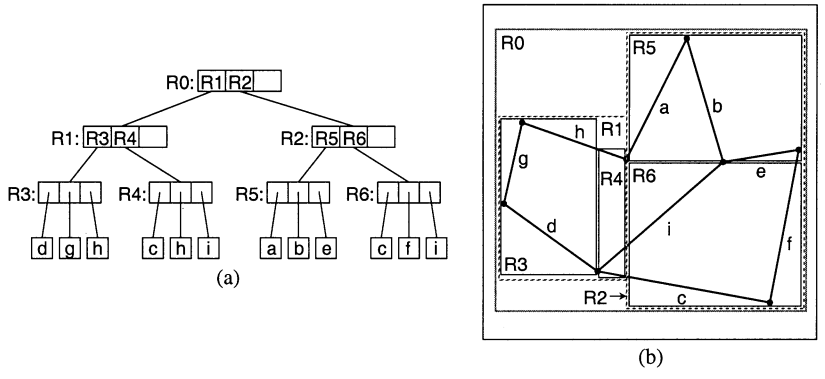

FIGURE 18.7 (a) R^+-tree for the collection of line segments in Fig.18.5 with $m = 2$ and $M = 3$, and (b) the spatial extents of the bounding rectangles. Notice that the leaf nodes in the index also store bounding rectangles, although this is only shown for the non-leaf nodes.

Methods such as the R^+-tree (as well as the R-tree) have the drawback that the decomposition is data-dependent. This means that it is difficult to perform tasks that require composition of different operations and data sets (e.g., set-theoretic operations such as overlay). The problem is that although these methods

[5] From a theoretical viewpoint, the bounding rectangles for the objects at the leaf nodes should also be disjoint However, this may be impossible (e.g., when the objects are line segments and if many of the line segments intersect at a point).

are good are distinguishing between occupied and unoccupied space in a particular image, they are unable to correlate occupied space in two distinct images, and likewise for unoccupied space in the two images.

In contrast, the remaining two approaches to the decomposition of space into disjoint cells have a greater degree of data-independence. They are based on a regular decomposition. The space can be decomposed either into blocks of uniform size (e.g., the uniform grid [19]) or adapt the decomposition to the distribution of the data (e.g., a quadtree-based approach such as [54]). In the former case, all the blocks are congruent (e.g., the 4×4 grid in Fig. 18.5). In the latter case, the widths of the blocks are restricted to be powers of two[6] and their positions are also restricted. Since the positions of the subdivision lines are restricted, and essentially the same for all images of the same size, it is easy to correlate occupied and unoccupied space in different images.

The uniform grid is ideal for uniformly distributed data, while quadtree-based approaches are suited for arbitrarily distributed data. In the case of uniformly distributed data, quadtree-based approaches degenerate to a uniform grid, albeit they have a higher overhead. Both the uniform grid and the quadtree-based approaches lend themselves to set-theoretic operations, and thus they are ideal for tasks that require the composition of different operations and data sets. In general, since spatial data are not usually uniformly distributed, the quadtree-based regular decomposition approach is more flexible. The drawback of quadtree-like methods is their sensitivity to positioning in the sense that the placement of the objects relative to the decomposition lines of the space in which they are embedded effects their storage costs and the amount of decomposition that takes place. This is overcome to a large extent by using a bucketing adaptation that decomposes a block only if it contains more than b objects.

18.4 Region Data

There are many ways of representing region data. We can represent a region either by its boundary (termed a **boundary-based representation**) or by its interior (termed an **interior-based representation**). In this section, we focus on representations of collections of regions by their interior. In some applications, regions are really objects that are composed of smaller primitive objects by use of geometric transformations and Boolean set operations. *Constructive solid geometry* (CSG) [48] is a term usually used to describe such representations. They are beyond the scope of this chapter. Instead, unless noted otherwise, our discussion is restricted to regions consisting of congruent cells of unit area (volume) with sides (faces) of unit size that are orthogonal to the coordinate axes.

Regions with arbitrary boundaries are usually represented by either using approximating bounding rectangles or more general boundary-based representations that are applicable to collections of line segments that do not necessarily form regions. In that case, we do not restrict the line segments to be perpendicular to the coordinate axes. Such representations are discussed in Section 18.6. It should be clear that although our presentation and examples in this section deal primarily with two-dimensional data, they are valid for regions of any dimensionality.

The region data is assumed to be uniform in the sense that all the cells that comprise each region are of the same type. In other words, each region is homogeneous. Of course, an image may consist of several distinct regions. Perhaps the best definition of a region is as a set of four-connected cells (i.e., in two dimensions, the cells are adjacent along an edge rather than a vertex) each of which is of the same type. For example, we may have a crop map where the regions correspond to the four-connected cells on which the same crop is grown. Each region is represented by the collection of cells that comprise it. The set of

[6] More precisely, for arbitrary attributes that can be locational and nonlocational, there exist $j \geq 0$ such that the product of w_i, the width of the block along attribute i, and 2^j is equal to the length of the range of values of attribute i.

collections of cells that make up all of the regions is often termed an *image array,* because of the nature in which they are accessed when performing operations on them. In particular, the array serves as an access structure in determining the region associated with a location of a cell as well as all remaining cells that comprise the region.

When the region is represented by its interior, then often we can reduce the storage requirements by aggregating identically valued cells into blocks. In the rest of this section we discuss different methods of aggregating the cells that comprise each region into blocks as well as the methods used to represent the collections of blocks that comprise each region in the image.

The collection of blocks is usually a result of a space decomposition process with a set of rules that guide it. There are many possible decompositions. When the decomposition is recursive, we have the situation that the decomposition occurs in stages and often, although not always, the results of the stages form a containment hierarchy. This means that a block b obtained in stage i is decomposed into a set of blocks b_j that span the same space. Blocks b_j are, in turn, decomposed in stage $i + 1$ using the same decomposition rule. Some decomposition rules restrict the possible sizes and shapes of the blocks as well as their placement in space. Some examples include

- Congruent blocks at each stage
- Similar blocks at all stages
- All sides of a block are of equal size
- All sides of each block are powers of two.

Other decomposition rules dispense with the requirement that the blocks be rectangular (i.e., there exist decompositions using other shapes such as triangles, etc.), while still others do not require that they be orthogonal, although, as stated before, we do make these assumptions here. In addition, the blocks may be disjoint or be allowed to overlap. Clearly, the choice is large. In the following, we briefly explore some of these decomposition processes. We restrict ourselves to disjoint decompositions, although this need not be the case (e.g., the field tree [18]).

The most general decomposition permits aggregation along all dimensions. In other words, the decomposition is arbitrary. The blocks need not be uniform or similar. The only requirement is that the blocks span the space of the environment. The drawback of arbitrary decompositions is that there is little structure associated with them. This means that it is difficult to answer queries such as determining the region associated with a given point, besides exhaustive search through the blocks. Thus, we need an additional data structure known as an index or an access structure. A very simple decomposition rule that lends itself to such an index in the form of an array is one that partitions a d-dimensional space having coordinate axes x_i into d-dimensional blocks by use of h_i hyperplanes that are parallel to the hyperplane formed by $x_i = 0$ $(1 \leq i \leq d)$. The result is a collection of $\prod_{i=1}^{d}(h_i + 1)$ blocks. These blocks form a grid of irregular-sized blocks rather than congruent blocks. There is no recursion involved in the decomposition process. We term the resulting decomposition an *irregular grid,* as the partition lines are at arbitrary positions in contrast to a *uniform grid* [19] where the partition lines are positioned so that all of the resulting grid cells are congruent.

Although the blocks in the irregular grid are not congruent, we can still impose an array access structure by adding d access structures termed *linear scales.* The linear scales indicate the position of the partitioning hyperplanes that are parallel to the hyperplane formed by $x_i = 0$ $(1 \leq i \leq d)$. Thus, given a location l in space, say (a,b) in two-dimensional space, the linear scales for the x and y coordinate values indicate the column and row, respectively, of the array access structure entry which corresponds to the block that contains l. The linear scales are usually represented as one-dimensional arrays although they can be implemented using tree access structures such as binary search trees, range trees, segment trees, etc.

Perhaps the most widely known decompositions into blocks are those referred to by the general terms *quadtree* and **octree** [50, 51]. They are usually used to describe a class of representations for two- and three-dimensional data (and higher as well), respectively, that are the result of a recursive decomposition

of the environment (i.e., space) containing the regions into blocks (not necessarily rectangular) until the data in each block satisfies some condition (e.g., with respect to its size, the nature of the regions that comprise it, the number of regions in it, etc.). The positions and/or sizes of the blocks may be restricted or arbitrary. It is interesting to note that quadtrees and octrees may be used with both interior-based and boundary-based representations, although only the former are discussed in this section.

There are many variants of quadtrees and octrees (see also Sections 18.2, 18.5, and 18.6), and they are used in numerous application areas including high energy physics, VLSI, finite element analysis, and many others. Below, we focus on *region quadtrees* [35] and to a lesser extent on *region octrees* [32, 43] They are specific examples of interior-based representations for two- and three-dimensional region data (variants for data of higher dimension also exist), respectively, that permit further aggregation of identically-valued cells.

Region quadtrees and region octrees are instances of a restricted-decomposition rule where the environment containing the regions is recursively decomposed into four or eight, respectively, rectangular congruent blocks until each block is either completely occupied by a region or is empty (such a decomposition process is termed *regular*). For example, Fig. 18.8(a) is the block decomposition for the region quadtree corresponding to three regions A, B, and C. Notice that in this case, all the blocks are square, have sides whose size is a power of 2, and are located at specific positions. In particular, assuming an origin at the upper-left corner of the image containing the regions, then the coordinate values of the upper-left corner of each block (e.g., (a, b) in two dimensions) of size $2^i \times 2^i$ satisfy the property that $a \bmod 2^i = 0$ and $b \bmod 2^i = 0$.

The traditional, and most natural, access structure for a region quadtree corresponding to a d-dimensional image is a tree with a fanout of 2^d [e.g., Fig. 18.8(b)]. Each leaf node in the tree corresponds to a different block b and contains the identity of the region associated with b. Each non-leaf node f corresponds to a block whose volume is the union of the blocks corresponding to the 2^d sons of f. In this case, the tree is a containment hierarchy and closely parallels the decomposition in the sense that they are both recursive processes and the blocks corresponding to nodes at different depths of the tree are similar in shape.

Determining the region associated with a given point p is achieved by a process that starts at the root of the tree and traverses the links to the sons whose corresponding blocks contain p. This process has an $O(m)$ cost where the image has a maximum of m levels of subdivision (e.g., an image all of whose sides are of length 2^m).

Observe that using a tree with fanout 2^d as an access structure for a regular decomposition means that there is no need to record the size and location of the blocks as this information can be inferred

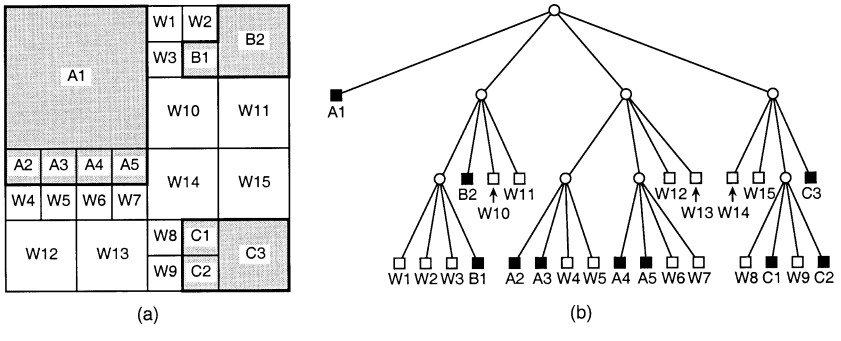

FIGURE 18.8 (a) Block decomposition and (b) its tree representation for the region quadtree corresponding to a collection of three regions A, B, and C.

from knowledge of the size of the underlying space. This is because the 2^d blocks that result from each subdivision step are congruent. For example, in two dimensions, each level of the tree corresponds to a quartering process that yields four congruent blocks. Thus, as long as we start from the root, we know the location and size of every block.

One of the motivations for the development of data structures such as the region quadtree is a desire to save space. The formulation of the region quadtree that we have just described makes use of an access structure in the form of a tree. This requires additional overhead to encode the internal nodes of the tree as well as the pointers to the subtrees. In order to further reduce the space requirements, a number of alternative access structures to the tree with fanout 2^d have been proposed. They are all based on finding a mapping from the domain of the blocks to a subset of the integers (i.e., to one dimension) and then using the result of the mapping as the index in one of the familiar tree-like access structures (e.g., a binary search tree, range tree, B^+-tree, etc.). The effect of these mappings is to provide an ordering on the underlying space. There are many possible orderings (e.g., Chapter 2 in [50]), with the most popular shown in Fig. 18.9. The domain of these mappings is the location of the cells in the underlying space, and thus we need to use some easily identifiable cell in each block such as the one in the block's upper-left corner. Of course, we also need to know the size of each block. This information can be recorded in the actual index as each block is uniquely identified by the location of the cell in its upper-left corner.

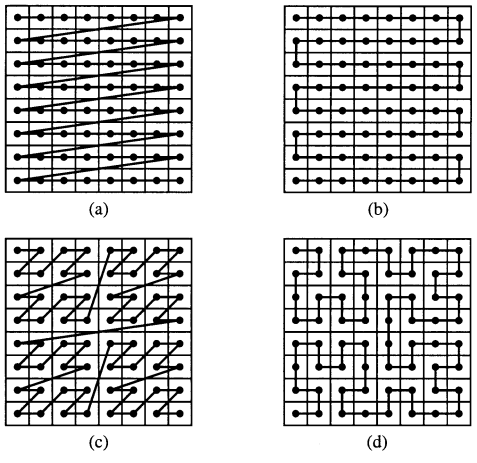

FIGURE 18.9 The result of applying four common different space-ordering methods to an 8×8 collection of cells whose first element is in the upper-left corner: (a) row order, (b) row-prime order, (c) Morton order, (d) Peano–Hilbert.

Since the size of each block b in the region quadtree can be specified with a single number indicating the depth in the tree at which b is found, we can simplify the representation by incorporating the size into the mapping. One mapping simply concatenates the result of interleaving the binary representations of the coordinate values of the upper-left corner (e.g., (a, b) in two dimensions) and i of each block of size 2^i so that i is at the right. The resulting number is termed a *locational code* and is a variant of the Morton order [Fig. 18.9(c)]. Assuming such a mapping and sorting the locational codes in increasing order yields an ordering equivalent to that which would be obtained by traversing the leaf nodes (i.e., blocks) of the tree representation [e.g., Fig. 18.8(b)] in the order `NW`, `NE`, `SW`, `SE`. The Morton ordering [as well as the Peano–Hilbert ordering shown in Fig. 18.9(d)] is particularly attractive for quadtree-like block decompositions, because all cells within a quadtree block appear in consecutive positions in the

ordering. Alternatively, these two orders exhaust a quadtree block before exiting it. Therefore, once again, determining the region associated with point p consists of simply finding the block containing p.

As the dimensionality of the space (i.e., d) increases, each level of decomposition in the region quadtree results in many new blocks as the fanout value 2^d is high. In particular, it is too large for a practical implementation of the tree access structure. In this case, an access structure termed a *bintree* [36, 53, 60] with a fanout value of 2 is used. The bintree is defined in a manner analogous to the region quadtree except that at each subdivision stage, the space is decomposed into two equal-sized parts. In two dimensions, at odd stages we partition along the y axis and at even stages we partition along the x axis. In general, in the case of d dimensions, we cycle through the different axes every d levels in the bintree.

The region quadtree, as well as the bintree, is a regular decomposition. This means that the blocks are congruent—that is, at each level of decomposition, all of the resulting blocks are of the same shape and size. We can also use decompositions where the sizes of the blocks are not restricted in the sense that the only restriction is that they be rectangular and be a result of a recursive decomposition process. In this case, the representations that we described must be modified so that the sizes of the individual blocks can be obtained. An example of such a structure is an adaptation of the point quadtree [17] to regions. Although the point quadtree was designed to represent points in a higher dimensional space, the blocks resulting from its use to decompose space do correspond to regions. The difference from the region quadtree is that in the point quadtree, the positions of the partitions are arbitrary, whereas they are a result of a partitioning process into 2^d congruent blocks (e.g., quartering in two dimensions) in the case of the region quadtree.

As in the case of the region quadtree, as the dimensionality d of the space increases, each level of decomposition in the point quadtree results in many new blocks since the fanout value 2^d is high. In particular, it is too large for a practical implementation of the tree access structure. In this case, we can adapt the k-d tree [7], which has a fanout value of 2, to regions. As in the point quadtree, although the k-d tree was designed to represent points in a higher dimensional space, the blocks resulting from its use to decompose space do correspond to regions. Thus, the relationship of the k-d tree to the point quadtree is the same as the relationship of the bintree to the region quadtree. In fact, the k-d tree is the precursor of the bintree and its adaptation to regions is defined in a similar manner in the sense that for d-dimensional data we cycle through the d axes every d levels in the k-d tree. The difference is that in the k-d tree, the positions of the partitions are arbitrary, whereas they are a result of a halving process in the case of the bintree.

The k-d tree can be further generalized so that the partitions take place on the various axes at an arbitrary order, and, in fact, the partitions need not be made on every coordinate axis. The k-d tree is a special case of the *BSP tree* (denoting *binary space partitioning*) [23] where the partitioning hyperplanes are restricted to be parallel to the axes, whereas in the BSP tree they have an arbitrary orientation. The BSP tree is a binary tree. In order to be able to assign regions to the left and right subtrees, we need to associate a direction with each subdivision line. In particular, the subdivision lines are treated as separators between two halfspaces.[7] Let the subdivision line have the equation $a \cdot x + b \cdot y + c = 0$. We say that the right subtree is the "positive" side and contains all subdivision lines formed by separators that satisfy $a \cdot x + b \cdot y + c \geq 0$. Similarly, we say that the left subtree is "negative" and contains all subdivision lines formed by separators that satisfy $a \cdot x + b \cdot y + c < 0$. As an example, consider Fig. 18.10(a), which is an arbitrary space decomposition whose BSP tree is given in Fig. 18.10(b). Notice the use of arrows to indicate the direction of the positive halfspaces. The BSP tree is used in computer graphics to facilitate viewing.

[7] A (linear) *halfspace* in d-dimensional space is defined by the inequality $\Sigma_{i=0}^{d} a_i \cdot x_i \geq 0$ on the $d+1$ homogeneous coordinates ($x_0 = 1$). The halfspace is represented by a column vector a. In vector notation, the inequality is written as $a \cdot x \geq 0$. In the case of equality, it defines a hyperplane with a as its normal. It is important to note that halfspaces are volume elements; they are not boundary elements.

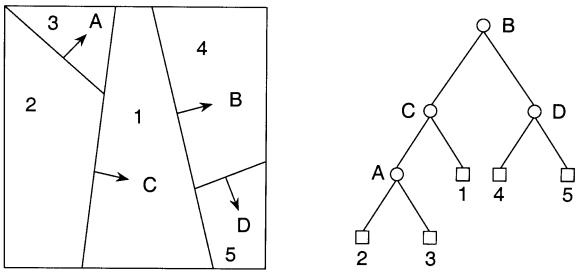

FIGURE 18.10 (a) An arbitrary space decomposition and (b) its BSP tree. The arrows indicate the direction of the positive halfspaces.

As mentioned before, the various hierarchical data structures that we described can also be used to represent regions in three dimensions and higher. As an example, we briefly describe the region octree which is the three-dimensional analog of the region quadtree. It is constructed in the following manner. We start with an image in the form of a cubical volume and recursively subdivide it into eight congruent disjoint cubes (called octants) until blocks are obtained of a uniform color or a predetermined level of decomposition is reached. Figure 18.11(a) is an example of a simple three-dimensional object whose region octree block decomposition is given in Fig. 18.11(b) and whose tree representation is given in Fig. 18.11(c).

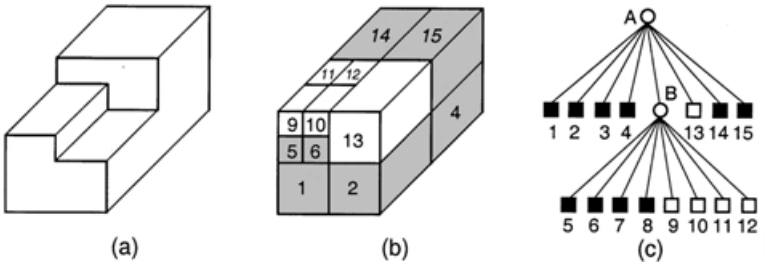

FIGURE 18.11 (a) Example three-dimensional object; (b) its region octree block decomposition; and (c) its tree representation.

The aggregation of cells into blocks in region quadtrees and region octrees is motivated, in part, by a desire to save space. Some of the decompositions have quite a bit of structure, thereby leading to inflexibility in choosing partition lines, etc. In fact, at times, maintaining the original image with an array access structure may be more effective from the standpoint of storage requirements. In the following, we point out some important implications of the use of these aggregations. In particular, we focus on the region quadtree and region octree. Similar results could also be obtained for the remaining block decompositions.

The aggregation of similarly valued cells into blocks has an important effect on the execution time of the algorithms that make use of the region quadtree. In particular, most algorithms that operate on images represented by a region quadtree are implemented by a preorder traversal of the quadtree, and thus their execution time is generally a linear function of the number of nodes in the quadtree. A key to the analysis of the execution time of quadtree algorithms is the **Quadtree Complexity Theorem** [32], which states that the number of nodes in a region quadtree representation for a simple polygon (i.e., with nonintersecting edges and without holes) is $O(p+q)$ for a $2^q \times 2^q$ image with perimeter p measured in terms of the

width of unit-sized cells (i.e., pixels). In all but the most pathological cases (e.g., a small square of unit width centered in a large image), the q factor is negligible, and thus, the number of nodes is $O(p)$.

The Quadtree Complexity Theorem also holds for three-dimensional data [42] (i.e., represented by a region octree) where perimeter is replaced by surface area, as well as for objects of higher dimensions d for which it is proportional to the size of the $(d-1)$-dimensional interfaces between these objects. The most important consequence of the Quadtree complexity theorem is that it means that most algorithms that execute on a region quadtree representation of an image, instead of one that simply imposes an array access structure on the original collection of cells, usually have an execution time that is proportional to the number of blocks in the image rather than the number of unit-sized cells. In its most general case, this means that the use of the region quadtree, with an appropriate access structure, in solving a problem in d-dimensional space will lead to a solution whose execution time is proportional to the $(d-1)$-dimensional space of the surface of the original d-dimensional image. On the other hand, use of the array access structure on the original collection of cells results in a solution whose execution time is proportional to the number of cells that comprise the image. Therefore, region quadtrees and region octrees act like dimension-reducing devices.

18.5 Rectangle Data

The rectangle data type lies somewhere between the point and region data types. It can also be viewed as a special case of the region data type in the sense that it is a region with only four sides. Rectangles are often used to approximate other objects in an image for which they serve as the minimum rectilinear enclosing object. For example, bounding rectangles are used in cartographic applications to approximate objects such as lakes, forests, hills, etc. In such a case, the approximation gives an indication of the existence of an object. Of course, the exact boundaries of the object are also stored; but they are only accessed if greater precision is needed. For such applications, the number of elements in the collection is usually small, and most often the sizes of the rectangles are of the same order of magnitude as the space from which they are drawn.

Rectangles are also used in VLSI design rule checking as a model of chip components for the analysis of their proper placement. Again, the rectangles serve as minimum enclosing objects. In this application, the size of the collection is quite large (e.g., millions of components) and the sizes of the rectangles are several orders of magnitude smaller than the space from which they are drawn.

It should be clear that the actual representation that is used depends heavily on the problem environment. At times, the rectangle is treated as the Cartesian product of two one-dimensional intervals with the horizontal intervals being treated in a different manner than the vertical intervals. In fact, the representation issue is often reduced to one of representing intervals. For example, this is the case in the use of the plane-sweep paradigm [47] in the solution of rectangle problems such as determining all pairs of intersecting rectangles. In this case, each interval is represented by its left and right endpoints. The solution makes use of two passes.

The first pass sorts the rectangles in ascending order on the basis of their left and right sides (i.e., x coordinate values) and forms a list. The second pass sweeps a vertical scan line through the sorted list from left to right halting at each one of these points, say p. At any instant, all rectangles that intersect the scan line are considered *active* and are the only ones whose intersection needs to be checked with the rectangle associated with p. This means that each time the sweep line halts, a rectangle either becomes active (causing it to be inserted in the set of active rectangles) or ceases to be active (causing it to be deleted from the set of active rectangles). Thus, the key to the algorithm is its ability to keep track of the active rectangles (actually just their vertical sides) as well as to perform the actual one-dimensional intersection test.

Data structures such as the segment tree [8], interval tree [14], and the priority search tree [41] can be used to organize the vertical sides of the active rectangles so that, for N rectangles and F intersecting

pairs of rectangles, the problem can be solved in $O(N \cdot \log_2 N + F)$ time. All three data structures enable intersection detection, insertion, and deletion to be executed in $O(\log_2 N)$ time. The difference between them is that the segment tree requires $O(N \cdot \log_2 N)$ space while the interval tree and the priority search tree only need $O(N)$ space.

The key to the use of the priority search tree to solve the rectangle intersection problem is that it treats each vertical side (y_B, y_T) as a point (x, y) in a two-dimensional space (i.e., it transforms the corresponding interval into a point as discussed in Section 18.1). The advantage of the priority search tree is that the storage requirements for the second pass only depend on the maximum number M of vertical sides that can be active at any one time. This is achieved by implementing the priority search tree as a red-black balanced binary tree [24], thereby guaranteeing updates in $O(\log_2 M)$ time. This also has an effect on the execution time of the second pass which is $O(N \cdot \log_2 M + F)$ instead of $O(N \cdot \log_2 N + F)$. Of course, the first pass which must sort the endpoints of the horizontal sides still takes $O(N \cdot \log_2 N)$ time for all three representations.

Most importantly, the priority search tree enables a more dynamic solution than either the segment or interval trees as only the endpoints of the horizontal sides need to be known in advance. On the other hand, for the segment and interval trees, the endpoints of both the horizontal and vertical sides must be known in advance. Of course, in all cases, all solutions based on the plane-sweep paradigm are inherently not dynamic as the paradigm requires that we examine all of the data one by one. Thus, the addition of even one new rectangle to the database forces the re-execution of the algorithm on the entire database.

In this chapter, we are primarily interested in dynamic problems. The data structures that are chosen for the collection of the rectangles are differentiated by the way in which each rectangle is represented. One representation discussed in Section 18.1 reduces each rectangle to a point in a higher dimensional space, and then treats the problem as if we have a collection of points [28]. Again, each rectangle is a Cartesian product of two one-dimensional intervals where the difference from its use with the plane-sweep paradigm is that each interval is represented by its centroid and extent. Each set of intervals in a particular dimension is, in turn, represented by a grid file [45], which is described in Section 18.2.

The second representation is region-based in the sense that the subdivision of the space from which the rectangles are drawn depends on the physical extent of the rectangle — not just one point. Representing the collection of rectangles, in turn, with a tree-like data structure has the advantage that there is a relation between the depth of node in the tree and the size of the rectangle(s) that is (are) associated with it. Interestingly, some of the region-based solutions make use of the same data structures that are used in the solutions based on the plane-sweep paradigm.

There are three types of region-based solutions currently in use. The first two solutions use the R-tree and the R^+-tree (discussed in Section 18.3) to store rectangle data (in this case the objects are rectangles instead of arbitrary objects). The third is a quadtree-based approach and uses the MX-CIF quadtree [34].

In the *MX-CIF quadtree,* each rectangle is associated with the quadtree node corresponding to the smallest block which contains it in its entirety. Subdivision ceases whenever a node's block contains no rectangles. Alternatively, subdivision can also cease once a quadtree block is smaller than a predetermined threshold size. This threshold is often chosen to be equal to the expected size of the rectangle [34]. For example, Fig. 18.12 is the MX-CIF quadtree for a collection of rectangles. Rectangles can be associated with both terminal and nonterminal nodes.

It should be clear that more than one rectangle can be associated with a given enclosing block, and thus, often we find it useful to be able to differentiate between them. This is done in the following manner [34]. Let P be a quadtree node with centroid (CX,CY), and let S be the set of rectangles that are associated with P. Members of S are organized into two sets according to their intersection (or collinearity of their sides) with the lines passing through the centroid of P's block—that is, all members of S that intersect the line $x = CX$ form one set and all members of S that intersect the line $y = CY$ form the other set.

If a rectangle intersects both lines (i.e., it contains the centroid of P's block), then we adopt the convention that it is stored with the set associated with the line through $x = CX$. These subsets are implemented as binary trees (really tries), which in actuality are one-dimensional analogs of the MX-CIF quadtree. For

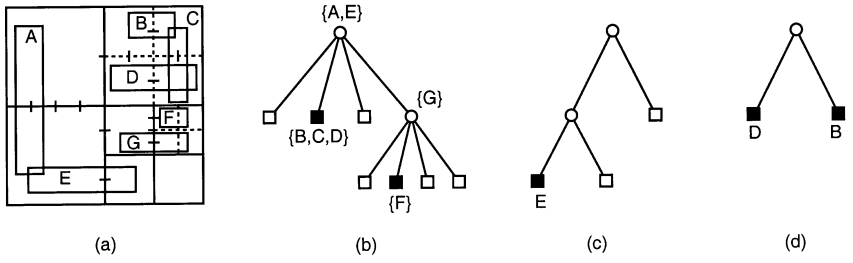

FIGURE 18.12 (a) Collection of rectangles and the block decomposition induced by the MX-CIF quadtree; (b) the tree representation of (a); (c) the binary trees for the y axes passing through the root of the tree in (b), and (d) the NE son of the root of the tree in (b).

example, Fig. 18.12(b) and Fig. 18.12(d) illustrate the binary trees associated with the y axes passing through the root and the NE son of the root, respectively, of the MX-CIF quadtree of Fig. 18.12(c). Interestingly, the MX-CIF quadtree is a two-dimensional analog of the interval tree described above. More precisely, the MX-CIF is a two-dimensional analog of the tile tree [40] which is a regular decomposition version of the interval tree. In fact, the tile tree and the one-dimensional MX-CIF quadtree are identical when rectangles are not allowed to overlap.

18.6 Line Data and Boundaries of Regions

Section 18.4 was devoted to variations on hierarchical decompositions of regions into blocks, an approach to region representation that is based on a description of the region's interior. In this section, we focus on representations that enable the specification of the boundaries of regions, as well as curvilinear data and collections of line segments. The representations are usually based on a series of approximations which provide successively closer fits to the data, often with the aid of bounding rectangles. When the boundaries or line segments have a constant slope (i.e., linear and termed *line segments* in the rest of this discussion), then an exact representation is possible.

There are several ways of approximating a curvilinear line segment. The first is by digitizing it and then marking the unit-sized cells (i.e., pixels) through which it passes. The second is to approximate it by a set of straight line segments termed a *polyline*. Assuming a boundary consisting of straight lines (or polylines after the first stage of approximation), the simplest representation of the boundary of a region is the polygon. It consists of vectors which are usually specified in the form of lists of pairs of x and y coordinate values corresponding to their start and end points. The vectors are usually ordered according to their connectivity. One of the most common representations is the chain code [21], which is an approximation of a polygon's boundary by use of a sequence of unit vectors in the four (and sometimes eight) principal directions.

Chain codes, and other polygon representations, break down for data in three dimensions and higher. This is primarily due to the difficulty in ordering their boundaries by connectivity. The problem is that in two dimensions connectivity is determined by ordering the boundary elements $e_{i,j}$ of boundary b_i of object o so that the end vertex of the vector v_j corresponding to $e_{i,j}$ is the start vertex of the vector v_{j+1} corresponding to $e_{i,j+1}$. Unfortunately, such an implicit ordering does not exist in higher dimensions as the relationship between the boundary elements associated with a particular object are more complex.

Instead, we must make use of data structures that capture the topology of the object in terms of its faces, edges, and vertices. The winged-edge data structure is one such representation that serves as the basis of the boundary model (also known as *BRep* [5]). Such representations are not discussed further here.

Polygon representations are very local. In particular, if we are at one position on the boundary, we don't know anything about the rest of the boundary without traversing it element by element. Thus, using such

representations, given a random point in space, it is very difficult to find the nearest line to it as the lines are not sorted. This is in contrast to hierarchical representations which are global in nature. They are primarily based on rectangular approximations to the data as well as on a regular decomposition in two dimensions. In the rest of this section, we discuss a number of such representations.

In Section 18.3 we already examined two hierarchical representations (i.e., the R-tree and the R^+-tree) that propagate object approximations in the form of bounding rectangles. In this case, the sides of the bounding rectangles had to be parallel to the coordinate axes of the space from which the objects are drawn. In contrast, the *strip tree* [4] is a hierarchical representation of a single curve that successively approximates segments of it with bounding rectangles that does not require that the sides be parallel to the coordinate axes. The only requirement is that the curve be continuous; it need not be differentiable.

The strip tree data structure consists of a binary tree whose root represents the bounding rectangle of the entire curve. The rectangle associated with the root corresponds to a rectangular strip, that encloses the curve, whose sides are parallel to the line joining the endpoints of the curve. The curve is then partitioned in two at one of the locations where it touches the bounding rectangle (these are not tangent points as the curve only needs to be continuous; it need not be differentiable). Each subcurve is then surrounded by a bounding rectangle and the partitioning process is applied recursively. This process stops when the width of each strip is less than a predetermined value.

In order to be able to cope with more complex curves such as those that arise in the case of object boundaries, the notion of a strip tree must be extended. In particular, closed curves and curves that extend past their endpoints require some special treatment. The general idea is that these curves are enclosed by rectangles which are split into two rectangular strips, and from now on the strip tree is used as before.

The strip tree is similar to the point quadtree in the sense that the points at which the curve is decomposed depend on the data. In contrast, a representation based on the region quadtree has fixed decomposition points. Similarly, strip tree methods approximate curvilinear data with rectangles of arbitrary orientation, while methods based on the region quadtree achieve analogous results by use of a collection of disjoint squares having sides of length power of two. In the following we discuss a number of adaptations of the region quadtree for representing curvilinear data.

The simplest adaptation of the region quadtree is the MX quadtree [32, 33]. It is built by digitizing the line segments and labeling each unit-sized cell (i.e., pixel) through which it passes as of type `boundary`. The remaining pixels are marked `WHITE` and are merged, if possible, into larger and larger quadtree blocks. Figure 18.13(a) is the MX quadtree for the collection of line segment objects in Fig. 18.5. A drawback of the MX quadtree is that it associates a thickness with a line. Also, it is difficult to detect the presence of a vertex whenever five or more line segments meet.

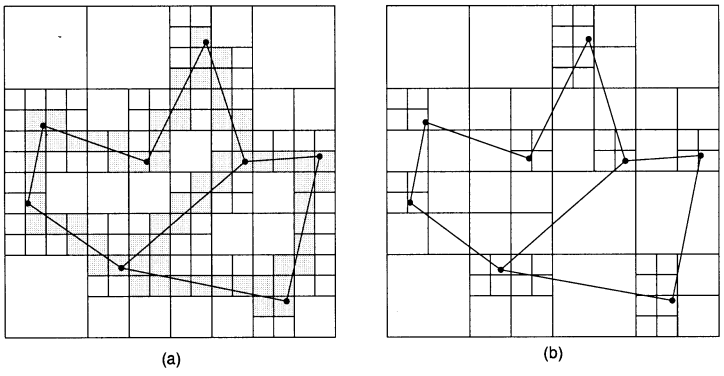

FIGURE 18.13 (a) MX quadtree and (b) edge quadtree for the collection of line segments of Fig.18.5.

The edge quadtree [57, 61] is a refinement of the MX quadtree based on the observation that the number of squares in the decomposition can be reduced by terminating the subdivision whenever the square contains a single curve that can be approximated by a single straight line. For example, Fig. 18.13(b) is the edge quadtree for the collection of line segment objects in Fig. 18.5. Applying this process leads to quadtrees in which long edges are represented by large blocks or a sequence of large blocks. However, small blocks are required in the vicinity of corners or intersecting edges. Of course, many blocks will contain no edge information at all.

The PM quadtree family [44, 54] (see also edge-EXCELL [59]) represents an attempt to overcome some of the problems associated with the edge quadtree in the representation of collections of polygons (termed *polygonal maps*). In particular, the edge quadtree is an approximation because vertices are represented by pixels. There are a number of variants of the PM quadtree. These variants are either vertex-based or edge-based. They are all built by applying the principle of repeatedly breaking up the collection of vertices and edges (forming the polygonal map) until obtaining a subset that is sufficiently simple so that it can be organized by some other data structure.

The PM_1 quadtree [54] is an example of a vertex-based PM quadtree. Its decomposition rule stipulates that partitioning occurs as long as a block contains more than one line segment unless the line segments are all incident at the same vertex which is also in the same block [e.g., Fig. 18.14(a)]. Given a polygonal map whose vertices are drawn from a grid (say $2^m \times 2^m$), and where edges are not permitted to intersect at points other than the grid points (i.e., vertices), it can be shown that the maximum depth of any leaf node in the PM_1 quadtree is bounded from above by $4m + 1$ [52]. This enables a determination of the maximum amount of storage that will be necessary for each node.

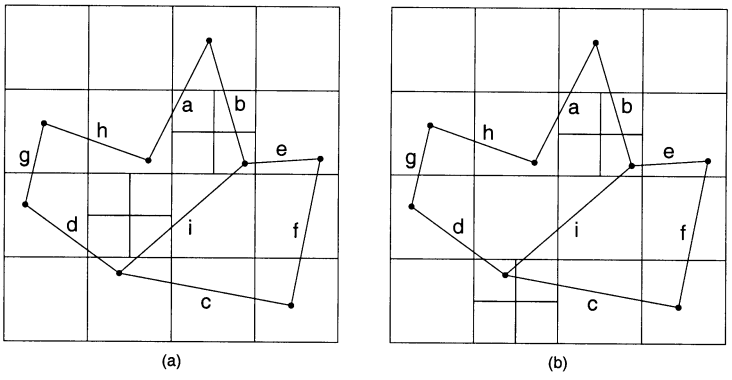

FIGURE 18.14 (a) PM_1 quadtree and (b) PMR quadtree for the collection of line segments of Fig. 18.5.

A similar representation has been devised for three-dimensional images (e.g., [3] and the references cited in [51]). The decomposition criteria are such that no node contains more than one face, edge, or vertex unless the faces all meet at the same vertex or are adjacent to the same edge. This representation is quite useful, since its space requirements for polyhedral objects are significantly smaller than those of a region octree.

The PMR quadtree [44] is an edge-based variant of the PM quadtree. It makes use of a probabilistic splitting rule. A node is permitted to contain a variable number of line segments. A line segment is stored in a PMR quadtree by inserting it into the nodes corresponding to all the blocks that it intersects. During this process, the occupancy of each node that is intersected by the line segment is checked to see if the insertion causes it to exceed a predetermined *splitting threshold.* If the splitting threshold is exceeded, then the node's block is split *once,* and only once, into four equal quadrants.

For example, Fig. 18.14(b) is the PMR quadtree for the collection of line segment objects in Fig. 18.5 with a splitting threshold value of 2. The line segments are inserted in alphabetic order (i.e., a–i). It should be clear that the shape of the PMR quadtree depends on the order in which the line segments are inserted. Note the difference from the PM_1 quadtree in Fig. 18.14(a)—that is, the NE block of the SW quadrant is decomposed in the PM_1 quadtree while the SE block of the SW quadrant is not decomposed in the PM_1 quadtree.

On the other hand, a line segment is deleted from a PMR quadtree by removing it from the nodes corresponding to all the blocks that it intersects. During this process, the occupancy of the node and its siblings is checked to see if the deletion causes the total number of line segments in them to be less than the predetermined splitting threshold. If the splitting threshold exceeds the occupancy of the node and its siblings, then they are merged and the merging process is reapplied to the resulting node and its siblings. Notice the asymmetry between the splitting and merging rules.

The PMR quadtree is very good for answering queries such as finding the nearest line to a given point [29, 30] (see [31] for an empirical comparison with hierarchical object representations such as the R-tree and R^+-tree). It is preferred over the PM_1 quadtree (as well as the MX and edge quadtrees) as it results in far fewer subdivisions. In particular, in the PMR quadtree there is no need to subdivide in order to separate line segments that are very "close" or whose vertices are very "close," which is the case for the PM_1 quadtree. This is important, since four blocks are created at each subdivision step. Thus, when many subdivision steps that occur in the PM_1 quadtree result in creating many empty blocks, the storage requirements of the PM_1 quadtree will be considerably higher than those of the PMR quadtree. Generally, as the splitting threshold is increased, the storage requirements of the PMR quadtree decrease while the time necessary to perform operations on it will increase.

Using a random image model and geometric probability, it has been shown [39], theoretically and empirically using both random and real map data, that for sufficiently high values of the splitting threshold (i.e., ≥ 4), the number of nodes in a PMR quadtree is asymptotically proportional to the number of line segments and is independent of the maximum depth of the tree. In contrast, using the same model, the number of nodes in the PM_1 quadtree is a product of the number of lines and the maximal depth of the tree (i.e., n for a $2^n \times 2^n$ image). The same experiments and analysis for the MX quadtree confirmed the results predicted by the Quadtree complexity theorem (see Section 18.4), which is that the number of nodes is proportional to the total length of the line segments.

Observe that although a bucket in the PMR quadtree can contain more line segments than the splitting threshold, this is not a problem. In fact, it can be shown [51] that the maximum number of line segments in a bucket is bounded by the sum of the splitting threshold and the depth of the block (i.e., the number of times the original space has been decomposed to yield this block).

18.7 Research Issues and Summary

A review has been presented of a number of representations of multidimensional data. Our focus has been on multidimensional spatial data with extent rather than just multidimensional point data. Moreover, the multidimensional data was not restricted to locational attributes in that the handling of nonlocational attributes for point data was also described. There has been a particular emphasis on hierarchical representations. Such representations are based on the "divide-and-conquer" problem-solving paradigm. They are of interest because they enable focusing computational resources on the interesting subsets of data. Thus, there is no need to expend work where the payoff is small. Although many of the operations for which they are used can often be performed equally as efficiently, or more so, with other data structures, hierarchical data structures are attractive because of their conceptual clarity and ease of implementation.

When the hierarchical data structures are based on the principle of regular decomposition, we have the added benefit that different data sets (often of differing types) are in registration. This means that they are partitioned in known positions that are often the same or subsets of one another for the different data

sets. This is true for all the features including regions, points, rectangles, lines, volumes, etc. This means that a query such as "finding all cities with more than 20,000 inhabitants in wheat growing regions within 30 miles of the Mississippi River" can be executed by simply overlaying the region (crops), point (i.e., cities), and river maps even though they represent data of different types. Alternatively, we may extract regions such as those within 30 miles of the Mississippi River. Such operations find use in applications involving spatial data such as geographic information systems.

Current research in multidimensional representations is highly application-dependent in the sense that the work is driven by the application. Many of the recent developments have been motivated by the interaction with databases. The choice of a proper representation plays a key role in the speed with which responses are provided to queries. Knowledge of the underlying data distribution is also a factor and research is ongoing to make use of this information in the process of making a choice. Most of the initial applications in which the representation of multidimensional data has been important have involved spatial data of the kind described in this chapter. Such data is intrinsically of low dimensionality (i.e., two and three). Future applications involve higher dimensional data for applications such as image databases where the data are often points in feature space. The incorporation of the time dimension is also an important issue that confronts many database researchers.

18.8 Defining Terms

Bintree: A regular decomposition k-d tree for region data.

Boundary-based representation: A representation of a region that is based on its boundary.

Bucketing methods: Data organization methods that decompose the space from which spatial data is drawn into regions called buckets. Some conditions for the choice of region boundaries include the number of objects that they contain or on their spatial layout (e.g., minimizing overlap or coverage).

Fixed-grid method: Space decomposition into rectangular cells by overlaying a grid on it. If the cells are congruent (i.e., of the same width, height, etc.), then the grid is said to be uniform.

Interior-based representation: A representation of a region that is based on its interior (i.e., the cells that comprise it).

K-d tree: General term used to describe space decomposition methods that proceed by recursive decomposition across a single dimension at a time of the space containing the data until some condition is met such as that the resulting blocks contain no more than b objects (e.g., points, lines, etc.) or that the blocks are homogeneous. The k-d tree is usually a data structure for points which cycles through the dimensions as it decomposes the underlying space.

Multidimensional data: Data that has several attributes. It includes records in a database management system, locations in space, and also spatial entities that have extent such as lines, regions, volumes, etc.

Octree: A quadtree-like decomposition for three dimensional data.

Quadtree: General term used to describe space decomposition methods that proceed by recursive decomposition across all the dimensions (technically two dimensions) of the space containing the data until some condition is met such as that the resulting blocks contain no more than b objects (e.g., points, lines, etc.) or that the blocks are homogeneous (e.g., region data). The underlying space is not restricted to two-dimensions although this is the technical definition of the term. The result is usually a disjoint decomposition of the underlying space.

Quadtree complexity theorem: The number of nodes in a quadtree region representation for a simple polygon (i.e., with nonintersecting edges and without holes) is $O(p+q)$ for a $2^q \times 2^q$ image with perimeter p measured in pixel widths. In most cases, q is negligible, and thus, the number of nodes is proportional to the perimeter. It also holds for three-dimensional data

where the perimeter is replaced by surface area, and in general for d-dimensions where instead of perimeter we have the size of the $(d-1)$-dimensional interfaces between the d-dimensional objects.

R-tree: An object hierarchy where associated with each element of the hierarchy is the minimum bounding rectangle of the union of the minimum bounding rectangles of the elements immediately below it. The elements at the deepest level of the hierarchy are groups of spatial objects. The result is usually a nondisjoint decomposition of the underlying space. The objects are aggregated on the basis of proximity and with the goal of minimizing coverage and overlap.

Regular decomposition: A space decomposition method that partitions the underlying space by recursively halving it across the various dimensions instead of permitting the partitioning lines to vary.

Further Information

It is impossible to give a complete enumeration of where research on multidimensional data structures is published, since it is often mixed with the application. Hands-on experience with some of the representations described in this chapter can be obtained by looking at the JAVA applets on `http://www.cs.umd.edu/~hjs/quadtree/index.html`. Multidimensional spatial data is covered in the texts by Samet [50, 51]. Their perspective is one from computer graphics, image processing, geographic information systems (GIS), databases, solid modeling, as well as VLSI design and computational geometry. A more direct computational geometry perspective can be found in the books by Edelsbrunner [16], Preparata and Shamos [47], and Overmars et al. [13].

New developments in the field of multidimensional data structures are reported in many different conferences, again since it is so application-driven. Some good starting pointers from the GIS perspective are the Symposium on Spatial Databases and the International Workshop on Spatial Data Handling, which are held in alternating years. From the standpoint of computational geometry, the annual ACM Symposium on Computational Geometry and the annual ACM-SIAM Symposium on Discrete Algorithms are good sources. From the perspective of databases, the annual ACM Conference on the Management of Data (SIGMOD) and the Very Large Database Conference (VLDB) usually contain a few papers dealing with the application of such representation. Other useful sources are the proceedings of the annual SIGGRAPH Conference.

Journals where such research appears are as varied as the applications. Theoretical results can be found in *SIAM Journal of Computing* while those from the GIS perspective may be found in a new journal called *GeoInformatica.* Many related articles are also found in the computer graphics and computer vision journals such as *ACM Transactions on Graphics,* the old *Computer Vision, Graphics and Image Processing,* which has been renamed *Graphical Models and Image Processing* and *Image Understanding,* and *IEEE Transactions on Pattern Analysis and Machine Intelligence.*

Computational Geometry I

D.T. Lee

Northwestern University

19.1 Introduction

Computational geometry, since its inception [42] in 1975, has received a great deal of attention from researchers in the area of design and analysis of algorithms. It has evolved into a discipline of its own. It is concerned with the computational complexity of geometric problems that arise in various disciplines such as pattern recognition, computer graphics, geographical information system, computer vision, **CAD/CAM,** robotics, VLSI layout, operations research, statistics, etc. In contrast with the classical approach to proving mathematical theorems about geometry-related problems, this discipline emphasizes the computational aspect of these problems and attempts to exploit the underlying geometric properties possible, e.g., the metric space, to derive efficient algorithmic solutions.

An objective of this discipline in the theoretical context is to study the computational complexity (giving lower bounds) of geometric problems, and to devise efficient algorithms (giving upper bounds) whose complexity preferably *matches* the lower bounds. That is, not only are we interested in the *intrinsic* difficulty of geometric computational problems under a certain computation model, but we are also concerned with the algorithmic solutions that are efficient or provably optimal in the worst or average case. In this regard, the **asymptotic time** (or **space**) **complexity** of an algorithm, i.e., the behavior of an algorithm, as the input size approaches infinity, is of interest. Due to its applications to various science and engineering related disciplines, researchers in this field have begun to address the *efficacy* of the algorithms, the issues concerning *robustness* and *numerical stability* [25, 50], and the actual running times of their implementations.

In this and the following chapter we concentrate mostly on the theoretical development of this field in the context of sequential computation, and discuss a number of typical topics and the algorithmic

approaches. We will adopt the *real* RAM (random access machine) model of computation in which all arithmetic operations, comparisons, kth-root, exponential or logarithmic functions take unit time.

19.2 Convex Hull

The convex hull of a set of points in $\Re^k$ is the most fundamental problem in computational geometry. Given is a set of points in $\Re^k$, and we are interested in computing its convex hull, which is defined to be the smallest convex set containing these points. There are two ways to represent a convex hull. An *implicit* representation is to list all the **extreme points,** whereas an *explicit* representation is to list all the extreme d-faces of dimensions $d = 0, 1, \ldots, k-1$. Thus, the complexity of any convex hull algorithm would have two parts, computation part and the output part. An algorithm is said to be *output-sensitive* if its complexity depends on the size of output.

Convex Hulls in Two and Three Dimensions

For an arbitrary set of n points in two and three dimensions, we can compute the convex hull using the *Graham scan, gift-wrapping* method, or *divide-and-conquer* paradigm, which are briefly described below.

Note that the convex hull of an arbitrary set of points in two dimensions is a convex polygon. We'll describe algorithms that compute the *upper hull* of S, since the convex hull is just the union of the *upper* and *lower hulls.* Let v_0 denote the point with minimum x-coordinate; if there are more than one, pick the one with the maximum y coordinate. Let v_{n-1} be similarly defined except that it denotes the point with the maximum x-coordinate. In two dimensions, the upper hull consists of two vertical lines passing through v_0 and v_{n-1} respectively and a sequence of edges, known as a *polygonal chain,* $\mathcal{C} = \{\overline{v_{j_{i-1}}, v_{j_i}} \mid i = 1, 2, \ldots, k\}$, where $v_{j_0} = v_0$ and $v_{j_k} = v_{n-1}$, such that the entire set S of points lies on one side of the lines $\mathcal{L}_i$ containing each edge $\overline{v_{j_{i-1}}, v_{j_i}}$. See Fig. 19.1(a) for an illustration of the upper hull. The lower hull is similarly defined.

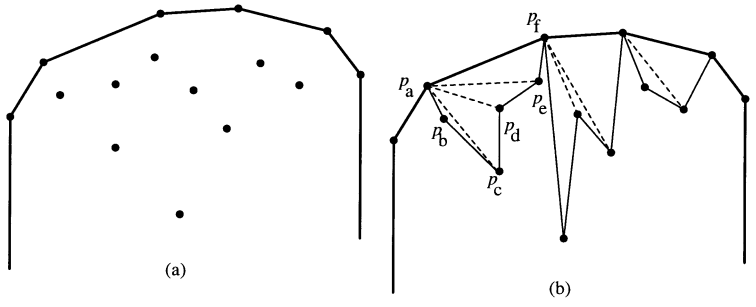

FIGURE 19.1 The upper hull of a set of points.

The *Graham scan* computes the convex hull by (i) sorting the input set of points in ascending order of their x-coordinates (in case of ties, in ascending order of their y-coordinates), (ii) connecting these points into a polygonal chain P stored as a doubly linked list L, and (iii) performing a linear scan to compute the upper hull of the polygon [42].

The triple (v_i, v_j, v_k) of points is said to form a *right* turn if and only if the determinant

$$\begin{vmatrix} x_i & y_i & 1 \\ x_j & y_j & 1 \\ x_k & y_k & 1 \end{vmatrix} < 0 ,$$

where (x_i, y_i) are the x- and y-coordinates of v_i. If the determinant is positive, then the triple (v_i, v_j, v_k)

of points is said to form a *left* turn. The points v_i, v_j, and v_k are *collinear* if the determinant is zero. This is also known as the **side test,** determining on which side of the line defined by points v_i and v_j the point v_k lies.

It is obvious that when we scan points in L in ascending order of x-coordinate, the middle point of a triple (v_i, v_j, v_k) that does not form a right turn is not on the upper hull and can be deleted. The following is the algorithm.

ALGORITHM GRAHAM_SCAN

Input: A set S of points sorted in lexicographically ascending order of their (x, y)-coordinate values.

Output: A sorted list L of points in ascending x-coordinates.

```
begin
    if (|S| == 2) return (v0, vn−1);
    i = 0; vn−1 =next(vn−1); /* set sentinel */
    pa = v0; pb =next(pa), pc =next(pb);
    while (pb ≠ vn−1) do
        if (pa, pb, pc) forms a right turn
        then begin /* advance */
                pa = pb; pb = pc;
                pc = next(pb);
             end
        else begin /* backtrack */
                delete pb;
                if (pa ≠ v0)
                then pa = prev(pa);
                pb = next(pa); pc = next(pb);
             end
    pt =next(v0);
    L = {v0, pt};
    while (pt ≠ vn−1) do
        begin
            pu =next(pt);
            L = L ∪ {pt, pu};
            pt = pu;
        end;
    return (L);
end.
```

Step (i) being the dominating step, ALGORITHM GRAHAM_SCAN, takes $O(n \log n)$ time. Figure 19.1(b) shows the initial list L and vertices not on the upper-hull are removed from L. For example, p_b is removed since (p_a, p_b, p_c) forms a left turn; p_c is removed since (p_a, p_c, p_d) forms a left turn; p_d, and p_e are removed for the same reason.

One can also use the *gift-wrapping* technique to compute the upper hull. Starting with a vertex that is known to be on the upper hull, say the point $v_0 = v_{i_0}$. We sweep clockwise the half-line emanating from v_0 in the direction of the positive y-axis. The first point v_{i_1} this half-line hits will be the next point on the upper hull. We then march to v_{i_1}, repeat the same process by sweeping clockwise the half-line emanating from v_{i_1} in the direction from v_{i_0} to v_{i_1}, and find the next vertex v_{i_2}. This process terminates when we reach v_{n-1}. This is similar to wrapping an object with a *rope.* Finding the next vertex takes time proportional to the number of points not yet known to be on the upper hull. Thus, the total time spent

is $O(n\mathcal{H})$, where $\mathcal{H}$ denotes the number of points on the upper hull. The gift-wrapping algorithm is output-sensitive, and is more efficient than the ALGORITHM GRAHAM_SCAN if the number of points on the upper hull is small, i.e., $o(\log n)$.

One can also compute the upper hull recursively by divide-and-conquer. This method is more amenable to parallelization. The divide-and-conquer paradigm consists of the following steps.

ALGORITHM UPPER_HULL_D&C (*2d-Point S*)

Input: A set S of points.

Output: A sorted list L of points in ascending x-coordinates.

1. If $|S| \leq 3$, compute the upper hull UH(S) explicitly and **return** (UH(S)).
2. Divide S by a vertical line $\mathcal{L}$ into two approximately equal subsets S_l and S_r such that S_l and S_r lie, respectively to the left and to the right of $\mathcal{L}$.
3. UH(S_l) = Upper_Hull_D&C(S_l).
4. UH(S_r) = Upper_Hull_D&C(S_r).
5. UH(S) =**Merge**($UH(S_l), UH(S_r)$).
6. **return** (UH(S)).

The key step is the **Merge** of two upper hulls, each of which is the solution to a subproblem derived from the recursive step. These two upper hulls are separated by a vertical line $\mathcal{L}$. The **Merge** step basically calls for computation of a common tangent, called *bridge* over line $\mathcal{L}$, of these two upper hulls (Fig. 19.2).

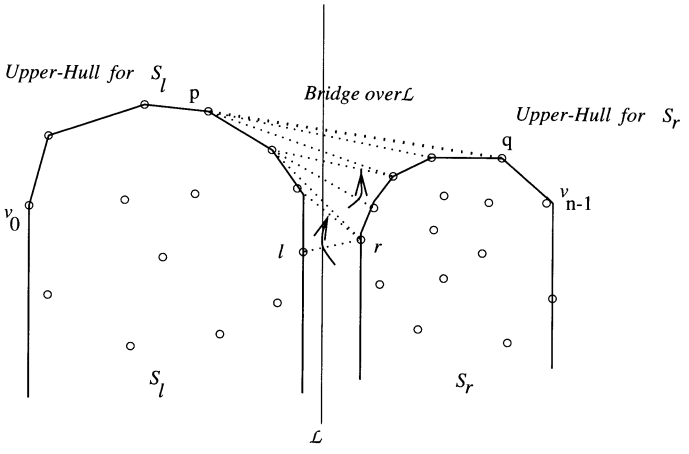

FIGURE 19.2 The bridge $\overline{p, q}$ over the vertical line $\mathcal{L}$.

The computation of the *bridge* begins with a segment connecting the rightmost point l of the left upper hull to the leftmost point r of the right upper hull, resulting in a sorted list L. Using the *Graham scan* one can obtain in *linear* time the two endpoints of the bridge, ($\overline{p, q}$ shown in Fig. 19.2), such that the entire set of points lies on one side of the line, called *supporting line,* containing the bridge. The running time of the divide-and-conquer algorithm is easily shown to be $O(n \log n)$ since the merge step can be done in $O(n)$ time.

A more sophisticated output-sensitive and *optimal* algorithm which runs in $O(n \log \mathcal{H})$ time has been developed by Kirkpatrick and Seidel [35]. It is based on a variation of the divide-and-conquer paradigm, called **divide-and-marriage-before-conquest** method. It has been shown to be asymptotically optimal; a lower bound proof of $\Omega(n \log \mathcal{H})$ can be found in [35]. The main idea in achieving the optimal result is that

of eliminating *redundant* computations. Observe that in the divide-and-conquer approach after the bridge is obtained, some vertices belonging to the left and right upper hulls that are *below* the bridge are deleted. Had we known that these vertices are not on the final hull, we could have saved time without computing them. Kirkpatrick and Seidel capitalized on this concept and introduced the **marriage-before-conquest** principle putting **Merge** step before the two recursive calls.

The divide-and-conquer scheme can be easily generalized to three dimensions. The merge step in this case calls for computing common supporting faces that *wrap* two recursively computed convex polyhedra. It is observed by Preparata and Shamos [42] that the common supporting faces are computed from connecting two *cyclic* sequences of edges, one on each polyhedron (Fig. 19.3). See [2] for a characterization of the two cycles of *seam* edges. The computation of these supporting faces can be accomplished in linear time, giving rise to an $O(n \log n)$ time algorithm. By applying the marriage-before-conquest principle Edelsbrunner and Shi [23] obtained an $O(n \log^2 \mathcal{H})$ algorithm.

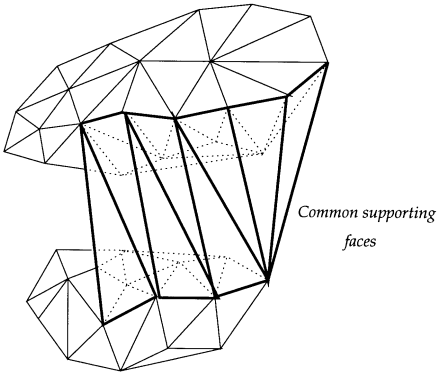

FIGURE 19.3 Common supporting faces of two disjoint convex polyhedra.

The gift-wrapping approach for computing the convex hull in three dimensions would mimic the process of wrapping a gift with a piece of paper. One starts with a plane supporting S, i.e., a plane determined by three points of S such that the entire set of points lie on one side. In general, the supporting face is a triangle $\Delta(a, b, c)$. Pivoting at an edge, say (a, b) of this triangle, one rotates the plane in space until it hits a third point v, thereby determining another supporting face $\Delta(a, b, v)$. This process repeats until the entire set of points are *wrapped* by a collection of supporting faces. These supporting faces are called 2-faces, the edges common to two supporting faces, 1-faces, and the vertices (or extreme points) common to 2-faces and 1-faces are called 0-faces. The gift-wrapping method has a running time of $O(n\mathcal{H})$, where $\mathcal{H}$ is the total number of i-faces, $i = 0, 1, 2$.

The following optimal output-sensitive algorithm that runs in $O(n \log \mathcal{H})$ time in two dimensions is due to Chan [10]. A similar algorithm for three dimensions can be obtained. It is a modification of the *gift-wrapping* method, (also known as the Jarvis' March method,) and uses a *grouping* technique.

ALGORITHM 2DHULL(S)

1. For $i = 1, 2, \ldots$ do
2. $\quad P \leftarrow$ HULL2D($S, \mathcal{H}_0, \mathcal{H}_0$), where $\mathcal{H}_0 = \min\{2^{2^i}, n\}$
3. $\quad$ If $P \neq nil$ then return P.

FUNCTION HULL2D($S, m, \mathcal{H}_0$)

1. Partition S into subsets $S_1, S_2, \ldots, S_{\lceil \frac{n}{m} \rceil}$, each of size at most m
2. For $i = 1, 2, \ldots, \lceil \frac{n}{m} \rceil$ do

3. Compute $CH(S_i)$ and preprocess it in a suitable data structure
4. $p_0 \leftarrow (0, -\infty)$, $p_1 \leftarrow$ the rightmost point of S
5. For $j = 1, 2, \ldots, \mathcal{H}_0$ do
6. For $i = 1, 2, \ldots, \lceil \frac{n}{m} \rceil$ do
7. Compute a point $q_i \in S_i$ that maximizes $\angle p_{j-1} p_j q_i$
8. $p_{j+1} \leftarrow$ a point q from $\{q_1, \ldots, q_{\lceil \frac{n}{m} \rceil}\}$ maximizing $\angle p_{j-1} p_j q$
9. If $p_{j+1} = p_1$ then return list $(p_1, \ldots, p_j)$
10. return nil

Let us analyze the complexity of the algorithm. In Step 2, we use an $O(m \log m)$ time algorithm for computing the convex hull for each subset of m points, e.g., Graham's scan for S in two dimensions, and Preparata–Hong algorithm for S in three dimensions. Thus, it takes $O((\frac{n}{m})m \log m) = O(n \log m)$ time. In Step 5 we build a suitable data structure that supports the computation of the supporting vertex or supporting face in logarithmic time. In two dimensions we can use an array that stores the vertices on the convex hull in say, clockwise, order. In three dimensions we use Dobkin–Kirkpatrick hierarchical representation of the faces of the convex hull [20]. Thus, Step 5 takes $\mathcal{H}_0(\frac{n}{m})O(\log m)$ time. Setting $m = \mathcal{H}_0$ gives an $O(n \log \mathcal{H}_0)$ time. Note that setting $m = 1$ we have the Jarvis' March, and setting $m = n$ the two dimensional convex hull algorithm degenerates to the Graham's Scan. Since we do not know $\mathcal{H}$ in advance, we use in Step 2 of ALGORITHM 2DHULL(S) a sequence $\mathcal{H}_i = 2^{2^i}$ such that $\mathcal{H}_1 + \ldots \mathcal{H}_{k-1} < \mathcal{H} \leq \mathcal{H}_1 + \ldots \mathcal{H}_k$ to guess it. The total running time is

$$O\left(\sum_{i=1}^{k} n \log \mathcal{H}_i\right) = O\left(\sum_{i=1}^{\lceil \log \log \mathcal{H} \rceil} n 2^i\right) = O\left(n \log \mathcal{H}\right)$$

Convex Hulls in k-Dimensions, $k > 3$

For convex hulls of higher dimensions, a recent result by Chazelle [13] showed that the convex hull can be computed in time $O(n \log n + n^{\lfloor k/2 \rfloor})$, which is optimal in all dimensions $k \geq 2$ in the worst case. But this result is insensitive to the output size. The gift-wrapping approach generalizes to higher dimensions and yields an output-sensitive solution with running time $O(n\mathcal{H})$, where $\mathcal{H}$ is the total number of i-faces, $i = 0, 1, \ldots, k-1$ and $\mathcal{H} = O(n^{\lfloor k/2 \rfloor})$ [22]. One can also use *beneath-beyond* method [42] of adding points one at a time in ascending order along one of the coordinate axis.[1] We compute the convex hull $CH(S_{i-1})$ for points $S_{i-1} = \{p_1, p_2, \ldots, p_{i-1}\}$. For each added point p_i we update $CH(S_{i-1})$ to get $CH(S_i)$ for $i = 2, 3, \ldots, n$ by deleting those t-faces, $t = 0, 1, \ldots, k-1$, that are internal to $CH(S_{i-1} \cup \{p_i\})$. It is shown by Seidel [22] that $O(n^2 + \mathcal{H} \log h)$ time is sufficient, where h is the number of extreme points. Most recently Chan [10] obtained an algorithm based on gift-wrapping method that runs in $O(n \log \mathcal{H} + (n\mathcal{H})^{1-1/(\lfloor k/2 \rfloor + 1)} \log^{O(1)} n)$ time. Note that the algorithm is optimal when $k = 2, 3$. In particular, it is optimal when $\mathcal{H} = o(n^{1-\epsilon})$ for some $0 < \epsilon < 1$.

We conclude this section with the following theorem [10].

THEOREM 19.1 *The convex hull of a set S of n points in $\Re^k$ can be computed in $O(n \log \mathcal{H})$ time for $k = 2$ or $k = 3$, and in $O(n \log \mathcal{H} + (n\mathcal{H})^{1-1/(\lfloor k/2 \rfloor + 1)} \log^{O(1)} n)$ time for $k > 3$, where $\mathcal{H}$ is the number of i-faces, $i = 0, 1, \ldots, k-1$.*

[1] If the points of S are not given *a priori*, the algorithm can be made **on-line** by adding an extra step of checking if the newly added point is internal or external to the current convex hull. If internal, just discard it.

Convex Layers of a Planar Set

The convex layers $\mathcal{C}(S)$ of a set S of n points in the Euclidean plane is obtained by a process, known as *onion peeling,* i.e., compute the convex hull of S and remove its vertices from S, until S becomes empty. Figure 19.4 shows the convex layer of a point set. This onion peeling process of a point set is central in the study of robust estimators in statistics, in which the outliers, points lying on the outermost convex layers, should be removed. In this section we describe an efficient algorithm due to Chazelle [11] that runs in optimal $O(n \log n)$ time.

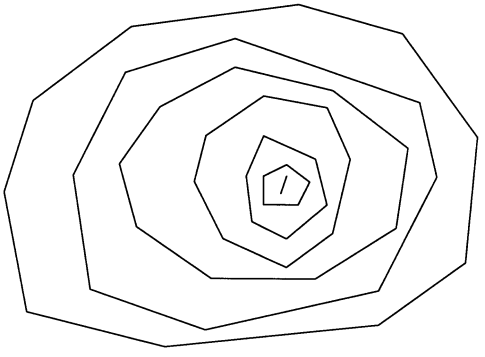

FIGURE 19.4 Convex layers of a point set.

As described in "Convex Hulls in Two and Three Dimensions," each convex layer of $\mathcal{C}(S)$ can be decomposed into two convex polygonal chains, called upper and lower hulls (Fig. 19.5).

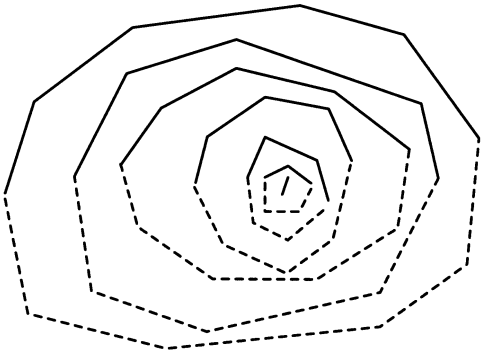

FIGURE 19.5 Decomposition of each convex layer into upper and lower hulls.

Let l and r denote the points with the minimum and maximum x-coordinate, respectively, in a convex layer. The upper (respectively, lower) hull of this layer runs clockwise (respectively, counterclockwise) from l to r. The upper and lower hulls are the same if the convex layer has one or two points. Assume that the set S of points $p_0, p_1, \ldots, p_{n-1}$ are ordered in nondescending order of their x-coordinates. We shall concentrate on the computation of upper hulls of $\mathcal{C}(S)$; the other case is symmetric. Consider the complete binary tree $\mathcal{T}(S)$ with leaves $p_0, p_1, \ldots, p_{n-1}$ from left to right. Let $S(v)$ denote the set of points stored at the leaves of the subtree rooted at node v of $\mathcal{T}$ and let $U(v)$ denote its upper hull of the convex hull of $S(v)$. Thus, $U(\rho)$, where ρ denotes the root of $\mathcal{T}$ is the upper hull of the convex hull of S– in the outermost layer. The union of all the upper hulls $U(v)$ for all nodes v is a tree, called *hull graph* [11].

(A similar graph is also computed for the lower hull of the convex hull.) To minimize the amount of space, at each internal node v we store the bridge (common tangent) connecting a point in $U(v_l)$ and a point in $U(v_r)$, where v_l, v_r are the left and right children of node v. Figures 19.6(a) and (b) illustrate the binary tree $\mathcal{T}$ and the corresponding hull graph, respectively.

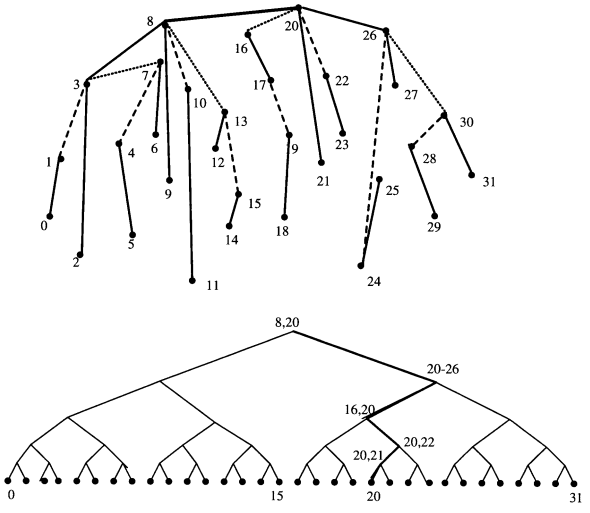

FIGURE 19.6 A complete binary tree and hull graph of upper hulls.

Computation of the hull graph proceeds from bottom up. Computing the bridge at each node takes time linear in the number of vertices on the respective upper hulls in the left and right subtrees. Thus, the total time needed to compute the hull graph is $O(n \log n)$. The bridges computed at each node v which are incident upon a vertex p_k are naturally separated into two subsets divided by the vertical line $\mathcal{L}(p_k)$ passing through p_k. Those on the left are arranged in a list $L(p_k)$ in counterclockwise order from the positive y direction of $\mathcal{L}(p_k)$, and those on the right are arranged in a list $R(p_k)$ in clockwise order. This adjacency list at each vertex in the hull graph can be maintained fairly easily. Suppose the bridge at node v connects vertex p_j in the left subtree and vertex p_k in the right subtree. The edge $\overline{p_j, p_k}$ will be inserted at the *first* position in the current lists $R(p_j)$ and $L(p_k)$. That is, edge $\overline{p_j, p_k}$ is the *top* edge in both lists $R(p_j)$ and $L(p_k)$. It is easy to retrieve the vertices on the upper hull of the outermost layer from the hull graph beginning at the root node of $\mathcal{T}$.

To compute the upper hull of the next convex layer, one needs to remove those vertices on the first layer (including those vertices in the lower hull). Thus, update of the hull graph includes deletion of vertices on both upper hull and lower hull. Deletions of vertices on the upper hull can be performed in an arbitrary order. But if deletions of vertices on the lower hull from the hull-graph are done in say clockwise order, then the update of the adjacency list of each vertex p_k can be made easy, e.g., $R(p_k) = \emptyset$. The deletion of a vertex p_k on the upper hull entails removal of edges incident on p_k in the hull graph. Let $v_1, v_2, \ldots, v_l$ be the list of internal nodes on the leaf-to-root path from p_k. The edges in $L(p_k)$ and $R(p_k)$ are deleted from bottom up in $O(1)$ time each, i.e., the top edge in each list gets deleted last. Figure 19.6(b) shows the leaf-to-root path when vertex p_{20} is deleted. Figures 19.7(a)–(f) show the updates of bridges when p_{20} is deleted and Fig. 19.7(g) is the final upper-hull after the update is finished. It can be shown that the overall time for deletions can be done in $O(n \log n)$ time [11].

THEOREM 19.2 *The convex layers of a set of n points in the plane can be computed in $O(n \log n)$ time.*

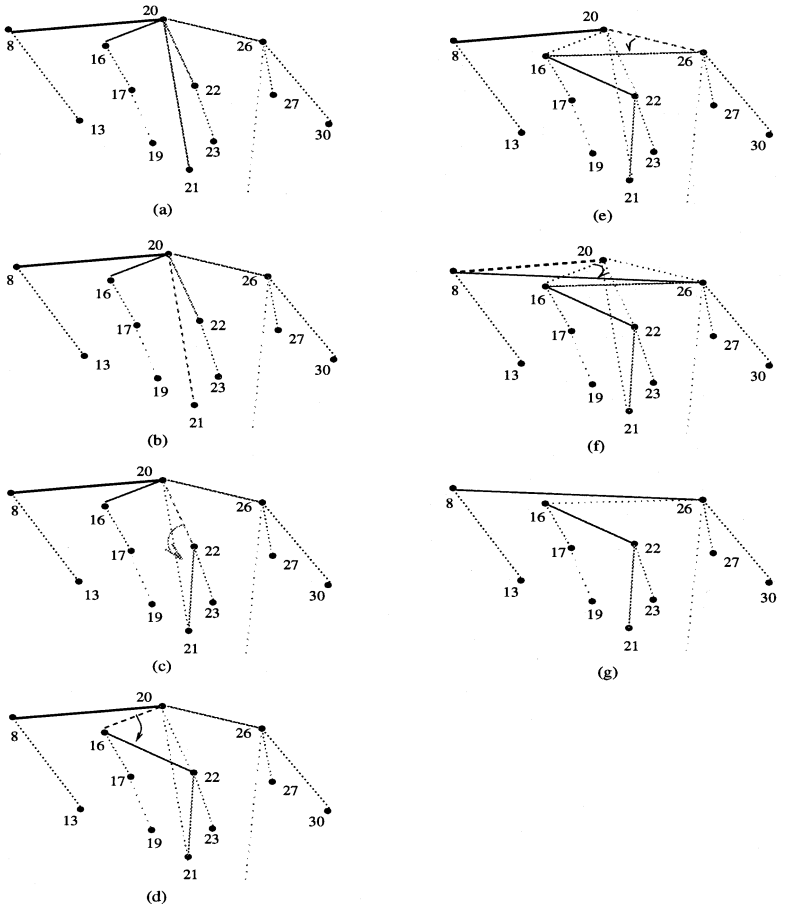

FIGURE 19.7 Update of hull graph.

Applications of Convex Hulls

Convex hulls have applications in clustering, linear regression, and Voronoi diagrams (see Chapter 20.) The following problems have solutions derived from the convex hull.

Problem C1 (Set Diameter) Given a set S of n points, find the two points that are the farthest apart, i.e., find $p_i, p_j \in S$ such that $d(p_i, p_j) = \max\{d(p_k, p_l)\}\ \forall p_k, p_l \in S$, where $d(p, q)$ denotes the Euclidean distance between p and q.

In two dimensions $O(n \log n)$ time is both sufficient and necessary in the worst case [42]. It is easy to see that the farthest pair must be extreme points of the convex hull of S. Once the convex hull is computed, the pair in two dimensions can be found in linear time by observing that it admits a pair of parallel supporting lines. Various attempts, including geometric sampling and parametric search method, have been made to solve this problem in three dimensions. Most recently, Ramos [43] obtained an $O(n \log^2 n)$ time deterministic algorithm, which is an $O(\log n)$ factor off from the best randomized algorithm due to Clarkson and Shor [17].

Problem C2 (Smallest Enclosing Rectangle) Given a set S of n points, find the smallest rectangle that encloses the set.

Problem C3 (Regression Line) Given a set S of n points, find a line such that the maximum distance from S to the line is minimized.

These two problems can be solved in optimal time $O(n \log n)$ using the convex hull of S [38] in two dimensions. In k-dimensions Houle et al. [31] gave an $O(n^{\lfloor k/2+1 \rfloor})$ time and $O(n^{\lfloor (k+1)/2 \rfloor})$ space algorithm. The time complexity is essentially that of computing the convex hull of the point set.

19.3 Maxima Finding

In this section we discuss a problem concerned with *extremes* of a point set which is somewhat related to that of convex hull problems. Consider a set S of n points in $\Re^k$ in the Cartesian coordinate system. Let $(x_1(p), x_2(p), \ldots, x_k(p))$ denote the coordinates of point $p \in \Re^k$. Point p is said to *dominate* point q, denoted $p \succeq q$, (or q is dominated by p, denoted $q \preceq p$) if $x_i(p) \geq x_i(q)$ for all $1 \leq i \leq k$. A point p is said to be *maximal* (or a *maximum*) in S if no point in S dominates p. The maxima-finding problem is that of finding the set $\mathcal{M}(S)$ of maximal elements for a set S of points in $\Re^k$.

Maxima in Two and Three Dimensions

In two dimensions the problem can be done fairly easily by a plane-sweep technique. (For a more detailed description of plane-sweep technique, see, e.g., [36] or "Trapezoidalization".) Assume that the set S of points $p_1, p_2, \ldots, p_n$ are ordered in nondescending order of their x-coordinates, i.e., $x(p_1) \leq x(p_2) \leq \cdots \leq x(p_n)$.

We shall scan the points from right to left. The point p_n is necessarily a maximal element. As we scan the points, we maintain the maximum y-coordinate among those that have been scanned so far. Initially, $\max_y = y(p_n)$. The next point p_i is a maximal element if and only if $y(p_i) > \max_y$. If $y(p_i) > \max_y$, then $p_i \in \mathcal{M}(S)$, and $\max_y$ is set to $y(p_i)$, and we continue. Otherwise $p_i \preceq p_j$ for some $j > i$. Thus, after the initial sorting, the set of maxima can be computed in linear time. Note that the set of maximal elements satisfies the property that their x- and y-coordinates are totally ordered: if they are ordered in strictly ascending x-coordinate, their y-coordinates are ordered in strictly descending order.

In three dimensions we can use the same strategy. We will scan the set in descending order of the x-coordinate by a plane $\mathcal{P}$ orthogonal to the x-axis. Point p_n as before is a maximal element. Suppose we have computed $\mathcal{M}(S_{i+1})$, where $S_{i+1} = \{p_{i+1}, \ldots, p_n\}$, and we are scanning point p_i. Consider the orthogonal projection S^x_{i+1} of the points in S_{i+1} to $\mathcal{P}$ with $x = x(p_i)$. We now have an instance of an *on-line* two dimensional maximal problem, i.e., for point p_i, if $p^x_i \preceq p^x_j$ for some $p^x_j \in S^x_{i+1}$, then it is not a maximal element, otherwise it is (p^x_i denotes the projection of p_i onto $\mathcal{P}$). If we maintain the points in $\mathcal{M}(S^x_{i+1})$ as a **height-balanced binary search tree** in either y- or z-coordinate, then testing whether p_i is maximal or not can be done in logarithmic time. If it is dominated by some point in $\mathcal{M}(S^x_{i+1})$, then it is ignored. Otherwise, it is in $\mathcal{M}(S^x_{i+1})$ (and also in $\mathcal{M}(S_{i+1})$); $\mathcal{M}(S^x_{i+1})$ will then be updated to be $\mathcal{M}(S^x_i)$ accordingly. The update may involve deleting points in $\mathcal{M}(S^x_{i+1})$ that are no longer maximal because they are dominated by p^x_i. Figure 19.8 shows the effect of adding a maximal element p^x_i to the set $\mathcal{M}(S^x_{i+1})$ of maximal elements. Points in the shaded area will be deleted. Thus, after the initial sorting, the set of maxima in three dimensions can be computed in $O(n \log \mathcal{H})$ time, as the *on-line* two dimensional maximal problem takes $O(\log \mathcal{H})$ time to maintain $\mathcal{M}(S^x_i)$ for each point p_i, where $\mathcal{H}$ denotes the size of $\mathcal{M}(S)$.

Since the total number of points deleted is at most n, we conclude the following:

LEMMA 19.1 Given a set of n points in two and three dimensions, the set of maxima can be computed in $O(n \log n)$ time.

For two and three dimensions one can solve the problem in optimal time $O(n \log \mathcal{H})$, where $\mathcal{H}$ denotes the size of $\mathcal{M}(S)$. The key observation is that we need not *sort* S in its entirety. For instance, in two dimensions one can solve the problem by divide-and-marriage-before-conquest paradigm. We first use a

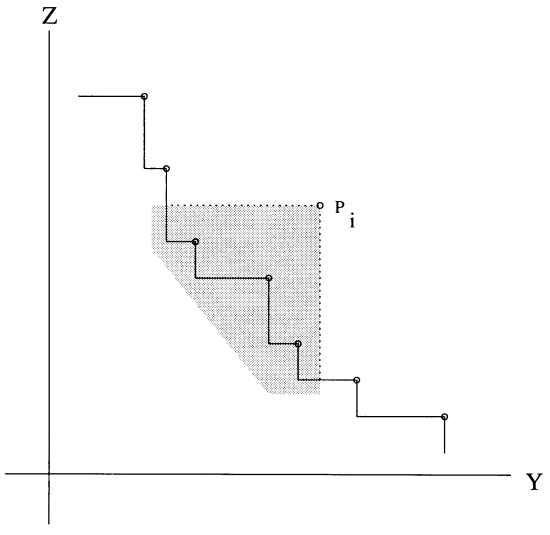

FIGURE 19.8 Update of maximal elements.

linear time median finding algorithm to divide the set into two halves L and R with points in R having larger x-coordinate values than those of points in L. We then recursively compute $\mathcal{M}(R)$. Before we recursively compute $\mathcal{M}(L)$ we note that points in L that are dominated by points in $\mathcal{M}(R)$ can be eliminated from consideration. We trim L before we invoke the algorithm recursively. That is, we compute $\mathcal{M}(L')$ recursively, where $L' \subseteq L$ consists of points $q \not\preceq p$ for all $p \in \mathcal{M}(R)$. A careful analysis of the running time shows that the complexity of this algorithm is $O(n \log \mathcal{H})$. For three dimensions we note that other than the initial sorting step, the subsequent plane-sweep step takes $O(n \log \mathcal{H})$ time. It turns out that one can replace the full-fledged $O(n \log n)$ sorting step with a so-called *lazy sorting* of S using a technique similar to those described in "Convex Hulls in Two and Three Dimensions" to derive an output-sensitive algorithm.

THEOREM 19.3 *Given a set S of n points in two and three dimensions, the set $\mathcal{M}(S)$ of maxima can be computed in $O(n \log \mathcal{H})$ time, where $\mathcal{H}$ is the size of $\mathcal{M}(S)$.*

Maxima in Higher Dimensions

The set of maximal elements in $\Re^k$, $k \geq 4$, can be solved by a generalization of plane-sweep method to higher dimensions. We just need to maintain a data structure for $\mathcal{M}(S_{i+1})$, where $S_{i+1} = \{p_{i+1}, \ldots, p_n\}$, and test for each point p_i if it is a maximal element in S_{i+1}, reducing the problem to one dimension lower, assuming that the points in S are sorted and scanned in descending lexicographical order. Thus, in a straightforward manner we can compute $\mathcal{M}(S)$ in $O(n^{k-2} \log n)$ time. However, we shall show that one can compute the set of maxima in $O(n \log^{k-2} n)$ time, for $k > 3$ by divide-and-conquer[2].

Let us first consider a *bichromatic maxima-finding* problem. Consider a set of n *red* and a set of m *blue* points, denoted R and B, respectively. The bichromatic maxima-finding problem is to find a subset of points in R that are not dominated by any points in B and vice versa. That is, find $\mathcal{M}(R, B) = \{r | r \not\preceq b, b \in B\}$ and $\mathcal{M}(B, R) = \{b | b \not\preceq r, r \in R\}$.

[2]This was improved to $O(n \log^{k-3} n \log \log n)$ time by Gabow et al. [27].

In three dimensions, this problem can be solved by plane-sweep in a manner similar to the maxima-finding problem as follows. As before, the sets R and B are sorted in nondescending order of x-coordinates and we maintain two subsets of points $\mathcal{M}(R^x_{i+1})$ and $\mathcal{M}(B^x_{j+1})$, which are the maxima of the projections of R_{i+1} and B_{j+1} onto the yz-plane for $R_{i+1} = \{r_{i+1}, \ldots, r_n\} \subseteq R$ and $B_{j+1} = \{b_{j+1}, \ldots, b_m\} \subseteq B$, respectively. When the next point $r_i \in R$ is scanned, we test if r^x_i is dominated by any points in $\mathcal{M}(B^x_{j+1})$. The point $r_i \in \mathcal{M}(R, B)$, if r^x_i is not dominated by any points in $\mathcal{M}(B^x_{j+1})$. We then update the set of maxima for $R^x_i = R^x_{i+1} \cup \{r^x_i\}$. That is, if $r^x_i \preceq q$ for $q \in \mathcal{M}(R^x_{i+1})$, then $\mathcal{M}(R^x_i) = \mathcal{M}(R^x_{i+1})$. Otherwise, the subset of $\mathcal{M}(R^x_{i+1})$ dominated by r^x_i is removed, and r^x_i is included in $\mathcal{M}(R^x_i)$. If the next point scanned is $b_j \in B$, we perform similar operations. Thus, for each point scanned we spend $O(\log n + \log m)$ time.

LEMMA 19.2 The bichromatic maxima-finding problem for a set of n red and m blue points in three dimensions can be solved in $O(N \log N)$ time, where $N = m + n$.

Using Lemma 19.2 as basis, one can solve the bichromatic maxima-finding problem in $\Re^k$ in $O(N \log^{k-2} N)$ time for $k \geq 3$ using multidimensional divide-and-conquer.

LEMMA 19.3 The bichromatic maxima-finding problem for a set of n red and m blue points in $\Re^k$ can be solved in $O(N \log^{k-2} N)$ time, where $N = m + n$, and $k \geq 3$.

Let us now turn to the maxima-finding problem in $\Re^k$. We shall use an ordinary divide-and-conquer method to solve the maxima-finding problem. Assume that the points in $S \subseteq \Re^k$ have been sorted in all dimensions. Let L_x denote the median of all the x-coordinate values. We first divide S into two subsets S_1 and S_2, each of size approximately $|S|/2$ such that the points in S_1 have x-coordinates larger than L_x and those of points in S_2 are less than L_x. We then recursively compute $\mathcal{M}(S_1)$ and $\mathcal{M}(S_2)$. It is clear that $\mathcal{M}(S_1) \subseteq \mathcal{M}(S)$. However, some points in $\mathcal{M}(S_2)$ may be dominated by points in $\mathcal{M}(S_1)$, and hence, are not in $\mathcal{M}(S)$. We then project points in S onto the hyperplane $\mathcal{P}$: $x = L_x$. The problem now reduces to the bichromatic maxima-finding problem in $\Re^{k-1}$, i.e., finding among $\mathcal{M}(S_2)$ those that are maxima with respect to $\mathcal{M}(S_1)$. By Lemma 19.3 we know that this bichromatic maxima-finding problem can be solved in $O(n \log^{k-3} n)$ time. Since the merge step takes $O(n \log^{k-3} n)$ time, we conclude the following:

THEOREM 19.4 *The maxima-finding problem for a set of n points in $\Re^k$ can be solved in $O(n \log^{k-2} n)$ time, for $k \geq 3$.*

We note here also that if we apply the *trimming* operation of S_2 with $\mathcal{M}(S_1)$, i.e., removing points in S_2 that are dominated by points in $\mathcal{M}(S_1)$, before recursion, one can compute $\mathcal{M}(S)$ more efficiently as stated in the following theorem.

THEOREM 19.5 *The maxima-finding problem for a set S of n points in $\Re^k$, $k \geq 4$, can be solved in $O(n \log^{k-2} \mathcal{H})$ time, where $\mathcal{H}$ is the number of maxima in S.*

Maximal Layers of a Planar Set

The maximal layers of a set of points in the plane can be obtained by a process similar to that of convex layers discussed in "Convex Layers of a Planar Set." A brute-force method would yield an $O(\delta \cdot n \log \mathcal{H})$ time, where δ is the number of layers and $\mathcal{H}$ is the maximum number of maximal elements in any layer. In this section we shall present an algorithm due to Atallah and Kosaraju [6] for computing not only the maximal layers, but also some other functions associated with dominance relation.

Consider a set S of n points. As in the previous section, let $\mathcal{D}_S(p)$ denote the set of points in S dominated by p, i.e., $\mathcal{D}_S(p) = \{q \in S | q \preceq p\}$. Since p is always dominated by itself, we shall assume $\mathcal{D}_S(p)$ does not include p, when $p \in S$. The first subproblem we consider is the *maxdominance problem,* which is defined as follows: for each $p \in S$, find $\mathcal{M}(\mathcal{D}_S(p))$. That is, for each $p \in S$ we are interested in computing the set of maximal elements among those points that are dominated by p. Another related problem is to compute the labels of each point p from the labels of those points in $\mathcal{M}(\mathcal{D}_S(p))$. More specifically, suppose each point is associated with a weight $w(p)$. The label $l_S(p)$ is defined to be $w(p)$ if $\mathcal{D}_S(p) = \emptyset$ and is $w(p) + \max\{l_S(q), q \in \mathcal{M}(\mathcal{D}_S(p))\}$. The max function can be replaced with min or any other associative functional operation. In other words, $l_S(p)$ is equal to the maximum among the labels of all the points dominated by p. Suppose we let $w(p) = 1$ for all $p \in S$. Then those points with labels equal to 1 are points that do not dominate any points. These points can be thought of as *minimal* points in S. That a point p_i has label λ implies there exists a sequence of λ points $p_{j_1}, p_{j_2}, \ldots, p_{j_\lambda} = p_i$, such that $p_{j_1} \preceq p_{j_2} \preceq \cdots \preceq p_{j_\lambda} = p_i$. In general, points with label λ are on the λ^{th} minimal layer and the maximum label gives the number of minimal layers. If we modify the definition of domination to be p dominates q if and only if $x(p) \leq x(q)$ and $y(p) \leq y(q)$, then the minimal layers obtained using the method to be described below correspond to the maximal layers.

Let us now discuss the labeling problem defined earlier. We recall a few terms as used in [6].[3]

Let L and R denote two subsets of points of S separated by a vertical line, such that $x(l) \leq x(r)$ for all $l \in L$ and $r \in R$. $leader_R(p)$, $p \in R$ is the point $\mathcal{H}_p$ in $\mathcal{D}_R(p)$ with the largest y-coordinate. $Strip_L(p, R)$, $p \in R$ is the subset of points of $\mathcal{D}_L(p)$ dominated by p but with y-coordinates greater than $leader_R(p)$, i.e., $Strip_L(p, R) = \{q \in \mathcal{D}_L(p) | y(q) > y(\mathcal{H}_p)\}$ for $p \in R$. $Left_L(p, R)$, $p \in R$, is defined to be the largest $l_S(q)$ over all $q \in Strip_L(p, R)$ if $Strip_L(p, R)$ is nonempty, and $-\infty$ otherwise.

Observe that for each $p \in R$ $\mathcal{M}(\mathcal{D}_S(p))$ is the concatenation of $\mathcal{M}(\mathcal{D}_R(p))$ and $Strip_L(p, R)$. Assume that the points in $S = \{p_1, p_2, \ldots, p_n\}$ have been sorted as $x(p_1) < x(p_2) < \cdots < x(p_n)$. We shall present a divide-and-conquer algorithm that can be called with $R = S$ and $Left_\emptyset(p, S) = -\infty$ for all $p \in S$ to compute $l_S(p)$ for all $p \in S$. The correctness of the algorithm hinges on the following lemma.

LEMMA 19.4 For any point $p \in R$, if $\mathcal{D}_S(p) \neq \emptyset$, then $l_S(p) = w(p) + \max\{Left_L(p, R), \max\{l_S(q), q \in \mathcal{M}(\mathcal{D}_R(p))\}\}$.

ALGORITHM MAXDOM_LABEL(R)

Input: A consecutive sequence of m points of S, i.e., $R = \{p_r, p_{r+1}, \ldots, p_{r+m-1}\}$ and for each $p \in R$, $Left_L(p, R)$, where $L = \{p_1, p_2, \ldots, p_{r-1}\}$. Assume a list Q_R of points of R sorted by increasing y-coordinate.

Output: The labels $l_S(q)$, $q \in R$.

1. If $m = 1$ then we set $l_S(p_r)$ to $w(p_r) + Left_L(p_r, R)$, if $Left_L(p_r, R) \neq -\infty$ and to $w(p_r)$ if $Left_L(p_r, R) = -\infty$, and **return.**
2. Partition R by a vertical line $\mathcal{V}$ into subsets R_1 and R_2 such that $|R_1| = |R_2| = m/2$ and R_1 is to the left of R_2. Extract from Q_R the lists Q_{R_1} and Q_{R_2}.
3. Call MAXDOM_LABEL(R_1). Since $Left_L(p, R_1)$ equals $Left_L(p, R)$, this call will return the labels for all $q \in R_1$ which are the final labels for $q \in R$.
4. Compute $Left_{R_1}(p, R_2)$.

[3] Some of the notation is slightly modified. In [6] min is used in the *label* function, instead of max. See [6] for details.

5. Compute $Left_{L\cup R_1}(p, R_2)$, given $Left_{R_1}(p, R_2)$ and $Left_L(p, R)$. That is, for each $p \in R_2$, set $Left_{L\cup R_1}(p, R_2)$ to be $\max\{Left_{R_1}(p, R_2), Left_L(p, R)\}$.
6. Call MAXDOM_LABEL(R_2). This will return the labels for all $q \in R_2$ which are the final labels for $q \in R$.

All steps other than Step 4 are self-explanatory. Steps 4 and 5 are needed in order to set up the correct invariant condition for the second recursive call. The computation of $Left_{R_1}(p, R_2)$ and its complexity is the key to the correctness and time complexity of the algorithm MAXDOM_LABEL(R). We briefly discuss this problem and show that this step can be done in $O(m)$ time. Since all other steps take linear time, the overall time complexity is $O(m \log m)$.

Consider in general two subsets L and R of points separated by a vertical line $\mathcal{V}$, with L lying to the left of R and points in $L \cup R$ are sorted in ascending y-coordinate (Fig. 19.9). Suppose we have computed the labels $l_L(p)$, $p \in L$. We compute $Left_L(p, R)$ by using a plane sweep technique scanning points in $L \cup R$ is ascending y-coordinate. We will maintain for each point $r \in R$ $Strip_L(r, R)$ along with the highest and rightmost points in the subset, denoted $1st_L(r, R)$ and $last_L(r, R)$, respectively, and $leader_R(r)$. For each point $p \in L \cap Strip_L(r, R)$ for some $r \in R$ we maintain a label $max\_l(p)$, which is equal to $\max\{l_L(q) | q \in Strip_L(r, R)$ and $y(q) < y(p)\}$.

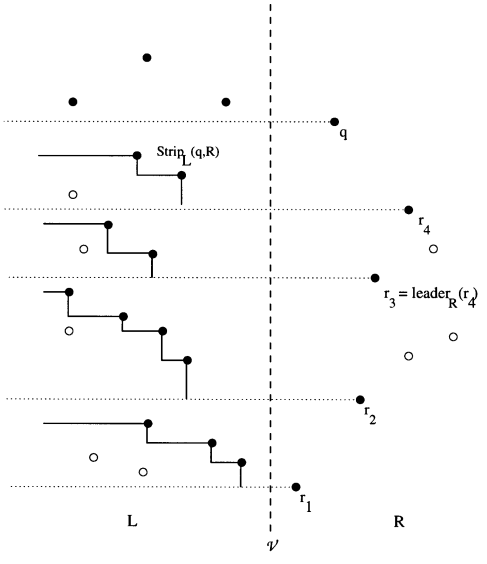

FIGURE 19.9 Computation of $Left_L(p, R)$.

A stack ST_R will be used to store $leader_R(r_i)$ of $r_i \in R$ such that any element r_t in ST_R is $leader_R(r_{t+1})$ for point r_{t+1} above r_t, and the top element r_i of ST_R is the last scanned point in R. For instance in Fig. 19.9 ST_R contains r_4, r_3, r_2, and r_1 when r_4 is scanned. Another stack ST_L is used to store $Strip_L(r, R)$ for a yet-to-be-scanned point $r \in R$. (The staircase above r_4 in Fig. 19.9 is stored in ST_L. The solid staircases indicate $Strip_L(r_i, R)$ for $r_i, i = 2, 3, 4$.)

Let the next point scanned be denoted q. If $q \in L$, we pop off the stack ST_L all points that are dominated by q until q'. And we compute $max\_l(q)$ to be the larger of $l_L(q)$ and $max\_l(q')$. We then push q onto ST_L. That is, we update ST_L to make sure that all the points in ST_L are maximal.

Suppose $q \in R$. Then $Strip_L(q, R)$ is initialized to be the entire contents of ST_L and let $1st_L(q, R)$ be the top element of ST_L and $last_L(q, R)$ be the bottom element of ST_L.

If the top element of ST_R is equal to $leader_R(q)$, we set $Left_L(q, R)$ to $max\_l(q')$, where q' is $1st_L(q, R)$,

initialize ST_L to be empty and continue to scan the next point. Otherwise we need to pop off the stack ST_R all points that are *not* dominated by q, until q', which is $leader_R(q)$. As shown in Fig. 19.9, $r_i, i = 4, 3, 2$ will be popped off ST_R when q is scanned. As point r_i is popped off ST_R, $Strip_L(r_i, R)$ is *concatenated* with $Strip_L(q, R)$ to maintain its maximality. That is, the points in $Strip_L(r_i, R)$ are scanned from $1st_L(r_i, R)$ to $last_L(r_i, R)$ until a point, if any, α_i is encountered such that $x(\alpha_i) > x(last_L(q, R))$. $max\_1(q')$, $q' = 1st_L(q, R)$, is set to be the larger of $max\_1(q')$ and $max\_1(\alpha)$ and $last_L(q, R)$ is temporarily set to be $last_L(r_i, R)$. If no such α_i exists, then the entire $Strip_L(r_i, R)$ is ignored. This process repeats until $leader_R(q)$ of q is on top of ST_R. At that point, we would have computed $Strip_L(q, R)$ and $Left_L(q, R)$ is $max\_1(q')$, where $q' = 1st_L(q, R)$. We initialize ST_L to be empty and continue to scan the next point.

It has been shown in [6] that this scanning operation takes linear time (with path compression), so the overall algorithm takes $O(m \log m)$ time.

THEOREM 19.6 *Given a set S of n points with weights $w(p_i)$, $p_i \in S, i = 1, 2, \ldots, n$,* ALGORITHM MAXDOM_LABEL(S) *returns $l_S(p)$ for each point $p \in S$ in $O(n \log n)$ time.*

Now let us briefly describe the algorithm for the *maxdominance problem.* That is to find for each $p \in S$, $\mathcal{M}(\mathcal{D}_S(p))$.

ALGORITHM MAXDOM_LIST(S)

Input: A sorted sequence of n points of S, i.e., $S = \{p_1, p_2, \ldots, p_n\}$, where $x(p_1) < x(p_2) < \cdots < x(p_n)$.

Output: $\mathcal{M}(\mathcal{D}_S(p))$ for each $p \in S$ and the list Q_S containing the points of S in ascending y-coordinates.

1. If $n = 1$ then we set $\mathcal{M}(\mathcal{D}_S(p_1)) = \emptyset$ and **return.**
2. Call ALGORITHM MAXDOM_LIST(L), where $L = \{p_1, p_2, \ldots, p_{n/2}\}$. This call returns $\mathcal{M}(\mathcal{D}_S(p))$ for each $p \in L$ and the list Q_L.
3. Call ALGORITHM MAXDOM_LIST(R), where $R = \{p_{n/2+1}, \ldots, p_n\}$. This call returns $\mathcal{M}(\mathcal{D}_R(p))$ for each $p \in R$ and the list Q_R.
4. Compute for each $r \in R$ $Strip_L(r, R)$ using the algorithm described in Step 4 of ALGORITHM MAXDOM_LABEL(R).
5. For every $r \in R$ compute $\mathcal{M}(\mathcal{D}_S(p))$ by concatenating $Strip_L(r, R)$ and $\mathcal{M}(\mathcal{D}_R(p))$.
6. Merge Q_L and Q_R into Q_S and return.

Since Steps 4, 5, and 6, excluding the output time, can be done in linear time, we have the following.

THEOREM 19.7 *The maxdominance problem of a set S of n points can be solved in $O(n \log n + \mathcal{F})$ time, where $\mathcal{F} = \Sigma_{p \in S} |\mathcal{M}(\mathcal{D}_S(p))|$.*

19.4 Row Maxima Searching in Monotone Matrices

The *row maxima-searching problem* in a matrix is that given an $n \times m$ matrix M of real entries, find the leftmost maximum entry in each row.

A matrix is said to be *monotone,* if $i_1 > i_2$ implies that $j(i_1) \geq j(i_2)$, where $j(i)$ is the index of the leftmost column containing the maximum in row i. It is *totally monotone* if all of its submatrices are monotone.

In fact if every 2×2 submatrix $M[i, j; k, l]$ with $i < j$ and $k < l$ is monotone, then the matrix is totally monotone. Or equivalently if $M(i, k) < M(i, l)$ implies $M(j, k) < M(j, l)$ for any $i < j$ and $k < l$, then M is totally monotone.

The algorithm for solving the row maxima-searching problem is due to Aggarwal et al. [1], and is commonly referred to as the SMAWK algorithm. Specifically the following results were obtained: $O(m \log n)$ time for an $n \times m$ monotone matrix, and $\theta(m)$ time, $m \geq n$, and $\theta(m(1 + \log(n/m)))$ time, $m < n$, if the matrix is totally monotone.

We use as an example the distance matrix between pairs of vertices of a convex n-gon P, represented as a sequence of vertices $p_1, p_2, \ldots, p_n$ in counterclockwise order. For an integer j, let $*j$ denote $((j-1) \bmod n) + 1$. Let M be an $n \times (2n-1)$ matrix defined as follows. If $i < j \leq i + n - 1$ then $M[i, j] = d(p_i, p_{*j})$, where $d(p_i, p_j)$ denotes the Euclidean distance between two vertices p_i and p_j. If $j \leq i$ then $M[i, j] = j - i$, and if $j \geq i + n$ then $M[i, j] = -1$. The problem of computing for each vertex its farthest neighbor is now the same as the row maxima-searching problem.

Consider submatrix $M[i, j; k, l]$, with $i < j$ and $k < l$, that has only positive entries, i.e., $i < j < k < l < i + n$. In this case vertices p_i, p_j, p_{*k}, and p_{*l} are in counterclockwise order around the polygon. From the triangle inequality we have $d(p_i, p_{*k}) + d(p_j, p_{*l}) \geq d(p_i, p_{*l}) + d(p_j, p_{*k})$. Thus, $M[i, j; k, l]$ is monotone. The nonpositive entries ensure that all other 2×2 submatrices are monotone. We'll show below that the all farthest neighbor problem for each vertex of a convex n-gon can be solved in $O(n)$ time.

A straightforward divide-and-conquer algorithm for the row maxima-searching problem in monotone matrices is as follows.

ALGORITHM MAXIMUM_D&C

1. Find the maximum entry $j = j(i)$, in the ith row, where $i = \lceil \frac{n}{2} \rceil$.
2. Recursively solve the row maxima-searching problem for the submatrices $M[1, \ldots, i-1; 1, \ldots, j]$ when $i, j > 1$ and $M[i+1, \ldots, n; j, \ldots, m]$ when $i < n$ and $j < m$.

The time complexity required by the algorithm is given by the recurrence

$$f(n, m) \leq m + \max_{1 \leq j \leq m} \left(f(\lceil n/2 \rceil - 1, j) + f(\lfloor n/2 \rfloor, m - j + 1) \right).$$

with $f(0, m) = f(n, 1) =$ constant. We have $f(n, m) = O(m \log n)$.

Now let us consider the case when the matrix is totally monotone. We distinguish two cases (a) $m \geq n$ and (b) $m < n$.

Case (a): Wide matrix $m \geq n$.

An entry $M[i, j]$ is *bad* if $j \neq j(i)$, i.e., column j is not a solution to row i. Column j, $M[*, j]$ is *bad* if all $M[i, j]$, $1 \leq i \leq n$ are bad.

LEMMA 19.5 For $j_1 < j_2$ if $M[r, j_1] \geq M[r, j_2]$, then $M[i, j_2]$, $1 \leq i \leq r$, are bad; otherwise $M[i, j_1]$, $r \leq i \leq n$, are bad.

Consider an $n \times n$ matrix C, the *index* of C is defined to be the largest k such that $C[i, j]$, $1 \leq i < j$, $1 \leq j \leq k$ are bad.

The following algorithm REDUCE reduces in $O(m)$ time a totally monotone $m \times n$ matrix M to an $n \times n$ matrix C, a submatrix of M, such that for $1 \leq i \leq n$ it contains column $M^{j(i)}$. That is, bad columns of M (which are known not to be contain solutions) are eliminated.

ALGORITHM REDUCE(M)

1. $C \leftarrow M$; $k \leftarrow 1$;

2. **while** C has more than n columns **do**

   case $C(k,k) \geq C(k,k+1)$ and $k < n$: $k \leftarrow k+1$;
   $C(k,k) \geq C(k,k+1)$ and $k = n$: Delete column C^{k+1};
   $C(k,k) < C(k,k+1)$: Delete column C^k; **if** $k > 1$ **then** $k \leftarrow k-1$
   end case

3. **return**(C)

The following algorithm solves the maxima-searching problem in an $n \times m$ totally monotone matrix, where $m \geq n$.

ALGORITHM MAX_COMPUTE(M)

1. $B \leftarrow$ REDUCE(M);
2. **if** $n = 1$ **then** output the maximum and **return**;
3. $C \leftarrow B[2, 4, \ldots, 2\lfloor n/2 \rfloor; 1, 2, \ldots, n]$;
4. Call MAX_COMPUTE(C);
5. From the known positions of the maxima in the even rows of B, find the maxima in the odd rows.

The time complexity of this algorithm is determined by the following recurrence:

$$f(n,m) \leq c_1 n + c_2 m + f\,(n/2, n)$$

with $f(0,m) = f(n,1) =$ constant. We therefore have $f(n,m) = O(m)$.

Case (b): Narrow matrix $m < n$.

In this case we decompose the problem into m subproblems each of size $\lfloor n/m \rfloor \times m$ as follows. Let $r_i = \lfloor in/m \rfloor$, for $0 \leq i \leq m$. Apply MAX_COMPUTE to the $m \times m$ submatrix $M[r_1, r_2, \ldots, r_m; 1, 2, \ldots, m]$ to get $c_1, c_2, \ldots, c_m$, where $c_i = j(r_i)$. This takes $O(m)$ time. Let $c_0 = 1$. Consider submatrices $B_i = M[r_{i-1}+1, r_{i-1}+2, \ldots, r_i - 1; c_{i-1}, c_{i-1}+1, \ldots, c_i]$ for $1 \leq i \leq m$ and $r_{i-1} \leq r_i - 2$. Applying the straightforward divide-and-conquer algorithm to the submatrices, B_i, we obtain the column positions of the maxima for all remaining rows. Since each submatrix has at most $\lfloor n/m \rfloor$ rows, the time for finding the maxima is at most $c(p_i - p_{i-1} + 1)\log(n/m)$ for some constant c. Summing over all $1 \leq i \leq m$ we get the total time, which is $O(m(1 + \log(n/m)))$. The bound can be shown to be tight [1].

The applications of the matrix searching algorithm include the problems of finding all farthest neighbors for all vertices of a convex n-gon ($O(n)$ time), and finding the extremal (maximum perimeter or area) polygons (inscribed k-gons) of a convex n-gon ($O(kn + n \log n)$). If one adopts a more recent algorithm, the above problems can be solved in $O(n)$ time [30]. It is also used in solving the largest empty rectangle problem discussed in the section on geometric optimization in the next chapter.

19.5 Decomposition

Polygon decomposition arises in pattern recognition [48] in which recognition of a shape is facilitated by first decomposing it into simpler components, called *primitives,* and comparing them to templates previously stored in a library via some similarity measure. This class of decomposition is called *component-directed* decomposition. The primitives are often convex.

Trapezoidalization

We'll consider first *trapezoidalization* of a polygon P with n vertices, i.e., decomposition of the interior of a polygon into a collection of *trapezoids* with two horizontal sides, one of which may degenerate into a point, reducing a trapezoid to a triangle. Without loss of generality let us assume that no edge of P is horizontal. For each vertex v let us consider the horizontal line passing through v, denoted $\mathcal{H}_v$. The vertices of P are classified into three types. A vertex v is *regular* if the other two vertices adjacent to v lie on different sides of $\mathcal{H}_v$. A vertex v is a V-*cusp* if the two vertices adjacent to v are above $\mathcal{H}_v$, and is a Λ-*cusp* if the two vertices adjacent to v are below $\mathcal{H}_v$. In general the intersection of $\mathcal{H}_v$ and the interior of P consists of a number of horizontal segments, one of which contains v. Let this segment be denoted $\overline{v_l, v_r}$, where v_l and v_r are called the *left* and *right* projections of v on the boundary of P, denoted ∂P, respectively. If v is regular, either $\overline{v, v_l}$ or $\overline{v, v_r}$ lies totally in the interior of P. If v is a V-cusp or Λ-cusp, then $\overline{v_l, v_r}$ either lies totally in the interior of P or degenerates to v itself.

Consider only the segments $\overline{v_l, v_r}$ that are *nondegenerate.* These segments collectively partition the interior of P into a collection of trapezoids, each of which contains no vertex of P in its interior [Fig. 19.10(a)].

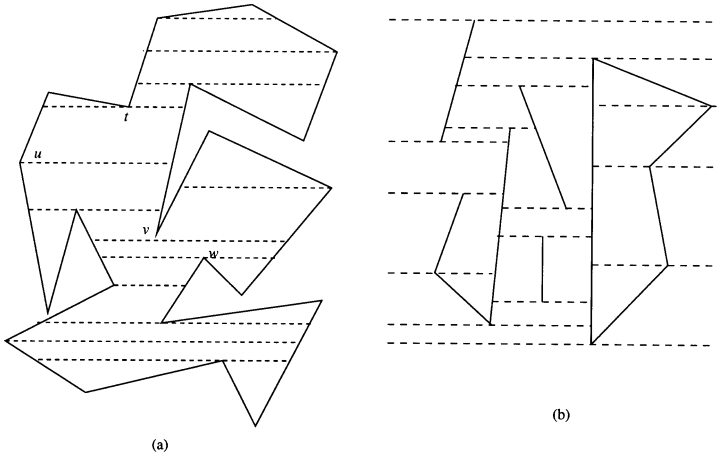

FIGURE 19.10 Trapezoidalization of a polygon.

The trapezoidalization can be generalized to a **planar straight-line graph** $G(V, E)$, where the entire plane is decomposed into trapezoids, some of which are unbounded. This trapezoidalization is sometimes referred to as horizontal **visibility map** of the edges, as the horizontal segments connect two edges of G that are *visible* (horizontally) [Fig. 19.10(b)]. The trapezoidalization of a planar straight-line graph $G(V, E)$ can be computed by plane-sweep technique in $O(n \log n)$ time, where $n = |V|$ [42], while the trapezoidalization of a simple polygon can be found in linear time [12].

The plane-sweep algorithm works as follows. The vertices of the graph $G(V, E)$ are sorted in descending y-coordinates. We'll sweep the plane by a horizontal sweep-line from top down. Associated with this approach there are two basic data structures containing all *relevant* information that should be maintained.

1. *Sweep-line status,* which records the information of the geometric structure that is being swept. In this example the sweep-line status keeps track of the set of edges intersecting the current sweep-line.
2. *Event schedule,* which defines a sequence of *event points* that the sweep-line status will change. In this example, the sweep-line status will change only at the vertices.

The event schedule is normally represented by a data structure, called *priority queue.* The content of the queue may not be available entirely at the start of the plane-sweep process. Instead, the list of events may change dynamically. In this case, the events are static; they are the y-coordinates of the vertices. The sweep-line status is represented by a suitable data structure that supports insertions, deletions, and computation of the left and right projections, v_l and v_r, of each vertex v. In this example a *red-black tree* or any *height-balanced binary search tree* is sufficient for storing the edges that intersect the sweep-line according to the x-coordinates of the intersections. Suppose at event point v_{i-1} we maintain a list of edges intersecting the sweep-line from left to right. Analogous to the trapezoidalization of a polygon, we say that a vertex v is *regular* if there are edges incident on v that lie on different sides of $\mathcal{H}_v$; a vertex v is a V-*cusp* if the all the vertices adjacent to v are above $\mathcal{H}_v$; v is a Λ-*cusp* if all the vertices adjacent to v are below $\mathcal{H}_v$. For each event point v_i we do the following.

1. v_i is regular. Let the leftmost and rightmost edges that are incident on v_i and above $\mathcal{H}_{v_i}$ are $E_l(v_i)$ and $E_r(v_i)$, respectively. The left projection v_{il} of v_i is the intersection of $\mathcal{H}_{v_i}$ and the edge to the left of $E_l(v_i)$ in the sweep-line status. Similarly the right projection v_{ir} of v_i is the intersection of $\mathcal{H}_{v_i}$ and the edge to the right of $E_r(v_i)$ in the sweep-line status. All the edges between $E_l(v_i)$ and $E_r(v_i)$ in the sweep-line status are replaced in an order-preserving manner by the edges incident on v_i that are below $\mathcal{H}_{v_i}$.
2. v_i is a V-cusp. The left and right projections of v_i are computed in the same manner as in Step 1 above. All the edges incident on v_i are then *deleted* from the sweep-line status.
3. v_i is a Λ-cusp. We use binary search in the sweep-line status to look for the two adjacent edges $E_l(v_i)$ and $E_r(v_i)$ such that v_i lies in between. The left projection v_{il} of v_i is the intersection of $\mathcal{H}_{v_i}$ and $E_l(v_i)$ and the right projection v_{ir} of v_i is the intersection of $\mathcal{H}_{v_i}$ and $E_r(v_i)$. All the edges incident on v_i are then inserted in an order-preserving manner between $E_l(v_i)$ and $E_r(v_i)$ in the sweep-line status.

Figure 19.11 illustrates these three cases. Since the update of the sweep-line status for each event point takes $O(\log n)$ time, the total amount of time needed is $O(n \log n)$.

THEOREM 19.8 *Given a planar straight-line graph $G(V, E)$, the horizontal* **visibility map** *of G can be computed in $O(n \log n)$ time, where $n = |V|$. However, if G is a simple polygon then the horizontal visibility map can be computed in linear time.*

Triangulation

In this section we consider triangulating a planar straight-line graph by introducing noncrossing edges so that each face in the final graph is a triangle and the outermost boundary of the graph forms a convex polygon. Triangulation of a set of (discrete) points in the plane is a special case. This is a fundamental problem that arises in computer graphics, geographical information systems, and finite element methods. Let us start with the simplest case.

Polygon Triangulation

Consider a simple polygon P with n vertices. It is obvious that to triangulate the interior of P (into $n - 2$ triangles) one needs to introduce at most $n - 3$ diagonals. A pioneering work is due to Garey et al. [28] who gave an $O(n \log n)$ algorithm and a linear algorithm if the polygon is *monotone.* A polygon is monotone if there exists a straight line $\mathcal{L}$ such that the intersection of ∂P and any line orthogonal to $\mathcal{L}$ consists of no more than two points. The shaded area in Fig. 19.12(a) is a monotone polygon.

The $O(n \log n)$ time algorithm can be illustrated by the following two-step procedure.

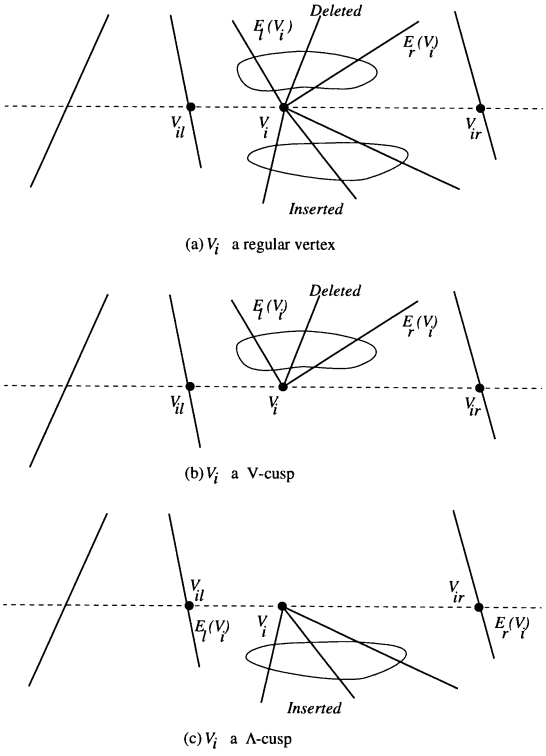

FIGURE 19.11 Updates of sweep-line status.

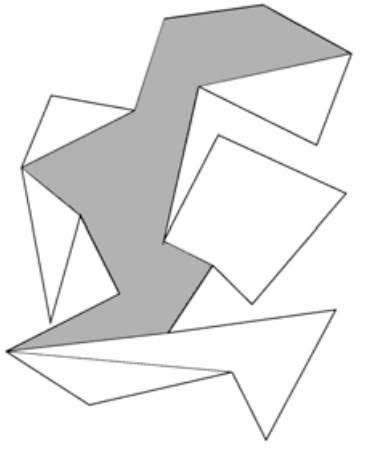

FIGURE 19.12 Decomposition of a simple polygon into monotone subpolygons.

1. Decompose P into a collection of monotone subpolygons with respect to the y-axis in time $O(n \log n)$.
2. Triangulate each monotone subpolygons in linear time.

To find a decomposition of P into a collection of monotone polygons we first obtain the horizontal visibility map described in "Trapezoidalization." In particular we obtain for each cusp v the left and right projections and the associated trapezoid below $\mathcal{H}_v$ if v is a V-cusp, and above $\mathcal{H}_v$ if v is a Λ-cusp. (Recall that $\mathcal{H}_v$ is the horizontal line passing through v.) For each V-cusp v we introduce an edge $\overline{v, w}$ where w

is the vertex through which the other base of the trapezoid below passes. $\overline{t, u}$ and $\overline{v, w}$ in Fig. 19.10(a) illustrate these two possibilities, respectively. For each Λ-cusp we do the same thing. In this manner we convert each vertex into a regular vertex, except the cusps v for which $\overline{v_l, v_r}$ lies totally outside of P, where v_l and v_r are the left and right projections of v in the horizontal visibility map. This process is called *regularization* [42]. Figure 19.12 shows a decomposition of the simple polygon in Fig. 19.10(a) into a collection of monotone polygons.

We now describe an algorithm that triangulates a monotone polygon P in linear time. Assume that the monotone polygon has v_0 as the topmost vertex and v_{n-1} as the lowest vertex. We have two polygonal chains from v_0 to v_{n-1}, denoted $\mathcal{L}$ and $\mathcal{R}$, that define the left and right boundary of P, respectively. Note that vertices on these two polygonal chains are already sorted in descending order of their y-coordinates. The algorithm is based on a *greedy* method, i.e., whenever a triangle can be formed by connecting vertices either on the same chain or on opposite chains, we do so immediately. We shall examine the vertices in order, and maintain a polygonal chain $\mathcal{C}$ consisting of vertices whose internal angles are greater than π. Initially $\mathcal{C}$ consists of two vertices v_0 and v_1 that define an edge $\overline{v_0, v_1}$. Suppose $\mathcal{C}$ consists of vertices $v_{i_0}, v_{i_1}, \ldots, v_{i_k}, k \geq 1$. We distinguish two cases for each vertex v_l examined, $l < n-1$. Without loss of generality we assume $\mathcal{C}$ is a left chain, i.e., $v_{i_k} \in \mathcal{L}$. The other case is treated symmetrically.

1. $v_l \in \mathcal{L}$. Let v_{i_j} be the last vertex on $\mathcal{C}$ that is visible from v_l. That is, the internal angle $\angle(v_{i_j}, v_{i_{j'}}, v_l)$, where $j < j' \leq k$, is less than π, and either $v_{i_j} = v_{i_0}$ or the internal angle $\angle(v_{i_{j-1}}, v_{i_j}, v_l)$ is greater than π. Add diagonals $\overline{v_l, v_{i_{j'}}}$, for $j \leq j' < k$. Update $\mathcal{C}$ to be composed of vertices $v_{i_0}, v_{i_1}, \ldots, v_{i_j}, v_l$.
2. $v_l \in \mathcal{R}$. In this case we add diagonals $\overline{v_l, v_{i_{j'}}}$, for $0 \leq j' \leq k$. $\mathcal{C}$ is updated to be composed of v_{i_k} and v_l and it becomes a right chain.

Figures 19.13(a) and (b) illustrate these two cases, respectively, in which the shaded portion has been triangulated.

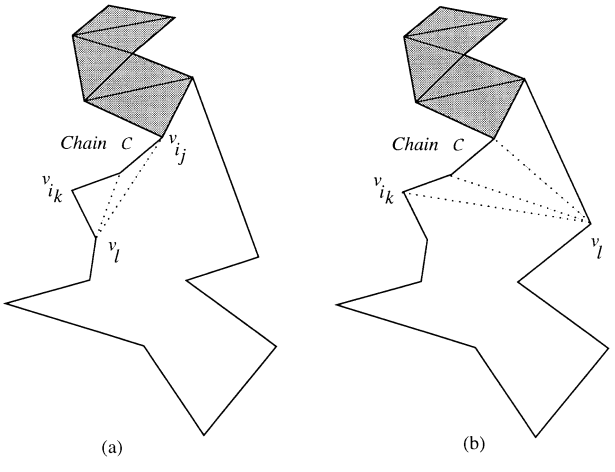

FIGURE 19.13 Triangulation of a monotone polygon.

Fournier and Montuno [26] and independently Chazelle and Incerpi [14] showed that triangulation of a polygon is linear-time equivalent to computing the horizontal visibility map. Based on this result Tarjan and Van Wyk [47] first devised an $O(n \log\log n)$ time algorithm that computes the *horizontal visibility map* and hence, an $O(n \log\log n)$ time algorithm for triangulating a simple polygon. A simpler algorithm of the same complexity was give in [34]. A Las Vegas algorithm with $O(n \log^* n)$ expected time was given

in [18]. A recent breakthrough result of Chazelle [12] finally settled the longstanding open problem, i.e., triangulating a simple polygon in linear time. But the method is quite involved. As a result of this linear triangulation algorithm, a number of problems can be solved asymptotically in linear time. Note that if the polygons have holes, the problem of triangulating the interior is shown to require $\Omega(n \log n)$ time [4].

Planar Straight-Line Graph Triangulation

The triangulation is also known as the *constrained triangulation.* This problem includes the triangulation of a set of points. A triangulation of a given planar straight-line graph $G(V, E)$ with $n = |V|$ vertices is a planar graph $\mathcal{G}(V, \mathcal{E})$ such that $E \subseteq \mathcal{E}$ and each face is a triangle, except the exterior one, which is unbounded. A constrained triangulation $\mathcal{G}(V, \mathcal{E})$ of a $G(V, E)$ can be obtained as follows.

1. Compute the convex hull of the set of vertices, ignoring all the edges. Those edges that belong to the convex hull are necessarily in the constrained triangulation. They define the boundary of the exterior face.
2. Compute the horizontal visibility map for the graph, $G' = G \cup \mathrm{CH}(V)$, where $\mathrm{CH}(V)$ denotes the convex hull of V, i.e., for each vertex, its left and right projections are calculated, and a collection of trapezoids are obtained.
3. Apply the *regularization* process by introducing edges to vertices in the graph G' that are not regular. An isolated vertex requires two edges, one from above and one from below. Regularization will yield a collection of *monotone* polygons that comprise collectively the interior of $\mathrm{CH}(V)$.
4. Triangulate each monotone subpolygon.

It is easily seen that the algorithm runs in time $O(n \log n)$, which is asymptotically optimal. (This is because the problem of sorting is linearly reducible to the problem of constrained triangulation.)

Delaunay and Other Special Triangulations

Sometimes we want to look for *quality* triangulation, instead of just an arbitrary one. For instance, triangles with large or small angles is not desirable. The Delaunay triangulation of a set of points in the plane is a triangulation that satisfies the *empty circumcircle property,* i.e., the circumcircle of each triangle does not contain any other points in its interior. It is well-known that the Delaunay triangulation of points in general position is unique and it will maximize the minimum angle. In fact, the **characteristic angle vector** of the Delaunay triangulation of a set of points is *lexicographically maximum.* The notion of Delaunay triangulation of a set of points can be generalized to a planar straight-line graph $G(V, E)$. That is, we'd like to have G as a subgraph of a triangulation $\mathcal{G}(V, \mathcal{E}')$, $E \subseteq \mathcal{E}'$, such that each triangle satisfies the *empty circumcircle* property: no vertex *visible* from the vertices of triangle is contained in the interior of the circle. This *generalized* Delaunay triangulation is thus a constrained triangulation that maximizes the minimum angle. The generalized Delaunay triangulation was first introduced by the author and an $O(n^2)$ (respectively, $O(n \log n)$) algorithm for constructing the generalized triangulation of a planar graph (respectively a simple polygon) with n vertices was given in [37]. As the generalized Delaunay triangulation (also known as *constrained* Delaunay triangulation) is of fundamental importance, we describe in "Constrained Delaunay Triangulation" an optimal algorithm due to Chew [16] that computes the constrained Delaunay triangulation for a planar straight-line graph $G(V, E)$ with n vertices in $O(n \log n)$ time. Triangulations that minimize the maximum angle or maximum edge length [24] were also studied. But if the constraints are on the measure of the triangles, for instance, each triangle in the triangulation must be nonobtuse, then **Steiner points** must be introduced. See Bern and Eppstein (in [21, p. 23–90]) for a survey of triangulations satisfying different criteria and discussions of triangulations in two and three dimensions. Bern and Eppstein gave an $O(n \log n + \mathcal{F})$ algorithm for constructing a nonobtuse triangulation of polygons using $\mathcal{F}$ triangles. Bern et al. [9] showed that $\mathcal{F}$ is $O(n)$ and gave an $O(n \log n)$

time algorithm for simple polygons without holes, and an $O(n \log^2 n)$ time algorithm for polygons with holes.

The problem of triangulating a set P of points in $\Re^k$, $k \geq 3$ is less studied. In this case the convex hull of P is to be partitioned into $\mathcal{F}$ nonoverlapping simplices, the vertices of which are points in P. A simplex in k-dimensions consists of exactly $k+1$ points, all of which are extreme points. In $\Re^3$ $O(n \log n + \mathcal{F})$ time suffices, where $\mathcal{F}$ is linear if no three points are collinear, and $O(n^2)$ otherwise. See [21] for more references on three dimensional triangulations and Delaunay triangulations in higher dimensions.

Constrained Delaunay Triangulation

Consider a **planar straight-line graph** $G(V, E)$, where V is a set of points in the plane, and edges in E are nonintersecting except possibly at the endpoints. Let $n = |V|$. Without loss of generality we assume that the edges on the convex hull CH(V) are all in E. These edges, if not present, can be computed in $O(n \log n)$ time (cf. "Convex Hulls in Two and Three Dimensions").

In the constrained Delaunay triangulation $G_{DT}(V, \mathcal{E})$ the edges in $\mathcal{E} \setminus E$ are called *Delaunay* edges. It can be shown that two points $p, q \in V$ define a Delaunay edge if there exists a circle $\mathcal{K}$ passing through p and q which does not contain in its interior any other point visible from p and from q.

Let us assume without loss of generality that the points are in general position that no two have the same x-coordinate, and no four are cocircular. Let the points in V be sorted by ascending order of x-coordinate so that $x(p_i) < x(p_j)$ for $i < j$. Let us associate this set V (and graph $G(V, E)$) with it a bounding rectangle R_V with diagonal points $U(u.x, u.y)$, $L(l.x, l.y)$, where $u.x = x(p_n)$, $u.y = \max y(p_i)$, $l.x = x(p_1)$, $l.y = \min y(p_i)$. That is, L is at the lower left corner with x- and y-coordinates equal to the minimum of the x- and y-coordinates of all the points in V, and U is at the upper right corner. Given an edge $\overline{p_i, p_j}$, $i < j$, its x-interval is the interval $(x(p_i), x(p_j))$. The x-interval of the bounding rectangle R_V, denoted by $\mathcal{X}_V$, is the interval $(x(p_1), x(p_n))$. The set V will be recursively divided by vertical lines $\mathcal{L}$'s and so will be the bounding rectangles. We first divide V into two halves V_l and V_r by a line $\mathcal{L}(X = m)$, where $m = \frac{1}{2}(x(p_{\lfloor n/2 \rfloor}) + x(p_{\lfloor n/2 \rfloor + 1}))$. The edges in E that lie totally to the left and to the right of $\mathcal{L}$ are assigned respectively to the left graph $G_l(V_l, E_l)$ and to the right graph $G_r(V_r, E_r)$, which are associated respectively with bounding rectangle R_{v_l} and R_{V_r} whose x-intervals are $\mathcal{X}_{V_l} = (x(p_1), m)$ and $\mathcal{X}_{V_r} = (m, x(p_n))$, respectively. The edges $\overline{p, q} \in E$ that are intersected by the dividing line and that do not *span*[4] the associated x-interval $\mathcal{X}_V$ will each get *cut* into two edges and a *pseudo* point $\epsilon(p, q)$ on the edge is introduced. Two edges, called *half-edges*, $\overline{p, \epsilon(p, q)} \in E_l$ and $\overline{\epsilon(p, q), q} \in E_r$ are created. Figure 19.14(a) shows the creation of half-edges with pseudo points shown in hollow circles. Note that the edge $\overline{p, q}$ in the shaded area is not considered "present" in the associated bounding rectangle, $\overline{u, v}$ spans the x-interval for which no pseudo point is created, and $\overline{s, t}$ is a half-edge that spans the x-interval of the bounding rectangle to the left of the dividing line $\mathcal{L}$.

It can be shown that for each edge $\overline{p, q} \in E$, the number of half-edges so created is at most $O(\log n)$. Within each bounding rectangle the edges that span its x-interval will divide the bounding rectangle into various parts. The constrained Delaunay triangulation gets computed for each part recursively. At the bottom of recursion each bounding rectangle contains at most three vertices of V, the edges incident on them, plus a number of half-edges spanning the x-interval including the pseudo endpoints of half-edges. Figure 19.14(b) illustrates an example of the constrained Delaunay triangulation at some intermediate step. No edges shall intersect one another, except at the endpoints.

As is usually the case for divide-and-conquer paradigm, the **merge** step is the key to the method. We describe below the **merge** step that combines constrained Delaunay triangulations in adjacent bounding rectangles that share a common dividing vertical edge $\mathcal{L}$.

[4] An edge $\overline{p, q}$, $x(p) < x(q)$ is said to span an x-interval (a, b), if $x(p) < a$ and $x(q) > b$.

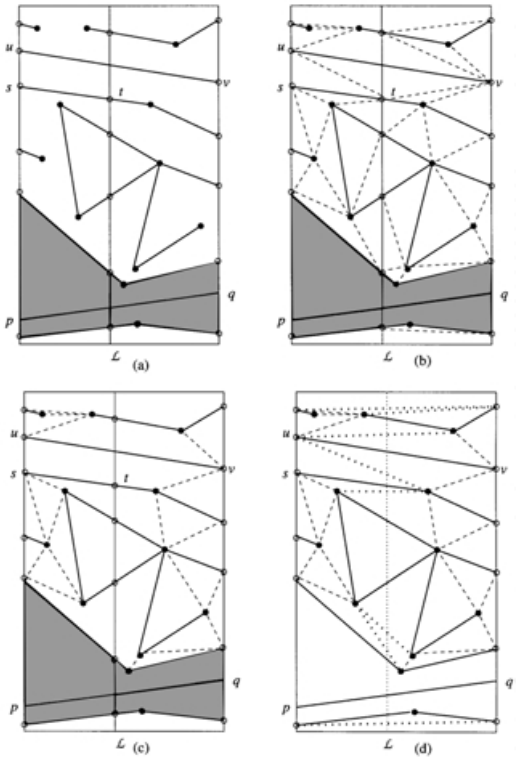

FIGURE 19.14 Computation of constrained Delaunay triangulation for subgraphs in adjacent bounding rectangles.

1. Eliminate the pseudo points along the boundary edge $\mathcal{L}$, including the Delaunay edges incident on those pseudo points. This results in a partial constrained Delaunay triangulation within the union of these two bounding rectangles. Figure 19.14(c) illustrates the partial constrained Delaunay triangulation as a result of the removal of the Delaunay edges incident on the pseudo points on the border of the constrained Delaunay triangulation shown in Fig. 19.14(b).
2. Compute new Delaunay edges that cross $\mathcal{L}$ as follows. Let A and B be the two endpoints of an edge that crosses $\mathcal{L}$ with A on the left and B on the right of $\mathcal{L}$, and $\overline{A, B}$ is known to be part of the desired constrained Delaunay triangulation. That is, either $\overline{A, B}$ is an edge of E or a Delaunay edge just created. Either A or B may be a pseudo point. Let $\overline{A, C}$ be the first edge counterclockwise from edge $\overline{A, B}$. To decide if $\overline{A, C}$ remains to be a Delaunay edge in the desired constrained Delaunay triangulation, we consider the next edge $\overline{A, C_1}$, if it exists. counterclockwise from $\overline{A, C}$. If $\overline{A, C_1}$ does not exist, or $\overline{A, C}$ is in E, $\overline{A, C}$ will remain. Otherwise we test if the circumcircle $\mathcal{K}(A, C, C_1)$ contains B in its interior. If so, $\overline{A, C}$ is eliminated, and the test continues on $\overline{A, C_1}$. Otherwise, $\overline{A, C}$ stays. We do the same thing to test edges incident on B, except that we consider edges incident on B in clockwise direction from $\overline{B, A}$. Assume now we have determined that both $\overline{A, C}$ and $\overline{B, D}$ remain. The next thing to do is to decide which of edge $\overline{B, C}$ and $\overline{A, D}$ should belong to the desired constrained Delaunay triangulation. We apply the circle test: test if circle $\mathcal{K}(A, B, C)$ contains D in the interior. If not, $\overline{B, C}$ is the desired Delaunay edge. Otherwise $\overline{A, D}$ is. We then repeat this step.

Step 2 of the *merge step* is similar to the method is constructing unconstrained Delaunay triangulation given in [37] and can be accomplished in time linear in the number of edges in the combined bounding

rectangle. The dotted lines in Fig. 19.14(d) are the Delaunay edges introduced in Step 2. We therefore conclude with the following theorem.

THEOREM 19.9 *Given a planar straight-line graph $G(V, E)$ with n vertices, the constrained Delaunay triangulation of G can be computed in $O(n \log n)$ time, which is asymptotically optimal.*

An implementation of this algorithm can be found in `http://www.ece.nwu.edu/~theory`.

Other Decompositions

Partitioning a simple polygon into shapes such as convex polygons, **star-shaped polygons,** spiral polygons, etc., has also been investigated. After a polygon has been triangulated one can partition the polygon into star-shaped polygons in linear time. This algorithm provided a very simple proof of the traditional art gallery problem originally posed by Klee, i.e., $\lfloor n/3 \rfloor$ vertex guards are always sufficient to see the entire region of a simple polygons with n vertices. But if a partition of a simple polygon into a minimum number of star-shaped polygons is desired, Keil [33] gave an $O(n^5 N^2 \log n)$ time, where N denotes the number of reflex vertices. However, the problem of *decomposing* a simple polygon into a minimum number of star-shaped parts that may overlap is shown to be **NP-hard** [41]. This problem sometimes is referred to as the *covering* problem, in contrast to the *partitioning* problem, in which the components are not allowed to overlap. The problem of partitioning a polygon into a minimum number of convex parts can be solved in $O(N^2 n \log n)$ time [33]. It is interesting to note that it may not be possible to partition a simple polygon into convex quadrilaterals, but it is always possible for rectilinear polygons. The problem of determining if a convex quadrilateralization of a polygonal region (with holes) exists is NP-complete. It is interesting to note that $\lfloor n/4 \rfloor$ vertex guards are always sufficient for the art gallery problem in a rectilinear polygon. An $O(n \log n)$ algorithm for computing a convex quadrilateralization or positioning at most $\lfloor n/4 \rfloor$ guards is known (see [41] for more information). The minimum covering problem by star-shaped polygons for rectilinear polygons is still *open.* For variations and results of art gallery problems the reader is referred to [41, 46]. Polynomial time algorithms for computing the minimum partition of a simple polygon into simpler parts while allowing Steiner points can be found in [4].

The minimum partition or covering problem for simple polygons becomes NP-hard when the polygons are allowed to have *holes* [33]. Asano et al. [3] showed that the problem of partitioning a simple polygon with h holes into a minimum number of trapezoids with two horizontal sides can be solved in $O(n^{h+2})$ time, and that the problem is NP-complete if h is part of the input. An $O(n \log n)$ time 3-approximation algorithm was presented.

The problem of partitioning a rectilinear polygon with holes into a minimum number of rectangles (allowing Steiner points) arises in VLSI artwork data. Imai and Asano [32] gave an $O(n^{3/2} \log n)$ time and $O(n \log n)$ space algorithm for partitioning a rectilinear polygon with holes into a minimum number of rectangles (allowing Steiner points). The problem of covering a rectilinear polygon (without holes) with a minimum number of rectangles, which is a special case of a *Boolean basis problem,* however, is NP-hard [39].

Given a polyhedron with n vertices and r notches (features causing nonconvexity), $\Omega(r^2)$ convex components are required for a complete convex decomposition in the worst case. Chazelle and Palios [15] gave an $O((n + r^2) \log r)$ time $O(n + r^2)$ space algorithm for this problem. Bajaj and Dey addressed a more general problem where the polyhedron may have holes and internal voids [8]. The problem of minimum partition into convex parts and the problem of determining if a nonconvex polyhedron can be partitioned into tetrahedra without introducing Steiner points are NP-hard [44].

19.6 Research Issues and Summary

We have covered in this chapter a number of topics in computational geometry, including convex hulls, maximal-finding problems, decomposition, and maxima searching in monotone matrices. Results, some of which are classical, and some which represent the state of the art of this field, were presented. More topics will be covered in the next chapter (Chapter 20).

In "Convex Layers of a Planar Set" an optimal algorithm for computing the layers of planar convex hulls is presented. It shows an interesting fact: within the same time as computing the convex hull (the outermost layer) of a point set in two dimensions, one can compute *all* layers of convex hull. Whether or not one can do the same for higher dimensions $\Re^k$, $k > 2$ remains to be seen. It is known that finding a minimum covering of a simple polygon by star-shaped polygons is NP-hard, but the problem for rectilinear polygons, however, is still *open,* Although the triangulation problem of a simple polygon has been solved by Chazelle [12], the algorithm is far from being practical. As this problem is at the heart of this field, a simpler and more practical algorithm is of great interest.

19.7 Defining Terms

Asymptotic time or space complexity: Asymptotic behavior of the time (or space) complexity of an algorithm when the size of the problem approaches infinity. This is usually denoted in big-Oh notation of a function of input size. A time or space complexity $T(n)$ is $O(f(n))$ means that there exists a constant $c > 0$ such that such that $T(n) \leq c \cdot f(n)$ for sufficiently large n, i.e., $n > n_0$, for some n_0.

CAD/CAM: Computer-aided design and computer-aided manufacturing, a discipline that concerns itself with the design and manufacturing of products aided by a computer.

Characteristic angle vector: A vector of minimum angles of each triangle in a triangulation arranged in nondescending order. For a given point set the number of triangles is the same for all triangulations, and therefore each of these triangulation has a characteristic angle vector.

Divide-and-Marriage-before-Conquest: A problem-solving paradigm derived from divide-and-conquer. A term coined by the Kirkpatrick and Seidel [35], authors of this method. After the divide step in a divide-and-conquer paradigm, instead of conquering the subproblems by recursively solving them, a merge operation is performed first on the subproblems. This method is proven more effective than conventional divide-and-conquer for some applications.

Extreme point: A point in S is an extreme point if it cannot be expressed as a convex combination of other points in S. A convex combination of points $p_1, p_2, \ldots, p_n$ is $\Sigma_{i=1}^{n} \alpha_i p_i$, where $\alpha_i, \forall i$ is nonnegative, and $\Sigma_{i=1}^{n} \alpha_i = 1$.

Geometric duality: A transform between a point and a hyperplane in $\Re^k$ that preserves incidence and order relation. For a point $p = (\mu_1, \mu_2, \ldots, \mu_k)$, its dual $\mathcal{D}(p)$ is a hyperplane denoted by $x_k = \Sigma_{j=1}^{k-1} \mu_j x_j - \mu_k$; for a hyperplane $\mathcal{H} : x_k = \Sigma_{j=1}^{k-1} \mu_j x_j + \mu_k$, its dual $\mathcal{D}(\mathcal{H})$ is a point denoted by $(\mu_1, \mu_2, \ldots, -\mu_k)$. See [19, 22] for more information.

Height-balanced binary search tree: A data structure used to support membership, insert/delete operations each in time logarithmic in the size of the tree. A typical example is the *AVL* tree or *red-black* tree.

NP-hard problem: A complexity class of problems that are intrinsically *harder* than those that can be solved by a Turing machine in nondeterministic polynomial time. When a decision version of a combinatorial optimization problem is proven to belong to the class of NP-complete problems, which includes well-known problems such as *satisfiability. traveling salesman problem,* etc., an optimization version is NP-hard. For example, to decide if there exist k star-shaped polygons whose union is equal to a given simple polygon, for some parameter k, is NP-complete. The

optimization version, i.e., finding a minimum number of star-shaped polygons whose union is equal to a given simple polygon, is NP-hard.

On-line algorithm: An algorithm is said to be *on-line* if the input to the algorithm is given one at a time. This is in contrast to the *off-line* case where the input is known in advance. The algorithm that works on-line is similar to the off-line algorithms that work incrementally, i.e., it computes a partial solution by considering input data one at a time.

Planar straight-line graph: A graph that can be embedded in the plane without crossings in which every edge in the graph is a straight line segment. It is sometimes referred to as *planar subdivision* or *map.*

Star-shaped polygon: A polygon P in which there exists an interior point p such that all the boundary points of P are visible from p. That is, for any point q on the boundary of P, the intersection of the line segment $\overline{p, q}$ with the boundary of P is the point q itself.

Steiner point: A point that is not part of the input set. It is derived from the notion of Steiner tree. Consider a set of three points determining a triangle $\Delta(a, b, c)$ all of whose angles are smaller than 120°, in the Euclidean plane, finding a shortest tree interconnecting these three points is known to require a *fourth* point s in the interior such that each side of $\Delta(a, b, c)$ subtends the angle at s equal to 120°. The optimal tree is called the *Steiner tree* of the three points, and the fourth point is called the *Steiner point.*

Visibility map: A planar subdivision that encodes the visibility information. Two points p and q are *visible* if the straight line segment $\overline{p, q}$ does not intersect any other object. A horizontal (or vertical) visibility map of a planar straight-line graph is a partition of the plane into regions by drawing a horizontal (or vertical) straight line through each vertex p until it intersects an edge e of the graph or extends to infinity. The edge e is said to be horizontally (or vertically) visible from p.

Further Information

For some problems we present efficient algorithms in pseudo code and for others that are of more theoretical interest we only give a sketch of the algorithms and refer the reader to the original articles. A recent textbook by de Berg et al. [19] contains a very nice treatment of this topic. The reader who is interested in *parallel* computational geometry is referred to [5]. For current research results, the reader may consult the Proceedings of the Annual ACM symposium on Computational Geometry, and the following three journals, *Discrete & Computational Geometry, International Journal of Computational Geometry & Applications,* and *Computational Geometry: Theory and Applications.* More references can be found in [29, 36, 45, 49]. The ftp site /pub/geometry/geombib.tar.gz at ftp.cs.usask.ca contains close to 10,000 entries of bibliography in this field.

David Avis announced a convex hull/vertex enumeration code, *lrs,* based on reverse search and made it available at this site ftp://mutt.cs.mcgill.ca/pub/C/lrs.html. It finds all vertices and rays of a polyhedron in $\Re^k$ for any k, defined by a system of inequalities, and finds a system of inequalities describing the convex hull of a set of vertices and rays. For more details consult the user's manual found at the site. See [7] for more information about other convex hull codes. Those who are interested in the implementations or would like to have more information about other software available can consult `http://www.geom.umn.edu/software/cglist/`.

The following WWW page on *Geometry in Action* maintained by David Eppstein at `http://www.ics.uci.edu/~eppstein/geom.html` and computational geometry page by J. Erickson at `http://www.cs.duke.edu/~jeffe/compgeom` give a comprehensive description of research activities of computational geometry.

Computational Geometry II

D. T. Lee
Northwestern University

20.1 Introduction

This chapter is a follow-up of the previous Chapter 19, which dealt with geometric problems and their efficient solutions. The classes of problems that we address in this chapter include proximity, optimization, intersection, searching, point location, and some discussions of geometric software that is under development.

20.2 Proximity

Geometric problems abound pertaining to the questions of how *close* two geometric entities are among a collection of objects or how *similar* two geometric patterns match each other. For example, in pattern classification and clustering, features that are *similar* according to some metric are to be clustered in a group. The two aircrafts that are *closest* at any time instant in the air space will have the largest likelihood

of collision with each other. In some cases one may be interested in how *far apart* or how *dissimilar* the objects are. Some of these *proximity*-related problems will be addressed in this section.

Closest Pair

Consider a set S of n points in $\Re^k$. The *closest pair problem* is to find in S a pair of points whose distance is the minimum, i.e., find p_i and p_j, such that $d(p_i, p_j) = \min_{k \neq l}\{d(p_k, p_l)$, for all points $p_k, p_l \in S\}$, where $d(a, b)$ denotes the Euclidean distance between a and b. (The result below holds for any distance metric in Minkowski's norm.) Enumerating all pairs of distances to find the pair with the minimum distance would take $O(d \cdot n^2)$ time. As is well-known, in one dimension one can solve the problem much more efficiently: Since the closest pair of points must occur consecutively on the real line, one can sort these points and then scan them in order to solve the closest pair problem in $O(n \log n)$ time. The time complexity turns out to be best possible, since the problem has a lower bound of $\Omega(n \log n)$, following from a linear time transformation from the *element uniqueness problem* [85].

But unfortunately there is no total ordering for points in $\Re^k$ for $k \geq 2$, and thus, sorting is not applicable. We will show that using *divide-and-conquer* approach one can solve this problem in $O(n \log n)$ optimal time. Let us consider the case when $k = 2$. In the following we only compute the minimum distance of the closest pair; the actual identity of the closest pair that realizes the minimum distance can be found easily by some straightforward bookkeeping operations. Consider a vertical separating line $\mathcal{V}$ that divides S into S_1 and S_2 such that $|S_1| = |S_2| = n/2$. Let δ_i denote the minimum distance defined by the closest pair of points in S_i, $i = 1, 2$. Observe that the minimum distance defined by the closest pair of points in S is either δ_1, δ_2, or $d(p, q)$ for some $p \in S_1$ and $q \in S_2$. In the former case, we are done. In the latter, points p and q must lie in the vertical strip of width $\delta = \min\{\delta_1, \delta_2\}$ on each side of the separating line $\mathcal{V}$ (Fig. 20.1). The problem now reduces to that of finding the closest pair between points in S_1 and S_2 that lie inside the strip $\mathcal{L}$ of width 2δ. This subset $\mathcal{L}$ of points possesses a special property, known as *sparsity*, i.e., for each square box[1] of length 2δ the number of points in $\mathcal{L}$ is bounded by a constant $c = 4 \cdot 3^{k-1}$, since in each set S_i, there exists no point that lies in the interior of the δ-ball centered at each point in S_i, $i = 1, 2$ [85] (Fig. 20.2). It is this sparsity property that enables us to solve the *bichromatic closest pair problem* in $O(n)$ time.

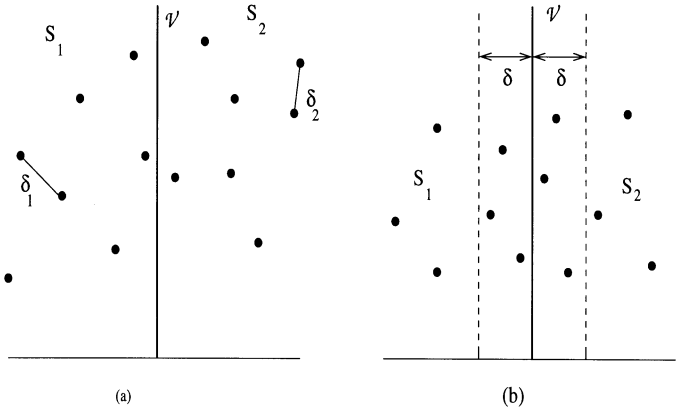

FIGURE 20.1 Divide-and-conquer scheme for closest pair problem.

[1] A box is a hypercube in higher dimensions.

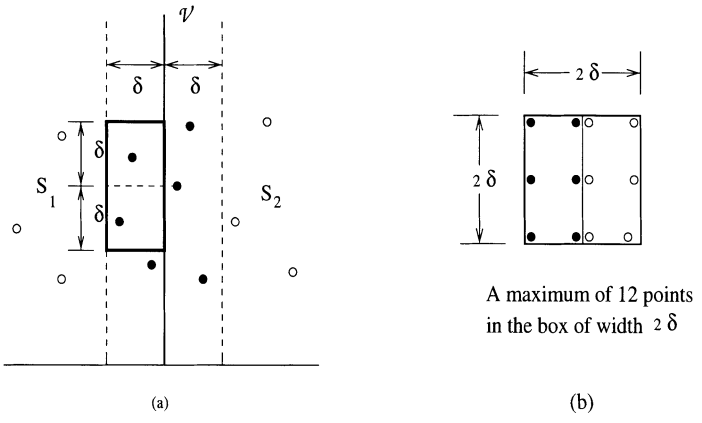

FIGURE 20.2 The box of width 2δ dissected by the separating line has at most 12 points; each point in S_2 needs to examine at most 6 points in S_1 to find its closest neighbor.

The bichromatic closest pair problem is defined as follows. Given two sets of red and blue points, denoted R and B, find the closest pair $r \in R$ and $b \in B$, such that $d(r, b)$ is minimum among all possible distances $d(u, v), u \in R, v \in B$. Let $\overline{S}_i \subseteq S_i$ denote the set of points that lie in the vertical strip. In two dimensions, the sparsity property ensures that for each point $p \in \overline{S}_1$ the number of candidate points $q \in \overline{S}_2$ for the closest pair is at most six (Fig. 20.2). We therefore can scan these points $\overline{S}_1 \cup \overline{S}_2$ in order along the separating line $\mathcal{V}$ and compute the distance between each point in $\overline{S}_1$ (respectively, $\overline{S}_2$) scanned and its six candidate points in $\overline{S}_2$ (respectively, $\overline{S}_1$). The pair that gives the minimum distance δ_3 is the bichromatic closest pair. The minimum distance of all pairs of points in S is then equal to $\delta_S = min\{\delta_1, \delta_2, \delta_3\}$.

Since the merge step takes linear time, the entire algorithm takes $O(n \log n)$ time. This idea generalizes to higher dimensions, except that to ensure the sparsity property of the set $\mathcal{L}$, the separating hyperplane should be appropriately chosen so as to obtain an $O(n \log n)$ time algorithm [85], which is asymptotically optimal.

We note that the bichromatic closest pair problem is in general more difficult than the closest pair problem. Edelsbrunner and Sharir [46] showed that in three dimensions the number of possible closest pairs is $O((|R| \cdot |B|)^{2/3} + |R| + |B|)$. Agarwal et al. [2] gave an $O(n^{2(1-1/(\lceil k/2 \rceil + 1))+\epsilon})$ time algorithm and a randomized algorithm with an expected running time of $O(n^{4/3} \log^c n)$ for some constant c, where $n = |R| + |B|$. Only when the two sets possess the sparsity property defined above can the problem be solved in $O(n \log n)$ time, where $n = |R| + |B|$. A more general problem, known as *fixed radius all nearest-neighbor problem in a sparse set* [85], i.e., given a set M of points in $\Re^k$ that satisfies the sparsity condition, find all pairs of points whose distance is less than a given parameter δ, can be solved in $O(|M| \log |M|)$ time [85].

The closest pair of vertices u and v of a simple polygon P such that $\overline{u, v}$ lies totally within P can be found in linear time [57]; $\overline{u, v}$ is also known as a diagonal of P.

Voronoi Diagrams

The Voronoi diagram $\mathcal{V}(S)$ of a set S of points, called *sites*, $S = \{p_1, p_2, \ldots, p_n\}$ in $\Re^k$ is a partition of $\Re^k$ into Voronoi cells $V(p_i), i = 1, 2, \ldots, n$, such that each cell contains points that are closer to site p_i than to any other site $p_j, j \neq i$, i.e.,

$$V(p_i) = \left\{ x \in R^k \middle| d(x, p_i) \leq d(x, p_j) \forall p_j \in \Re^k, j \neq i \right\}.$$

In two dimensions, $\mathcal{V}(S)$ is a planar graph and is of size linear in $|S|$. In dimensions $k \geq 2$, the total number of d-faces of dimensions $d = 0, 1, \ldots, k-1$, in $\mathcal{V}(S)$ is $O(n^{\lceil d/2 \rceil})$.

Figure 20.3(a) shows the Voronoi diagram of 16 point sites in two dimensions. Figure 20.3(b) shows the straight-line dual graph of the Voronoi diagram, which is called the Delaunay triangulation (cf. "Triangulation" of Chapter 19). In this triangulation the vertices are the sites, and two vertices are connected by an edge if their Voronoi cells are adjacent.

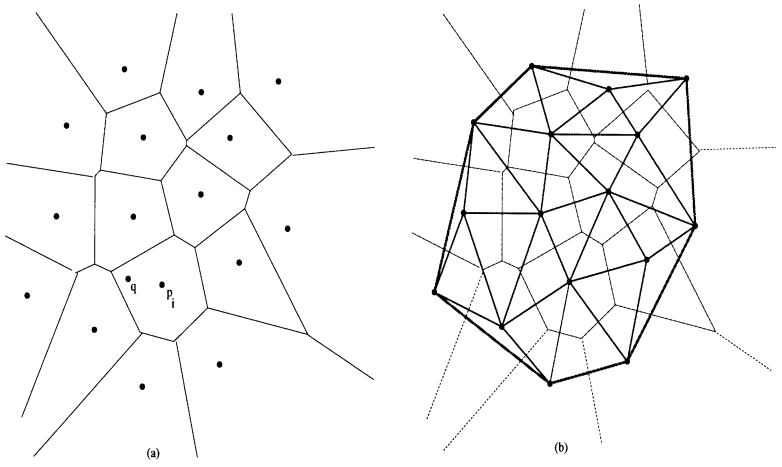

FIGURE 20.3 The Voronoi diagram of a set of 16 points in the plane.

Construction of Voronoi Diagrams in Two Dimensions

The Voronoi diagram possesses many proximity properties. For instance, for each site p_i, the closest site must be among those whose Voronoi cells are adjacent to $V(p_i)$. Thus, the closest pair problem for S in $\Re^2$ can be solved in linear time after the Voronoi diagram has been computed. Since this pair of points must be adjacent in the Delaunay triangulation, all one has to do is to examine all adjacent pairs of points and report the pair with the smallest distance. A divide-and-conquer algorithm to compute the Voronoi diagram of a set of points in the L_p-metric for all $1 \leq p \leq \infty$ is known [64]. There are a rich body of literature concerning the Voronoi diagram. The interested reader is referred to recent surveys [41, 88].

We give below a brief description of a plane-sweep algorithm, known as the *wavefront approach,* due to Dehne and Klein [39]. Let $S = \{p_1, p_2, \ldots, p_n\}$ be a set of point sites in $\Re^2$ sorted in ascending x-coordinate value, i.e., $x(p_1) < x(p_2) < \cdots < x(p_n)$. Consider that we sweep a vertical line $\mathcal{L}$ from left to right and as we sweep $\mathcal{L}$, we compute the Voronoi diagram $\mathcal{V}(S_t)$, where

$$S_t = \{p_i \in S \,|x\,(p_i) \; < t\} \cup \{\mathcal{L}_t\} \; .$$

Here $\mathcal{L}_t$ denotes the vertical line whose x-coordinate equals t. As is well known, $\mathcal{V}(S_t)$ will contain not only straight line segments, which are portions of perpendicular *bisectors* of two point sites, but also parabolic curve segments, which are portions of bisectors of one point site and $\mathcal{L}_t$. The *wavefront* W_t, consisting of a sequence of parabolae, called *waves,* is the boundary of the Voronoi cell $V(\mathcal{L}_t)$ with respect to S_t. Figures 20.4(a) and (b) illustrate two instances, $\mathcal{V}(S_t)$ and $\mathcal{V}(S_{t'})$. Those Voronoi cells that do not contribute to the wavefront are final, whereas those that do will change as $\mathcal{L}$ moves to the right. There are two possible *events* at which the wavefront needs an *update.* One, called *site event,* is when a site is hit by $\mathcal{L}$ and a *new* wave appears. The other, called *spike event,* is when an old wave disappears. Let p_i and p_j be two sites such that the associated waves are adjacent in W_t. The bisector of p_i and p_j defines an

edge of $\mathcal{V}(S_t)$ to the left of W_t. Its extension into the cell $V(\mathcal{L}_t)$ is called a *spike*. The spikes can be viewed as tracks along which two neighboring waves travel. A wave disappears from W_t, once it has reached the point where its two neighboring spikes intersect. In Fig. 20.4(a) dashed lines are spikes and v is a potential spike event point. Without p_7 the wave of p_3 would disappear first and then the wave of p_4. After p_7, a site event, has occurred, a new point v' will be created and it defines an earlier spike event than v. v' will be a spike event point at which the wave of p_4 disappears and waves of p_5 and p_7 become adjacent. Note that the spike event corresponding to v' does not occur at $\mathcal{L}_t$, when $t = x(v')$. Instead, it occurs at $\mathcal{L}_t$, when $t = x(v') + d(v', p_4)$. If there is no site event between $\mathcal{L}_{x(p_7)}$ and $\mathcal{L}_t$, then the wave of p_4 will disappear. It is not difficult to see that after all site events and spikes events have been processed at time τ, $\mathcal{V}(S)$ is identical to $\mathcal{V}(S_\tau)$ with the wavefront removed.

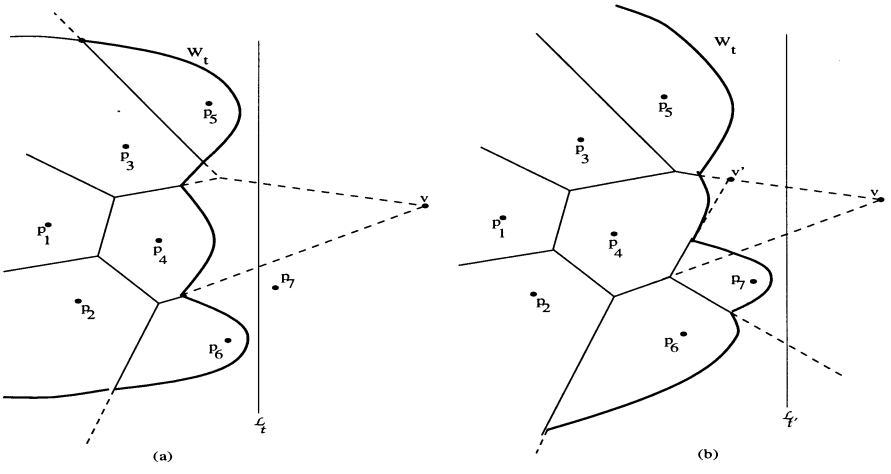

FIGURE 20.4 The Voronoi diagrams of $\mathcal{V}(S_t)$ and $\mathcal{V}(S_{t'})$.

Since the waves in W_t can be stored in a **height-balanced binary search tree** and the site events and spike events can be maintained as a **priority queue,** the overall time and space needed are $O(n \log n)$ and $O(n)$, respectively.

Although $\Omega(n \log n)$ is a lower bound for computing the Voronoi diagram for an arbitrary set of n sites, this lower bound does not apply to special cases, e.g., when the sites are on the vertices of a convex polygon. In fact the Voronoi diagram of a convex polygon can be computed in linear time [6]. This demonstrates further that additional properties of the input can sometimes help reduce the complexity of the problem.

Construction of Voronoi Diagrams in Higher Dimensions

The Voronoi diagrams in $\Re^k$ are related to the convex hulls $\Re^{k+1}$ via a **geometric duality** transformation. Consider a set S of n sites in $\Re^k$, which is the hyperplane $\mathcal{H}^0$ in $\Re^{k+1}$ such that $x_{k+1} = 0$, and a paraboloid $\mathcal{P}$ in $\Re^{k+1}$ represented as $x_{k+1} = x_1^2 + x_2^2 + \cdots + x_k^2$. Each site $p_i = (\mu_1, \mu_2, \ldots, \mu_k)$ is transformed into a hyperplane $\mathcal{H}(p_i)$ in $\Re^{k+1}$ denoted as $x_{k+1} = 2\Sigma_{j=1}^{k} \mu_j x_j - (\Sigma_{j=1}^{k} \mu_j^2)$. That is, $\mathcal{H}(p_i)$ is tangent to the paraboloid $\mathcal{P}$ at point $\mathcal{P}(p_i) = (\mu_1, \mu_2, \ldots, \mu_k, \mu_1^2 + \mu_2^2 + \cdots + \mu_k^2)$, which is just the vertical projection of site p_i onto the paraboloid $\mathcal{P}$. See Fig. 20.5 for an illustration of the transformation in one dimension. The half-space defined by $\mathcal{H}(p_i)$ and containing the paraboloid $\mathcal{P}$ is denoted as $\mathcal{H}^+(p_i)$. The intersection of all half-spaces $\bigcap_{i=1}^{n} \mathcal{H}^+(p_i)$ is a convex body and the boundary of the convex body is denoted $CH(\mathcal{H}(S))$. Any point $q \in \Re^k$ lies in the Voronoi cell $V(p_i)$ if the vertical projection of q onto $CH(\mathcal{H}(S))$ is contained in $\mathcal{H}(p_i)$. The distance between point q and its closest site p_i can be shown to be equal to the square root of the vertical distance between its vertical projection $\mathcal{P}(q)$

on the paraboloid $\mathcal{P}$ and on $CH(\mathcal{H}(S))$. Moreover every κ-face of $CH(\mathcal{H}(S))$ has a vertical projection on the hyperplane $\mathcal{H}^0$ equal to the κ-face of the Voronoi diagram of S in $\mathcal{H}^0$.

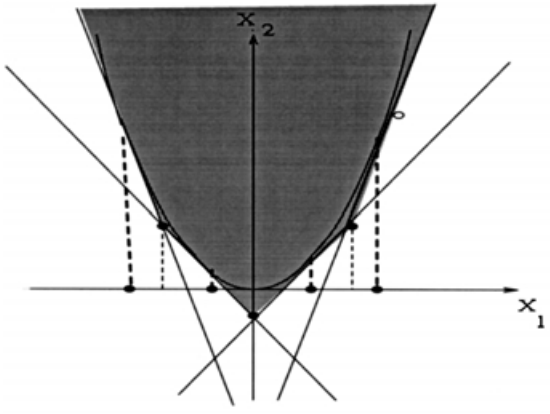

FIGURE 20.5 The paraboloid transformation of a site in one dimension to a line tangent to a parabola.

We thus obtain the result which follows from the theorem for the convex hull in Chapter 19.

THEOREM 20.1 *The Voronoi diagram of a set S of n points in $\Re^k$, $k \geq 2$ can be computed in $O(n \log \mathcal{H})$ time for $k = 2$, and in $O(n \log \mathcal{H} + (n\mathcal{H})^{1-1/(\lfloor (k+1)/2 \rfloor + 1)} \log^{O(1)} n)$ time for $k > 2$, where $\mathcal{H}$ is the number of i-faces, $i = 0, 1, \ldots, k$.*

It has recently been shown that the Voronoi diagram in $\Re^k$, for $k = 3, 4$, can be computed in $O((n + \mathcal{H}) \log^{k-1} \mathcal{H})$ time [11].

Farthest Neighbor Voronoi Diagram

The Voronoi diagram defined in the subsection "Voronoi Diagrams" is also known as the *nearest neighbor* Voronoi diagram. The *nearest neighbor* Voronoi diagram partitions the space into cells such that each site has its own cell, which contains all points that are closer to this site than to any other site. A variation of this partitioning concept is a partition of the space into cells, each of which is associated with a site, and contains all points that are *farther* from the site than from any other site. This diagram is called the *farthest neighbor* Voronoi diagram. Unlike the *nearest neighbor* Voronoi diagram, a farthest neighbor Voronoi diagram only has a subset of sites which have a Voronoi cell associated with them. Those sites that have a nonempty Voronoi cell are those that lie on the convex hull of S. A similar partitioning of the space is known as the order κ*-nearest neighbor* Voronoi diagram, in which each Voronoi cell is associated with a subset of κ sites in S for some fixed integer κ such that these κ sites are the closest among all other sites. For $\kappa = 1$ we have the *nearest neighbor* Voronoi diagram, and for $\kappa = n - 1$ we have the *farthest neighbor* Voronoi diagram. The construction of the order κ*-nearest neighbor* Voronoi diagram in the plane can be found in, e.g., [85]. The order κ Voronoi diagrams in $\Re^k$ are related to the levels of hyperplane arrangements in $\Re^{k+1}$ using the paraboloid transformation discussed in "Construction of Voronoi Diagrams in Higher Dimensions." See, e.g., [1] for details. Below is a discussion of the *farthest neighbor* Voronoi diagram in two dimensions.

Given a set S of sites $s_1, s_2, \ldots, s_n$, the f-neighbor Voronoi cell of site s_i is the locus of points that are farther from s_i than from any other site s_j, $i \neq j$, i.e.,

$$f\_V(s_i) = \left\{ p \in \Re^2 \middle| d(p, s_i) \geq d\left(p, s_j\right), s_i \neq s_j \right\} .$$

The union of these f-neighbor Voronoi cells is called the *farthest neighbor* Voronoi diagram of S. Figure 20.6 shows the *farthest neighbor* Voronoi diagram for a set of 16 sites. Note that only sites that are on the convex hull $CH(S)$ will have a non-empty f-neighbor Voronoi cell [85] and that all the f-neighbor Voronoi cells are unbounded.

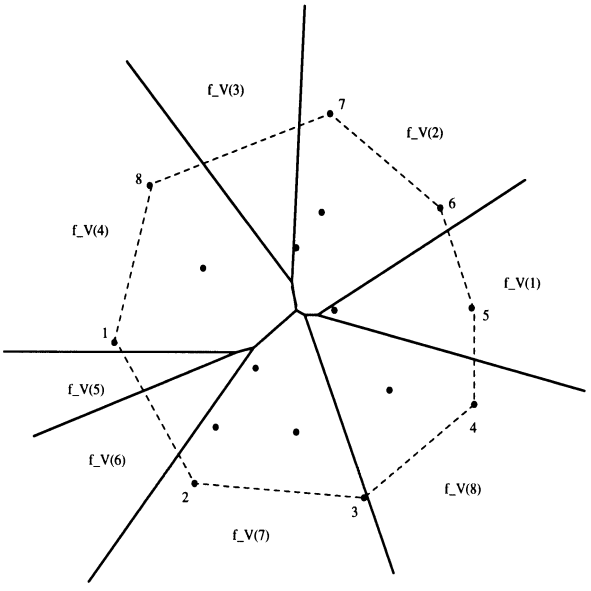

FIGURE 20.6 The farthest neighbor Voronoi diagram of a set of 16 sites in the plane.

Since the *farthest neighbor* Voronoi diagram in the plane is related to the convex hull of the set of sites, one can use the *divide-and-marriage-before-conquest* paradigm to compute the *farthest neighbor* Voronoi diagram of S in two dimensions in time $O(n \log \mathcal{H})$, where $\mathcal{H}$ is the number of sites on the convex hull. Once the convex hull is available, the linear time algorithm [6] for computing the Voronoi diagram for a convex polygon can be applied.

Weighted Voronoi Diagrams

When the sites have weights such that the distance from a point to the sites is weighted, the structure of the Voronoi diagram can be drastically different than the unweighted case. We consider a few examples.

EXAMPLE 20.1: Power Diagrams

Suppose each site s in $\Re^k$ is associated with a nonnegative weight, w_s. For an arbitrary point p in $\Re^k$ the weighted distance from p to s is defined as

$$\delta(s, p) = d(s, p)^2 - w_s^2 .$$

If w_s is positive, and if $d(s, p) \geq w_s$, then $\sqrt{\delta(s, p)}$ is the length of the tangent of p to the ball, $b(s)$, of radius w_s and centered at s. $\delta(s, p)$ is also called the *power of* p with respect to the ball $b(s)$. The locus of points p equidistant from two sites $s \neq t$ of equal weight, will be a hyperplane called the *chordale* of s and t, (see Fig. 20.7). Point q is equidistant to sites a and b and the distance is the length of the tangent line $\overline{q, c} = \overline{q, d}$.

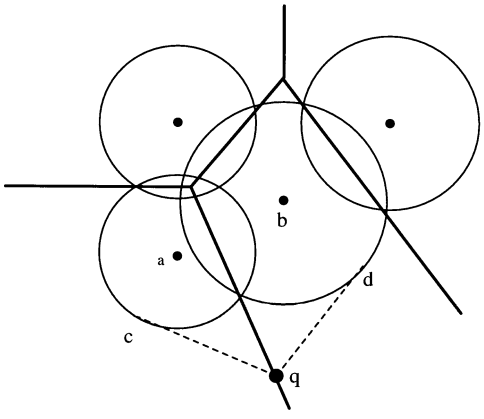

FIGURE 20.7 The power diagram in two dimensions. $\delta(q, a) = \delta(q, b) =$ length of $\overline{q, c}$.

The power diagram in two dimensions can be used to compute the contour of the union of n disks, and the connected components of n disks in $O(n \log n)$ time, and in higher dimensions it can be used to compute the union or intersection of n axis-parallel cones in $\Re^k$ with apexes in a common hyperplane in time $O(CH_{k+1}(n))$, the multiplicative weighted nearest-neighbor Voronoi diagram (defined below) for n points in $\Re^k$ in time $O(CH_{k+2}(n))$, and the Voronoi diagrams for n spheres in $\Re^k$ in time $O(CH_{k+2}(n))$, where $CH_\ell(n)$ denotes the time for constructing the convex hull of n points in $\Re^\ell$ [88]. For the best time bound for $CH_\ell(n)$, consult "Convex Hull" of Chapter 19. For more results on the union of spheres and the volumes see [45].

EXAMPLE 20.2: Multiplicative-Weighted Voronoi Diagrams

Suppose each site $s \in \Re^k$ is associated with a positive weight w_s. The distance from a point $p \in \Re^k$ to s is defined as

$$\delta_{multi-w}(s, p) = d(p, s)/w_s \ .$$

In two dimensions, the locus of points equidistant to two sites $s \neq t$ is a disk, if $w_s \neq w_t$, and a perpendicular bisector of line segment $\overline{s, t}$, if $w_s = w_t$. Each cell associated with a site s consists of all points closer to s than to any other site and may be disconnected. In the worst case the multiplicative-weighted nearest neighbor Voronoi diagram of a set S of n points in two dimensions can have $O(n^2)$ regions and can be computed in $O(n^2)$ time. But in one dimension, the diagram can be computed optimally in $O(n \log n)$ time. On the other hand the multiplicative-weighted farthest neighbor Voronoi diagram has a very different characteristic. Each Voronoi cell associated with a site remains connected, and the size of the diagram is still linear in the number of sites. An $O(n \log^2 n)$ time algorithm for constructing such a diagram is given in [69]. See [89] for more applications of the diagram.

EXAMPLE 20.3: Additive-Weighted Voronoi Diagrams

Suppose each site $s \in \Re^k$ is associated with a positive weight w_s. The distance of a point $p \in \Re^k$ to a site s is defined as

$$\delta_{add-w}(s, p) = d(p, s) - w_s \ .$$

In two dimensions, the locus of points equidistant to two sites $s \neq t$ is a branch of a hyperbola if $w_s \neq w_t$, and a perpendicular bisector of line segment $\overline{s, t}$ if $w_s = w_t$. The Voronoi diagram has properties similar to the ordinary unweighted diagram. For example, each cell is still connected and the size of the diagram is linear. If the weights are positive, the diagram is the same as the Voronoi diagram of a set of spheres

centered at site s and of radius w_s, and in two dimensions this diagram for n disks can be computed in $O(n \log n)$ time [15, 81], and in $k \geq 3$ one can use the notion of power diagram (cf. Example 20.1) to compute the diagram [88].

Generalizations of Voronoi Diagrams

We consider two variations of Voronoi diagrams that are of interest and have applications.

EXAMPLE 20.4: Geodesic Voronoi Diagrams

The nearest neighbor geodesic Voronoi diagram is a Voronoi diagram of sites in the presence of obstacles. The distance from point p to a site s, called the *geodesic* distance between p and s, is the length of the shortest path from p to s avoiding all the obstacles (cf. "Shortest Paths in Two Dimensions"). The locus of points equidistant to two sites s and t is in general a collection of hyperbolic segments. The cell associated with a site is the locus of points whose geodesic distance to the site is shorter than to any other site [84]. The farthest neighbor geodesic Voronoi diagram can be similarly defined. Efficient algorithms for computing either kind of geodesic Voronoi diagram for k point sites in an n-sided simple polygon in $O((n+k)\log(n+k))$ time can be found in [84]. Figure 20.8 illustrates the geodesic Voronoi diagram of a set of point sites within a simple polygon; the whole shaded region is $V(s_i)$.

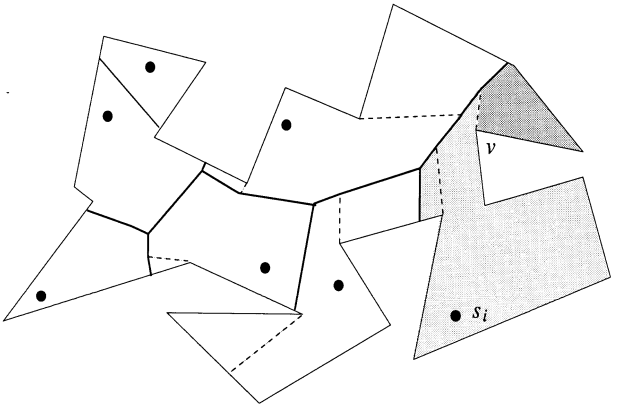

FIGURE 20.8 The geodesic Voronoi diagram within a simple polygon.

EXAMPLE 20.5: Skew Voronoi Diagrams

Most recently a *directional* distance function between two points in the plane is introduced in [8] that models a more realistic distance measure. The distance, called *skew distance,* from point p to point q is defined as

$$\tilde{d}(p,q) = d(p,q) + k \cdot d_y(p,q)\ ,$$

where $d_y(p,q) = y(q) - y(p)$, and $k \geq 0$ is a parameter. This distance function is *asymmetric* and satisfies $\tilde{d}(p,q) + \tilde{d}(q,p) = 2d(p,q)$, and the triangle inequality. Imagine we have a tilted plane $\mathcal{T}$ obtained by rotating the xy-plane by an angle α about the x-axis. The height (z-coordinate) $h(p)$ of a point p on $\mathcal{T}$ is related to its y-coordinate by $h(p) = y(p) \cdot \sin\alpha$.

The distance function defined above reflects the cost that is proportional to the difference of their heights; the distance is *smaller* going *downhill* than going *uphill.* That is, the distance from p to q defined

as $\tilde{d}(p,q) = d(p,q) + \kappa \cdot (h(q) - h(p))$ for $\kappa > 0$ serves this purpose; $\tilde{d}(p,q)$ is less than $\tilde{d}(q,p)$ if $h(q)$ is smaller than $h(p)$.

Because the distance is *directional,* one can define two kinds of Voronoi diagrams defined by the set of sites. A skew Voronoi cell *from* a site p, $\mathcal{V}_{from}(p)$ is defined as the set of points that are closest to p than to any other site. That is,

$$\mathcal{V}_{from}(p) = \left\{ x \,\middle|\, \tilde{d}(p,x) \leq \tilde{d}(q,x) \right\}$$

for all $q \neq p$. Similarly one can define a skew Voronoi cell *to* a site p as follows:

$$\mathcal{V}_{to}(p) = \left\{ x \,\middle|\, \tilde{d}(x,p) \leq \tilde{d}(x,q) \right\}$$

for all $q \neq p$.

The collection of these Voronoi cells for all sites is called the *skew* (or *directional*) Voronoi diagram.

For each site p we define a r-disk centered at p, denoted $from_r(p)$ to be the set of points to which the skew distance from p is r. That is, $from_r(p) = \{x | \tilde{d}(p,x) = r\}$. Symmetrically we can also define a r-disk centered at p, denoted $to_r(p)$ to be the set of points from which the skew distance to p is r. That is, $to_r(p) = \{x | \tilde{d}(x,p) = r\}$. The subscript r is omitted, when $r = 1$. It can be shown that $to_r(p)$ is just a mirror reflection of $from_r(p)$ about the horizontal line passing through p. We shall consider only the skew Voronoi diagram which is the collection of the cells $\mathcal{V}_{from}(p)$ for all $p \in S$.

LEMMA 20.1 For $k > 0$, the unit-disk $from(p)$, is a conic with focus p, directrix the horizontal line at y-distance $1/k$ above p, and eccentricity k. Thus, $from(p)$ is an ellipse for $k < 1$, a parabola for $k = 1$, and a hyperbola for $k > 1$. For $k = 0$, $from(p)$ is a disk with center p (which can be regarded as an ellipse of eccentricity zero).

Note that when k equals 0, the skew Voronoi diagram reduces to the ordinary nearest neighbor Voronoi diagram. When $k < 1$, it leads to known structures: By Lemma 20.1, the skew distance $\tilde{d}$ is a *convex distance function* and the Voronoi diagrams for convex distance functions are well-studied (see, e.g., [88]). They consist of $O(n)$ edges and vertices, and can be constructed in time $O(n \log n)$ by divide-and-conquer.

When $k \geq 1$, since the unit disks are no longer bounded, the skew Voronoi diagrams have different behavior from the ordinary ones. As it turns out, some of the sites do not have nonempty skew Voronoi cells in this case. In this regard, it looks like ordinary farthest neighbor Voronoi diagram discussed earlier.

Let $L_0(p,k)$ denote the locus of points x such that $\tilde{d}(p,x) = 0$. It can be shown that for $k = 1$ $L_0(p,k)$ is a vertical line emanating downwards from p; and for $k > 1$, it consists of two rays, emanating from and extending below p, with slopes $1/(\sqrt{k^2-1})$ and $-1/(\sqrt{k^2-1})$ respectively. Let $N(p,k)$ denote the area below $L_0(p,k)$ (for $k > 1$). Let the *0-envelope,* $E_0(S)$, be the upper boundary of the union of all $N(p,k)$ for $p \in S$. $E_0(S)$ is the upper envelope of the graphs of all $L_0(p,k)$, when being seen as functions of the x-coordinate. For each point u lying above $E_0(S)$, we have $\tilde{d}(p,u) > 0$ for all $p \in S$, and for each point v lying below $E_0(S)$, there is at least one $p \in S$ with $\tilde{d}(p,v) < 0$. See Fig. 20.9 for an example of a 0-envelope (shown as the dashed polygonal line) and the corresponding skew Voronoi diagram. Note that the skew Voronoi cells associated with sites q and t are empty. The following results are obtained [8].

LEMMA 20.2 For $k > 1$, the 0-envelope $E_0(S)$ of a set S of n sites can be computed in $O(n \log \mathcal{H})$ time and $O(n)$ space, where $\mathcal{H}$ is the number of edges of $E_0(S)$.

LEMMA 20.3 Let $p \in S$ and $k > 1$. Then $\mathcal{V}_{from}(p) \neq \emptyset$ if and only if $p \in E_0(S)$. $\mathcal{V}_{from}(p)$ is unbounded if and only if p lies on the upper hull of $E_0(S)$. For $k = 1$ $\mathcal{V}_{from}(p)$ is unbounded for all p.

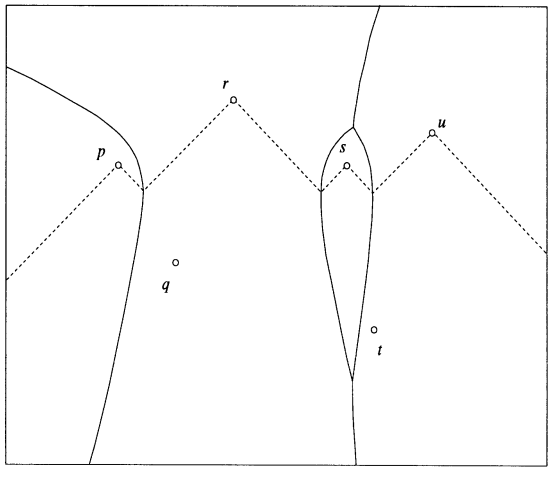

FIGURE 20.9 The 0-envelope and the skew Voronoi diagram when $k = 1.5$.

THEOREM 20.2 *For any $k \geq 0$ the skew Voronoi diagram for n sites can be computed in $O(n \log \mathcal{H})$ time and $O(n)$ space, where $\mathcal{H}$ is the number of non-empty skew Voronoi cells in the resulting Voronoi diagram.*

The sites mentioned so far are point sites. They can be of different shapes. For instance, they can be line segments, or polygonal objects. The Voronoi diagram for the edges of a simple polygon P that divides the interior of P into Voronoi cells is also known as the *medial axis,* or *skeleton* of P [85]. The distance function used can also be convex distance function or other norms.

20.3 Optimization

The geometric optimization problems arise in operations research, VLSI layout, and other engineering disciplines. We give a brief description of a few problems in this category that have been studied in the past.

Minimum Cost Spanning Tree

The minimum (cost) spanning tree, MST, of an undirected, weighted graph $G(V, E)$, in which each edge has a nonnegative weight, is a well studied problem in graph theory and can be solved in $O(|E| \log |V|)$ time [85]. When cast in the Euclidean or other L_p-metric plane in which the input consists of a set S of n points, the complexity of this problem becomes different. Instead of constructing a *complete* graph with edge weight being the distance between its two endpoints, from which to extract an MST, a sparse graph, known as the *Delaunay triangulation* of the point set, is computed. The Delaunay triangulation of S, which is a planar graph, is the straight-line dual of the Voronoi diagram of S. That is, two points are connected by an edge if and only if the Voronoi cells of these two sites share an edge. (cf. Section 19.5 of Chapter 19). It can be shown that the MST of S is a subgraph of the Delaunay triangulation. Since the MST of a planar graph can be found in linear time [85], the problem can be solved in $O(n \log n)$ time. In fact, this is asymptotically optimal, as the closest pair of the set of points must define an edge in the MST, and the closest pair problem is known to have an $\Omega(n \log n)$ lower bound, as mentioned in "Closest Pair."

This problem in dimensions three or higher can be solved in subquadratic time, e.g., in three dimensions, $O((n \log n)^{1.5})$ time is sufficient and in $k \geq 3$ dimensions $O(n^{2(1-1/(\lceil k/2 \rceil + 1))+\epsilon})$ time suffices [2]. Interestingly enough, if we want to find an MST that spans at least k nodes in a planar graph (or in the

Euclidean plane), for some parameter $k \leq n$, then the problem, called k-MST problem, is NP-hard [86]. Approximation algorithms for the k-MST problem can be found in [19, 52].

Steiner Minimum Tree

The *Steiner minimum tree,* SMT, of a set of vertices $S \subseteq V$ in an undirected weighted graph $G(V, E)$ is a spanning tree of $S \cup Q$ for some $Q \subseteq V$ such that the total weight of the spanning tree is minimum. This problem differs from MST in that we need to identify a set $Q \subseteq V$ of so-called *Steiner vertices* so that the total cost of the spanning tree is minimized. Of course if $S = V$, SMT is the same as MST. It is the identification of the Steiner vertices that makes this problem intractable. In the plane, we are given a set S of points and are to find a shortest tree interconnecting points in S, while additional Steiner points are allowed. Both Euclidean and rectilinear (L_1-metric) SMT problems are known to be NP-hard. In the geometric setting, the rectilinear SMT problem arises mostly in VLSI net routing, in which a number of terminals need to be interconnected using horizontal and vertical wire segments using the shortest wire length. As this problem is intractable, heuristics are proposed. For more information, the reader is referred to a recent special issue of *Algorithmica* on Steiner trees, edited by Hwang [59]. Most heuristics for the L_1 SMT problem are based on a classical theorem, known as the *Hanan grid theorem,* which states that the Steiner points of an SMT must be at the grid defined by drawing horizontal and vertical lines through each of the given points. However, when the number of orientations permitted for routing is greater than 2, the Hanan grid theorem no longer holds true. In [68] Lee and Shen established a *multi-level grid* theorem, which states that the Steiner points of an SMT for n points must be at the grid defined by drawing λ lines in the feasible orientation recursively for up to $n - 2$ levels, where λ denotes the number of orientations of the wires allowed in routing. That is, the given points are assumed to be at the 0th level. At each level, λ lines in the feasible orientations are drawn through each *new* grid points created at the previous level. In this λ-geometry plane feasible orientations are assumed to make an angle $i\pi/\lambda$ with the positive x-axis. For the rectilinear case, $\lambda = 2$. Figure 20.10 shows that Hanan grid is insufficient for determining a Steiner SMT for $\lambda = 3$. Steiner point s_3 does not lie on the Hanan grid.

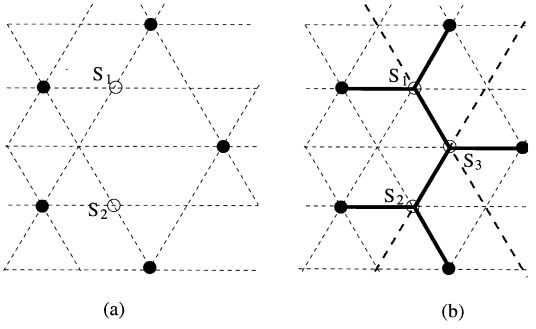

FIGURE 20.10 Hanan grid theorem fails for $\lambda = 3$. Steiner point s_3 does not lie on the Hanan grid.

DEFINITION 20.1 The *performance ratio* of any approximation $\mathcal{A}$ in metric space $\mathcal{M}$ is defined as

$$\rho_{\mathcal{M}}(\mathcal{A}) = \inf_{P \in \mathcal{M}} \frac{L_s(P)}{L_{\mathcal{A}}(P)}$$

where $L_s(P)$ and $L_{\mathcal{A}}(P)$ denote, respectively, the lengths of a Steiner minimum tree and of the approximation $\mathcal{A}$ on P in space $\mathcal{M}$. When the MST is the approximation, the performance ratio is known as the *Steiner ratio,* denoted simply as ρ.

It is well-known that the Steiner ratios for the Euclidean and rectilinear SMTs are $\frac{\sqrt{3}}{2}$ and $\frac{2}{3}$, respectively [59]. The λ-*Steiner ratio*[2] for the λ-geometry SMTs is no less than $\frac{\sqrt{3}\cos(\pi/2\lambda)}{2}$. The following interesting result regarding Steiner ratio is reported in [68], which shows that the Steiner ratio is not an increasing function from $\frac{2}{3}$ to $\frac{\sqrt{3}}{2}$, as λ varies from 2 to ∞.

THEOREM 20.3 *The λ-Steiner ratio is $\frac{\sqrt{3}}{2}$, when λ is multiple of 6, and $\frac{\sqrt{3}\cos(\pi/2\lambda)}{2}$ when λ is multiple of 3 but not multiple of 6.*

Minimum Diameter Spanning Tree

The minimum *diameter* spanning tree MDST of an undirected weighted graph $G(V, E)$ is a spanning tree such that its **diameter,** i.e., total weight of the longest path in the tree is minimum. This arises in applications to communication network where a tree is sought such that the maximum delay, instead of the total cost, is to be minimized. Using a graph-theoretic approach one can solve this problem in $O(|E||V|\log|V|)$ time. However, by the triangle inequality one can show that there exists an MDST such that the longest path in the tree consists of no more than *three* segments [58]. Based on this an $O(n^3)$ time algorithm was obtained.

THEOREM 20.4 *Given a set S of n points, the minimum diameter spanning tree for S can be found in $\theta(n^3)$ time and $O(n)$ space.*

We remark that the problem of finding a spanning tree whose total cost **and** the diameter are both bounded is NP-complete [58]. In [86] the problem of finding a *minimum diameter cost spanning tree* is studied. In this problem for each pair of vertices v_i and v_j there is a weighting function $w_{i,j}$ and the *diameter cost* of a spanning tree is defined to be the maximum over $w_{i,j} * d_{i,j}$, where $d_{i,j}$ denotes the distance between vertices v_i and v_j. To find a spanning tree with minimum diameter cost as defined above is shown to be NP-hard [86].

Another similar problem that arises in VLSI clock tree routing is to find a tree from a source to multiple sinks such that every source-to-sink path is a *shortest* rectilinear path and the total wire length is to be minimized. This problem, also known as *rectilinear Steiner arborescence problem* (see [59]), is still not known to be solvable in polynomial time. The problem is widely believed to be NP-hard. Recently we have shown that the problem of finding a minimum spanning tree such that the longest source-to-sink path is bounded by a given parameter is NP-complete.

Minimum Enclosing Circle

Given a set S of points the problem is to find a smallest disk enclosing the set. This problem is also known as the (unweighted) 1-center problem. That is, find a center such that the maximum distance from the center to the points in S is minimized. More formally, we need to find the center $c \in \Re^2$ such that $\max_{p_j \in S} d(c, p_j)$ is minimized. The weighted 1-center problem, in which, the distance function $d(c, p_j)$ is multiplied by the weight w_j, is a well-known min–max problem, also referred to as the *emergency center problem* in operations research. In two dimensions, the 1-center problem can be solved in $O(n)$ time. The minimum enclosing ball problem in higher dimensions is also solved by using linear programming

[2]The λ-*Steiner ratio* is defined as the greatest lower bound of the length of SMT over the length of MST in the λ-*geometry* plane.

technique [97]. The general p-center problem, i.e., finding p circles whose union contains S such that the maximum radius is minimized, is known to be NP-hard. For a special case when $p = 2$ Eppstein [48] gave an $O(n \log^2 n)$ randomized algorithm based on parametric search technique. For the problem of finding a minimum enclosing ellipsoid for a point set in $\Re^k$ and other types of geometric *location* problem see [47, 97].

Largest Empty Circle

This problem, in contrast to the minimum enclosing circle problem, is to find a circle centered in the interior of the convex hull of the set S of points that does not contain any given point and the radius of the circle is to be maximized. This is mathematically formalized as a max–min problem, the minimum distance from the center to the set is maximized. The weighted version is also known as the *obnoxious center* problem in facility location. For the unweighted version the center must be either at a vertex of the Voronoi diagram for S in the convex hull, or at the intersection of a Voronoi edge and the boundary of the convex hull. $O(n \log n)$ time is sufficient for this problem. Following the same strategy one can solve the largest *empty square* problem for S in $O(n \log n)$ time as well, using the Voronoi diagram in the L_∞-metric [64]. The time complexity of the algorithm is asymptotically optimal, as the maximum gap problem, i.e., finding the maximum gap between two consecutive numbers on the real line, which requires $\Omega(n \log n)$ time, is reducible to this problem [85]. In contrast to the minimum enclosing ellipsoid problem is the largest empty ellipsoid problem, which has also been studied [43].

Largest Empty Rectangle

In "Applications of Convex Hulls" of Chapter 19, we mentioned the *smallest enclosing rectangle* problem. Here we look at the problem of finding a largest rectangle that is empty. That is, given a rectangle containing a set S of n points find the largest area sub-rectangle with sides parallel to those of the original rectangle, whose interior contains no points from S [7]. The problem also arises in document analysis of printed-page layout [16] in which *white* space in the black-and-white image of the form of a maximal empty rectangle is to be recognized. A related problem, called *largest empty corner rectangle* problem is that given two subsets S_l and S_r of S separated by a vertical line, find the largest rectangle containing no other points in S such that lower left corner and upper right corner of the rectangle are in S_l and S_r, respectively. This problem can be solved in $O(n \log n)$ time, where $n = |S|$, using fast matrix searching technique (cf. "Row Maxima Searching in Monotone Matrices" of Chapter 19). With this as a subroutine, one can solve the largest empty rectangle problem in $O(n \log^2 n)$ time [7]. When the points define a rectilinear polygon that is orthogonally convex, the largest empty rectangle that can fit inside the polygon can be found in $O(n\alpha(n))$ time, where $\alpha(n)$ is the slowly growing inverse of Ackermann's function using a result of Klawe and Kleitman [63]. When the polygon P is arbitrary and may contain *holes,* Daniels et al. [37] gave an $O(n \log^2 n)$ algorithm, for finding the largest empty rectangle in P, which matches the best known result when P is a rectilinear polygon [7].

Minimum-Width Annulus

Given a set of S of n points find an annulus (defined by two concentric circles) whose center lies internal to the convex hull of S such that the *width* of the annulus is minimized. This problem arises in dimensional tolerancing and metrology which deals with the specification and measurement of error tolerances in geometric shapes. To measure if a manufactured circular part is *round,* an **ANSI** standard is to use the width of an annulus covering the set of points obtained from a number of measurements. This is known as the *roundness* problem [51, 94]. It can be shown that the center of the annulus can be located at the intersection of the nearest neighbor and the farthest neighbor Voronoi diagrams, as discussed in "Voronoi Diagrams" [51]. The center can be computed in $O(n \log n)$ time [51]. If the input is defined by a

simple polygon P with n vertices, then the problem is to find a minimum-width annulus that contains the boundary of P. The center of the smallest annulus can be located at the medial axis of P [94]. In particular, the problem can be solved in $O(n \log n + k)$, where k denotes the number of intersection points of the medial axis of the simple polygon and the farthest neighbor Voronoi diagram of the vertices of P. In [94] k is shown to be $\theta(n^2)$. However, if the polygon is convex, one can solve this problem in linear time [94]. Note that the minimum-width annulus problem is equivalent to the *best circle approximation* problem, in which a circle approximating a given shape (or a set of points) is sought such that the *error* is minimized. The error of the approximating circle is defined to be the maximum over all distances between points in the set and the approximating circle. To be more precise, the error is equal to one half of width of the smallest annulus. See Fig. 20.11.

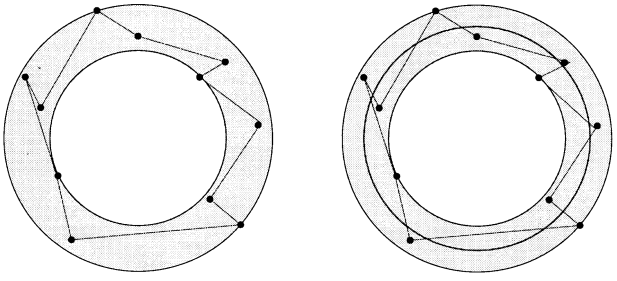

FIGURE 20.11 Minimum-width annulus and best circle approximation.

If the center of the smallest annulus of a point set can be arbitrarily placed, the center *may* lie at infinity and the annulus degenerates to a pair of parallel lines enclosing the set of points. When the center is to be located at infinity, the problem becomes the well-known *minimum-width* problem, which is to find a pair of parallel lines enclosing the set such that the distance between them is minimized. The *width* of a set of n points can be computed in $O(n \log n)$ time, which is optimal [4]. In three dimensions the *width* of a set is also used as a measure for flatness of a *plate,* a so-called *flatness* problem in computational metrology. Chazelle et al. [29] gave an $O(n^{8/5+\epsilon})$ time algorithm for this problem, improving over a previously known algorithm that runs in $O(n^2)$ time.

If, instead of annulus width, the annulus area is to be minimized, then this problem can be solved in linear time via a reduction to fixed-dimensional linear programming [4]. Shermer and Yap [92] introduced the notion of *relative roundness,* where one wants to minimize the ratio of the annulus width and the radius of the inner circle. An $O(n^2)$ algorithm was presented. Duncan et al. [42] define another notion of roundness, called *referenced roundness,* which becomes equivalent to the flatness problem when the radius of the reference circle is set to infinity. Specifically given a reference radius ρ of an annulus A that contains S, i.e., ρ is the mean of the two concentric circles defining the annulus, find an annulus of a minimum width among all annuli with radius ρ containing S, or for a given $\epsilon > 0$, find an annulus containing S whose width is upper bounded by ϵ. They presented an $O(n \log n)$ algorithm for two dimensions and a near quadratic-time algorithm for three dimensions.

20.4 Geometric Matching

Matching in general graphs is one of the classical subjects in combinatorial optimization and has applications in operations research, pattern recognition and VLSI design. Only geometric versions of the matching problem are discussed here. For graph-theoretic matching problems see [82].

Given a weighted undirected complete graph on a set of $2n$ vertices, a *complete matching* is a set of n edges such that each vertex has exactly one edge incident on it. The weight of a matching is the sum of the weights of the edges in the matching. In a metric space, the vertices are points in the plane and the weight of an edge between two points is the distance between them. The *Euclidean minimum weight matching problem* is that given $2n$ points, find n matching pairs of points (p_i, q_i) such that $\Sigma d(p_i, q_i)$ is minimized.

It was not known if geometric properties can be exploited to obtain an algorithm that is faster than the $\theta(n^3)$ algorithm for general graphs (see [82]). Vaidya [96] settled this question in the affirmative. His algorithm is based on a well-studied primal-dual algorithm for weighted matching. Making use of additive weighted Voronoi diagram discussed in "Weighted Voronoi Diagrams" and the range search tree structure (see "Range Searching"), Vaidya solved the problem in $O(n^{2.5} \log^4 n)$ time. This algorithm also generalizes to $\Re^k$ but the complexity is increased by a $\log^k n$ factor.

The *bipartite minimum weight matching problem* is defined similarly, except that we are given a set of red points $R = \{r_1, r_2, \ldots, r_n\}$ and a set of blue points $B = \{b_1, b_2, \ldots, b_n\}$ in the plane, and look for n matching pairs of points $(r, b) \in R \times B$ with minimum cost. In [96] Vaidya gave an $O(n^{2.5} \log n)$ time algorithm for Euclidean metric and an $O(n^2 \log^3 n)$ algorithm for L_1-metric.

If these $2n$ points are given as vertices of a polygon, the problems of minimum weight matching and bipartite matching can be solved in $O(n \log n)$ time if the polygon is convex and in $O(n \log^2 n)$ time if the polygon is simple. In this case the weight of each matching pair of vertices is defined to be the geodesic distance between them [73]. However, if a *maximum* weight matching is sought, an $\log n$ factor can be shaved off [73].

Because of the triangle inequality, one can easily show that in a minimum weight matching the line segments defined by the matched pairs of points cannot intersect one another. Generalizing this *nonintersecting* property the following *geodesic minimum matching* problem in the presence of obstacles can be formulated. Given $2m$ points and polygonal obstacles in the plane, find a matching of these $2m$ points such that the sum of the geodesic distances between matched pairs is minimized. These m paths must not cross each other (they may have portions of the paths overlapping each other). There is no efficient algorithm known to date, except for the obvious method of reducing it to a minimum matching of a complete graph, in which the weight of an edge connecting any two points is the geodesic distance between them. Note that finding a geodesic matching without optimization is trivial, since these m noncrossing paths can always be found. This geodesic minimum matching problem in the general polygonal domain seems nontrivial. The *noncrossing* constraint and the optimization objective function (minimizing total weight) makes the problem hard.

When the matching of these $2m$ points is given *a priori,* finding m noncrossing paths minimizing the total weight seems very difficult. This resembles global routing problem in VLSI for which m 2-terminal nets are given, and a routing is sought that optimizes a certain objective function, including total wire length, subject to some capacity constraints [71]. The noncrossing requirement is needed when single layer routing or planar routing model is used. Global routing problems in general are NP-hard. Since the paths defined by matching pairs in an optimal routing cannot cross each other, paths obtained by earlier matched pairs become *obstacles* for subsequently matched pairs. Thus, the *sequence* in which the pairs of points are matched is very crucial. In fact, the path defined by a matched pair of points need not be the shortest. Thus, to route the matched pairs in a greedy manner sequentially does not give an optimal routing. Consider the configuration shown in Fig. 20.12 in which $R = X, Y, Z$, $B = x, y, z$, and points (X, x), (Y, y) and (Z, z) are to be matched. Note that in this optimal routing, none of the matched pairs is realized by a shortest path, i.e., a straight line. This problem is referred to as the *shortest k-pair noncrossing path* problem. However, if the m matching pairs of points are on the boundary of a simple polygon, and the path must be confined to the interior of the polygon, Papadopoulou [83] gave an $O(n + m)$ algorithm for finding an optimal set of m noncrossing paths, if a solution exists, where n is the number of vertices of the polygon.

Atallah and Chen [14] consider the following bipartite matching problem: Given n red and n blue disjoint isothetic rectangles in the plane, find a matching of these n red-blue pairs of rectangles such that

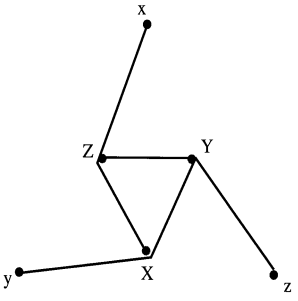

FIGURE 20.12 An instance of 3 noncrossing pair matching problem.

the *rectilinear* paths connecting the matched pairs are noncrossing and monotone. Surprisingly enough, they show that such a matching satisfying the constraints always exists and give an asymptotically optimal $O(n \log n)$ algorithm for finding such a matching.

To conclude this section we remark that the *min–max* versions of the general matching or bipartite matching problems are open. In the red-blue matching if one of the sets is allowed to translate, rotate or scale we have a different matching problem. In this setting we often look for the *best match* according to min-max criterion, i.e., the maximum *error* in the matching is to be minimized. A dual problem can also be defined, i.e., given a maximum error bound, determine if a matching exists, and if so, what kind of *motions* are needed. In [60] Imai et al. called this problem *geometric fitting*.

20.5 Planar Point Location

Planar point location is a fundamental problem in computational geometry. Given a planar subdivision, and a query point, we want to find the region that contains the query point. Figure 20.13 shows an example of a planar subdivision. This problem arises in geographic information systems, in which one often is interested in locating, for example, a certain facility in a map. Consider the skew Voronoi diagram, discussed earlier in "Generalizations of Voronoi Diagrams," for a set S of emergency dispatchers. Suppose an emergency situation arises at a location q and that the nearest dispatcher p is to be called so that the distance $\tilde{d}(p, q)$ is the smallest among all distances $\tilde{d}(r, q)$, for $r \in S$. This is equivalent to locating q in the Voronoi cell $\mathcal{V}_{from}(p)$ of the skew Voronoi diagram that contains q. In situations like this it is vital that the nearest dispatcher be located quickly. We therefore address the point-location problem under the assumption that the underlying planar map is *fixed* and the main objective is to have a *fast* response time to each query. Toward this end we preprocess the planar map into a suitable structure so that it would facilitate the point-location task.

An earlier preprocessing scheme is based on the *slab method* [85], in which parallel lines are drawn through each vertex, thus, partitioning the plane into parallel slabs. Each parallel slab is further divided into subregions by the edges of the subdivision that can be linearly ordered. Any given query point q can thus, be located by two binary searches; one to locate among the $n+1$ horizontal slabs the slab containing q, and followed by another to locate the region defined by a pair of consecutive edges which are ordered from left to right. We use a three tuple, $(P(n), S(n), Q(n))$= (preprocessing time, space requirement, query time) to denote the performance of the search strategy. The slab method gives an $(O(n^2), O(n^2), O(\log n))$ algorithm. Since preprocessing time is only performed once, the time requirement is not as critical as the space requirement, which is permanently engaged. The primary goal of any search strategy is to minimize the query time and the space required. Lee and Preparata [85] first proposed a *chain decomposition* method to decompose a monotone planar subdivision with n points into a collection of $m \leq n$ monotone chains organized in a complete binary tree. Each node in the binary tree is associated with a monotone chain of at most n edges, ordered in y-coordinate. This set of monotone chains forms a totally ordered set partitioning the plane into collections of regions. In particular, between two adjacent chains there are a

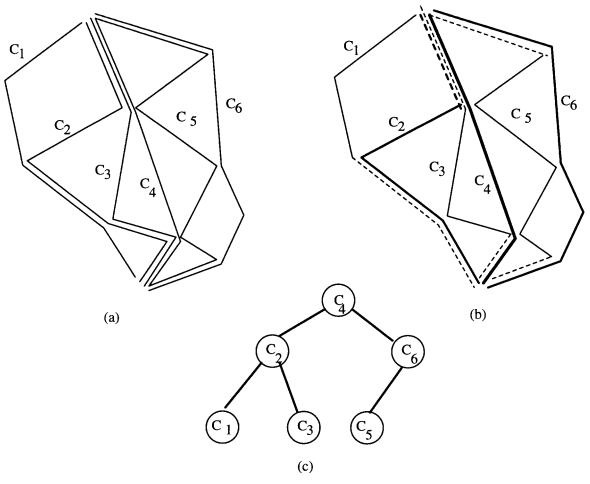

FIGURE 20.13 Chain decomposition method for a planar subdivision.

number of disjoint regions. The point location process begins with the root node of the complete binary tree. When visiting a node, the query point is compared with the node, hence, the associated chain, to decide on which side of the chain the query point lies. Each chain comparison takes $O(\log n)$ time, and total number of nodes visited is $O(\log m)$. The search on the binary tree will lead to two adjacent chains, and hence, identify a region that contains the point. Thus, the query time is $O(\log m \log n) = O(\log^2 n)$. Unlike the slab method in which each edge may be stored as many as $O(n)$ times, resulting in $O(n^2)$ space, it can be shown that with an appropriate chain assignment scheme, each edge in the planar subdivision is stored only once. Thus, the space requirement is $O(n)$. For example, in Fig. 20.13 the edges shared by the root chain C_4 and its descendant chains are assigned to the root chain; in general any edge shared by two nodes on the same root-to-leaf path will be assigned to the node that is an ancestor of the other node. The chain decomposition scheme gives rise to an $(O(n \log n), O(n), O(\log^2 n))$ algorithm. The binary search on the chains is not efficient enough. Recall that after each *chain comparison,* we will move down the binary search tree to perform the next chain comparison and start over another binary search on the *same* y-coordinate of the query point to find an edge of the chain, against which a comparison is made to decide if the point lies to the left or right of the chain. A more efficient scheme is to be able to perform a binary search of the y-coordinate at the root node and to spend only $O(1)$ time per node as we go down the chain tree, shaving off an $O(\log n)$ factor from the query time. This scheme is similar to the ones adopted by Chazelle and Guibas [38, 85] in fractional cascading search paradigm and by Willard [38] in his range tree search method. With the linear time algorithm for triangulating a simple polygon (cf. Section 19.5 of Chapter 19), we conclude with the following optimal search structure for planar point-location.

THEOREM 20.5 *Given a planar subdivision of n vertices, one can preprocess the subdivision in linear time and space such that each point location query can be answered in* $O(\log n)$ *time.*

The point location problem in arrangements of hyperplanes is also of significant interest. See, e.g., [31]. **Dynamic** versions of the point location problem, where the underlying planar subdivision is subject to changes (insertions and deletions of vertices or edges) have also been investigated. See [34] for a survey of dynamic computational geometry.

20.6 Path Planning

This class of problems is mostly cast in the following setting. Given are a set of obstacles O, an object, called *robot,* and an initial and final position, called source and destination, respectively. We wish to find a path for the robot to move from the source to the destination avoiding all the obstacles. This problem arises in several contexts. For instance, in robotics this is referred to as the *piano movers' problem* or *collision avoidance* problem, and in VLSI design this is the *routing* problem for 2-terminal nets. In most applications we are searching for a collision avoidance path that has a *shortest* length, where the distance measure is based on the Euclidean or L_1-metric. For more information regarding motion planning see, e.g., [10].

Shortest Paths in Two Dimensions

In two dimensions, the Euclidean shortest path problem in which the robot is a point, and the obstacles are simple polygons, is well studied. A most fundamental approach is by using the notion of *visibility graph.* Since the shortest path must make turns at polygonal vertices, it is sufficient to construct a graph whose vertices include the vertices of the polygonal obstacles, the source and the destination, and whose edges are determined by vertices that are mutually *visible,* i.e., the segment connecting the two vertices does not intersect the interior of any obstacle. Once the visibility graph is constructed with edge weight equal to the Euclidean distance between the two vertices, one can then apply the Dijkstra's shortest path algorithms [85] to find a shortest path between the source and destination. The Euclidean shortest path between two points is referred to as the *geodesic* path and the distance as the *geodesic* distance. The visibility graph for a set of polygonal obstacles with a total of n vertices can be computed trivially in $O(n^3)$ time. The computation of the visibility graph is the dominating factor for the complexity of any visibility graph based shortest path algorithm. Research results aiming at more efficient algorithms for computing the visibility graph and for computing the geodesic path in time proportional to the size of the graph have been obtained. For example, in [53] Ghosh and Mount gave an output sensitive algorithm that runs in $O(\mathcal{F} + n \log n)$ time for computing the visibility graph, where $\mathcal{F}$ denotes the number of edges in the graph.

Mitchell [75] used the so-called *continuous Dijkstra* wavefront approach to the problem for general polygonal domain of n obstacle vertices and obtained an $O(n^{3/2+\epsilon})$ time algorithm. He constructed a *shortest path map* that partitions the plane into regions such that all points q that lie in the same region have the same vertex sequence in the shortest path from the given source to q. The shortest path map takes $O(n)$ space and enables us to perform shortest path queries, i.e., find a shortest path from the given source to any query points, in $O(\log n)$ time. Hershberger and Suri [56] on the other hand used plane subdivision approach and presented an $O(n \log^2 n)$-time and $O(n \log n)$-space algorithm to compute the *shortest path map* of a given source point. They later improved the time bound to $O(n \log n)$. If the source-destination path is confined in a simple polygon with n vertices, the shortest path can be found in $O(n)$ time [38].

In the context of VLSI routing one is mostly interested in rectilinear paths (L_1-metric) whose edges are either horizontal or vertical. As the paths are restricted to be rectilinear, the shortest path problem can be solved more easily. Lee et al. [70] gave a survey on this topic.

In a two-layer routing model, the number of segments in a rectilinear path reflects the number of *vias,* where the wire segments change layers, which is a factor that governs the fabrication cost. In robotics, a straight line motion is not as costly as *making turns.* Thus, the number of segments (or *turns*) has also become an objective function. This motivates the study of the problem of finding a path with the least number of segments, called the *minimum link path problem* [78, 93].

These two cost measures, length and number of links, are in conflict with each other. That is, a shortest path may have far too many links, whereas a minimum link path may be arbitrarily long compared with a shortest path. A path that is optimal in both criteria is called a *smallest path.* In fact it can be easily

shown that in a general polygonal domain, a smallest path does not exist. However, a smallest rectilinear path in a simple rectilinear polygon exists, and can be found in linear time. Instead of optimizing both measures *simultaneously* one can either seek a path that optimizes a linear function of both length and the number of links, known as the *combined* metric [98] or optimizes them in a lexicographical order. For example, we optimize the length first, and then the number of links, i.e., among those paths that have the same shortest length, find one whose number of links is the smallest and vice versa. In rectilinear case see, e.g., [98]. In [77] algorithms for computing a shortest (in L_2-norm) k-link path in a polygon and for approximating shortest k-link paths in polygons with holes were presented.

A generalization of the collision avoidance problem is to allow collision with a cost. Suppose each obstacle has a weight which represents the cost if the obstacle is *penetrated* [76]. Lee et al. (see [70]) studied this problem in the rectilinear case. They showed that a shortest rectilinear path between two given points in the presence of weighted rectilinear polygons can be found in $O(n \log^{3/2} n)$ time and space. Chen et al. [32] showed that a data structure can be constructed in $O(n \log^{3/2} n)$ time and $O(n \log n)$ space that enables one to find a shortest path from a given source to any query point in $O(\log n + \mathcal{H})$ time, where $\mathcal{H}$ is the number of links in the path. Another generalization is to include in the set of obstacles some subset $F \subset O$ of obstacles, whose vertices are *forbidden* for the solution path to make turns. Of course, when the weight of obstacles is set to be ∞, or the forbidden set $F = \emptyset$, these generalizations reduce to the ordinary collision avoidance problem.

Shortest Paths in Three Dimensions

The Euclidean shortest path problem between two points in a three dimensional polyhedral environment turns out to be much harder than its two dimensional counterpart. Consider a convex polyhedron P with n vertices in three dimensions and two points s, d on the surface of P. A shortest path from s to d on the surface will cross a sequence of edges, denoted $\xi(s, d)$. $\xi(s, d)$ is called the *shortest path edge sequence* induced by s and d and consists of distinct edges. For given s and d, the shortest path from s to d is not unique. However, $\xi(s, d)$ is unique. If $\xi(s, d)$ is known, the shortest path between s and d can be computed by a planar unfolding procedure so that these faces crossed by the path lie in a common plane and the path becomes a straight line segment.

Shortest paths on the surface of a convex polyhedron P possess the following topological properties (i) they do not pass through vertices of P and do not cross an edge of P more than once, (ii) they do not intersect themselves, i.e., they must be simple, and (iii) except for the case of two shortest paths sharing a common subpath, they intersect transversely in at most one point, i.e., they cross each other. If the shortest paths are grouped into *equivalent classes* according to the sequences of edges that they cross, then the number of such equivalent classes, denoted $|\xi(P)|$ is $\theta(n^4)$, where n is the number of vertices of P. These equivalent classes can be computed in $O(|\xi(P)|n^3 \log n)$ time. Chen and Han [33] gave an $O(n^2)$ algorithm for finding a shortest path between a fixed source s and any destination d, where n is the number of vertices and edges of the polyhedron, which may or may not be convex. If s and d lie on the surface of two different polyhedra, $O(N^{O(k)})$ time suffices for computing the shortest path between them amidst a set of k polyhedra, where N denotes the total number of vertices of these obstacles.

The crux of the problem lies in the fact that the number of possible edge sequences may be exponential in the number of obstacles, if s and d lie on the surface of different polyhedra. It was established that the problem of determining the shortest path edge sequence is indeed NP-hard [10]. Figure 20.14 shows an example of a possible shortest path edge sequence induced by s and d in the presence of 3 convex polyhedra. Approximation algorithms for this problem can be found in e.g., Choi et al. [35].

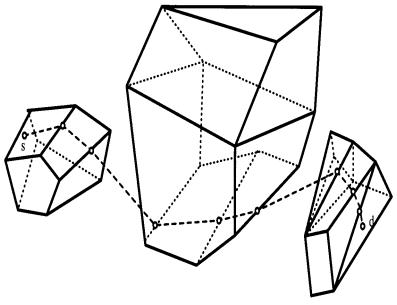

FIGURE 20.14 A possible shortest path edge sequence between points s and d.

20.7 Searching

This class of problems is cast in the form of query-answering. Given is a collection of objects, with preprocessing allowed, one is to find objects that satisfy the queries. The problem can be **static** or dynamic, depending on if the database to be searched is allowed to change over the course of query-answering sessions, and it is studied mostly in two modes, *count mode* and *report mode.* In the former case only the *number* of objects satisfying the query is to be answered, whereas in the latter the actual identity of the objects is to be reported. In the report mode the query time of the algorithm consists of two components, *search time* and *retrieval time,* and expressed as $Q_{\mathcal{A}}(n) = O(f(n) + \mathcal{F})$, where n denotes the size of the database, $f(n)$ a function of n, and $\mathcal{F}$ the size of output. Sometimes we may need to perform some semigroup operations to those objects that satisfy the query. For instance, we may have weights $w(v)$ assigned to each object v, and we want to compute $\Sigma w(v)$ for all $v \cap q \neq \emptyset$. This is referred to as *semigroup range searching* [22]. The semigroup range searching problem is the most general form: if the semigroup operation is set union, we get report-mode range searching problem and if the semigroup operation is just addition (of uniform weight), we have the count-mode range searching problem. We will not discuss the semigroup range searching here. It is obvious that algorithms that handle the report-mode queries can also handle the count-mode queries ($\mathcal{F}$ is the answer). It seems *natural* to expect that the algorithms for count-mode queries would be more efficient (in terms of the order of magnitude of the space required and query time), as they need not search for the objects. However, it was argued that in the report-mode range searching, one could take advantage of the fact that since reporting takes time, the more to report, the *sloppier* the search can be. For example, if we were to know that the ratio $n/\mathcal{F}$ is $O(1)$, we could use a sequential search on a linear list. This notion is known as *filtering search* [85]. In essence more objects than necessary are identified by the search mechanism, followed by a filtering process leaving out unwanted objects. As indicated below the count-mode range searching problem is harder than the report-mode counterpart [23].

Range Searching

This is a fundamental problem in database applications. We'll discuss this problem and the algorithm in the two dimensional space. The generalization to higher-dimensions is straightforward using a known technique, called multidimensional divide-and-conquer [85]. Given is a set of n points in the plane, and the ranges are specified by a product $(l_1, u_1) \times (l_2, u_2)$. We would like to find points $p = (x, y)$ such that $l_1 \leq x \leq u_1$ and $l_2 \leq y \leq u_2$. Intuitively we want to find those points that lie inside a query rectangle specified the range. This is called *orthogonal range searching,* as opposed to other kinds of range searching problems discussed below, e.g., half-space range searching, and simplex range searching, etc. Unless otherwise specified, a range refers to an orthogonal range. We discuss the static case, as this belongs to the class of **decomposable searching problems,** the **dynamization transformation** techniques

can be applied. We note that the range tree structure mentioned below can be made dynamic by using a weight-balanced tree, called $BB(\alpha)$ tree.

For count-mode queries it can be solved by using the locus method as follows. Divide the plane into $O(n^2)$ cells by drawing horizontal and vertical line through each point. The answer to the query q, i.e., find the number of points dominated by q (those points whose x- and y-coordinates are both no greater than those of q), can be found by locating the cell containing q. Let it be denoted by $Dom(q)$. Thus, the answer to the count-mode range-queries can be obtained by some simple arithmetic operations of $Dom(q_i)$ for the four corners, q_1, q_2, q_3, q_4 of the query rectangle. Let q_4 be the northeast corner and q_2 be the southwest corner. The answer will be $Dom(q_4) - Dom(q_1) - Dom(q_3) + Dom(q_2)$. Thus, in $\Re^k$ we have $Q(k,n) = O(k \log n)$, $S(k,n) = P(k,n) = O(n^k)$. To reduce space requirement at the expense of query time has been a goal of further research on this topic. Bentley introduced a data structure, called *range trees* [85]. Using this structure the following results were obtained: for $k \geq 2$, $Q(k,n) = O(\log^{k-1} n)$, $S(k,n) = P(k,n) = O(n \log^{k-1} n)$ (see [67] for more references).

For report-mode queries, by using filtering search technique the space requirement can be further reduced by a $\log \log n$ factor. If the range satisfies additional conditions, e.g., *grounded* in one of the coordinates, say $l_1 = 0$, or the aspect ratio of the intervals specifying the range is fixed, less space is needed. For instance, in two dimensions, the space required is linear (a saving of $\log n / \log \log n$ factor) for these two cases. By using the so-called functional approach to data structures Chazelle [22] developed a *compression* scheme to reduce further the space requirement. Thus, in k-dimensions, $k \geq 2$, for the count-mode range queries we have $Q(k,n) = O(\log^{k-1} n)$ and $S(k,n) = O(n \log^{k-2} n)$ and for report-mode range queries $Q(k,n) = O(\log^{k-1} n + \mathcal{F})$, and $S(k,n) = O(n \log^{k-2+\epsilon} n)$ for some $0 < \epsilon < 1$.

As regards the lower bound of range searching in terms of space-time tradeoffs, Chazelle [23] showed that in k-dimensions, if the query time is $O(\log^c n + \mathcal{F})$ for any constant c, the space required is $\Omega(n(\log n / \log \log n)^{k-1})$ for pointer machine models and the bound is tight for any $c \geq 1$ if $k = 2$, and any $c \geq k - 1 + \epsilon$ (for any $\epsilon > 0$) if $k > 2$. See also [24, 95] for more lower bound results related to orthogonal range searching problems.

Other Range Searching Problems

There are other range searching problems, called simplex range searching problem, and the half-space range searching problems that have been well-studied. A simplex range in $\Re^k$ is a range whose boundary is specified by $k + 1$ hyperplanes. In two dimensions it is a triangle. For this problem there is a lower bound on the query time for simplex range queries: let m denote the space required, $Q(k,n) = \Omega((n/\log n)m^{1/k})$, $k > 2$ and $Q(2,n) = \Omega(n/\sqrt{m})$ [38].

The report-mode half-space range searching problem in the plane can be solved optimally in $Q(n) = O(\log n + \mathcal{F})$ time and $S(n) = O(n)$ space, using geometric duality transform [38]. But this method does not generalize to higher dimensions. In [3] Agarwal and Matoušek obtained a general result for this problem: for $n \leq m \leq n^{\lfloor k/2 \rfloor}$, with $O(m^{1+\epsilon})$ space and preprocessing, $Q(k,n) = O((n/m^{1/\lfloor k/2 \rfloor}) \log n + \mathcal{F})$. As half-space range searching problem is also decomposable, standard dynamization techniques can be applied.

A general method for simplex range searching is to use the notion of *partition tree.* The search space is partitioned in a hierarchical manner using cutting hyperplanes [25], and a search structure is built in a tree structure. Using a **cutting theorem** of hyperplanes Matoušek [74] showed that for k-dimensions, there is a linear space search structure for the simplex range searching problem with query time $O(n^{1-1/k})$, which is optimal in two dimensions and within $O(\log n)$ factor of being optimal for $k > 2$. For more detailed information regarding geometric range searching see [74].

The above discussion is restricted to the case in which the database is a collection of points. One may consider also other kinds of objects, such as line segments, rectangles, triangles, etc., whatever applications may take. The inverse of the orthogonal range searching problem is that of *point enclosure searching problem.* Consider a collection of isothetic rectangles. The point enclosure searching is to find all rectangles that

contain the given query point q. We can cast these problems as *intersection searching* problem, i.e., given a set S of objects, and a query object q, find a subset $\mathcal{F}$ of S such that for any $f \in \mathcal{F}, f \cap q \neq \emptyset$. We have then the rectangle enclosure searching problem, rectangle containment problem, segment intersection searching problem, etc. Janardan and Lopez [61] generalized the intersection searching in the following manner. The database is a collection of *groups* of objects, and the problem is to find all groups of objects intersecting a query object. A group is considered to be intersecting the query object if any object in the group intersects the query object. When each group has only one object, this reduces to the ordinary searching problems.

20.8 Intersection

This class of problems arises in, for example, architectural design, computer graphics, etc. In an architectural design no two objects can share a common region. In computer graphics the well-known hidden-line or hidden-surface elimination problems [40] are examples of intersection problems. This class encompasses two types of problems, *intersection detection* and *intersection computation.*

Intersection Detection

The intersection detection problem is of the form: Given a set of objects, do any two intersect? For instance, given n line segments in the plane, are there two that intersect? The intersection detection problem has a lower bound of $\Omega(n \log n)$ [85].

In two dimensions the problem of detecting if two polygons of r and b vertices intersect was easily solved in $O(n \log n)$ time, where $n = r + b$ using the red-blue segment intersection algorithm [30]. However, this problem can be reduced in linear time to the problem of detecting the self intersection of a polygonal curve. The latter problem is known as the *simplicity* test and can be solved optimally in linear time by Chazelle's linear time triangulation algorithm (cf. Section 19.5 of Chapter 19). If the two polygons are convex, then $O(\log n)$ suffices in detecting if they intersect [27]. Note that although detecting if two convex polygons intersect can be done in logarithmic time, detecting if the boundary of the two convex polygons intersect requires $\Omega(n)$ time [27]. Mount [79] investigated the intersection detection of two simple polygons and computed a separator of m links in $O(m \log^2 n)$ time if they don't intersect.

In three dimensions, detecting if two convex polyhedra intersect can be solved in linear time [27] by using a hierarchical representation of the convex polyhedron, or by formulating it as a linear programming problem in 3 variables.

Intersection Reporting/Counting

One of the simplest such intersecting reporting problems is that of *reporting* pairwise intersection, e.g., intersecting pairs of line segments in the plane. An earlier result due to Bentley and Ottmann [85] used the plane sweep technique that takes $O((n + \mathcal{F}) \log n)$ time, where $\mathcal{F}$ is the output size. This is based on the observation that the line segments intersected by a vertical sweep-line can be ordered according to the y-coordinates of their intersection with the sweep-line, and the sweep-line status can be maintained in logarithmic time per event point, which is either an endpoint of a line segment or the intersection of two line segments. It is not difficult to see that the lower bound for this problem is $\Omega(n \log n + \mathcal{F})$; thus, the above algorithm is $O(\log n)$ factor from the optimal. This segment intersection reporting problem has been solved optimally by Chazelle and Edelsbrunner [28], who used several important algorithm design and data structuring techniques, as well as some crucial combinatorial analysis. In contrast to this asymptotically time-optimal *deterministic* algorithm, a simpler randomized algorithm was obtained [36] for this problem which is both time- and space-optimal. That is, it requires only $O(n)$ space (instead of

$O(n+\mathcal{F})$ as reported in [28]). Balaban [17] most recently reported a deterministic algorithm that solves this problem optimally both in time and space.

On a separate front, the problem of finding intersecting pairs of segments from two different sets was considered. This is called *bichromatic line segment* intersection problem.

Chazelle et al. [30] used *hereditary segment trees* structure and fractional cascading and solved both segment intersection reporting and counting problems optimally in $O(n \log n)$ time and $O(n)$ space. (The term $\mathcal{F}$ should be included in case of reporting.) If the two sets of line segments form connected subdivisions, then merging or overlay of these two subdivisions can be computed in $O(n+\mathcal{F})$ [50]. See [5] for more applications of the bichromatic intersection problem.

The *rectangle intersection reporting* problem arises in the design of VLSI circuitry, in which each rectangle is used to model a certain circuitry component. These rectangles are isothetic, i.e., their sides are all parallel to the coordinate axes. This is a well-studied classical problem, and optimal algorithms ($O(n \log n + \mathcal{F})$ time) have been reported (see [67] for references). The k-dimensional hyperrectangle intersection reporting (respectively, counting) problem can be solved in $O(n^{k-2} \log n + \mathcal{F})$ time and $O(n)$ space (respectively, in time $O(n^{k-1} \log n)$ and space $O(n^{k-2} \log n)$). Gupta et al. [55] gave an $O(n \log n \log\log n + \mathcal{F} \log\log n)$ time and linear space algorithm for the *rectangle enclosure reporting* problem that calls for finding all enclosing pairs of rectangles.

Intersection Computation

Computing the actual intersection is a basic problem, whose efficient solutions often lead to better algorithms for many other problems.

Consider the problem of computing the common intersection of half-planes by divide-and-conquer. Efficient computation of intersection of two convex polygons is required during the merge step. The intersection of two convex polygons can be solved very efficiently by plane-sweep in linear time, taking advantage of the fact that the edges of the input polygons are ordered. Observe that in each vertical strip defined by two consecutive sweep-lines, we only need to compute the intersection of two trapezoids, one derived from each polygon [85].

The problem of intersecting two convex polyhedra was first studied by Muller and Preparata [85], who gave an $O(n \log n)$ algorithm by reducing the problem to the problems of intersection detection and convex hull computation. Following this result one can easily derive an $O(n \log^2 n)$ algorithm for computing the common intersection of n half-spaces in three dimensions by divide-and-conquer. However, using geometric duality and the concept of separating plane, Preparata and Muller [85] obtained an $O(n \log n)$ algorithm for computing the common intersection of n half-spaces, which is asymptotically optimal. There appears to be a difference in the approach to solving the common intersection problem of half-spaces in two and three dimensions. In the latter we resorted to geometric duality instead of divide-and-conquer. This *inconsistency* was later resolved. Chazelle [26] combined the hierarchical representation of convex polyhedra, geometric duality, and other ingenious techniques to obtain a linear time algorithm for computing the intersection of two convex polyhedra. From this result several problems can be solved optimally: (1) the common intersection of half-spaces in three dimensions can now be solved by divide-and-conquer optimally, (2) the merging of two Voronoi diagrams in the plane can be done in linear time by observing the relationship between the Voronoi diagram in two dimensions and the convex hull in three dimensions (cf. Section 19.2 of Chapter 19), and (3) the medial axis of a simple polygon or the Voronoi diagram of vertices of a convex polygon [6] can be solved in linear time.

20.9 Research Issues and Summary

We have covered in this chapter a number of topics in computational geometry, including proximity, optimization, planar point location, geometric matching, path planning, searching, and intersection.

These topics discussed here and in the previous chapter are not meant to be exhaustive. New topics arise as the field continues to flourish.

In Section 20.3 we discussed the problems of smallest enclosing circle and the largest empty circle. These are the two extremes: either the circle is empty or it contains *all* the points. The problem of finding a *smallest* (respectively, *largest*) circle containing at least (respectively, at most) k points for some integer $0 \leq k \leq n$ is also a problem of interest. Moreover, the shape of the object is not limited to circles. A number of open problems remain. What is the complexity of the rectilinear Steiner arborescence problem? Given two points s and t in a simple polygon, is it NP-complete to decide whether there exists a path with at most k links and of length at most L? What is the complexity of the shortest k-pair noncrossing path problem discussed in Section 20.4? How fast can one solve the geodesic minimum matching problem for $2m$ points in the presence of polygonal obstacles? Can one solve the largest empty rectangle problem for a rectilinear polygon in $O(n \log n)$ time? The best known algorithm to date runs in $O(n \log^n)$ time [7]. Is $\Omega(n \log n)$ a lower bound of the minimum-width annulus problem? Can the technique used in [51] be applied to the polygonal case to yield an $O(n \log n)$ time algorithm for the minimum-width annulus problem?

Recently researchers in computational geometry begin to address the issues concerning the actual running times of the algorithms and their robustness when the computations in their implementations are not *exact.* It is understood that the real-RAM computation model with an implicit infinite precision arithmetic is unrealistic in practice. In addition to the robustness issue concerning the accuracy of the output of an algorithm, one needs to find a *new* cost measure to evaluate the efficiency of an algorithm. In the infinite-precision model, the asymptotic time complexity was accepted as an adequate cost measure. However, when the input data have a finite precision representation and computation time varies with the precision required, an alternative cost measure is warranted. The notion of the **degree** of a geometric algorithm could be an important cost measure for comparing the efficiency of algorithms when they are actually implemented [72]. This could play a similar role as the asymptotic time complexity has in the past for the real-RAM computation model.

On the applied side there are new efforts put into development of geometric software. A library of geometric software including visualization tools and application programs is under development. A website containing geometric software is maintained at the Geometry Center, University of Minnesota, at http://www.geom.umn.edu/software/cglist. A project, known as the CGAL project [49], is underway by researchers in Europe to organize a system library containing primitive geometric abstract data types useful for geometric algorithm developers. This is concurrent with the LEDA [80] project at the Max-Planck-Institut für Informatik, Saarbrücken, Germany. Other projects related to the efforts of building geometric software or problem solving environment, include GASP, GeoLab, GeoMAMOS, XYZ Geobench, etc. See [66] for more information.

20.10 Defining Terms

ANSI: American National Standards Institute.

Bisector: A bisector of two elements e_i and e_j is defined to be the locus of points equidistant from both e_i and e_j. That is, $\{p | d(p, e_i) = d(p, e_j)\}$. For instance, if e_i and e_j are two points in the Euclidean plane, the bisector of e_i and e_j is the perpendicular bisector to the line segment $\overline{e_i, e_j}$.

Cutting theorem: This theorem [25] states that for any set $\mathcal{H}$ of n hyperplanes in $\Re^k$, and any parameter r, $1 \leq r \leq n$, there always exists a $(1/r)$-cutting of size $O(r^k)$. In two dimensions, a $(1/r)$-cutting of size s is a partition of the plane into s disjoint triangles, some of which are unbounded, such that no triangle in the partition intersects more than n/r lines in $\mathcal{H}$. In $\Re^k$, triangles are replaced by simplices. Such a cutting can be computed in $O(nr^{k-1})$ time.

Decomposable searching problems: A searching problem with query Q is decomposable if there exists an efficiently computable associative, and commutative binary operator @ satisfying the condition: $Q(x, A \cup B) = @(Q(x, A), Q(x, B))$. In other words, one can decompose the searched domain into subsets, find answers to the query from these subsets, and combine these answers to form the solution to the original problem.

Degree of an algorithm or problem: Assume that each input variable is of arithmetic degree 1 and that the arithmetic degree of a polynomial is the common arithmetic degree of its monomials, whose degree is defined to be the sum of the arithmetic degrees of its variables. An algorithm has degree d if its test computation involves evaluation of multivariate polynomials of arithmetic degree d. A problem has degree d if any algorithm that solves it has degree *at least* d [72].

Diameter of a graph: The distance between two vertices u and v in a graph is the sum of weights of the edges of a shortest path between them. (For unweighted graph, it is the number of edges of a shortest path.) The **diameter of a graph** is the maximum among all distances between all possible pairs of vertices.

Dynamic versus static: This refers to cases when the underlying problem domain can be subject to updates, i.e., insertions and deletions. If no updates are permitted, the problem or data structure is said to be static; otherwise, it is said to be dynamic.

Dynamization transformation: A data structuring technique that can transform a static data structure into dynamic one. In so doing, the performance of the dynamic structure will exhibit certain space-time tradeoffs. See, e.g., [65, 85] for more references.

Geometric duality: A transform between a point and a hyperplane in $\Re^k$, that preserves incidence and order relation. For a point $p = (\mu_1, \mu_2, \ldots, \mu_k)$, its dual $\mathcal{D}(p)$ is a hyperplane denoted by $x_k = \Sigma_{j=1}^{k-1} \mu_j x_j - \mu_k$; for a hyperplane $\mathcal{H} : x_k = \Sigma_{j=1}^{k-1} \mu_j x_j + \mu_k$, its dual $\mathcal{D}(\mathcal{H})$ is a point denoted by $(\mu_1, \mu_2, \ldots, -\mu_k)$. There are other duality transformations. What is described in the text is called the *paraboloid* transform. See [38, 44, 85] for more information.

Height-balanced binary search tree: A data structure used to support membership, insert/delete operations each in time logarithmic in the size of the tree. A typical example is the *AVL* tree or *red-black* tree.

Orthogonally convex rectilinear polygon: A rectilinear polygon P is orthogonally convex if every horizontal or vertical segment connecting two points in P lies totally within P.

Priority queue: A data structure used to support insert and delete operations in time logarithmic in the size of the queue. The elements in the queue are arranged so that the element of the *minimum* priority is always at one end of the queue, readily available for delete operation. Deletions only take place at that end of the queue. Each delete operation can be done is constant time. However, since restoring the above property after each deletion takes logarithmic time, we often say that each delete operation takes logarithmic time. A heap is a well-known priority queue.

21.1 Introduction

Robots are versatile mechanical devices equipped with actuators and sensors under the control of a computing system. They perform tasks by executing motions in the physical space. This space is populated by various objects and is subject to the laws of nature. A typical task consists of achieving a goal spatial arrangement of objects from a given initial arrangement, for example, assembling a product. Robots are programmable, which means that they can perform a variety of tasks by simply changing the software commanding them. This software embeds robot algorithms, which are abstract descriptions of processes consisting of motions and sensing operations in the physical space.

Robot algorithms differ in significant ways from traditional computer algorithms. The latter have full control over, and perfect access to the data they use, letting aside, for example, problems related to floating-point arithmetic. In contrast, robot algorithms eventually apply to physical objects in the real world, which they attempt to control despite the fact that these objects are subject to the independent and imperfectly modeled laws of nature. Data acquisition through sensing is also local and noisy. Robot algorithms hence raise controllability (or reachability) and observability (or recognizability) issues that are classical in control theory, but not present in computer algorithms.

On the other hand, control theory often deals with well-defined processes in strictly confined environments. In contrast, robot tasks tend to be underspecified, which requires addressing combinatorial issues ignored in control theory. For instance, to reach a goal among **obstacles** that are not represented in the input model, but are sensed during execution, a robot must search "on the fly" for a collision-free **path,** a notoriously hard computational problem.

This blend of control and computational issues is perhaps the main characteristic of robot algorithms. It is presented at greater length in Section 21.2, along with other features of these algorithms. Section 21.3 then surveys specific areas of robotics (e.g., part manipulation, assembly sequencing, motion planning, sensing) and presents algorithmic techniques that have been developed in those areas.

21.2 Underlying Principles

Robot Algorithms Control

The primary goal of a robot algorithm is to describe a procedure for controlling a subset of the real world—the **workspace**—in order to achieve a given goal, say, a spatial arrangement of several physical objects. The real world, which is subject to the laws of nature (such as gravity, inertia, friction), can be regarded as performing its own actions, for instance, applying forces. These actions are not arbitrary, and to some extent, they can be modeled, predicted, and controlled. Thus, a robot algorithm should specify robot's operations whose combination with the (re-)actions of the real world will result in achieving the goal. Note that the robot is itself an important object in the workspace; for example, it should not collide with obstacles. Therefore, the algorithm should also control the relation between the robot and the workspace. The robot's internal controller, which drives the actuators and preprocesses sensory data, defines the primitive operations that can be used to build robot algorithms.

The design of a robot algorithm requires identifying a set of relevant states of the workspace (one being the goal) and selecting operations to take the workspace through a sequence of states ending at the goal. But, due to various inaccuracies (one is in modeling physical laws), an operation may transform a state into one among several possible states. The algorithm can then use sensing to refine its knowledge during execution. In turn, because workspace sensing is imperfect, a state may not be directly recognizable, meaning that no combination of sensors may be capable to return the state's identity. As a result, the three subproblems—choosing pertinent states, selecting operations to transit among these states toward the goal, and constructing state-recognition functions—are strongly interdependent and cannot be solved sequentially.

To illustrate part of the above discussion, consider the task of orienting a convex polygonal part P on a table using a robot arm equipped with a parallel-jaw gripper. This is a typical problem in industrial part feeding ("Part Feeding"). If an overhead vision system is available to measure P's orientation, we can use the following (simplified) algorithm:

ORIENT(P, θ_g)
1 Measure P's initial orientation θ_i
2 Move the gripper to the grasp position of P
3 Close the gripper
4 Rotate the gripper by $\theta_g - \theta_i$
5 Open the gripper
6 Move the gripper to a resting position

The states of interest are defined by the orientations of P, the position of the gripper relative to P, and whether the gripper holds P or does not. (Only the initial and goal orientations, θ_i and θ_g, are explicitly considered.) Step 1 acquires the initial state. Step 4 achieves the goal state. Steps 2 and 3 produce intermediate states. Steps 5 and 6 achieve a second goal not mentioned above, that the robot be away from P at the end of the orientation operation.

A very different algorithm for this same part-orienting task consists of squeezing P several times between the gripper's jaws, at appropriately selected orientations of the gripper (see Fig. 21.1). This algorithm, which requires no workspace sensing, is based on the following principle. Let P be at an arbitrary initial orientation. Any squeezing operation will achieve a new orientation that belongs to a set of $2n$ (n being

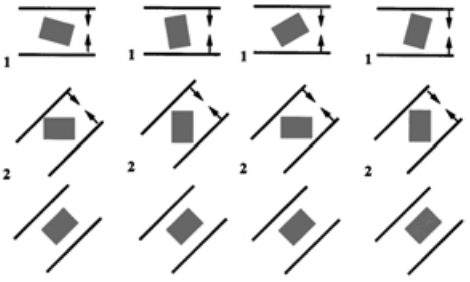

FIGURE 21.1 Orienting a convex polygonal part [20].

the number of sides of P) possible orientations determined by the geometry of P and the orientation of the jaws. If P is released and squeezed again with another orientation of the gripper, the set of possible orientations of P can be reduced further. For any n-sided convex polygon P, there is a sequence of $2n - 1$ squeezes that achieves a single orientation of P (up to symmetries), for an arbitrary initial orientation of P [20].

The states considered by the second algorithm are individual orientations of P and sets of orientations. The state achieved by each squeeze is determined by the jaws' orientation and the previous state. Its prediction is based on understanding the simple mechanics of the operation. The fact that any convex polygon admits a finite sequence of squeezes ending at a unique orientation guarantees that any goal is reachable from any state. However, when the number of parameters that the robot can directly control is smaller than the number of parameters defining a state, the question of whether the goal state is reachable is more problematic (see "Path Planning for Nonholonomic Robots").

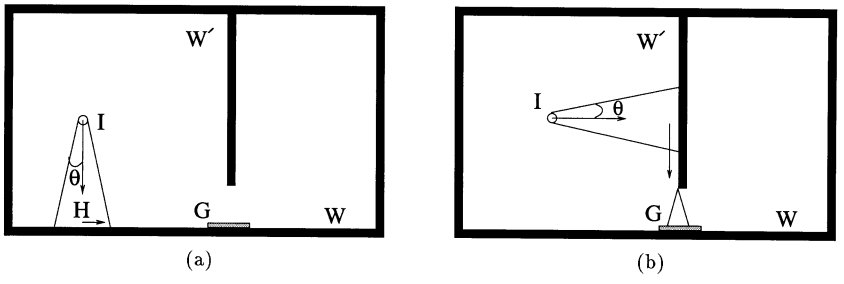

FIGURE 21.2 Goal recognition in mobile robot navigation.

State recognition can also be difficult. To illustrate, consider a mobile robot navigating in an office environment. Its controller uses dead-reckoning techniques to control the motion of the wheels. But these techniques yield cumulative errors in the robot's position with respect to a fixed coordinate system. For better localization, the robot algorithm may sense environmental features (e.g., a wall, a door). However, because sensing is imperfect, a feature may be confused with a similar feature at a different place; this may occasionally cause a major localization mistake. Thus, the robot algorithm must be designed so that enough environmental features will be sensed to make each successive state reliably recognizable.

To be more specific, consider the workspace of Fig. 21.2. Obstacles are shown in bold lines. The robot is modeled as a point with perfect touch sensing. It can be commanded to move along any direction $\phi \in [0, 2\pi)$ in the plane, but imperfect control makes it move within a cone $\phi \pm \theta$, where the angle θ models directional uncertainty. The robot's goal is to move into G, the goal state, which is a subset of the wall W (for instance, G is an outlet for recharging batteries). The robot's initial location is not precisely known: it is anywhere in the disk I, the initial state. One candidate algorithm (illustrated in

Fig. 21.2a) first commands the robot to move perpendicularly to W until it touches it. Despite directional uncertainty, the robot is guaranteed to eventually touch W, somewhere in the region denoted by H. From state H, it can slide along the wall (using touch to maintain contact) toward G. The robot is guaranteed to eventually reach G. But can it reliably recognize this achievement? The answer depends on the growth of the dead-reckoning localization error as the robot moves along W. Clearly, if this error grows by more than half the difference in the size of G and H, G is not reliably recognizable.

An alternative algorithm is possible, using the wall W' (Fig. 21.2b). It commands the robot to first move toward W' until it touches it and then slide along it toward W. At the end of W', it continues heading toward W, but with directional uncertainty. The robot is nevertheless guaranteed to be in G when it senses that it has touched W.

Robot Algorithms Plan

Consider the following variant of the part-orienting task. Parts are successively fed with arbitrary orientations on a table by an independent machine. They have different and arbitrary convex polygonal shape, but whenever a part arrives, the feeding machine provides a geometric model of the part to the robot, along with its goal orientation. In the absence of a vision sensor, the multi-squeeze approach can still be used, but now the robot algorithm must include a planner to compute automatically the successive orientations of the gripper.

As another example, consider the pick-and-place task which requires a robot arm to transfer an object from one position to another. If the obstacles in the workspace are not known in advance, the robot algorithm needs sensing to localize them, as well as a planner to generate a collision-free path. If all obstacles cannot be sensed at once, the algorithm may have to interweave sensing, planning, and acting.

The point is that, for most tasks, the set of states that may have to be considered at execution time is too large to be explicitly anticipated. The robot algorithm must incorporate a planner. In first approximation, the planner can be seen as a separate algorithm that automatically generates a control algorithm for achieving a given task. The robot algorithm is the combination of the planning and the control algorithms. More generally, however, it is not sufficient to invoke the planner once, and planning and control are interleaved. The effect of planning is to dynamically change the control portion of the robot algorithm, by changing the set of states of the workspace that are explicitly considered.

Planning, which often requires exploring large search spaces, raises critical complexity issues. For example, finding a collision-free path for a three-dimensional **linkage** among polyhedral obstacles is PSPACE-hard [47], and the proof of this result provides strong evidence that any complete algorithm will require exponential time in the **number of degrees of freedom**. Planning the motion of a point robot among polyhedral obstacles, with bounded uncertainty in control and sensing, is NEXPTIME-hard [10].

The computational complexity of planning leads to looking for efficient solutions to restricted problems. For example, for part orienting, there exists a complete planning algorithm that computes a sequence of squeezes achieving a single orientation (up to symmetries) of a given convex polygonal part in quadratic time in the number of sides of the part [20]. Another way of dealing with complexity is to trade off completeness against time, by accepting weaker variants of completeness. A **complete planner** is guaranteed to find a solution whenever one exists, and to notify that there exists none otherwise. A weaker variant is probabilistic completeness: if there exists a solution, the planner will find one only with high probability. This variant can be very useful if one can show that the probability of not finding a solution (when one exists) tends rapidly toward 0 as the running time increases. In Section 21.3 we will present planning algorithms that embed similar approaches.

The complexity of a robot algorithm has also some interesting relations with the reachability and recognizability issues introduced in the previous subsection. We will mention several such relations in Section 21.3 (in particular, in "Path Planning for Nonholonomic Robots" and in "Motion Planning with Uncertainty").

The potentially high cost of planning and the fact that it may have to be done on-line raise an additional issue. A robot algorithm must carefully allocate time between computations aimed at planning and computations aimed at controlling and sensing the workspace. If the workspace is changing in an unpredictable way (say, under the influence of other agents), spending too much time on planning may result in obsolete control algorithms; on the other hand, not enough planning may yield irreversible failures. The problem of allocating time between planning and control remains poorly understood, though several promising ideas have been proposed. For example, it has been suggested to develop planners that return a plan in whatever amount of time is allocated to them and can be called back later to incrementally improve the previous plan if more time is allocated to planning [7]. Deliberative techniques have been proposed to decide what amount of time should be given to planning and control and update this decision as more information is collected [43].

Robot Algorithms Reason About Geometry

Imagine a robot whose task is to maintain a botanic garden. To set and update its goal agenda, this robot needs knowledge in domains like botany and fertilization. The algorithms using this knowledge can barely be considered parts of a robot algorithm. But, on the other hand, all robots, including gardener robots, accomplish tasks by eventually moving objects (including themselves) in the real world. Hence, at some point, all robots must reason about the geometry of their workspace. Actually, geometry is not enough, since objects have mass inducing gravitational and inertial forces, while contacts between objects generate frictional forces. All robots must therefore reason with classical mechanics. However, Newtonian concepts of mechanics translate into geometric constructs (e.g., forces are represented as vectors), so that most of the reasoning of a robot eventually involves dealing with geometry.

Computing with continuous geometric models raises discretization issues. For example, a typical planner computing a robot's path first discretizes the robot's free space (the set of collision-free **configurations** of the robot) in order to build a connectivity graph to which well-known search algorithms can be applied. One discretization approach is to place a fine regular grid across **configuration space** and search that grid for a sequence of adjacent points in free space. The grid is just a computational tool and has no physical meaning. Its resolution is arbitrarily chosen despite its critical role in the computation: if it is too coarse, planning is likely to fail; if it is too fine, planning will take too much time. Instead, criticality-driven discretizations have been proposed, whose underlying principle is widely applicable. They consist of partitioning the continuous space of interest into cells, such that some pertinent property remains invariant over each cell and changes when the boundary separating two cells is crossed. The second part-orienting algorithm in "Robot Algorithms Control" is based on such a discretization. The set of all possible orientations of the part is represented as the unit circle (the cyclic interval $[0, 2\pi)$). For a given orientation of the gripper, this circle can be partitioned into arcs such that, for all initial orientations of the part in the same arc, the part's final orientation will be the same after the gripper has closed its jaws. The final orientation is the invariant associated with the cell. From this decomposition, it is a relatively simple matter to plan a squeezing sequence.

Several such criticality-driven discretizations have been proposed for path planning, assembly sequence planning, motion planning with uncertainty, robot localization, object recognition, and so on, as will be described in Section 21.3. Several of them use ideas and tools originally developed in computational geometry, for instance; plane sweep, topological sweep, computing arrangements.

Robot algorithms often require dealing with high-dimensional geometric spaces. Although criticality-based discretization methods apply to such spaces in theory (for instance, see [49]), their computational complexity is then overwhelming. This has led the development of randomized techniques that efficiently approximate the topology and geometry of such spaces by random discretization. Such techniques have been particularly successful for building probabilistically complete path planners ("Probabilistic Algorithms").

Robot Algorithms Have Physical Complexity

Just as the complexity of a computation characterizes the amount of time and memory this computation requires, we can define the physical complexity of a robot algorithm by the amount of physical resources it takes, e.g., the number of "hands," the number of motions, or the number of beacons. Some resources, like the number of motions, relate to the time spent executing the algorithm. Others, like the number of beacons, relate to the engineering cost induced by the algorithm. For example, one complexity measure of the multi-squeeze algorithm to orient a convex polygon ("Robot Algorithms Control") is the maximal number of squeeze operations this algorithm performs. As another example, consider an assembly operation merging several parts into a subassembly. The number of subsets of parts moving relative to each other (each subset moving as a single rigid body) measures the number of hands necessary to hold the parts during the operation. The number of hands required by an assembly sequence is the maximal number of hands needed by an operation, over all the operations in the sequence ("Assembly Sequencing"). The number of fingers to safely grasp or fixture an object is another complexity measure ("Grasping").

Though there is a strong conceptual analogy between computational and physical complexities, there are also major differences between the two notions. Physical complexity must be measured along many more dimensions than computational complexity. Moreover, while computational complexity typically measures an asymptotic trend, a tighter evaluation is usually needed for physical complexity since robot tasks involve relatively few objects.

One may also consider the inherent physical complexity of a task, a notion analogous to the inherent complexity of a computational problem. For example, to orient a convex polygon with n sides, $2n - 1$ squeezes may be needed in the worst case; no correct algorithm can perform better in all cases. By generating all feasible assembly sequences of a product, one could determine the number of hands needed by each sequence and return the smallest number. This number is a measure of the inherent complexity of assembling the product. No robot algorithm to assemble this product can require fewer hands.

Evaluating the inherent physical complexity of a task may lead to redefining the task, if it turns out to be too complex. For example, it has been shown that a product made of n parts may need up to n hands for its assembly ("Grasping"), thus requiring the delicate coordination of $n - 1$ motions. Perhaps a product whose assembly requires several hands could be redesigned so that two hands are sufficient, as is the case for most industrial products. Actually, designers strive to reduce physical complexity along various dimensions. For instance, many mass-produced devices are designed to be assembled with translations only, along very few directions (possibly a single one). The inherent physical complexity of a robot task is not a recent concept, but its formal application to task analysis is [54].

An interesting issue is how the computational and physical complexities of a robot algorithm relate to each other. For example, planning for mobile robot navigation with uncertainty is a provably hard computational problem ("Motion Planning with Uncertainty"). On the other hand, burying wires in the ground or placing enough infrared beacons allows robots to navigate reliably at small computational cost. But isn't it too much? Perhaps the intractability of motion planning with uncertainty can be eliminated with less costly engineering.

21.3 State of the Art and Best Practices

Robotics is a broad domain of research. In this subsection we study a number of specific areas: part manipulation, assembly sequencing, motion planning, and (briefly) sensing. For each area, we introduce problems and survey key algorithmic results.

Although we present the current research according to problem domain, there are several techniques that cross over many domains. One of the most frequently applied methods in robotics is the criticality-based discretization mentioned in "Robot Algorithms Reason About Geometry." This technique allows us to discretize a continuous space without giving up the completeness or exactness of the solution. It is closely related to the study of arrangements in computational geometry [23]. When criticality-based

discretization is done in a space representing all possible motions, it yields the so-called "nondirectional" data structures, which is another prevailing concept in robot algorithms and is exemplified in detail in "Monotone Two-Handed Assembly Sequency."

Randomization is another important paradigm in robotics. Randomized techniques have made it possible to cope practically with robot motion planning with many degrees of freedom (Section on "Probabilistic Algorithms"). Also, randomized algorithms are often simpler than their deterministic counterparts and hence better candidates for efficient implementation. Randomization has recently been applied to solving problems in grasping as well as in many other areas that involve geometric reasoning.

Throughout this section we interchangeably use the terms "body," "physical object," and "part" to designate a rigid physical object modeled as a compact manifold with boundary $B \subset \mathbb{R}^k$ ($k = 2$ or 3). B's boundary is also assumed piecewise-smooth.

Part Manipulation

Part manipulation is one of the most frequently performed operations in industrial robotics: parts are grasped from conveyor belts, they are oriented prior to feeding assembly workcells, and they are immobilized for machining operations.

Grasping

Part grasping has motivated various kinds of research, including the design of versatile mechanical hands, as well as simple, low-cost grippers. From an algorithmic point of view, the main goal is to compute "safe" grasps for an object whose model is given as input.

Force-Closure Grasp Informally, a grasp specifies the positions of "fingers" on a body B. A more formal definition uses the notion of a wrench, a pair $[\boldsymbol{f}, \boldsymbol{p} \times \boldsymbol{f}]$, where $\boldsymbol{p}$ denotes a point in the boundary ∂B of B, represented by its coordinate vector in a frame attached to B, $\boldsymbol{f}$ designates a force applied to B at $\boldsymbol{p}$, and $\times$ is the vector cross-product. If $\boldsymbol{f}$ is a unit vector, the wrench is said to be a unit wrench. A finger is any tool that can apply a wrench.

A grasp of B is a set of unit wrenches $\boldsymbol{w}_i = [\boldsymbol{f}_i, \boldsymbol{p}_i \times \boldsymbol{f}_i]$, $i = 1, \ldots, p$, defined on B. For each $\boldsymbol{w}_i$, if the contact is frictionless, $\boldsymbol{f}_i$ is normal to ∂B at $\boldsymbol{p}_i$; otherwise, it can span a friction cone (Coulomb law of friction).

The notion of a safe grasp is captured by force closure. A force-closure grasp $\{\boldsymbol{w}_i\}_{i=1,\ldots,p}$ on B is such that, for any arbitrary wrench $\boldsymbol{w}$, there exists a set of real values $\{f_1, \ldots, f_p\}$ achieving $\Sigma_{i=1}^{p} f_i \boldsymbol{w}_i = -\boldsymbol{w}$. In other words, a force-closure grasp can resist any external wrench applied to B. If contacts are nonsticky, we require that $f_i \geq 0$, for all $i = 1, \ldots, p$, and the grasp is called positive. Here, we only consider positive grasps. A form-closure grasp is a positive force-closure grasp when all finger-body contacts are frictionless.

Size of a Form/Force-Closure Grasp The following results characterize the physical complexity of achieving a safe grasp [40]:

- Bodies with rotational symmetry (e.g., discs in 2-space, spheres and cylinders in 3-space) admit no form-closure grasps.
- All other bodies admit a form-closure grasp with at most 4 fingers in 2-space and 12 fingers in 3-space.
- All polyhedral bodies have a form-closure grasp with 7 fingers.
- With frictional finger-body contacts, all bodies admit a force-closure grasp that consists of 3 fingers in 2-space and 4 fingers in 3-space.

Testing Force Closure A necessary and sufficient condition for a grasp $\{\boldsymbol{w}_i\}_{i=1,\ldots,p}$ to achieve force closure in 2-space (respectively, 3-space) is that the finger wrenches $\boldsymbol{w}_i$ span a space F of dimension

3 (respectively, 6) and that a strictly positive linear combination of them be zero. In other words, the origin of F (null wrench) should lie in the interior of the convex hull of the finger wrenches [40]. This condition provides an effective test for deciding in constant time whether a given grasp achieves force closure.

Computing Form/Force Closure Grasps Most research has concentrated on computing grasps with 2 to 4 nonsticky fingers. Algorithms that compute a single force-closure grasp of a polygonal/polyhedral part in time linear in the part's complexity have been derived in [40].

Finding the maximal regions on a body where fingers can be positioned independently while achieving force closure makes it possible to accommodate errors in finger placement. Geometric algorithms for constructing such regions are proposed in [42] for grasping polygons with two fingers (with friction) and four fingers (without friction), and for grasping polyhedra with three fingers (with frictional contact capable of generating torques) and seven fingers (without friction). Grasping of curved obstacles is addressed in [45].

Fixturing

Most manufacturing operations require fixtures to hold parts. To avoid the custom design of fixtures for each part, modular reconfigurable fixtures are often used. A typical modular fixture consists of a workholding surface, usually a plane, that has a lattice of holes where locators, clamps, and edge fixtures can be placed. Locators are simple round pins, while clamps apply pressure on the part.

Contacts between fixture elements and parts are generally assumed frictionless. In modular fixturing, contact locations are restricted by the lattice of holes, and form closure cannot always be achieved. In particular, when three locators and one clamp are used on a workholding plane, there exist polygons of arbitrary size for which no form-closure fixture exists; but, if parts are restricted to be rectilinear with all edges longer than four lattice units, a form-closure fixture always exists [56].

When the fixturing kit consists of a latticed workholding plane, three locators, and one clamp, it is possible to find all possible placements of a given part on the workholding surface where form closure can be achieved, along with the corresponding positions of the locators and the clamp [9].

Part Feeding

Part feeders account for a large fraction of the cost of a robotic assembly workcell. A typical feeder must bring parts at subsecond rates with high reliability. An example of a flexible feeder is given in [20] and described in "Robot Algorithms Control" above.

Part feeding often relies on nonprehensile manipulation, which exploits task mechanics to achieve a goal state without grasping and frequently allows accomplishing complex feeding tasks with simple mechanisms [2]. Pushing is one form of nonprehensile manipulation. Work on pushing originated in [38] where a simple rule is established to qualitatively determine the motion of a pushed object. This rule makes use of the position of the center of friction of the object on the supporting surface. Related results include a planning algorithm for a robot that tilts a tray with a planar part of known shape to orient it to a desired orientation [16] and an algorithm that computes the sequence of motions of a single articulated fence on a conveyor belt to achieve a goal orientation of an object [2].

Assembly Sequencing

Most mechanical products consist of multiple parts. The goal of assembly sequencing is to compute both an order in which parts can be assembled and the corresponding required movements of the parts. Assembly sequencing can be used during design to verify that the product will be easy to manufacture and service. An assembly sequence is also a robot algorithm at a high level of abstraction since parts are assumed free-flying, massless geometric objects.

Notion of an Assembly Sequence

An assembly A is a collection of bodies in some given relative placements. Subassemblies are separated if they are arbitrarily far apart from one another. An assembly operation is a motion that merges s separated subassemblies ($s \geq 2$) into a new subassembly, with each subassembly moving as a single body. No overlapping between bodies is allowed during the operation. The parameter s is called the number of hands of the operation. (Hence, a hand is seen here as a grasping or fixturing tool that can hold an arbitrary number of bodies in fixed relative placements.) Assembly partitioning is the reverse of an assembly operation.

An assembly sequence is a total ordering on assembly operations that merges the separated parts composing an assembly into this assembly. The maximum, over all the operations in the sequence, of the number of hands of an operation is the number of hands of the sequence.

A monotone assembly sequence contains no operation that brings a body to an intermediate placement (relative to other bodies), before another operation transfers it to its final placement. Therefore, the bodies in every subassembly produced by such a sequence are in the same relative placements as in the complete assembly. Note that a product may admit no monotone assembly sequence for a given number of hands, while it may admit such sequences if more hands are allowed.

Number of Hands in Assembly

The number of hands needed for various families of assemblies is a measure of the inherent physical complexity of an assembly task ("Robot Algorithms Have Physical Complexity"). It has been shown that an assembly of convex polygons in the plane has a two-handed assembly sequence of translations. In the worst case, s hands are necessary and sufficient for assemblies of s star-shaped polygons/polyhedra [41].

There exists an assembly of six tetrahedra without a two-handed assembly sequence of translations, but with a three-handed sequence of translations. Every assembly of five or fewer convex polyhedra admits a two-handed assembly sequence of translations. There exists an assembly of thirty convex polyhedra that cannot be assembled with two hands [51].

Complexity of Assembly Sequencing

When arbitrary sequences are allowed, assembly sequencing is PSPACE-hard. The problem remains PSPACE-hard even when the bodies are polygons, each with a constant maximal number of vertices [41]. When only two-handed monotone sequences are permitted and rigid motions are allowed, finding a partition of an assembly A into two subassemblies S and $A \setminus S$ is NP-complete. The problem remains NP-complete when both S and $A \setminus S$ are connected and motions are restricted to translations [26]. These latter results were obtained by reducing in polynomial time any instance of the 3-SAT problem to a mechanical assembly such that the partitioning of this assembly gives the solution of the 3-SAT problem instance.

Monotone Two-Handed Assembly Sequencing

A popular approach to assembly sequencing is disassembly sequencing. A sequence that separates an assembly to its individual components is first generated and next reversed. Most existing assembly sequencers can only generate two-handed monotone sequences. Such a sequence is computed by partitioning the assembly and, recursively, the obtained subassemblies into two separated assemblies.

The nondirectional blocking graph (NDBG, for short) is proposed in [54] to represent all the blocking relations in an assembly. It is a subdivision of the space of all allowable motions of separation into a finite number of cells such that within each cell the set of blocking relations between all pairs of parts remain fixed. Within each cell this set is represented in the form of a directed graph, called the directional blocking graph (DBG). The NDBG is the collection of the DBGs over all the cells in the subdivision. The NDBG is one example of a data structure obtained by a criticality-driven discretization technique ("Robot Algorithms Reason About Geometry").

We illustrate this approach for polyhedral assemblies when the allowable motions are infinite translations. The partitioning of an assembly consisting of polyhedral parts into two subassemblies is done as follows. For an ordered pair of parts P_i, P_j, the 3-vector $\boldsymbol{d}$ is a blocking direction if translating P_i to infinity in direction $\boldsymbol{d}$ will cause P_i to collide with P_j. For each ordered pair of parts the set of blocking directions is constructed on the unit sphere $\mathcal{S}^2$ by drawing the boundary arcs of the union of the blocking directions (each arc is a portion of a great circle). The resulting collection of arcs partitions $\mathcal{S}^2$ into maximal regions such that the blocking relation among the parts is the same for any direction inside such a region.

Next, the blocking graph is computed for one such maximal region. The algorithm then moves to an adjacent region and updates the DBG by the blocking relations that change at the boundary between the regions, and so on. After each time the construction of a DBG is completed, this graph is checked for strong connectivity in time linear in the number its edges. The algorithm stops the first time it encounters a DBG that is not strongly connected and it outputs the two subassemblies of the partitioning. The overall sequencing algorithm continues recursively with the resulting subassemblies. If all the DBGs that are produced during a partitioning step are strongly connected, the algorithm notifies that the assembly does not admit a two-handed monotone assembly sequence with infinite translations.

Polynomial time algorithms are proposed in [54] to compute and exploit NDBGs for restricted families of motions. In particular, the case of partitioning a polyhedral assembly by a single translation to infinity, is analyzed in detail, and it is shown that partitioning an assembly of m polyhedra with a total of v vertices takes $O(m^2v^4)$ time. Another case is where the separating motions are infinitesimal rigid motions. Then partitioning the polyhedral assembly takes $O(mc^5)$ time, where m is the number of pairs of parts in contact and c is the number of independent point-plane contact constraints. With the above algorithms, every feasible disassembly sequence can be generated in polynomial time.

Basic Path Planning

Motion planning is aimed at providing robots with the capability of deciding automatically which motions to execute. It arises in a variety of forms. The simplest—basic path planning—requires finding a geometric collision-free path for a single robot in a known static workspace. The path is represented by a curve segment connecting two points in the robot's configuration space [35]. This curve must not intersect a forbidden region, the C-obstacle region, which is the image of the workspace obstacles. Other motion planning problems require dealing with moving obstacles, multiple robots, movable objects, uncertainty, etc.

In this subsection we consider basic path planning. In the next three subsections we will review other motion planning problems and issues.

Configuration Space

A configuration of a robot $\mathcal{A}$ is any mathematical specification of the position and orientation of every body composing $\mathcal{A}$, relative to a fixed coordinate system. The configuration of a single body is also called a placement or a pose.

The robot's configuration space is the set of all its configurations. Usually, it is a smooth manifold. We will always denote the configuration space of a robot by $\mathcal{C}$ and its dimension by m. Given a robot $\mathcal{A}$, we will let $\mathcal{A}(\boldsymbol{q})$ denote the subset of the workspace occupied by $\mathcal{A}$ at configuration $\boldsymbol{q}$.

The number of degrees of freedom of a robot is the dimension m of its configuration space. We abbreviate "degree of freedom" by dof.

Given an obstacle B_i in the workspace, the subset $CB_i \subseteq \mathcal{C}$ such that, for any $\boldsymbol{q} \in CB_i$, $\mathcal{A}(\boldsymbol{q})$ intersects B_i is called a **C-obstacle**. The union $CB = \cup_i CB_i$ plus the configurations that violate the mechanical limits of the robot's joints is called the **C-obstacle region**. The **free space** is the complement of the C-obstacle region in $\mathcal{C}$, that is, $\mathcal{C} \backslash CB$. In most practical cases, C-obstacles are represented as semialgebraic sets with piecewise smooth boundaries.

A robot's path is a continuous map $\tau : [0, 1] \rightarrow \mathcal{C}$. A **free path** is a path that entirely lies in free space. A **semifree path** lies in the closure of free space.

The **basic path planning problem** is to compute a free or semifree path between two input configurations. A **complete motion planner** is guaranteed to find a (semi)free path between two given configurations whenever such a path exists, and to notify that no such path exists otherwise.

Complete Algorithms

Basic path planning for a three-dimensional linkage made of polyhedral links is PSPACE-hard [47]. The proof uses the robot's dofs to both encode the configuration of a polynomial space bounded Turing machine and design obstacles which force the robot's motions to simulate the computation of this machine. It provides strong evidence that any complete algorithm will require exponential time in the number of dofs. This result remains true in more specific cases, for instance when the robot is a planar arm in which all joints are revolute. However, it no longer holds in some very simple settings; for instance, planning the path of a planar arm within an empty circle is in P. For a collection of complexity results on motion planning see [30].

Most complete algorithms first capture the connectivity of the free space into a graph, either by partitioning the free space into a collection of cells (exact cell decomposition techniques), or by extracting a network of curves (roadmap techniques) [30]. General and specific complete planners have been proposed. The general ones apply to virtually any robot with an arbitrary number of dofs. The specific ones apply to a restricted family of robots usually having a fixed small number of dofs.

The general algorithm in [49] computes a cylindrical cell decomposition of the free space using the Collins method. It takes doubly exponential time in the number m of dofs of the robot. The roadmap algorithm in [10] computes a semifree path in time singly exponential in m. Both algorithms are polynomial in the number of polynomial constraints defining the free space and their maximal degree. Specific algorithms have been developed mainly for robots with 2 or 3 dofs. For a k-sided polygonal robot moving freely in a polygonal workspace, the algorithm in [24] takes $O((kn)^{2+\epsilon})$ time, where n is the total number of edges of the workspace, for any $\epsilon > 0$.

Probabilistic Algorithms

The complexity of path planning for robots with many dofs (more than 4 or 5) has led the development of computational schemes that trade off completeness against time. One such scheme, probabilistic planning [4], avoids computing an explicit geometric representation of the free space. Instead, it uses an efficient procedure to compute distances between bodies in the workspace. It samples the configuration space by selecting a large number of configurations at random and retaining only the free configurations as milestones. It then checks if each pair of milestones can be connected by a collision-free straight path in configuration space. This computation yields the graph (V, E), called a probabilistic roadmap, where V is the set of milestones and E is the set of pairs of milestones that have been connected.

Various strategies can be applied to sample the configuration space. The strategy in [27] proceeds as sketched above. Once a roadmap has been computed, it is used to process an arbitrary number of path planning queries.

The results reported in [4] bound the number of milestones generated by the algorithm in [27], under the assumption that the configuration space verifies some simple geometric property. One such property is ϵ-goodness: a set S of volume μ is said to be ϵ-good, if every point in S sees a subset of S of volume at least $\epsilon \times \mu$. Under such an assumption, the number of milestones needed to correctly answer path planning queries with probability $1 - \alpha$ is proportional to $(1/\epsilon)(\log(1/\epsilon) + \log(1/\alpha))$.

Heuristic Algorithms

Several heuristic techniques have been proposed to speedup path planning. Some of them work well in practice, but they usually offer no performance guarantee.

Heuristic algorithms often search a regular grid defined over configuration space and generate a path as a sequence of adjacent grid points. The search can be guided by a potential field, a function over the free space that has a global minimum at the goal configuration. This function may be constructed as the sum of an attractive and a repulsive field [28]. The attractive field has a single minimum at the goal and grows to infinity as the distance to the goal increases. The repulsive field is zero at all configurations where the distance between the robot and the obstacles is greater than some predefined value, and grows to infinity as the robot gets closer to an obstacle.

One may also construct grids at variable resolution. Hierarchical space decomposition techniques such as octrees and boxtrees have been used to that purpose [30].

Path Planning for Nonholonomic Robots

In some cases, the configuration parameters of a robot are not directly controllable. This is in particular the case with nonholonomic robots. Informally, for such robots, the number of parameters that can be controlled is smaller than the number of parameters defining a configuration, which raises controllability issues introduced in "Robot Algorithms Control."

Mathematical Background

The trajectories of a nonholonomic robot are constrained by $p \geq 1$ nonintegrable scalar equality constraints:

$$G(\boldsymbol{q}(t), \dot{\boldsymbol{q}}(t)) = \Big(G^1(\boldsymbol{q}(t), \dot{\boldsymbol{q}}(t)), \ldots, G^p(\boldsymbol{q}(t), \dot{\boldsymbol{q}}(t))\Big) = (0, \ldots, 0) \ ,$$

where $\dot{\boldsymbol{q}}(t) \in T_{\boldsymbol{q}(t)}(\mathcal{C})$ designates the velocity vector along the **trajectory** $\boldsymbol{q}(t)$. At every $\boldsymbol{q}$, the function $G_{\boldsymbol{q}} = G(\boldsymbol{q}, .)$ maps the tangent space[1] $T_{\boldsymbol{q}}(\mathcal{C})$ into $\mathbb{R}^p$. If $G_{\boldsymbol{q}}$ is smooth and its Jacobian has full rank (two conditions that are often satisfied), the constraint $G_{\boldsymbol{q}}(\dot{\boldsymbol{q}}) = (0, \ldots, 0)$ constrains $\dot{\boldsymbol{q}}$ to be in a linear subspace of $T_{\boldsymbol{q}}(\mathcal{C})$ of dimension $m - p$. The nonholonomic robot may also be subject to scalar inequality constraints of the form $H^j(\boldsymbol{q}, \dot{\boldsymbol{q}}) > 0$. The subset of $T_{\boldsymbol{q}}(\mathcal{C})$ that satisfies all the constraints on $\dot{\boldsymbol{q}}$ is called the set $\Omega(\boldsymbol{q})$ of controls at $\boldsymbol{q}$. A feasible path is a piecewise differentiable path whose tangent lies everywhere in the control set.

A car-like robot is a classical example of a nonholonomic robot. It is constrained by one equality constraint (the linear velocity must point along the car's axis). Limits on the steering angle impose two inequality constraints. Other nonholonomic robots include tractor-trailers, airplanes, and satellites.

A key question when dealing with a nonholonomic robot is: Despite the relatively small number of controls, can the robot span its configuration space? The study of this question requires introducing some controllability notions. Given an arbitrary subset $U \subset \mathcal{C}$, the configuration $\boldsymbol{q}_1 \in U$ is said to be U-accessible from $\boldsymbol{q}_0 \in U$ if there exists a piecewise constant control $\dot{\boldsymbol{q}}(t)$ in the control set whose integral is a trajectory joining $\boldsymbol{q}_0$ to $\boldsymbol{q}_1$ that fully lies in U. Let $A_U(\boldsymbol{q}_0)$ be the set of configurations U-accessible from $\boldsymbol{q}_0$. The robot is said to be locally controllable at $\boldsymbol{q}_0$ iff for every neighborhood U of $\boldsymbol{q}_0$, $A_U(\boldsymbol{q}_0)$ is also a neighborhood of $\boldsymbol{q}_0$. It is locally controllable iff this is true for all $\boldsymbol{q}_0 \in \mathcal{C}$. Car-like robots and tractor-trailers that can go forward and backward are locally controllable [5].

Let X and Y be two smooth vector fields on $\mathcal{C}$. The Lie bracket of X and Y, denoted by $[X, Y]$, is the smooth vector field on $\mathcal{C}$ defined by $[X, Y] = dY \cdot X - dX \cdot Y$, where dX and dY, respectively, denote the $m \times m$ matrices of the partial derivatives of the components of X and Y w.r.t. the configuration coordinates in a chart placed on $\mathcal{C}$. The Control Lie Algebra associated with the control set Ω, denoted by $L(\Omega)$, is the space of all linear combinations of vector fields in Ω closed by the Lie bracket operation. The following

[1] The tangent space $T_p(M)$ at a point p of a smooth manifold M is the vector space of all tangent vectors to curves contained in M and passing through p. It has the same dimension as M.

result derives from the Controllability Rank Condition Theorem [5]: *A robot is locally controllable if, for every* $\boldsymbol{q} \in \mathcal{C}$, $\Omega(\boldsymbol{q})$ *is symmetric with respect to the origin of* $T_{\boldsymbol{q}}(\mathcal{C})$ *and the set* $\{X(\boldsymbol{q}) \mid X(\boldsymbol{q}) \in L(\Omega(\boldsymbol{q}))\}$ *has dimension* m.

The minimal number of Lie brackets sufficient to express any vector in $L(\Omega)$ using vectors in Ω is called the degree of nonholonomy of the robot. The degree of nonholonomy of a car-like robot is 2. Except at some singular configurations, the degree of nonholonomy of a tractor towing a chain of s trailers is $2 + s$. Intuitively, the higher the degree of nonholonomy the more complex (and the slower) the robot's maneuvers to perform some motions.

Planning for Controllable Robots

Let $\mathcal{A}$ be a locally controllable nonholonomic robot. A necessary and sufficient condition for the existence of a feasible free path of $\mathcal{A}$ between two given configurations is that they lie in the same connected component of the open free space. Indeed, local controllability guarantees that a possibly nonfeasible path can be decomposed into a finite number of subpaths, each short enough to be replaced by a feasible free subpath [31]. Hence, deciding if there exists a free path for a locally controllable nonholonomic robot has the same complexity as deciding if there exists a free path for the holonomic robot having the same geometry.

Transforming a nonfeasible free path τ into a feasible one can be done by recursively decomposing τ into subpaths. The recursion halts at every subpath that can be replaced by a feasible free subpath. Specific substitution rules (e.g., Reeds and Shepp curves) have been defined for car-like robots [31]. The complexity of transforming a nonfeasible free path τ into a feasible one is of the form $O(\epsilon^d)$, where ϵ is the smallest clearance between the robot and the obstacles along τ and d is the degree of nonholonomy of the robot.

The algorithm in [5] directly constructs a nonholonomic path for a car-like or a tractor-trailer robot by searching a tree obtained by concatenating short feasible paths, starting at the robot's initial configuration. The planner is guaranteed to find a path if one exists, provided that the length of the short feasible paths is small enough. It can also find paths that minimize the number of cusps (changes of sign of the linear velocity).

Planning for Noncontrollable Robots

Path planning for nonholonomic robots that are not locally controllable is much less understood. Research has almost exclusively focused on car-like robots that can only move forward. The algorithm in [17] decides whether there exists such a path between two configurations, but it runs in time exponential in obstacle complexity. The algorithm in [1] computes a path in polynomial time under the assumptions that all obstacles are convex and their boundaries have a curvature radius greater than the minimum turning radius of the point (so called "moderate obstacles"). Other polynomial algorithms [5] require some sort of discretization.

Motion Planning with Uncertainty

In practice, robots deviate from planned paths due to errors in control and position sensing. Such errors raise recognizability issues which make planning more complex.

Problem Formulation

The inputs to a motion planning problem with uncertainty are the initial region $I \subset \mathcal{C}$, in which the robot is known to be prior to moving, the goal region $G \subset \mathcal{C}$, in which it should terminate its motion, and the uncertainty in control and sensing. Uncertainty is specified in the form of regions. For instance, the uncertainty in position sensing is the set of possible actual robot's configurations given the sensor readings. The output is a series of motion commands, if one exists, whose execution enables the robot to reach G

from I. Each command is described by a velocity vector $\boldsymbol{v}$ and a termination condition T. The vector $\boldsymbol{v}$ specifies the desired behavior of the robot over time (with or without compliance). The condition T is a Boolean function of the sensor readings and time which causes the motion to stop as soon as it becomes true. A plan may contain conditional branchings. In [10] this problem is shown NEXPTIME-hard for a point robot moving in 3-space among polyhedral obstacles.

Preimage of a Goal

Given a goal G and a command $(\boldsymbol{v}, T)$, a preimage of G is any region $P \subset \mathcal{C}$ such that executing the command from anywhere in P makes the robot reach and stop in G [36]. One way to compute a (nonmaximal) preimage is to restrict the termination condition so that it recognizes G independently of the region from which the motion started [15]. For example, one may shrink G to a subset K, called the kernel of G, such that whenever the robot is in K, all robot configurations consistent with the current sensor readings are in G. A preimage is then computed as the region from which the robot commanded along $\boldsymbol{v}$ is guaranteed to reach K. This region is called the backprojection of K for $\boldsymbol{v}$. This preimage computation approach has been well studied in a polygonal configuration space when G is a polygon [30].

One-Step Planning

In a polygonal configuration space, the kernel of a polygonal goal is either independent of the selected $\boldsymbol{v}$ or changes at a number of critical orientations of $\boldsymbol{v}$ that is linear in the workspace complexity [30]. Moreover, the backprojection of a polygonal region K, when the orientation of $\boldsymbol{v}$ varies, changes topology only at a quadratic number of critical directions. Its intersection with a polygonal initial region I of constant complexity also changes qualitatively at few directions of $\boldsymbol{v}$. Checking the containment of I by the backprojection at each such direction yields a one-step motion plan, if one exists, in amortized time $O(n^2 \log n)$, where n is the number of edges in $\mathcal{C}$ [8].

Multistep Planning

For multistep planning, algebraic approaches that check the satisfiability of a first-order semi-algebraic formula have been proposed. In [11] it is assumed that all possible trajectories have an algebraic description. The approach there is based on a two-player-game interpretation of planning, where the robot is one player and nature the other. Each step of a plan contributes three quantifiers: one existential quantifier applies to the direction of motion, and corresponds to choosing this direction; another existential quantifier applies to time, and corresponds to choosing when to terminate the motion; one universal quantifier applies to the sensor readings and represents the unknown action of nature. The formula representing an r-step plan thus contains r quantifier alternations; checking its satisfiability takes double-exponential time in r, which is itself polynomial in the total complexity of the robot and the workspace.

Landmark-Based Planning

Often a workspace contains features that can be reliably sensed and used to precisely localize the robot. Each such landmark feature induces a region in configuration space called the landmark area from which the robot can sense the corresponding feature.

The planner in [33] considers a point robot among n circular obstacles and $O(n)$ circular landmark areas. It assumes perfect position sensing and motion control in landmark areas. Outside these areas, it assumes that the robot has no position sensing and that directional errors in control are bounded by the angle θ. Given circular initial and goal regions I and G (with G intersecting at least one landmark area), the planner constructs a motion plan that enables the robot to move from landmark areas to landmark areas, until it reaches the goal. It proceeds backward by computing P_1 – the preimage of the landmark regions intersecting G. Then it computes the preimage P_2 of the landmark regions intersected by P_1, and

so on, until a preimage contains I. The planner runs in $O(n^4 \log n)$ time; it is complete and generates plans that minimize the number of steps to be executed in the worst case.

Other Motion Planning Issues

There are many other useful extensions of the basic path planning problem [30]. Below we briefly present some of them.

Dynamic Workspace

In the presence of moving obstacles, one can no longer plan a robot's motion as a mere geometric path. The path must be indexed by time and is then called a trajectory. It can be represented in the configuration×time space $\mathcal{C} \times [0, +\infty)$ of the robot. All workspace obstacles map to static forbidden regions in that space. A free trajectory is a free path in that space whose tangent at every point points positively along the time axis (or within a more restricted cone, if the robot's velocity modulus is bounded).

Computing a free trajectory for a rigid object in 3-space among arbitrarily moving obstacles (with known trajectories) is PSPACE-hard if the robot's velocity is bounded, and NP-hard otherwise [48]. The problem remains NP-hard for a point robot moving with bounded velocity in the plane among convex polygonal obstacles translating at constant linear velocities [10]. A complete planning algorithm is given in [48] for a polygonal robot that translates in the plane among polygonal obstacles translating at fixed velocities. This algorithm takes time exponential in the number of moving obstacles and polynomial in the total number of edges of the robot and the obstacles.

Coordination of Multiple Robots

The case of multiple robots can be trivially addressed by considering them as the components of a single robot, that is, by planning a path in the cross product of their configuration spaces. This product is called the composite configuration space of the robots and the approach is referred to as centralized planning.

One may try to reduce complexity by separately computing a path for each robot, before tuning the robots' velocities along their respective paths to avoid inter-robot collision (decoupled planning) [25]. Although inherently incomplete, decoupled planning may work well in some practical applications.

Manipulation Planning

Many robot tasks consist of achieving arrangements of physical objects. Such objects, called movable objects, cannot move autonomously; they must be moved by a robot. Planning with movable objects is called manipulation planning.

In [53] the robot $\mathcal{A}$ and the movable object M are both convex polygons in a polygonal workspace. The goal is to bring $\mathcal{A}$ and M to specified positions. $\mathcal{A}$ can only translate. To grasp M, $\mathcal{A}$ must have one of its edges that exactly coincides with an edge of M. While $\mathcal{A}$ grasps M, they move together as one rigid object. An exact cell decomposition algorithm is given that runs in $O(n^2)$ time after $O(n^3 \log^2 n)$ preprocessing, where n is the total number of edges in the workspace, the robot, and the movable object. An extension of this problem allowing an infinite set of grasps is solved by an exact cell decomposition algorithm in Alami et al. [3].

Heuristic algorithms have also been proposed. The planner in [29] first plans the path of the movable object M. During that phase, it only verifies that for every configuration taken by M there exists at least one collision-free configuration of the robot where it can hold M. In the second phase, the planner determines the points along the path of M where the robot must change grasps. It then computes the paths where the robot moves alone to (re)grasp M. The paths of the robot when it carries M are obtained through inverse kinematics. This planner is not complete, but it has solved complex tasks in practice.

Optimal Planning

There has been considerable research in computational geometry on finding shortest Euclidean paths, but minimal Euclidean length is usually not the most suitable criterion in robotics. Rather, one wishes to minimize execution time, which requires taking the robot's dynamics into account.

Optimal-Time Control Planning The input is a geometric free path τ parameterized by $s \in [0, L]$, the distance travelled from the starting configuration. The problem is to find the time parametrization $s(t)$ that minimizes travel time along τ, while satisfying actuator limits.

The dynamic equation of motion of a robot arm with m dofs can be written as $M(\boldsymbol{q})\ddot{\boldsymbol{q}} + V(\dot{\boldsymbol{q}}, \boldsymbol{q}) + G(\boldsymbol{q}) = \Gamma$, where $\boldsymbol{q}, \dot{\boldsymbol{q}}$, and $\ddot{\boldsymbol{q}}$, respectively, denote the robot's configuration, velocity, and acceleration [12]. M is the $m \times m$ inertia matrix of the robot, V the m-vector (quadratic in $\dot{\boldsymbol{q}}$) of centrifugal and Coriolis forces, and G the m-vector of gravity forces. Γ is the m-vector of the torques applied by the joint actuators.

Using the fact that the robot follows τ, this equation can be rewritten in the form: $\boldsymbol{m}\ddot{s} + \boldsymbol{v}\dot{s}^2 + \boldsymbol{g} = \Gamma$, where $\boldsymbol{m}$, $\boldsymbol{v}$, and $\boldsymbol{g}$ are derived from M, V, and G, respectively. Minimum-time control planning becomes a two-point boundary value problem: find $s(t)$ that minimizes $t_f = \int_0^L ds/\dot{s}$, subject to $\Gamma = \boldsymbol{m}\ddot{s} + \boldsymbol{v}\dot{s}^2 + \boldsymbol{g}$, $\Gamma_{min} \leq \Gamma \leq \Gamma_{max}$, $s(0) = 0$, $s(t_f) = L$, and $\dot{s}(0) = \dot{s}(L) = 0$. Numerical techniques solve this problem by finely discretizing the path τ.

Minimal-Time Trajectory Planning Finding a minimal-time trajectory is called kinodynamic motion planning. One approach is to first plan a geometric free path and then iteratively deform this path to reduce travel time. Each iteration requires checking the new path for collision and recomputing the optimal-time control. No bound has been established on the running time of this approach or the goodness of its outcome. Kinodynamic planning is NP-hard for a point robot under Newtonian mechanics in 3-space. The approximation algorithm in [13] computes a trajectory ϵ-close to optimal in time polynomial in both $1/\epsilon$ and the **workspace complexity.**

Discovery and On-Line Planning

On-line planning addresses the case where the workspace is initially unknown or partially unknown. As the robot moves, it acquires new partial information about the workspace through sensing. A motion plan is generated using the partial information that is available and updated as new information is acquired.

Early examples of on-line planners are reviewed in [37]. Most of these planners apply to a point robot in 2-space that must go from a start position s to a goal position g among unknown obstacles, each bounded by a Jordan curve of measurable length. The robot is equipped with perfect position and touch sensors. The planners select a mix of motions following either the line segment connecting s to g or boundaries of hit obstacles. The main consideration is the length of the generated path, expressed as a function of the distance between s and g, the number of obstacles, and their perimeters.

Another way of evaluating an on-line planner is competitive analysis. The competitive ratio of an on-line planner is the maximal ratio (over all possible workspaces) between the length of the path generated by the on-line algorithm and the length of the shortest path [44]. Competitive analysis is not restricted to path length and can be applied to other measures of performance as well.

Sensing

Sensing allows a robot to acquire information about its workspace and localize itself. Here we mention a few selected topics.

Model Building

Consider a mobile robot in an unknown workspace W. A first task for this robot is likely to be the construction of a geometric model (also called a map) of W [55]. This requires the robot to perform a series of sensing operations at different locations. Each operation yields a partial model. The robot must patch

together the successively obtained partial models to eventually form a complete map of the workspace. This problem is complicated by the fact that the robot has imperfect control and cannot accurately keep track of its position in a fixed coordinate system.

Robot Localization

A robot often has to localize itself relative to its workspace W. A model of W is given and localization is done by matching sensory inputs against this model to infer the robot configuration. This problem usually arises for mobile robots. Other types of robots, such as robot arms, often have absolute references (e.g., mechanical stops) and internal sensors (e.g., joint encoders) that provide configurations more directly. Mobile robots have wheel encoders allowing dead-reckoning, but the absence of absolute reference on the one hand and slipping on the ground on the other hand usually require sensor-based localization. GPS (global positioning system) has recently become a widely available alternative, but it does not work in all environments.

Two kinds of sensor-based localization problems can be distinguished, static and dynamic. In the static problem, the robot is placed at an arbitrary unknown configuration and the problem is to compute this configuration. In the dynamic problem, the robot moves continuously and must regularly update its configuration. The second problem consists of refining an available estimate of the current configuration; but the computation must be done in real time. The static problem is usually more complex; but computation time is less restricted. A preprocessing approach to the static localization problem for a point robot equipped with a 360° range sensor is presented in [22]. Practical techniques for localization are described in many papers [52].

Additional Issues in Sensing

Sensor placement is the problem of computing the set of placements from which a sensor can monitor a region within a given workspace [8]. Another problem is to choose a minimal set of sensors and their placement so as to completely cover a given region. Additionally, there has been considerable interest in reconstructing shapes of objects using simple sensors, called probes. See [50] for a review of problems and results in this area. Matching and aspect graphs are two related topics that have been well studied, mainly in computer vision.

21.4 Distance Computation

The efficient computation of (minimum) distances between bodies in 2- and 3-space is a crucial element of many algorithms in robotics.

Algorithms have been proposed to efficiently compute distances between two convex bodies. In [14], an algorithm is given which computes the distance between two convex polygons P and Q (together with the points that realize it) in $O(\log p + \log q)$ time, where p and q denote the number of vertices of P and Q, respectively. This time is optimal in the worst case. The algorithm is based on the observation that the minimal distance is realized between two vertices or between a vertex and an edge. It represents P and Q as sequences of vertices and edges and performs a binary search that eliminates half of the edges in at least one sequence at each step. A widely tested numerical descent technique is described in [18] to compute the distance between two convex polyhedra; extensive experience indicates that it runs in approximately linear time in the total complexity of the polyhedra.

Most robotics applications, however, involve many bodies. Typically, one must compute the minimum distance between two sets of bodies, one representing the robot, the other the obstacles. Each body can be quite complex and the number of bodies forming the obstacles can be large. The cost of accurately computing the distance between every pair of bodies is often prohibitive. In that context, simple bounding volumes, such as parallelepipeds and spheres, have been extensively used to reduce computation time. They are often coupled with hierarchical decomposition techniques, such as octrees, boxtrees, or sphere trees.

(For an example, see [46].) These techniques make it possible to rapidly eliminate pairs of bodies that are too far apart to contribute the minimum distance.

When motion is involved, incremental distance computation has been suggested for tracking the closest points on a pair of convex polyhedra [34]. It takes advantage of the fact that the closest features (faces, edges, vertices) change infrequently as the polyhedra move along finely discretized paths.

21.5 Research Issues and Summary

In this chapter we have introduced robot algorithms as abstract descriptions of processes consisting of motions and sensing operations in the physical space. Robot algorithms send commands to actuators and sensors in order to control a subset of the real world, the workspace, despite the fact that the workspace is subject to the imperfectly modeled laws of nature. Robot algorithms uniquely blend controllability, observability, computational complexity, and physical complexity issues, as described in Section 21.2. Research on robot algorithms is broad and touches many different areas. In Section 21.3 we have surveyed a number of selected areas in which research has been particularly active: part manipulation (grasping, fixturing, feeding), assembly sequencing, motion planning (including basic path planning, nonholonomic planning, planning with uncertainty, dynamic workspaces, and optimal-time planning), and sensing.

Many of the core issues reviewed in Section 21.2 have been barely addressed in currently existing algorithms. There is much more to understand in how controllability, observability, and complexity interact in robot tasks. The interaction between controllability and complexity has been studied to some extent for nonholonomic robots. The interaction between observability (or recognizability) and complexity has been considered in motion planning with uncertainty. But, in both cases, much more remains to be done.

Concerning the areas studied in Section 21.3, several specific problems remain open. We list a few below (by no means is this list exhaustive):

- Given a workspace W, find the optimal design of a robot arm that can reach everywhere in W without collision. The three-dimensional case is largely open. An extension of this problem is to design the layout of the workspace so that a certain task can be completed efficiently.
- Given the geometry of the parts to be manipulated, predict feeders' throughputs to evaluate alternative feeder designs. In relation to this problem, simulation algorithms have been used to predict the pose of a part dropped on a flat surface [39].
- In assembly planning, the complexity of an NDBG grows exponentially with the number of parameters that control the allowable motions. Are there situations where only a small portion of the full NDBG need be constructed?
- Develop efficient sampling techniques for searching the configuration space of robots with many degrees of freedom in the context of the scheme given in [4].
- Establish a nontrivial lower bound on the complexity of planning for a nonholonomic robot that is not locally controllable.

21.6 Defining Terms

Basic path planning problem: Compute a free or semifree path between two input configurations for a robot moving in a known and static workspace.

C-Obstacle: Given an obstacle B_i, the subset CB_i of the configuration space $\mathcal{C}$ such that, for any $\boldsymbol{q} \in CB_i$, $\mathcal{A}(\boldsymbol{q})$ intersects B_i. The union $CB = \cup_i CB_i$ plus the configurations that violate the mechanical limits of the robot's joints is called the **C-obstacle region**.

Complete motion planner: A planner guaranteed to find a (semi)free path between two given configurations whenever such a path exists, and to notify that no such path exists otherwise.

Configuration: Any mathematical specification of the position and orientation of every body composing a robot $\mathcal{A}$, relative to a fixed coordinate system. The configuration of a single body is also called a **placement** or a **pose**.

Configuration space: Set $\mathcal{C}$ of all configurations of a robot. For almost any robot, this set is a smooth manifold.

Free path: A path in free space.

Free space: The complement of the C-obstacle region in $\mathcal{C}$, that is, $\mathcal{C} \setminus \mathcal{CB}$.

Linkage: A collection of rigid objects, called links, in which some pairs of links are connected by joints (e.g., revolute and/or prismatic joints). Most industrial robot arms are serial linkages with actuated joints.

Number of degrees of freedom: The dimension m of $\mathcal{C}$.

Obstacle: The workspace W is often defined by a set of obstacles (bodies) B_i $(i = 1, \ldots, q)$ such that $W = \mathbb{R}^k \setminus \bigcup_1^q B_i$.

Path: A continuous map $\tau : [0, 1] \to \mathcal{C}$.

Semifree path: A path in the closure of free space.

Trajectory: Path indexed by time.

Workspace: A subset of the two- or three-dimensional physical space modeled by $W \subset \mathbb{R}^k, k = 2, 3$.

Workspace complexity: The total number of features (vertices, edges, faces, etc.) on the boundary of the obstacles.

Universitá di Padova

22.1 Introduction

There is abundance of algorithms developed in the field of image processing and computer vision ranging from simple algorithms that manipulate binary images based on local point operations to complex algorithms for the interpretation of the symbolic information extracted from the images.

Here we concentrate on algorithms for three central problems in image processing and computer vision that are representative of different types of algorithms developed in this area. The first problem, *connectivity analysis,* has been studied since the early days of binary images. It consists of separating the objects from the background by assigning different labels to the **connected components** of an image. The algorithms to identify connected components in binary images are rather straightforward: the first one is an iterative algorithm that performs several scans of the image and uses only local operations; the next two algorithms consist of only two scans of the image and use global information in the form of an equivalence table.

The second problem is that of grouping features extracted from the image (for instance, **edge points**) into parametric curves such as straight lines and circles. An algorithm to detect lines, based on the *Hough transform,* is described that maps the image data into a parameter space that is quantized into an accumulator array. The Hough transform is a robust technique since it is relatively insensitive to noise in the sensory data and to small gaps in a line.

The last problem is that of identifying and locating objects known *a priori* in an image, a problem that is generally called *model-based object recognition*. Our discussion will focus on the matching task, that is, finding correspondences between the image and model descriptions. This correspondence can be used to solve the localization problem, i.e., the determination of a geometrical transformation that maps the model into the observed object. Finding correspondences is difficult, due to the combinatorial

nature of the problem and to noise and uncertainty in the data. We deal mainly with the case of planar objects undergoing rigid transformations in 3D space followed by scaled orthographic projections. We first assume that both the model and the image data are represented in terms of sets of feature points and describe two approaches (*alignment* and *geometric hashing*) to solve the point set matching problem. Then we consider model and image representations in terms of object **boundary** descriptions. We review *dynamic programming* algorithms for matching two sequences of boundary segments, which resemble the algorithm for the string editing problem. For multiresolution boundary representations, a tree dynamic programming algorithm is discussed. Extensions of the *indexing* techniques and of the algorithms based on the *hypothesis-and-test* paradigm to take advantage of the richer boundary descriptions are also described.

22.2 Connected Components

The connected component problem consists of assigning a label to each 1-pixel of a binary image so that two 1-pixels are assigned the same label if and only if they are connected. Two pixels are said to be connected if there is a path of 1-pixels adjacent along the horizontal and vertical directions that links them. (A different definition of connectivity includes the diagonal direction as well.) The set of connected pixels is called a connected component. Figure 22.1 shows a binary image and its connected components labeled with integers. A simple iterative algorithm to determine the connected components performs a sequence

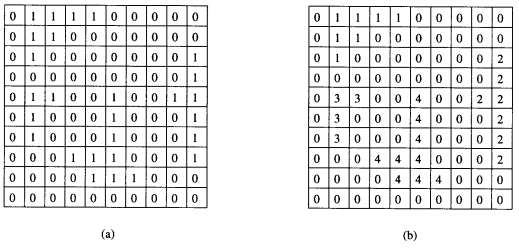

FIGURE 22.1 A 8×8 image (a) and its labeled connected components (b).

of scans over the image propagating a label from each 1-pixel to its adjacent 1-pixels. The algorithm starts with an arbitrary labeling. More precisely, the algorithm works as follows.

CONNECTED COMPONENT ALGORITHM-*Iterative*

Step 1. (*Initialization phase)*
Assign each 1-pixel a unique integer label.

Step 2. Scan the image top-down left-to-right.
Assign each 1-pixel the smallest between its own label and those of the adjacent pixels already examined in the scan sequence.

Step 3. Scan the image bottom-up right-to-left.
Like Step 2 above with a different scan order.

Alternate Step 2 and Step 3 until no changes occur.

Figure 22.2 shows a few steps of the algorithm (b-f) for the input image (a). It is clear that this algorithm is highly inefficient on conventional computers; however, it becomes attractive for implementation on parallel SIMD (single instruction multiple data stream) architectures where all the updates of the pixel's labels can be done concurrently. Another advantage of the iterative algorithm is that it does not require auxiliary memory, unlike the next two algorithms.

A common approach to finding the connected components is based on a two-pass algorithm. First the image is scanned in a top-bottom left-to-right fashion and a label is assigned to each 1-pixel based on

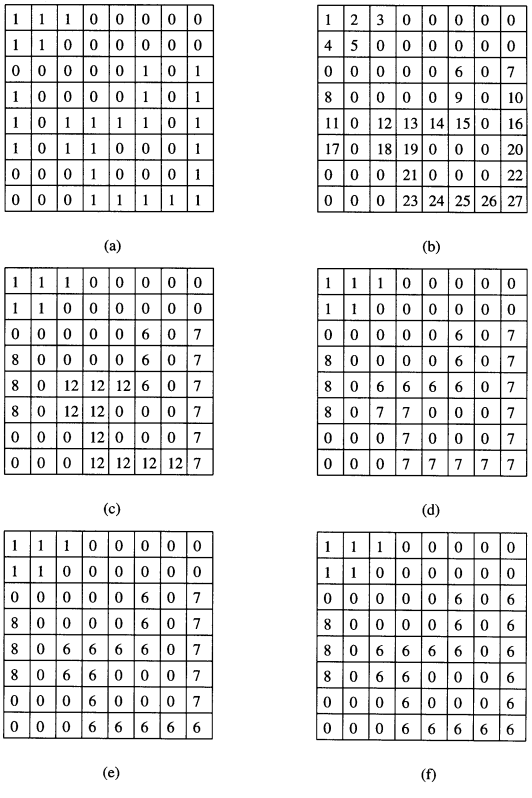

FIGURE 22.2 All the steps of the iterative algorithm for the input image (a).

the value of adjacent 1-pixels already labeled. If there are no adjacent 1-pixels, a new label is assigned. Conflicting situations may arise in which a pixel can be given two different labels. Equivalent classes of labels are then constructed and stored to be used in the second pass of the algorithm to disambiguate such conflicts. During the second scan of the image, each label is replaced by the one selected as the representative of the corresponding equivalence class; for instance, the smallest one in the class if the labels are integers. The details follow.

CONNECTED COMPONENT ALGORITHM-*Equivalence Table*

Step 1. Scan the image top-down left-to-right

for each 1-pixel **do**

if the upper and left adjacent pixels are all 0-pixels

then assign a new label

if the upper and left adjacent pixels have the same label

then assign that label

if only one adjacent pixel has a label

then assign this label

otherwise

Assign the smaller label to the pixel.

Enter the two equivalent labels into the equivalence table.

Step 2.

Find equivalence classes.

Choose a representative of each class

(i.e., the smallest label).

Step 3. Scan the image top-down left-to-right.
Replace the label of each 1-pixel with its smallest equivalent one.

Step 2. can be done using the algorithm for UNION-FIND. The drawback of the above algorithm is that it may require a large number of memory locations to store the equivalent classes.

The next algorithm overcomes this problem by building a local equivalence table that takes into account only two consecutive rows. Thus, as the image is processed the equivalences are found and resolved locally. The algorithm works in two passes over the image.

CONNECTED COMPONENT ALGORITHM-*Local Equivalence Table*

Step 1. Scan the image top-down left-to-right
for each row r of the image **do**
Initialize the local equivalence table for row r.
for each 1-pixel of row r **do**
if the upper and left adjacent pixels are all 0-pixels
then assign a new label
if the upper and left adjacent pixels have the same label
then assign this label
if only one adjacent pixel has a label
then assign this label
otherwise assign the smaller label to the pixel and
enter the two equivalent labels into the local table.
Find equivalence classes of the local table.
Choose a representative of each class.
for each 1-pixel of row r **do**
replace its label with the smallest equivalent label.

Step 2. Scan the image bottom-up right-to-left
for each row r of the image **do**
Initialize the local equivalence table for row r.
for each 1-pixel of row r **do**
for each adjacent pixel with a different label **do**
enter the two equivalent labels into the local table.
Find equivalence classes of the local table.
Choose a representative of each class.
for each 1-pixel of row r **do**
replace its label with the smallest equivalent label.

It has been shown by experiments that as the image size increases this algorithm works better than the classical algorithm on a virtual memory computer.

Modifications of the above algorithms involving different partitioning of the image into rectangular blocks are straightforward.

22.3 The Hough Transform

Line detection

The Hough transform is a powerful technique for the detection of lines in an image [11, 16]. Suppose we are given a set of image points — for instance edge points or some other local feature points — and we

want to determine subsets of them lying on straight lines. A straightforward but inefficient procedure to do that consists of determining for each pair of points the straight line through them and then of counting the number of other points lying on it (or close to it).

The Hough transform formulates the problem as follows. Consider the following parametric representation of a line:

$$y = mx + b$$

where the parameters m, b are the slope and the intercept, respectively. Given a point (x_1, y_1), the equation $b = -x_1 m + y_1$, for varying values of b and m, represents the parameters of all possible lines through (x_1, y_1). This equation in the (b, m) plane is the equation of a straight line. Similarly, point (x_2, y_2) maps into the line $b = -x_2 m + y_2$ of the parameter space. These two lines intersect at a point (b', m') that gives the parameters of the line through the (x_1, y_1) and (x_2, y_2). More generally, points aligned in the (x, y) plane along the line with parameters (b', m') correspond to lines in the (b, m) plane intersecting at (b', m'). Figure 22.3 illustrates this property.

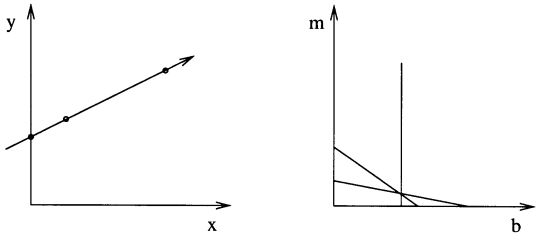

FIGURE 22.3 Mapping collinear image points into parameter space.

Thus the line detection problem is converted into the problem of finding intersections of sets of lines in the parameter space. We next see how to solve this latter problem efficiently in the presence of noise in the image data.

The parameter space is quantized into $h \times k$ cells that form an array A, called *accumulator array*; each entry of the array or cell corresponds to a pair (b, m). In other words, the parameter b is discretized into h values $b_1, b_2, \ldots, b_h$, and m in k values $m_1, m_2, \ldots, m_k$, where b_h and m_k are the largest possible values for the two parameters. See Fig. 22.4.

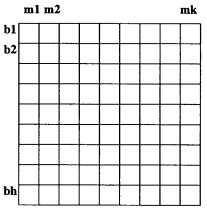

FIGURE 22.4 The parameter space.

The line detection algorithm proceeds in two phases. Phase 1 constructs the accumulator array as follows.

HOUGH ALGORITHM

Initialize all entries of the accumulator array A to zero.
for each image point (x, y) **do**
  for each $m_i, i = 1, k$ **do**

$b \leftarrow -m_i x + y$
round b to the nearest discretized value, say, b_j
$A(b_j, m_i) \leftarrow A(b_j, m_i) + 1$.

At the end of phase 1, the value t at $A(b, m)$ indicates that there are t image points along the line $y = mx + b$. Thus a maximum value in the array corresponds to the best choice of values for the line parameters describing the image data. Phase 2 of the algorithm determines such a peak in the accumulator array A, or more generally, the s largest peaks, for a given s.

Another way of looking at the Hough transform is as a "voting" process where the image points cast votes in the accumulator array.

The above parametric line representation has the drawback that the slope m approaches infinity for vertical lines complicating the construction of the Hough table. Since vertical lines tend to occur frequently in real applications this representation is rarely used. A better representation is

$$\rho = x \cos\theta + y \sin\theta$$

where the two parameters ρ and θ denote the distance of the line from the origin and the angle of the normal line, respectively, as illustrated in Fig. 22.5.

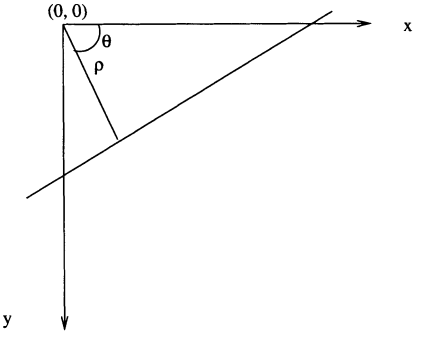

FIGURE 22.5 ρ, θ line representation.

An important property of the Hough transform is its insensitivity to noise and to missing parts of lines.

We now analyze the time complexity of the Hough algorithm. Let n be the number of points (edges or other feature points) and $k \times m$ the size of the accumulator array. Phase 1 of the above algorithm requires $O(nm)$ operations. Phase 2, that is finding the maximum in the array, requires $O(km)$ time for a total of $O(m \max(k, n))$ time.

Detection of Other Parametric Curves

The concept of the Hough transform can be extended in several ways. One extension is to other parametric curves with a reasonably small number of parameters; circles and ellipses are typical examples. Consider the case of circle detection. A circle can be represented by the equation

$$(x - a)^2 + (y - b)^2 = r^2$$

where the parameters a and b are the coordinates of the center and r is the radius. The transform maps the image points into a three-dimensional accumulator array indexed by discretized values of the center coordinates and of the radius. If it is known in advance that only circles with given radii may be present

in an image, which is sometimes true in real applications, only a few two-dimensional subarrays need to be considered. If space is a concern this approach can be used only for few parametric curves, since the array dimensionality grows with the number of the curve parameters.

Another generalization is to arbitrary shapes represented by boundary points [2].

22.4 Model-Based Object Recognition

The problem of object recognition, central to computer vision, is the identification and localization of given objects in a scene. The recognition process generally involves two stages. The first is the extraction from sensed data of information relevant to the problem and the construction of a suitable symbolic representation. The second is that of matching the image and model representations to establish a correspondence between their elements. This correspondence can be used to solve the localization problem, that is the determination of a geometrical transformation that maps the model into the observed object.

Matching is a difficult task, for a number of reasons. First, a brute-force matching is equivalent to a combinatorial search with exponential worst-case complexity. Heuristics may be used to reduce the complexity by pruning the search space that must be explored. Approaches with polynomial time complexity have also been proposed; but the execution time and memory requirements remain high. Second, images do not present perfect data: noise and occlusion greatly complicate the task.

There have been many recognition methods and systems proposed to handle this complexity. Surveys of recognition methods are [1, 3, 4, 8, 34]. The systems differ both in the choice of the representational models and of the matching algorithms used to relate the visual data to the model data. It is obvious that these two aspects influence each other and that the selection of a matching strategy heavily depends on which structures are used to represent data. Some methods use representational models that rely on few high-level features for fast interpretation of the image data. While this facilitates matching, the process of extracting high-level primitives from the raw data may be difficult and time consuming. Moreover, in the presence of occlusion the disappearance of few distinctive features may became fatal. Simpler features are easier to detect and tend to be dense, implying less sensitivity to noise and occlusion. However, low-level features do not have high discriminating power, thus affecting the time for matching.

There are a number of other issues that any recognition system needs to address.

1. *What class of objects is the system able to deal with?*
   The objects can be two-dimensional (2D) or three-dimensional (3D). 3D objects may be smoothly curved or approximated by polyhedra. A restricted class of 3D objects includes flat objects, that is,objects with one dimension much smaller than the other two. Flat objects have received a lot of attention, because a projective transformation applied to this class of objects can be effectively approximated by an **affine transformation,** which is easier to handle. Another important distinction is whether the objects are rigid or deformable or composed of parts that are allowed to move with respect to one another.
2. *What type of geometric transformation is allowed?*
   There is a hierarchy of transformations that has been considered in computer vision: from Euclidean transformations (rotations, translations) to similarity transformations (rotations, translations, and scaling) to affine transformations (represented by a set of linear equations) to the more general projective transformations. To remove the effects of a transformation it is useful to represent the objects by means of features that are invariant under that class of transformations. As the class of transformations becomes more general, the invariant features become more complex and harder to extract. For example, a well-known simple invariant to Euclidean transformations is the distance between two points; however, distance is not invariant to similarity. For a projective transformation four points are needed to define an invariant (cross-ratio).

3. *Robustness*
   Is the recognition system able to deal with real data? Some available systems give good results in controlled environments, with good lighting conditions and with isolated objects. Noisy and cluttered images represent challenging domains for most systems.

This chapter reviews algorithms to match an image against stored object models. Topics that are not covered in this chapter include model representation and organization. The objects are assumed to be given either by means of sets of feature points or by their boundaries (2D or 3D). For an introduction to feature and boundary extraction, see the references listed at the end of this chapter.

The objects may have undergone an affine transformation; thus we do not consider here the more general class of projective transformations.

Matching Sets of Feature Points

In this section we consider recognition of rigid flat objects from an arbitrary viewpoint. Models in the database are represented by sets of feature points. We assume that an image has been preprocessed and feature points have been extracted. Such points might be edge points or corners or correspond to any other relevant feature. The following discussion is independent on the choice of the points and on the method used to acquire them. In fact, as we will see later, similar techniques can be applied when other more complex features, for instance line segments, are used instead of points.

In object recognition to obtain independence from external factors such as viewpoints, it is convenient to represent a shape by means of geometric invariants, that is, shape properties that do not change under a class of transformations. For a flat object a projective transformation can be approximated by an affine transformation. For the definition and properties of affine transformations see Section "Defining Terms."

Affine Matching

There are two main approaches proposed to match objects under affine transformations: *alignment* and *geometric hashing* The first method, *alignment,* uses the hypothesis-and-test paradigm [17]. It computes an affine transformation based on an hypothesized correspondence between an object and model basis and then verifies the hypothesis by transforming the model to image coordinates and determining the fraction of model and image points brought into correspondence. This is taken as a measure of quality of the transformation. The above steps are repeated for all possible groups of three model and image points, since it is known that they uniquely determine an affine transformation.

The geometric hashing or, more generally, indexing methods [20, 21], build at compile time a look-up table that encodes model information in a redundant way. At run time, hypotheses of associations between an observed object and the models can be retrieved from the table and then verified by additional processing. Thus much of the complexity of the task is moved to a preprocessing phase where the work is done on the models alone. Strategies based on indexing do not consider each model separately and are therefore more convenient than search-based techniques in applications involving large databases of models. Crucial to indexing is the choice of image properties to index the table; these can be groups of features or other geometric properties derived from such groups. In the following, we first concentrate on hash methods based on triplets of features points, then on methods based on segments of a boundary object decomposition.

Hypothesize-and-Test (Alignment)

Given an image I containing n feature points, alignment consists of the following steps.

ALIGNMENT
for each model M. Let m be the number of model points
  for each triple of model points **do**
    for each triple of image points **do**
      hypothesize that they are in correspondence and
      compute the affine transformation based on this correspondence.
      for each of the remaining $m - 3$ model points **do**
        apply that transformation.
      Find correspondences between the transformed model points
        and the image points.
      Measure the *quality* of the transformation
      (based on the number of model points that are paired with image points.)

For a given model, these steps are repeated for all triples of model and image features. In the worst-case the number of hypotheses is $O(m^3n^3)$. Thus the total time is $O(T_v m^3 n^3)$, where T_v is the time for the verification of the hypothesized mapping. Since a verification step is likely to take time polynomial in the number of model and image features, this approach takes overall polynomial time which represents a significant improvement over several exponential time approaches to matching proposed in the literature. In the following, a more detailed description of the verification phase is given. Once a transformation is found, it is used to superimpose the model and the object. A distance measure between the two sets of points must be defined so that recognition occurs when such a distance is below a given threshold. One definition of distance is just the number of model and image points that can be brought into correspondence. An approximation to this value can be computed by determining for any transformed model point if an image point can be found in a given small region around it (for instance a small square of pixels of fixed side). In this way an image point can be double-counted if it matches two different model points. Nevertheless, in most cases the above provides a good approximation at a reasonable computational cost.

The search for image points that match each transformed model point can be done sequentially over the image points in time $O(nm)$. Alternatively, it can be made more efficient with some preprocessing of the image points and the use of auxiliary data structures. A practical solution uses a look-up table indexed by the quantized values of the image points coordinates. An entry of the table contains the set of image points located in the small region represented by the cell in the quantized space. Each transformed model point is entered into the table to retrieve, in constant time, possible matching points. Other information besides location of image points can be used to index the table, for instance orientation, which is already available if the features points are computed through an edge operator.

The algorithm above iterates over all the k models in the database leading to a total time complexity $O(kT_v m^3 n^3)$.

Indexing

The second method, *hashing* or *indexing,* is a table look-up method. It consists of representing each model object by storing transformation-invariant information about it in a hash table. This table is compiled off-line. At recognition time, similar invariants are extracted from the sensory data and used to index the table to find possible instances of the model. The indexing mechanism, referred to as *geometric hashing* for point set matching, is based on the following invariant. The coordinates of a point into a reference frame consisting of three noncollinear points are affine invariant. The algorithm consists of a preprocessing phase and a recognition phase.

INDEXING
Preprocessing phase
for each model M. Let m be the number of model points

for each triple of noncollinear model points **do**
form a basis (reference frame)
for each of the $m - 3$ remaining model points **do**
determine the point coordinates in that basis.
Use the triplet of coordinates (after a proper quantization)
as an index to an entry in the hash table, where the pair
(*M, basis*) is stored.

For k models the algorithm has an $O(km^4)$ time complexity. Notice that this process is carried out only once and off-line. At the end of the preprocessing stage an entry of the hash table contains a list of pairs: $(M_{i1}, basis_{i1})$, $(M_{i2}, basis_{i2})$, ..., $(M_{it}, basis_{it})$.

INDEXING
Recognition phase
Initialization
for each entry of the hash table **do**
set a counter to 0.
Choose three noncollinear points of I as a basis.
for each of the $n - 3$ remaining image points **do**
determine its coordinates in that basis.
Use the triplet of coordinates (after a proper quantization)
as an index to an entry in the hash table and
increment the corresponding counter.
Find the pair (*M, basis*) that achieved the maximum value
of the counter when summed over the hash table.

The last process can be seen as one of "voting," with a vote tallied by each image point to all pairs (*M, basis*) that appear at the corresponding entry in the table.

At the end of these steps after all votes have been cast, if the pair (*M, basis*) scores a large number of votes, then there is evidence that the model M is present in the image. If no pair achieves a high vote, then it might be that the selected basis in the image does not correspond to any basis in the model database, and therefore it is convenient to repeat the entire process with another selected basis in the image, until either a match is found or all bases of image points have been explored.

The time complexity of the recognition phase is $O(n)$ if a single selected image basis gives satisfactory results (high scores). Otherwise more bases need to be considered leading, in the worst case, to the time $O(n^4)$. In summary, the time complexity of recognition $T_{\text{recognition}}$ is bound by

$$O(n) \leq T_{\text{recognition}} \leq O\left(n^4\right)$$

There are a few issues that affect the performance of this approach. First, the choice of the basis. The three selected points of the basis should be far away to reduce the numerical error. Other issues are the sensitivity to quantization parameters and to noise. A precise analysis of this approach and a comparison with alignment under uncertainty of sensory data is beyond the scope of this chapter. The interested reader may refer to [15]. Although alignment is computationally more demanding, it is less sensitive to noise than hashing and able to deal with uncertainty under a bounded error noise model. On the other hand, indexing is especially convenient when large databases are involved, since it does not require to match each model separately and its time complexity is therefore not directly dependent on the size of the database.

One way to overcome the limitations of geometric hashing and make it less sensitive to noise is to use more complex global invariants to index the hash table at the expense of preprocessing time to extract such invariants. More complex invariants have a greater discriminating power and generate fewer false positive matches.

Matching Contours of Planar Shapes

It is natural to use contours as a representation for planar objects. Contour information can be in the form of a polygonal approximation, that is, a sequence of line segments of possibly varying lengths approximating the curve. A common boundary description is the eight-direction chain code [39] where all segments of the boundary decomposition have unit length and one of 8 possible directions. Another boundary description is given in terms of concave/convex curve segments. Boundary representations are simple and compact, since a small number of segments suffices to accurately describe most shapes. Techniques to derive boundary descriptions are reviewed in the references listed at the end of this chapter.

Contours have been used in a variety of ways in object recognition to make the process faster and more accurate. First, the availability of contours allows computation of global invariant properties of a shape that can be used for fast removal of candidate objects when searching in the model database; only models found to have similar global properties need be considered for further processing. Global features that can be used include

- The number of segments of a convex/concave boundary decomposition.
- For a close contour, a measure of the area over the length.

A combination of the above features allows a reduction of the candidate objects. An object with extreme values of the global attributes is more easily recognized than an object with average attributes. Obviously there must be a sufficiently high tolerance in the removal process so that good choices are not eliminated.

In the following, we first describe techniques based on dynamic programming that have been developed for contour matching. Then we will see how the methodologies of indexing and alignment based on point sets can take advantage of the contour information in the verification phase for more reliable results. The same methodologies can be further modified so that contour segments become the basic elements of the matching, that is, they are used instead of the feature points to formulate hypotheses.

Dynamic Programming

A number of approaches use dynamic programming to match shape contours. A shape boundary is described by a string of symbols representing boundary segments. For instance, if the segments result from the decomposition of the boundary into convex/concave parts, there might be just three symbols (for convex, concave, and straight) or more if different degrees of convexity or concavity are considered. The matching problem becomes then a string matching problem [39]. We briefly review the string matching algorithm. Then we will discuss adaptations of the basic algorithm to shape recognition that take into account noise and distortion.

Let $A = a_0, \cdots, a_{n-1}$ and $B = b_0, \cdots, b_{m-1}$ be two strings of symbols. Three types of edit operations, namely, *insertion, deletion,* and *change,* are defined to transform A into B.

- insertion: insert a symbol a into a string, denoted as $\lambda \rightarrow a$ where λ is the null symbol;
- deletion: delete a symbol from a string, denoted as $a \rightarrow \lambda$;
- change: change one symbol into another, denoted as $a \rightarrow b$.

A nonnegative real cost function $d(a \rightarrow b)$ is assigned to each edit operation $a \rightarrow b$. The cost of a sequence of edit operations that transforms A into B is given by the sum of the costs of the individual operations. The edit distance $D(A, B)$ is defined as the minimum of such total costs. Let $D(i, j)$ be the

distance between the substrings $a_0, \cdots, a_i$ and $b_0, \cdots, b_j$. It is $D(n, m) = D(A, B)$. Let $D(0, 0) = 0$; then $D(i, j), 0 < i < n, 0 < j < m$ is given by

$$D(i, j) = \min \begin{cases} D(i-1, j) + d(a_i \rightarrow \lambda) \\ D(i, j-1) + d(\lambda \rightarrow b_j) \\ D(i-1, j-1) + d(a_i \rightarrow b_j) \end{cases} \tag{22.1}$$

The matching problem can be seen as one of finding an optimal non-increasing path in the 2D table $D(i, j)$ from the entry $(0, 0)$ to the entry (n, m). If the elements of the table are computed horizontally from each row to the next one, then when computing $D(i, j)$ the values that are needed have already been computed. Since it takes constant time to compute $D(i, j)$, the overall time complexity is given by $O(nm)$. The space complexity is also quadratic.

Using Attributes

A number of variations of the above dynamic programming algorithm have been proposed to adapt it to the shape matching problem. First, attributes are associated to the symbols of the two strings. The choice of the attributes depends both on the type of transformations allowed for the shapes and on the types of boundary segments. Some of the commonly used attributes of concave/convex segments are the normalized length, and the degree of symmetry S_c. Let L_a be the length of segment a and L_A the total length of the segments of A. The normalized length is L_a/L_A. L_A is used as normalization factors to obtain scale invariance.

Let $f(l)$ be the curvature function along segment a.

$$S_a = \int_0^{L_a} \left(\int_0^s f(l)dl - 1/2 \int_0^{L_a} f(l)dl \right) ds$$

If $S_a = 0$ then the segment is symmetric, otherwise it is inclined to the left or to the right depending on whether S_a is positive or negative, respectively.

The attributes are used in the matching process to define the cost $d(i, j)$ of the edit operation that changes segment a_i into b_j. The cost $d(i, j)$ is defined as the weighted sum of the differences between the attributes of a_i and b_j.
Thus the cost function $d(i, j)$ is defined as

$$d(i, j) = w_1 \left| L_{a_i}/L_A - L_{b_j}/L_B \right| + w_2 \sigma \left(S_{a_i}, S_{b_j} \right)$$

where $\sigma(S_a, S_b)$ is taken to be 0 if S_a and S_b are both positive or negative or both close to zero, otherwise is 1. In the above expression w_1 and w_2 are weights used to take into account the different magnitude of the two terms when summed over all edit operations.

Consider now a shape represented by a polygonal approximation. Typical choices for the attributes of a segment a are the normalized length and the angle θ_a that the segment forms with a reference axis. In this case, the cost function can be defined as

$$d(i, j) = w_1 \left| L_{a_i}/L_A - L_{b_j}/L_B \right| + w_2 \gamma \left(\theta_{a_i}, \theta_{b_j} \right)$$

where, again, w_1 and w_2 are weights to make both terms to lie between 0 and 1.

Cyclic Matching

The above algorithm assumes that the correct starting points are known for the correspondences on both shapes. These could be, for instance, the topmost boundary segments when no rotation is present. A more reliable choice that is invariant to Euclidean transformations may be obtained by ranking the

segments according to some criterion, for instance the normalized length or the curvature. The segments on the two curves with highest rank are chosen as the starting points for the dynamic programming algorithm. Alternatively, when the starting points are not available or cannot be computed reliably, cyclic shifts of one of the two strings are needed to try to match segments starting at any point in one of the boundaries. Let B be the shortest string, i.e., $m < n$. To solve the cyclic matching problem a table with n rows and $2m$ columns is built. Paths in the $D(i, j)$ table that correspond to optimal solutions can start at any column $1 \leq j \leq m$ of the first row and end at column $j + m$ of the last row. The dynamic programming algorithm is repeated for each new starting symbol of the shortest string. This brute-force approach solves the cyclic matching problem in time $O(nm^2)$. A more efficient $O(mn \log n)$ solution can be obtained by using divide-and-conquer [24].

Merge Operation

To reduce the effect of noise and distortion and improve matching accuracy, another variant of the above method suggests the use of a fourth operation, called *merge* [37], in addition to the insert, delete, and change operations. Merge allows change of any set of consecutive segments of one string into any set of consecutive segments in the other string. Let $a_{<k,i>}$ denote the sequence of k segments $a_{i-k+1} \cdots a_i$. The merge operation $a_{<k,i>} \rightarrow b_{<h,j>}$ attempts to change the combined segments from the first string into the combined segments of the second. For $k = h = 1$, the merge operation reduces to a change. It has now to be defined what are the attributes associated with the merged segments. First the length of $a_{<k,i>}$ is simply the normalized sum of the lengths of all segments in the sequence. As for the direction, assume $k = 2$. Then the angle $\theta_{a_{<2,i>}}$ can defined as follows:

$$\begin{aligned}
\theta_{a_{2,i}} &= \theta_{a_{i-1}} + \left|\theta_{a_{i-1}} - \theta_{a_i}\right| \\
&\text{if} \quad \theta_{a_{i-1}} < \theta_{a_i} \text{ and } \left|\theta_{a_{i-1}} - \theta_{a_i}\right| \leq 180 \\
&= \theta_{a_i} + \left|\theta_{a_{i-1}} - \theta_{a_i}\right| \\
&\text{if} \quad \theta_{a_{i-1}} \geq \theta_{a_i} \text{ and } \left|\theta_{a_{i-1}} - \theta_{a_i}\right| \leq 180 \\
&= \theta_{a_{i-1}} + \left(360 - \left|\theta_{a_{i-1}} - \theta_{a_i}\right|\right) \\
&\text{if} \quad \theta_{a_{i-1}} \geq \theta_{a_i} \text{ and } \left|\theta_{a_{i-1}} - \theta_{a_i}\right| > 180 \\
&= \theta_{a_i} + \left(360 - \left|\theta_{a_{i-1}} - \theta_{a_i}\right|\right) \\
&\text{if} \quad \theta_{a_{i-1}} < \theta_{a_i} \text{ and } \left|\theta_{a_{i-1}} - \theta_{a_i}\right| > 180
\end{aligned}$$

To include the merge operation in the above algorithm (22.1) has to be replaced by

$$D(i, j) = \min \begin{cases} D(i-1, j) + d\,(a_i \rightarrow \lambda) \\ D(i, j-1) + d\,(\lambda \rightarrow b_j) \\ D_{\text{merge}}(i, j) \end{cases}$$

where

$$D_{\text{merge}}(i, j) = \min_{1 \leq k \leq i, 1 \leq h \leq j} D(i-k, j-h) + d\left(a_{<k,i>}, b_{<h,j>}\right)$$

When there is no limitation on the number of merged segments, the time complexity of the dynamic programming algorithm becomes $O(n^2m^2)$.

In summary, the dynamic programming algorithm is able to deal with rotation, translation, and scaling through the combined use of a distance measure invariant to these transformations and of a cyclic mapping of the two boundaries. Furthermore, noise can be dealt with through the use of concatenated segments in both shapes.

Multiscale Tree Matching

Another approach to match contours of planar shapes uses multiscale data representations. Given a scene containing multiple objects, a full pyramid of images, taken at various levels of resolution, is

first constructed (for instance, a Gaussian pyramid [6]). Then contours are extracted at all levels of resolution and each of them is decomposed into a sequence of segments (either curved or straight line segments) [25, 26].

There are two main ways of matching multiscale objects. One approach, the *coarse-to-fine* matching, tries to find a good initial pair of corresponding segments at the coarsest level of resolution and to expand, at the finer levels, the hypothesized correspondences [29, 30]. The coarse-to-fine approach has generally the disadvantage that mismatches at a coarse scale cause errors from which it is impossible to recover, since the algorithms usually proceed by subdividing the corresponding coarse elements into subelements. This limitation is heavy particularly for highly deformed shapes for which the matching is not very reliable at all levels. On the other hand, this method is fast, because it disregards large portions of the search space. Coarse-to-fine strategies have been successfully used in a variety of image processing and vision applications, including stereo matching, optical flow computation, etc.

Alternative approaches [9, 38] try to overcome the limitations of a coarse-to-fine strategy by processing the multiresolution data starting from the finest level. The shape contours are represented at all scales by sequences of concave/convex segments. In [9], a planar object is modeled as a tree, in which a node corresponds to a multiscale boundary segment and an arc connects nodes at successive levels of resolution. The children of a given node describe the structural changes to that segment at a finer level of resolution. The problem of matching an object against a model is formulated as the one of determining the best mapping between nodes at all levels of the two corresponding trees, according to a given distance between segments. The distance is chosen to be invariant under rotation, translation, and change of scale. The mapping has to satisfy the following constraint: for any path from a leaf node to the root of each of the two trees, there is exactly one node in the mapping. Thus, if a node is in the mapping none of its proper ancestors nor descendants is. Intuitively, such a constraint on the mapped nodes means that for any portion of the boundary at the finest resolution there is one matched segment at some resolution level that covers it.

This method applies to objects for which the entire boundaries are available, implying that it is able to deal with occlusion when this causes alterations in a boundary without breaking it into separate pieces.

We now describe a tree matching algorithm based on dynamic programming that has optimal $O(|T||T'|)$ time complexity, where $|T|$ and $|T'|$ are the number of nodes in the two trees. Let l be the number of leaves of T. $T[i]$ denotes the node of T whose position in the post-order traversal of T is i. Recall that in the post-order traversal the nodes are visited by recursively visiting the first subtree of the root, then the second subtree and so on, and finally visiting the root. In the post-order, $T[1], T[2], \ldots, T[i]$ is in general a forest. $anc(i)$ is the set of ancestor nodes of $T[i]$, including i itself. The postorder number of the father of node $T[i]$ is denoted by $p(i)$. $ll(i)$ and $rl(i)$ denote the postorder number of the leftmost leaf and the rightmost leaf, respectively, of the subtree rooted at $T[i]$; $ll(i) = rl(i) = i$ when $T[i]$ is a leaf node.

A measure of dissimilarity $d(i, j)$ between nodes i and j is defined as above as the weighted sum of the attributes of the segments. In addition $d(i, j)$ must contain a term that rewards matches at higher resolution levels.

The matching problem can be formulated as a minimization problem: find a set of pairs $M = \{(i_h, j_h)\}$ that satisfies the above constraint and minimizes the total cost function, that is,

$$F\left(T, T'\right) = Min_M \sum d\left(i_h, j_h\right)$$

The nodes of the two trees are processed according to the left-to-right post-order numbering. Let $D(i, j)$ be the distance between the two forests $T[1], T[2], \ldots, T[i]$ and $T'[1], T'[2], \ldots, T'[j]$, that is the cost of the best mapping involving nodes up to i and j and covering all leaves $1, \ldots, rl(i)$ and $1, \ldots, rl(j)$. $D(i, j) = F(T, T')$ when $i = |T|$ and $j = |T'|$. Let $D(0, 0) = 0$, $D(0, j) = D(i, 0) = \infty, i, j \neq 0$. $D(i, j)$ is given by the following relations:

- Case 1: if $i \neq p(i-1)$ and $j \neq p(j-1)$

$D(i, j) = D(i-1, j-1) + d(i, j)$;

- Case 2: if $i \neq p(i-1)$ and $j = p(j-1)$
  $D(i, j) = \min\{D(i, j-1), D(i-1, ll(j)-1) + d(i, j)\}$;
- Case 3: if $i = p(i-1)$ and $j \neq p(j-1)$
  $D(i, j) = \min\{D(i-1, j), D(ll(i)-1, j-1) + d(i, j)\}$;
- Case 4: if $i = p(i-1)$ and $j = p(j-1)$
  $D(i, j) = \min\{D(i-1, j-1), D(i-1, j), D(i, j-1), D(ll(i)-1, ll(j)-1) + d(i, j)\}$

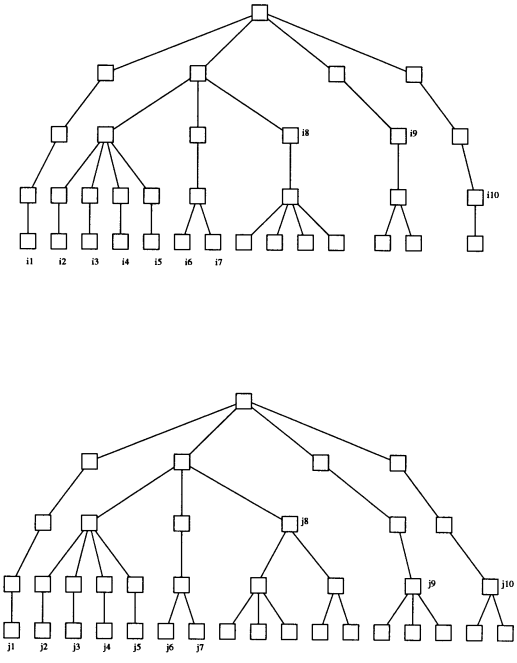

FIGURE 22.6 The matching set $M = \{(i_t, j_t)\}$ of two trees.

The above relations suggest the use of dynamic programming to solve the minimization problem. When computing $D(i, j)$, $1 \leq i \leq |T|$, $1 \leq j \leq |T'|$, all the values on the right side of the recurrence relation above have already been computed. Thus it takes constant time to extend the mapping to nodes i and j leading to a $O(|T||T'|)$ time algorithm. The space complexity is also quadratic.

Hypothesize-and-Test

A common scheme for matching uses three steps: a *hypothesis generation* step during which a few initial matchings are chosen and based on them a transformation is hypothesized, a *prediction* step that determines the matching of image and model features that are compatible with the initial hypothesis, and a *verification* step that evaluates all the resulting possible matchings. This scheme is quite general and can be applied to a variety of data representations. The alignment approach described in the previous section is one such example. The contour information can be effectively used in the alignment method to increase the reliability of the match. As described in the previous section, hypotheses are generated based on small groups of features points brought into correspondence and a geometric transformation is derived for each hypothesis. Then a hierarchical verification process is applied [17]. A preliminary verification phase checks the percentage of model points that lie within reasonable error ranges of the corresponding image

points. This step allows to rapidly eliminate false matches by considering only location and orientation of points (edge points). A more accurate and time-consuming verification procedure based on contour information is applied to the few surviving alignments. Each model segment is mapped through the hypothesized transformation into the image plane and all nearby image segments are determined. Then, for each pair of model and image segments, three cases are considered: (1) the segments are almost parallel and of approximately the same length; (2) the segments are parallel but one is much longer than the other; (3) the segments cross each other. The three cases contribute positive, neutral, or negative evidence to a match, respectively. The basic idea underlying this comparison strategy is that very unlikely two almost coincident segments can be the result of an accidental match. In summary, properties of segments such as length and parallelism can effectively contribute to the evaluation of the quality of a match at the expense of some additional processing.

The next application of the hypothesis-and-test paradigm to contour-based 2D shape descriptions generates hypotheses based on a limited number of corresponding segments. Since the choice of the initial pairing of segments strongly affects the performance of the process, the image segments are first ranked according to a given criterion, for instance length. Then segments in the image and the model are processed in decreasing ranking order of length. Additional constraints can be imposed before a hypothesis is generated. For each pair a and b of such segments, a hypothesis is generated if they are compatible. Compatibility is defined depending on the type of transformation. For similarity transformations a suitable definition can be: segments a and b are compatible (1) if the angle that a forms with its preceding segment along the boundary is close to the angle of b with its neighbor, and (2) assuming the scale factor is known, if the ratio of the lengths of the two segments is close to that value. The verification phase then tries to add more consistent pairings to the initial ones by using an appropriate definition of geometric consistency. The process stops as soon as a reasonably good match is found. We omit here the details of this last phase.

Indexing

The *indexing* methods, as described above, are based on the idea of representing an object by storing invariant information about groups of features in a hash table. Hypotheses of correspondences between an observed object and the models are retrieved from the table by indexing it with groups of features extracted from the object.

One approach to indexing uses information collected locally from the boundary shape in the form of the so-called *super-segment* [33]. A flat object can be approximated by a polygon. Since there exist many polygonal approximations of a boundary with different line fitting tolerances, several of them are used for the purpose of robustness. A super segment is a group of a fixed number of adjacent segments along the boundary, as in Fig. 22.7. Supersegments are the basic elements of the indexing mechanism. The quantized angles between consecutive segments are used to encode each super-segment. Assume that there are n segments in a super segment, then the code is

$$(\alpha_1, \alpha_2, ..., \alpha_{n-1}) \ .$$

Other geometric features of a super segment can be used in the encoding to increase the ability of the system to distinguish between different super segments. One such feature is the eccentricity, that is the ratio of the length of the small and long axis of the ellipse representing the second moment of inertia. A quantized value of the eccentricity is added to the above list of angles. The preprocessing and matching phases of indexing are similar to those described in the section on matching sets of feature points. Briefly, the super-segments of all models are encoded, and each code is used as a key for a table where the corresponding super segment is recorded as an entry. During the matching stage, all encoded super segments extracted from a scene provide indices to the hash table to generate the matching hypotheses.

A *verification phase* is needed to check the consistency of all multiple hypotheses generated by the matching phases. The hypotheses are first divided according to the models they belong to. For a model

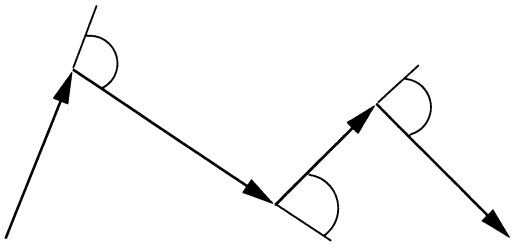

FIGURE 22.7 A super-segment.

M_i, let $h_{i1}, \ldots, h_{it}$ be the hypotheses of associations between super-segments of the image with super-segments of M_i. To check that subsets of such hypotheses are consistent, the following heuristics has been proposed. If three hypotheses are found to be consistent, then the remaining that are found to be consistent with at least one of the three provide an instantiation of the model in the image. Consistency is defined on the basis of few geometric constraints such as the distance, the angle, and the direction. More precisely, the *distances* of corresponding super-segments must be in the same range. The distance between two super-segments is defined as the distance between the locations of the segments taken as the midpoints of the middle segments. Similarly, angles and directions of corresponding super-segments must be in the same range. The orientation of a super-segment is the vector of the predecessor and successor segments of the middle segment.

An alternative approach to indexing suggests the use of information spatially distributed over the object rather than at localized portions of the shape. Groups of points along the curved boundary are collected and indices are computed on the basis of geometrical relationships between the points and local properties at those points. These local measures can include location and tangent or higher order local information as local curve shape.

The difficulty associated with indexing methods arises from the large memory requirements for representing multidimensional tables. Another crucial point is the distribution of data over the table.

Matching Relational Descriptions of Shapes

Graph Matching

An object can be represented by a set of features and their relationships. This representation may take the form of a graph, where nodes correspond to features and arcs represent geometric and topological relationships between features. Similarly, a 3D object can have an object-centered representation consisting of a list of 3D primitives (surface patches, 3D edges, vertices, etc.) and relationships between primitives such as connections between surfaces, edges, etc. Recognition of an object becomes a graph isomorphism problem. Given a graph $G_1 = (V_1, E_1)$ corresponding to a model object and graph $G_2 = (V_2, E_2)$ corresponding to an observed object, the graph isomorphism can be formulated as follows. Find a one-to-one mapping between the vertices of the two graphs $f : V_1 \rightarrow V_2$ such that vertices of V_1 are adjacent iff and only if their corresponding vertices of V_2 are adjacent. In other words, for $u, v \in V_1$, it is $uv \in E_1$ iff $f(u)f(v) \in E_2$. Above we considered only one relation for each graph, but the definition can easily extend to many relations. If an object is only partially visible in an image, a subgraph isomorphism can be used. Graph problems are covered in other chapters of this book. Here we sketch some commonly used heuristics to reduce the complexity of the algorithms for vision applications.

Some researchers [14] have approached the matching problem as one of search, using an *interpretation tree*. A node in the tree represents a pairing between an image feature and a model feature. Nodes at the first level of the tree represent all possible assignments of the first image feature. For each such assignment there a node at the second level for each pairing of the second image feature, and so on.

A path from the root of the tree to a leaf represents a set of consistent pairings that is a solution to

the correspondence problem from which a rigid transformation can be derived. Figure 22.8 shows the interpretation tree for n and m model and object features, respectively. The exponential complexity of the search can be reduced by pruning the interpretation tree using different types of constraints. Mostly geometric constraints involving angles and distances have been considered.

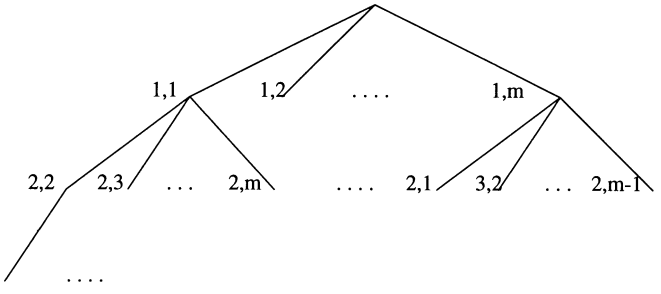

FIGURE 22.8 An interpretation tree with n levels and degree m.

Another approach to cope with the complexity of a brute-force backtracking tree search is the introduction of forward checking and look-ahead functions [31] in the search. Given a partial solution, the idea of forward checking is to find a lower bound on the error of all complete solutions that include the given partial one so that the search can pruned at earlier stages.

22.5 Research Issues and Summary

Most of the work done on image connectivity analysis dates back at least 15 years, and this can be considered a solved problem. Some more recent work has been done on parallel algorithms for image connected component determination for a variety of interconnection networks, including meshes, hypercubes, etc.

The Hough transform is a popular method for line detection, but it is rarely used for more complex parametric curves, due to the high memory requirements. Parallel algorithms for the Hough transform have also been proposed.

Substantial effort has been devoted over the past years to the problem of model-based object recognition, and this is still an area of active research. A number of recognition systems have been designed and built that are successful for limited application domains. The general problem of recognition remains complex, even though polynomial time solutions to matching have been proposed. Practical approaches rely on heuristics based mainly on geometric constraints to reduce the complexity. An interesting issue not covered in this chapter is the effect of noise and spurious elements in the recognition problem. Some recent approaches explicitly take into account a noise error model and formulate the matching problem as one of finding a transformation of model and image data that is consistent with the error model.

Other approaches to match point sets under translation and rotation, developed in the field of computational geometry, are based on the computation of the **Hausdorff distance.**

The problem of finding correspondences is the main component of other important vision tasks, for instance of the *stereo vision problem,* which is the problem of deriving three-dimensional information about an object from different views of the object.

It is also important to observe that some of the matching algorithms used in computer vision can be applied to other research areas, for instance molecular biology. The problem of matching the three-dimensional structure of proteins differs from the point set matching problem mostly in the dimensionality of the data, few tens of feature points for an object and few hundreds of atoms in a protein.

22.6 Defining Terms

Affine transformation: Affine transformations are a subgroup of projective transformations. When the depth of an object is small compared to its distance from the camera, the affine transformation effectively approximates a projective one. For a flat object there is a 2D affine transformation T between two different images of the same object:

$$T : \mathbf{x} \rightarrow A\mathbf{x} + \mathbf{t}$$

where A is 2×2 nonsingular matrix and $\mathbf{t}$ is a 2-vector.
An affine transformation maps parallel lines into parallel lines. Another well-known affine invariant is the following. Given three noncollinear points in the plane, they form a basis or reference frame in which the coordinates of any other point in the plane can be expressed. Such coordinates are affine invariant, meaning that they do not change when the points are transformed under an affine transformation. In other words, let $\mathbf{x_1}, \mathbf{x_2}, \mathbf{x_3}$ be the three noncollinear points, taken as a basis. Let $\mathbf{x}$ be another point and (α, β) its coordinates in the above basis, i.e.,

$$\mathbf{x} = \alpha\,(\mathbf{x_1} - \mathbf{x_3}) + \beta\,(\mathbf{x_2} - \mathbf{x_3}) + \mathbf{x_3}$$

The values α and β are invariant, that is,

$$T(\mathbf{x}) = \alpha\,(T\,(\mathbf{x_1}) - T\,(\mathbf{x_3})) + \beta\,(T\,(\mathbf{x_2}) - T\,(\mathbf{x_3})) + T\,(\mathbf{x_3})$$

The following fact is also known in affine geometry: Given three noncollinear points in the plane $\mathbf{x_1}, \mathbf{x_2}, \mathbf{x_3}$ and three corresponding points $\mathbf{x'_1}, \mathbf{x'_2}, \mathbf{x'_3}$ in the plane, there exists a unique affine transformation T such that $\mathbf{x'_1} = T(\mathbf{x_1})$ $\mathbf{x'_2} = T(\mathbf{x_2})$, and $\mathbf{x'_3} = T(\mathbf{x_3})$.
The affine transformation $T : \mathbf{x} \rightarrow A\mathbf{x} + \mathbf{t}$ can be determined from the set of corresponding points as follows. Let $\mathbf{m}_i$, $i = 1, 2, 3$ and $\mathbf{i}_i$, $i = 1, 2, 3$ be the set of corresponding model and image points, respectively, where

$$\mathbf{m}_i = \begin{pmatrix} m_{i,x} \\ m_{i,y} \end{pmatrix}$$

and

$$\mathbf{i}_i = \begin{pmatrix} i_{i,x} \\ i_{i,y} \end{pmatrix}$$

The six unknown parameters of the 2×2 matrix

$$A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}$$

and of the vector

$$\mathbf{t} = \begin{pmatrix} t_1 \\ t_2 \end{pmatrix}$$

can be computed by solving the following system of equations

$$\begin{pmatrix} i_{1,x} & i_{1,y} \\ i_{2,x} & i_{2,y} \\ i_{3,x} & i_{3,y} \end{pmatrix} - \begin{pmatrix} m_{1,x} & m_{1,y} & 1 \\ m_{2,x} & m_{2,y} & 1 \\ m_{3,x} & m_{3,y} & 1 \end{pmatrix} \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ t_1 & t_2 \end{pmatrix} = 0\,.$$

Boundary: A closed curve that separates an image component from the background and/or other components.

Connected component: A set C of connected image points. Two points (i, j) and (h, k) are connected if there is a path from (i, j) to (h, k) consisting only of points of C

$$(i, j) = (i_0, j_0), (i_1, j_1), \cdots (i_t, j_t) = (h, k)$$

such that (i_s, j_s) is adjacent to (i_{s+1}, j_{s+1}), $0 \leq s \leq t-1$. Two definitions of adjacency are generally used, 4-adjacency and 8-adjacency. Point (i, j) has four 4-adjacent points, those with coordinates $(i-1, j)$, $(i, j-1)$, $(i, j+1)$, and $(i+1, j+1)$. The 8-adjacent points are, in addition to the four above, the points along the diagonals, namely: $(i-1, j-1)$, $(i-1, j+1)$, $(i+1, j-1)$, and $(i+1, j+1)$.

Digital line: The set of image cells that have a nonempty intersection with a straight-line.

Edge detector: A technique to detect intensity discontinuities. It yields points lying on the boundary between objects and the background. Some of most popular edge detectors are listed. Given an image I, the *gradient operator* is based on the computation of the first-order derivatives, $\delta I/\delta x$ and $\delta I/\delta y$. In a **digital image** there are different ways of approximating such derivatives. The first approach involves only four adjacent pixels.

$$\begin{aligned} \delta I/\delta x &= I(x, y) - I(x-1, y) \\ \delta I/\delta y &= I(x, y) - I(x, y-1) \end{aligned}$$

Alternatively, using 8 adjacent values:

$$\begin{aligned} \delta I/\delta x = & [I(x+1, y-1) + 2I(x+1, y) + I(x+1, y+1)] \\ & - [I(x-1, y-1) + 2I(x-1, y) + I(x-1, y+1)] \end{aligned}$$

The computation of the above expressions can be obtained by applying the following *masks,* known as the *Sobel operators,* to all image points.

-1	-2	-1
0	0	0
1	2	1

-1	0	1
-2	0	2
-1	0	1

The *magnitude* of the gradient, denoted by $G(I(x, y))$, is

$$G(I(x, y)) = \left[(\delta I/\delta x)^2 + (\delta I/\delta y)^2\right]^{1/2}$$

or simply

$$G(I(x, y)) = |\delta I/\delta x| + |\delta I/\delta y|$$

The *Laplacian operator* is a second-order derivative operator defined as

$$L[I(x, y)] = \delta^2 I/\delta x^2 + \delta^2 I/\delta y^2$$

or, in the digital version, as

$$L[I(x, y)] = L[I(x+1, y) + I(x-1, y) + I(x, y+1) + I(x, y-1)] - 4I(x, y)\,.$$

The *zero-crossing operator* determines whether the digital Laplacian has a zero-crossing at a given pixel, that is whether the gradient edge detector has a relative maxima.

Edge point: An image point that is at the border between two image components, that is a point where there is an abrupt change in intensity.

Hausdorff distance: Let $A = \{a_1, a_2, \cdots, a_m\}$ and $B = \{b_1, b_2, \cdots, b_n\}$ two sets of points. The Hausdorff distance between A and B is defined as

$$H(A, B) = \max(h(A, B), h(B, A))) ,$$

where the *one-way Hausdorff distance from A to B* is

$$h(A, B) = \max_{a \in A} \min_{b \in B} d(a, b)$$

and $d(a, b)$ is the distance between two points a and b. The minimum Hausdorff distance is then defined as

$$D(A, B) = \min_{t \in E_2} H(t(A), B)$$

where E_2 is the group of planar motions and $t(A)$ is the transformed of A under motion t. The corresponding *Hausdorff decision problem* for a given ϵ is deciding whether the minimum Hausdorff distance is bounded by ϵ. This last problem is generally solved as a problem of intersection of unions of disks in the *transformation space*.

Image, digital image: A two-dimensional array I of regions or cells each with an assigned integer representing the *intensity value* or *gray level* of the cell. A binary image is an image with only two gray levels: 0 (white), 1 (black).

Polygonal approximation of a curve: A segmentation of a curve into piecewise linear segments that approximates it. One approach to determine it for an open curve is by considering the segment between its endpoints and recursively dividing a segment if the maximum distance between the segment and the curve points is above a given threshold. The segment is divided at the point of maximum distance.

VLSI Layout Algorithms[1]

Andrea S. LaPaugh
Princeton University

One of the many application areas that has made effective use of algorithm design and analysis is computer-aided design (CAD) of digital circuits. Many aspects of circuit design yield to combinatorial models and the algorithmic techniques discussed in other chapters. In this chapter we focus on one area within the field of computer-aided design: layout of very large scale integrated (VLSI) circuits, which is a particularly good example of the effective use of algorithm design and analysis. We will discuss specific problems in VLSI layout and how algorithmic techniques have been successfully applied. This chapter will not provide a broad survey of CAD techniques for layout, but will highlight a few problems that are important and have particularly nice algorithmic solutions. The reader may find more complete discussions of the field in the references discussed in the *Further Information* section at the end of this chapter.

Integrated circuits are made by arranging active elements (usually transistors) on a planar substrate and interconnecting these elements with conducting wires that are also patterned on the planar substrate [35]. There may be several layers that can be used for wires, but there are restrictions on how wires in different layers can connect, as well as requirements of separations between wires and elements. Therefore, the layout of integrated circuits is usually modeled as a planar embedding problem with several layers in the plane.

VLSI circuits contain hundreds of thousands to millions of transistors. Therefore, it is not feasible to consider the positioning of each transistor separately. Transistors are organized into subcircuits called components; this may be done hierarchically, resulting in several levels of component definition between

[1]Supported in part by the National Science Foundation, FAW award MIP-9023542.

the individual transistors and the complete VLSI circuit. The layout problem for VLSI circuits becomes one of positioning components and their interconnecting wires on a plane, following the design rules, and optimizing some measure such as area or wire length. Within this basic problem structure are a multitude of variations rising from changes in design rules and flexibilities within components as to size, shape, and regions where wires may connect to components. Graph models are used heavily, both to model the components and interconnections themselves and to capture constraint between objects. Geometric aspects of the layout problem must also be modeled. Most layout problems are optimization problems and most are NP-complete. Therefore, heuristics are also employed heavily. Below, we present several of the best known and best understood problems in VLSI layout.

23.1 Background

We will consider a design style known as "general cell." In **general cell layout,** components vary in size and degree of functional complexity. Some components may be from a predesigned component library and have rigidly defined layouts (e.g., a register bank) and others may be full custom designs, in which the building blocks are individual transistors and wires.[2] Components may be defined hierarchically, so that the degree of flexibility in the layout of each component is quite variable. Other design styles, such as standard cell, gate array, and sea-of-gates, are more constrained but share many of the same layout techniques.

The layout problem for a VLSI chip is often decomposed into two stages: placement of components and routing of wires. For this decomposition, the circuit is described as a set of components and a set of interconnections among those components. The components are first placed on the plane based on their size, shape, and interconnectivity. Paths for wires are then found to interconnect specified positions on the components. Thus a placement problem is to position a set of components in a planar region; either the region is bounded, or a measure such as total area of the region used is optimized. The area needed for the yet undetermined routing must be taken into account. A routing problem is, given a collection of sets of points in the plane, to interconnect each sets of points (called a **net**) using paths from an allowable set of paths. The allowable set of paths captures all the constraints on wire routes. In routing problems, the width of wires is abstracted away by representing only the midline of each wire and insuring enough room for the actual wires through the definition of the set of allowable paths.

The above description of the decomposition of a layout problem into placement and routing is meant to be very general. To discuss specific problems and algorithms, we will used a more constrained model. In our model, components will be rectangles. Each component will contain a set of points along its boundary, the **terminals**. Sets of these terminals are the nets, which must be interconnected. A layout consists of a placement of the components in the plane and a set of paths in the plane that do not intersect the components except at terminals and interconnect the terminals as specified by the nets. The paths are composed of segments in various layers of the plane. Further constraints on the set of allowable paths define the routing style, and will be discussed for each style individually. The area of a layout will be the area of the minimum-area rectangle that contains the components and wire paths. (See Fig. 23.1.)

While we still have a fairly general model, we have now restricted our component shapes to be rectangular, our terminals to be single points on component boundaries, and our routing paths to avoid components. (Components are thus assumed to be densely populated with circuitry.) While these assumptions are common and allow us to illustrate important algorithmic results, there is quite a bit of work on nonrectangular components (e.g., [17]), more flexible terminals (see [31]), and "over-the-cell"

[2] We will not discuss special algorithms for laying out transistors, used in tools called "cell generators" or "leaf cell generators" for building components from low-level layout primitives. The reader is referred to [29] as a starting point for an investigation of this topic.

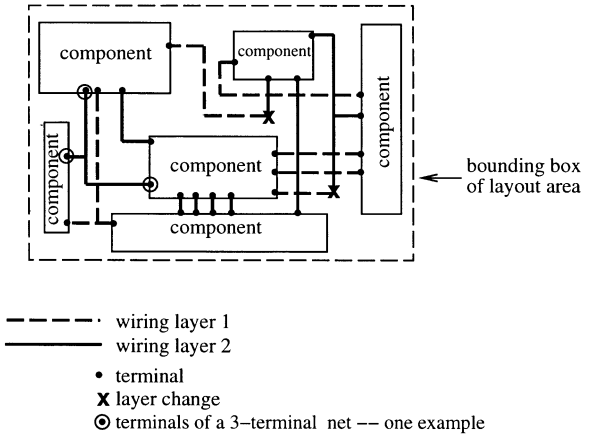

FIGURE 23.1 Example of a layout. This layout is rectilinear and has two layers for wiring.

routing (see [31]). Often, layouts are further constrained to be **rectilinear**. In rectilinear layouts, there is an underlying pair of orthogonal axes defining "horizontal" and "vertical" and the sides of the components are oriented parallel to these axes. The paths of wires are composed of horizontal and vertical segments. In our discussion below, we too will often assume rectilinear layouts.

If a VLSI system is too large to fit on one chip, then it is first partitioned into chip-sized pieces. During partitioning, the goal is to create the fewest chips with the fewest connections between chips. Estimates are used for the amount of space needed by wires to interconnect the components on one chip. The underlying graph problem for this task is **graph partitioning,** which is discussed below.

Closely related to the placement problem is the **floor planning** problem. Floor planning occurs before the designs of components in a general cell design have been completed. The resulting approximate layout is called a **floor plan.** Estimates are used for the size of each component, based on either the functionality of the component or a hierarchical decomposition of the component. Rough positions are determined for the components. These positions can influence the shape and terminal placement within each component as its layout is refined. For hierarchically defined components, one can work bottom up to get rough estimates of size, then top down to get rough estimates of position, then bottom up again to refine positions and sizes.

Once a layout is obtained for a VLSI circuit, either through the use of tools or by hand with a layout editor, there may still be room for improvement. **Compaction** refers to the process of modifying a given layout to remove extra space between features of the layout, space not required by design rules. Humans may introduce such space by virtue of the complexity of the layout task. Tools may place artificial restrictions on layout in order to have tractable models for the main problems of placement and routing. Compaction becomes a postprocessing step to make improvements too difficult to do during placement and routing.

23.2 Placement Techniques

Placement algorithms can be divided into two types: constructive initial placement algorithms and iterative improvement algorithms. A constructive initial placement algorithm has as input a set of components and a set of nets. The algorithm constructs a legal placement with the goal of optimizing some cost function for the layout. Common cost functions measure component area, estimated routing area, estimated total wire length, estimated maximum wire length of a net, or a combination of these. An iterative improvement algorithm has as input the set of components, set of nets, and an initial placement; it modifies the placement, usually repeatedly, to improve a cost function. The initial placement may be a random placement or may be the output of a constructive initial placement algorithm.

Iterative improvement of placements can proceed in a variety of ways. A set of allowable moves, that is, ways in which a placement can be modified, must be identified. These moves should be simple to carry out, including reevaluating the cost function. Typically, a component is rotated or a pair of components are exchanged. An iterative improvement algorithm repeatedly modifies the placement, evaluates the new placement, and decides whether the move should be kept as a starting point for further moves or as a tentative final placement. In the simplest of iterative improvement algorithms, a move is kept only if the placement cost function is improved by it. One more sophisticated paradigm for iterative improvement is simulated annealing (see Chapter 37.) It has been applied successfully to the placement problem, e.g.,[30].

For general cell placement, one of the most widely used initial placement algorithms is a recursive partitioning method (see [19, p. 333]). In this method, a rectangular area for the layout is estimated based on component sizes and connectivity. The algorithm partitions the set of components into two roughly equal-sized subsets such that the number of interconnections between the two subsets is minimized and simultaneously partitions the layout area into two subrectangles of sizes equal to the sizes of the subsets. (See Fig. 23.2.) This partitioning proceeds recursively on the two subsets and subrectangles until each component is in its own subset and the rectangle contains a region for each component.

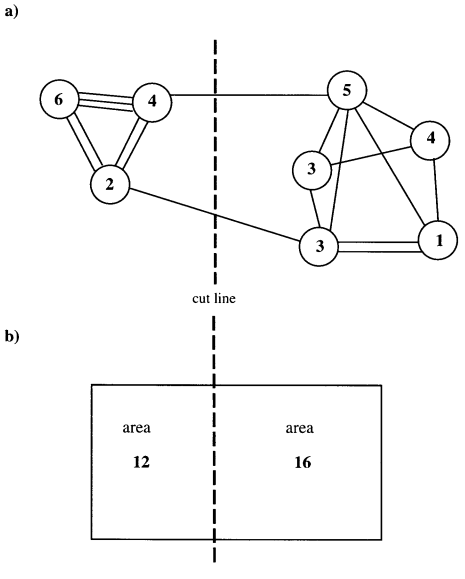

FIGURE 23.2 Partitioning used in placement construction. (a) Partitioning the circuit: Each vertex represents a component; the area of the component is the number inside the vertex. Connections between components are represented by edges. Multiple edges between vertices indicate multiple nets connecting components. (b) Partitioning the layout rectangle proportionally to the partition of component area.

The fundamental problem underlying placement by partitioning is **graph partitioning.**[3] Given a graph $G = (V, E)$, a vertex weight function $w : V \rightarrow N$, an edge cost function $c : E \rightarrow N$, and a balance factor $\beta \epsilon [1/2, 1]$, the graph partitioning problem is to partition V into two subsets V_1 and V_2 such that

$$\sum_{v \epsilon V_1} w(v) \quad \leq \quad \beta \sum_{v \epsilon V} w(v) \tag{23.1}$$

[3]Our definitions follow those in [19].

$$\sum_{v \in V_2} w(v) \quad \leq \quad \beta \sum_{v \in V} w(v) \tag{23.2}$$

and the cost of the partition,

$$\sum_{e \in E \cap (V_1 \times V_2)} c(e) \tag{23.3}$$

is minimized. This problem is NP-complete (see pages 209 and 210 of [7]). Graph partitioning is a well-studied problem. The version we have defined is actually *bipartitioning*. Heuristics for this problem form the core of heuristic algorithms for more general versions of the partition problem where one partitions into more than two vertex sets. The hypergraph version of partitioning, in which each edge is a set of two or more vertices rather than simply a pair of vertices, is a more accurate version for placement, since nets may contain many terminals on many components. But heuristics for the hypergraph version again are based on techniques used for the graph bipartitioning problem.

Among many techniques for graph partitioning, two—the Kernighan–Lin algorithm [13], and simulated annealing—are best known. Both are techniques for iteratively improving a partition. The Kernighan–Lin approach involves exchanging pairs of vertices across the partition. It was improved in the context of layout problems by Fiduccia and Mattheyses [6], who move a single vertex at a time. As applied to graph partitioning, simulated annealing also considers the exchange of vertices across the partition or the movement of a vertex from one side of the partition to the other. The methods of deciding which partitions are altered, which moves are tried, and when to stop the iteration process differentiate the two techniques. Recently, alternatives to iterative improvement have received increased attention for circuit applications, especially as performance-related criteria have been added to the partitioning problem. Examples of these alternatives are spectral methods, based on eigenvectors of the Laplacian, and the use of network flow. The reader is referred to [1] for a more complete discussion of partitioning heuristics.

A second group of algorithms for constructing placements is based on clustering. In this approach, components are selected one at a time and placed in the layout area according to their connectivity to components previously placed. Components are clustered so that highly connected sets of components are close to each other.

When the cost function for a layout involves estimating wire length, several methods can be used. The goal is to define a measure for each net that estimates the length of that net after it is routed. These estimated lengths can then be summed over all nets to get the estimate on the total wire length, or the maximum can be taken over all nets to get maximum net length. Two estimates are commonly used: (1) the half-perimeter of the smallest rectangle containing all terminals of a net; (2) the minimum Euclidean spanning tree of the net. Given a placement, the Euclidean spanning tree of a net is the spanning tree of a graph whose vertices are the terminals of the net, whose edges are all edges between vertices, and whose edge costs are the Euclidean distances in the given placement between the pair of terminals that are endpoints of the edges. Another often-used estimate is the minimum rectilinear spanning tree. This is because rectilinear layouts are common. For a rectilinear layout, the length of the shortest path between a pair of points, (x_a, y_a) and (x_b, y_b), is $|x_a - x_b| + |y_a - y_b|$ (assuming no obstacles). This distance, rather than the Euclidean distance, is used as the distance between terminals. (This is also called the L_1 or Manhattan metric.) A more accurate estimate of the wire length of a net would be the minimum Euclidean (or rectilinear) **Steiner tree** for the net. A Steiner tree for a set of points in the plane is a spanning tree for a superset of the points, i.e., additional points may be introduced to decrease the length of the tree. Finding minimum Steiner trees is NP-hard (see [7]), while finding minimum spanning trees can be done in $O(|E| + |V| \log |V|)$ time for general graphs[4] and in $O(|V| \log |V|)$ time for Euclidean or rectilinear spanning trees (see Chapters 6

[4]Actually, using more sophisticated techniques, finding minimum spanning trees can be done in time almost linear in $|E|$.

and 19). The cost of a minimum spanning tree is an upper bound on the cost of a minimum Steiner tree. For rectilinear Steiner trees, the half-perimeter measure and two thirds the cost of a minimum rectilinear spanning tree are lower bounds on the cost of a Steiner tree [11].

The minimum spanning tree is also useful for estimating routing area. The minimum spanning tree for each net is used as an approximation of the set of paths for the wires of the net. Congested areas of the layout can then be identified and space for routing allocated accordingly.

23.3 Compaction and the Single-Source Shortest Path Problem

Compaction can be done at various levels of design: an entire layout can be compacted at the level of transistors and wires; the layouts of individual components can be compacted; a layout of components can be compacted without changing the layout within components. To simplify our discussion, we will assume that layouts are rectilinear. For compaction, we model a layout as composed entirely of rectangles. These rectangles may represent the most basic geometric building blocks of the circuit: pieces of transistors and segments of wires, or may represent more complex objects such as complex components. We refer to these rectangles as the *features* of the layout. We distinguish two types of features: those that are of fixed size and shape and those that can be stretched or shrunk in one or both dimensions. For example, a wire segment may be able to stretch or shrink in one dimension, representing a lengthening or shortening of the wire, but be fixed in the other dimension, representing a wire of fixed width. We refer to the horizontal dimension of a feature as its *width* and the vertical dimension as its *height.*

Compaction is fundamentally a two-dimensional problem. However, two-dimensional compaction is very difficult. Algorithms based on branch and bound techniques for integer linear programming (see Chapter 32) have been developed, but none is efficient enough to use in practice (see [19], Chapter 6 of [27]). Therefore, the problem is commonly simplify by compacting in each dimension separately: first all features of a layout are pushed together horizontally as much as the design rules will allow, keeping their vertical positions fixed; then all features of a layout are pushed together vertically as much as the design rules will allow, keeping their horizontal positions fixed. The vertical compaction may in fact make possible more horizontal compaction, and so the process may be iterated. This method is not guaranteed to find a minimum area compaction, but, for each dimension, the compaction problem can be solved optimally. We are assuming that we start with a legal layout and that one-dimensional compaction cannot change order relationships in the compaction direction. That is, if two features are intersected by the same horizontal (vertical) line and one feature is to the left of (above) the other, then horizontal (vertical) compaction will maintain this property. The algorithm we present is based on the single-source shortest path algorithm (See Chapter 6). It is an excellent example of a widely used application of this graph algorithm.

The compaction approach we are presenting is called "constraint-based" compaction because it models constraints on and between features explicitly. We shall discuss the algorithm in terms of horizontal compaction, vertical compaction being analogous. We use a graph model in which vertices represent the horizontal positions of features; edges represent constraints between the positions of features. Constraints capture the layout design rules, relationships between features such as connectivity, and possibly other desirable constraints such as performance-related constraints. Design rules are of two types: feature-size rules and separation rules. Feature-size rules give exact sizes or minimum dimensions of features. For example, each type of wire has a minimum width; each transistor in a layout is of a fixed size. Separation rules require that certain features of a layout be at least a minimum distance apart to avoid electrical interaction or problems during fabrication. Connectivity constraints occur when a wire segment is allowed to connect to a component (or another wire segment) anywhere in a given interval along the

component boundary. Performance requirements may dictate that certain elements are not too far apart. A detailed discussion of the issues in the extraction of constraints from a layout can be found in Chapter 6 of [27].

In the simplest case, we start with a legal layout and only consider feature-size rules and separation rules. We assume all wire segments connect at fixed positions on component boundaries and there are no performance constraints. Furthermore, we assume all features that have a variable width attach at their left and right edges to features with fixed width, e.g., a wire segment stretched between two components. Then, we need only represent features with fixed width; we can use one variable for each feature. In this case, any constraints on the width of a variable-width feature are translated into constraints on the positions of the fixed-width features attached to either end (see Fig. 23.3). We are left with only separation

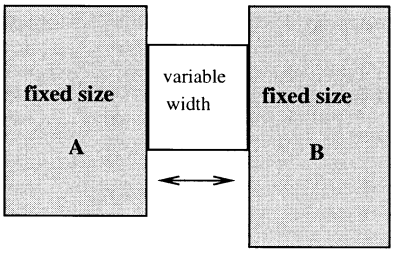

FIGURE 23.3 Generating separation constraints. The constraint on the separation between features A and B is the larger of the minimum separation between them and the minimum width of the flexible feature connecting them.

constraints, which are of the form

$$x_B \geq x_A + d_{\text{min}} \tag{23.4}$$

or equivalently

$$x_B - x_A \geq d_{\text{min}} \tag{23.5}$$

where B is a feature to the right of A, x_A is the horizontal position of A, x_B is the horizontal position of B, and the minimum separation between x_A and x_B is d_{min}. In our graph model, there is an edge from the vertex for feature A to the vertex for feature B with length d_{min}. We add a single extra source vertex to the graph and a 0-length edge from this source vertex to every other vertex in the graph. This source vertex represents the left edge of the layout. Then finding the longest path from this source vertex to every vertex in the graph will give the leftmost legal position of each feature—as if we had pushed each feature as far to the left as possible. Finding the longest path is converted to a single-source shortest path problem by negating all the lengths on edges. This is equivalent to rewriting the constraint as

$$x_A - x_B \leq -d_{\text{min}} \, . \tag{23.6}$$

From now on, we will write constraints in this form. Note that this graph is acyclic. Therefore, as explained below, the single-source shortest path problem can be solved in time $O(n + |E|)$ by a **topological sort,** where n is the number of features and E is the set of edges in the constraint graph.

A topological sorting algorithm is an algorithm for visiting the vertices of a directed acyclic graph (DAG). The edges of a DAG induce a partial order on the vertices: $v < u$ if there is a (directed) path from v to u in the graph. A topological order is any total ordering of the vertices that is consistent with this partial order. A topological sorting algorithm visits the vertices in some topological order. In Chapter 6, a topological sorting algorithm based on depth-first search is presented. For our purposes, a modified breadth-first search approach is more convenient. In this modification, we visit a node as soon as all its immediate predecessors have been visited (rather than as soon as any single immediate predecessor has been visited). For a graph $G = (V, E)$ this algorithm can be expressed as follows:

```
TOPOLOGICAL SORT (G)

1  S ← all vertices with no incoming edges (sources)
2  U ← V
3  while S is not empty
4     do choose any vertex v from S
5        VISIT v
6        for each vertex u such that (v, u)∈E
7           do E ← E − {(v, u)}
8              if u is now a source
9                 then S ← S ∪ {u}
10       U ← U − {v}
11       S ← S − {v}
12 if U is not empty
13    then error ▷ G is not acyclic
```

In our single-source shortest path problem, we start with only one source, s, the vertex representing the left edge of the layout. We compute the length of the shortest path from s to each vertex v, denoted $\ell(v)$. We initialize $\ell(v)$ before line 3 to be 0 for $\ell(s)$ and ∞ for all other vertices. Then for each vertex v we select at line 4, and each edge (v, u) we delete at line 7 we update for all shortest paths that go through v by $\ell(u) \leftarrow \min\{\ell(u), \ell(v) + length(v, u)\}$. When the topological sort has completed, $\ell(v)$ will contain the length of the shortest path from s to v (unless G was not acyclic to begin with). The algorithm takes $O(|V| + |E|)$ time.

In our simplest case, all our constraints were minimum separation constraints. In the general case, we may have maximum separation constraints as well. These occur when connectivity constraints are used and also when performance constraints that limit the length of wires are used. Then we have constraints of the form

$$x_B \leq x_A + d_{\max} \tag{23.7}$$

or equivalently

$$x_B - x_A \leq d_{\max}\,. \tag{23.8}$$

Such a constraint is modeled as an edge from the vertex for feature B to the vertex for feature A with weight $d_{\max}$. For example, to model a horizontal wire W that has an interval from l to r along which it can connect to a component C (see Fig. 23.4), we use the pair of constraints

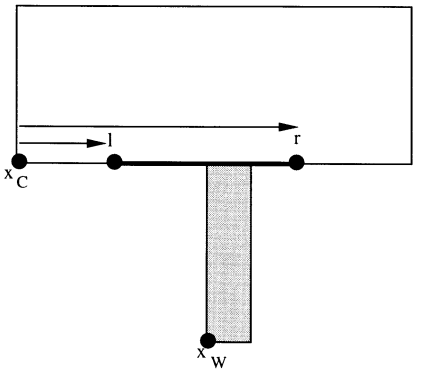

FIGURE 23.4 Modeling a connection that can be made along an interval of a component boundary.

$$x_C - x_W \leq -l \tag{23.9}$$

and

$$x_W - x_C \leq r\ . \tag{23.10}$$

Once we allow both minimum and maximum separation constraints, we have a much more general linear constraint system. All constraints are still of the form

$$x - y \leq d\ , \tag{23.11}$$

but the resulting constraint graph need not be acyclic. (Note that equality constraints $y - x = d$ may be expressed as $y - x \leq d$ and $x - y \leq -d$. Equality constraints may also be handled in a preprocessing step that merges vertices that are related by equality constraints.) To solve the single-source shortest path algorithm, we now need the $O(|V||E|)$-time Bellman–Ford algorithm (see [3]). This algorithm only works if the graph contains no negative cycle. If the constraint graph is derived from a layout that satisfies all the constraints, this will be true, since a negative cycle represents an infeasible set of constraints. However, if the initial layout does not satisfy all the constraints, for example, the designer adds constraints for performance to a rough layout, then the graph may be cyclic. The Bellman–Ford algorithm can detect this condition, but since the set of constraints is infeasible, no layout can be produced.

If the constraint graph is derived from a layout that satisfies all the constraints, an observation by Maley [21] allows us to use Dijkstra's algorithm to compute the shortest paths more efficiently. To use Dijkstra's algorithm, the weights on all the edges must be positive (see Chapter 6). Maley observed that when an initial layout exists, the initial positions of the features can be used to convert all lengths to positive lengths as follows. Let p_A and p_B be initial positions of features A and B. The constraint graph is modified so that the length of an edge (v_A, v_B) from the vertex for A to the vertex for B becomes $length(v_A, v_B) + p_B - p_A$. Since the initial layout satisfies the constraint $x_A - x_B \leq length(v_A, v_B)$, we have $p_B - p_A \geq -length(v_A, v_B)$ and $p_B - p_A + length(v_A, v_B) \geq 0$. Maley shows that this transformation of the edge lengths preserves the shortest paths. Since all edge weights have been converted to positive lengths, Dijkstra's algorithm can be used, giving a running time of $O(|V| \log |V| + |E|)$ or $O(|E| \log |V|)$, depending on the implementation used.[5]

Even when the constraint graph is not acyclic and an initial feasible layout is not available, restrictions on the type or structure of constraints can be use to get faster algorithms. For example, Lengauer and Mehlhorn give an $O(|V| + |E|)$-time algorithm when the constraint graph has a special structure called a "chain DAG" that is found when the only constraints other than minimum separation constraints are those coming from flexible connections such as those modeled by Eqs. (23.9) and (23.10) above (see [19, p. 614]). Liao and Wong [20] and Mata [23][6] present $O(|E_x| \times |E|)$-time algorithms, where E_x is the set of edges derived from constraints other than the minimum-separation constraints. These algorithms are based on the observation that $E - E_x$ is a directed acyclic graph (as in our simple case above). Topological sort is used as a subroutine to solve the single-source shortest path problem with edges $E - E_x$. The solution to this problem may violate constraints represented by E_x. Therefore, after finding the shortest paths for $E - E_x$, positions are modified in an attempt to satisfy the other constraints (represented by E_x), and the single-source shortest path algorithm for $E - E_x$ is run again. This technique is iterated until it converges to a solution for the entire set of constraints or the set of constraints is shown to be infeasible,

[5]The $O(|V| \log |V| + |E|)$ running time depends on using Fibonacci heaps for a priority queue. If the simpler binary heap is used, the running time is $O(|E| \log |V|)$. This comment also holds for finding minimum spanning trees using Prim's algorithm. See Chapter 6 for a discussion of the running times of Dijkstra's algorithm and Prim's algorithm.

[6]The technique used by Mata is the same as that by Liao and Wong, but Mata has a different stopping condition for his search, which can lead to more efficient execution.

which is proven to be within $|E_x|$ iterations. If $|E_x|$ is small, this algorithm is more efficient than using Bellman–Ford.

The single-dimensional compaction that we have discussed ignores many practical issues. One major issue is the introduction of bends in wires. The fact that a straight wire segment connects two components may be an artifact of the layout, but it puts the components in lock-step during compaction. Adding a bend to the wire would allow the components to move independently, stretching the bend accordingly. Although the bend may require extra area, the overall area might improve through compaction with the components moving separately.

Another issue is allowing components to change their order from left to right or top to bottom. This change might allow for a smaller layout, but the compaction problem becomes much more difficult. In fact, a definition of one-dimensional compaction that allows for such exchanges is NP-complete (see [19, p. 587]). Practically speaking, such exchanges may cause problems for wire routing. The compaction problem we have presented requires that the topological relationships between the layout features remain unchanged while space is compressed.

23.4 Floor Plan Sizing and Classic Divide and Conquer

The problem we will now consider, called **floor plan sizing,** is one encountered during certain styles of placement or floor planning. With some reasonable assumptions about the form of the layout, the problem can be solved optimally by a polynomial-time algorithm that is an example of classic divide and conquer.

Floor plan sizing occurs when a floor plan is initially specified as a partitioning of a rectangular layout area, representing the chip, into subrectangles, representing components [see Fig. 23.5(a)]. Each subrectangle corresponds to some component. We assume that the rectangular partitioning is rectilinear. For this discussion, given a set of components C, by "a floor plan for C," we shall mean such a rectangular partition of a rectangle into $|C|$ subrectangles, and a one-to-one mapping from C to the subrectangles. This partition indicates the relative position of components, but the subrectangles are constrained only to have approximately the same area as the components (possibly with some bloating to account for routing), not to have the same aspect ratio as the components. When the actual components are placed in the locations, the layout will change [see Fig. 23.5(b)]. Furthermore, it may be possible to orient each component so that the longer dimension may be either horizontal or vertical, affecting the ultimate size of the layout. In fact, if the component layouts have not been completed, the components may be able to assume many shapes while satisfying an area bound that is represented by the corresponding subrectangle. We will formalize this through the use of a **shape function.**

Definition: A **shape function** for a component is a mapping $s : [w_{min}, \infty] \rightarrow [h_{min}, \infty]$ such that s is monotonically decreasing, where $[w_{min}, \infty]$ and $[h_{min}, \infty]$ are intervals of $\Re^+$.

The interpretation of $s(w)$ is that it is the minimum height (vertical dimension) of any rectangle of width w that contains a layout of the component. w_{min} is the minimum width of any rectangle that contains a layout and h_{min} is the minimum height. The monotonicity requirement represents the fact that if there is a layout for a component that fits in a $w \times s(w)$ rectangle, it certainly must fit in a $(w+d) \times s(w)$ rectangle for any $d \geq 0$; therefore, $s(w+d) \leq s(w)$. In this discussion we will restrict ourselves to *piecewise linear* shape functions.

Given an actual shape (width and height) for each component, determining the minimum width and minimum height of the rectangular layout area becomes a simple compaction problem as discussed above. Each dimension is done separately, and two constraint graphs are build. We will discuss the horizontal constraint graph; the vertical constraint graph is analogous. The reader should refer to Fig. 23.5(c). The horizontal constraint graph has a vertex for each vertical side of the layout rectangle and each vertical side of a subrectangle (representing a component) in the rectangular partition. There is a directed edge from each vertex representing the left side of a subrectangle to each vertex representing the right side of a subrectangle; this edge has a length that is the width of the corresponding component. There are also

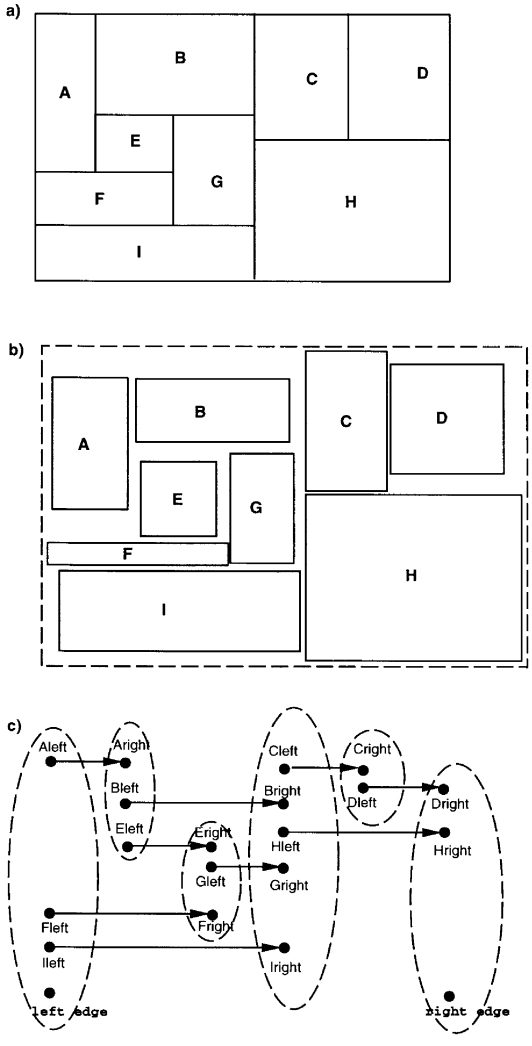

FIGURE 23.5 A floor plan and the derived layout. (a) A partition of a rectangle representing a floor plan. (b) A layout with actual components corresponding to the floor plan. (c) The horizontal constraint graph for the layout. Bidirectional 0-length edges are not shown. Instead, vertices constrained to have the same horizontal position due to chains of 0-length edges are shown in the same oval. They are treated as a single vertex.

two directed edges (one in each direction) between the vertices representing any two overlapping sides of the layout rectangle or subrectangles; the length of these edges is 0. Thus the vertex representing the left side of the layout rectangle has 0-length edges between it and the vertices representing the left sides of the leftmost subrectangles. Note that these constraints force two subrectangles that do not touch but are related through a chain of 0-length edges between one's left side and the other's right side to lie on opposite sides of a vertical line in the layout [e.g., components B and H in Fig. 23.5(a).]. This is an added restriction to the layout, but an important one for the correctness of the algorithm presented below for the sizing of **slicing floor plans.**

Given an actual width for each component and having constructed the horizontal constraint graph as described in the preceding paragraph, to determine the minimum width of the rectangular layout area, one simply finds the longest path from the vertex representing the left side of the layout rectangle to the

vertex representing the right side of the layout rectangle. To simplify the problem to one in an acyclic graph, vertices connected by pairs of 0-length edges can be collapsed into a single vertex; only the longest edge between each pair of (collapsed) vertices is needed. Then topological sort can be used to find the longest path between the left side and the right side of the floor plan, as discussed in the preceding section of this chapter.

We now have the machinery to state the problem of interest:

Floor plan sizing: Given a set C of components, a piecewise linear shape function for each component, and a floor plan for C, find an assignment of specific shapes to the components so that the area of the layout is minimized.

Stockmeyer [33] showed that for general floor plans, the floor plan sizing problem is NP-complete. This holds even if the components are of fixed shape, but can be rotated 90°. In this case, the shape function of each component is a step function with at most two steps: $s(x) = d_2$ for $d_1 \leq x < d_2$ and $s(x) = d_1$ for $d_2 \leq x$, where the dimensions of the component are d_1 and d_2 with $d_1 \leq d_2$. However, for floor plans of a special form, called **slicing floor plans,** Stockmeyer gave a polynomial-time algorithm for the floor plan sizing problem when components are of fixed shape but can rotate. Otten [24] generalized this result to any piecewise-linear shape function. A slicing floor plan is one in which the partition of the layout rectangle can be constructed by a recursive cutting of a rectangular region into two subregions using either a vertical or horizontal line segment (see Fig. 23.6). The rectangular regions that are not further partitioned are the subrectangles corresponding to components. The recursive partitioning method of constructing a placement discussed above produces a slicing floor plan.

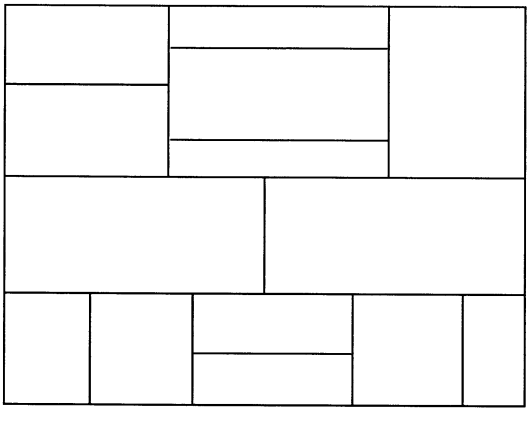

FIGURE 23.6 A slicing floor plan.

A slicing floor plan can be represented by a binary tree. The root of the tree represents the entire layout rectangle and is labeled with the direction of the first cut. Other interior vertices represent rectangular subregions that are to be further subdivided, and the label on any such vertex is the direction of the cut used to subdivide it. The two children of any vertex are the rectangular regions resulting from cutting the rectangle represented by the vertex. The leaves of the binary tree represent the rectangles corresponding to components.

The algorithm for the sizing of a slicing floor plan uses the binary tree representation in a fundamental way. The key observation is that one only needs the shape functions of the two subregions represented by the children of a vertex to determine the shape function of a vertex. If the shape functions can be represented succinctly and combined efficiently for each vertex, the shape function of the root can be determined efficiently. We will present the combining step for shape functions that are step functions (i.e., piecewise constant) following the description in [19], since it illustrates the technique but is a straightforward

calculation. Otten [24] shows how to combine piecewise linear slicing functions, but Lengauer [19] comments that arithmetic precision can become an issue in this case.

We shall represent a shape function that is a step function by a list of pairs $(w_i, s(w_i))$ for $0 \leq i \leq b_s$ and $w_0 = w_{min}$. The interpretation is that for all x, $w_i \leq x < w_{i+1}$ (with $w_{b_s+1} = \infty$), $s(x) = s(w_i)$. Parameter b_s is the number of *breaks* in the step function. The representation of the function is linear in the number of breaks. (This represents a step function whose constant intervals are left closed and right open and is the most logical form of step function for shape functions. However, other forms of step functions also can be represented in size linear in the number of breaks.)

Given step functions, s_l and s_r, for the shapes of two children of a vertex, the shape function, s, for the vertex will also be a step function. When the direction of the cut is horizontal, the shape functions can simply be added, that is, $s(x) = s_l(x) + s_r(x)$. w_{min} for s is the maximum of $w_{min,l}$ for s_l and $w_{min,r}$ for s_r. Each subsequent break point for s_l or s_r is a break point for s, so that $b_s \leq b_{s_l} + b_{s_r}$. Combining the shape functions takes time $O(b_{s_l} + b_{s_r})$. When the direction is vertical, the step functions must first be inverted, the inverted functions combined, and then the combined function inverted back. The inversion of a step function s is straightforward and can be done in $O(b_s)$ time.

To compute the shape function for the root of a slicing floor plan, one simply does a postorder traversal of the binary tree (see Chapter 6), computing the shape function for each vertex from the shape functions for the children of the vertices. The number of breaks in the shape function for any vertex is no more than the number of breaks in the shape functions for the leaves of the subtree rooted at that vertex. Let b be the maximum number of breaks in any shape function of a component. Then the running time of this algorithm for a slicing floor plan with n components is

$$\begin{aligned} T(n) &\leq T(n_l) + T(n_r) + bn & (23.12)\\ &\leq dbn\ , & (23.13) \end{aligned}$$

where d is the depth of the tree (the length of the longest path from the root to a leaf). We have the following:

> Given an instance of the floor plan sizing problem that has a slicing floor plan and step functions as shape functions for the components, there is an $O(dbn)$-time algorithm to compute the shape function of the layout rectangle.

Given the shape function for the layout rectangle, the minimum area shape can be found by computing the area at each break in time linear in the number of breaks, which is at most $O(bn)$.

Recently, Shi [32] presented a modification to this technique that improves the running time for imbalanced slicing trees. For general (nonslicing) floor plans, many heuristics have been proposed: for example, Pan and Liu [25] present a generalization of the slicing floor plan technique to general floor plans.

23.5 Routing Problems

We shall only discuss the most common routing model for general cell placement—the rectilinear **channel routing** model. In this model, the layout is rectilinear. The regions of the layout that are not covered by components are partitioned into nonoverlapping rectangles, called **channels.** The allowed partitions are restricted so that each channel only has components touching its horizontal edges (a horizontal channel) or its vertical edges (a vertical channel). These edges will be referred to as the "top" and "bottom" of the channel, regardless of whether the channel is horizontal or vertical. The orthogonal edges, referred to as the "left edge" and "right edge" of the channel, can only touch another channel. These channels compose the area for the wire routing. There are several strategies for partitioning the routing area into channels, i.e., "defining" the channels, but most use maximal rectangles where possible (i.e., no two channels can be merged to form a larger channel). The layout area becomes a rectangle that is partitioned into subrectangles of two types: components and channels. (See Fig. 23.7.)

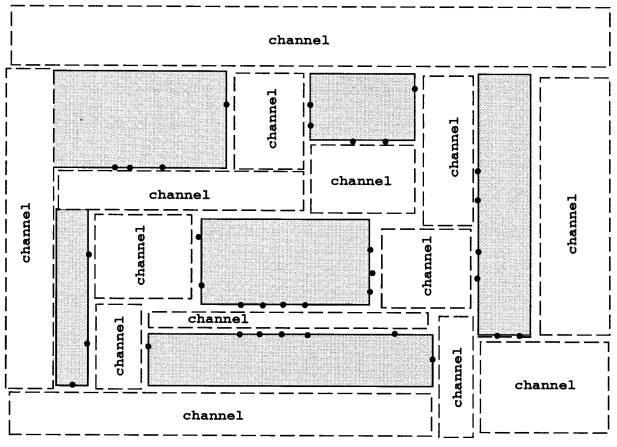

FIGURE 23.7 The decomposition of a layout into routing channels and components.

Given a layout with channels defined, the routing problem can be decomposed into two subproblems: **global routing** and local or detailed routing. **Global routing** is the problem of choosing which channels will be used to make the interconnections for each net. Actual paths are not produced. By doing global routing first, one can determine the actual paths for wires in each channel separately. The problem of detailed routing is to determine these actual paths and is more commonly referred to as "**channel routing.**" Of course, the segments of a wire path in each channel must join at the edges of the channel to produce an actual interconnection of terminals. To understand the approaches for handling this interfacing, we must have a more detailed definition of the channel routing problem, which we give next.

The channel routing problem is defined so that there are initial positional constraints in only one dimension. Recall that we define channels to abut components on only two parallel sides, the "top" and "bottom." This is so that the routes in the channel will only be constrained by terminal positions on two sides. The standard channel routing problem has the following input: a rectangle (the channel) containing points (terminals) at fixed positions along its top and bottom edges, a set of nets that must be routed in the channel, and an assignment of each of the terminals on the channel to one of these nets. Also, two (possibly empty) subsets of nets are specified: one containing nets whose routing must interface with the left edge of the channel and one containing nets whose routing must interface with the right edge of the channel. The positions at which wires must intersect the left and right edges of the channel are not specified. The dimension of the channel from the left edge to the right edge is called the *length* of the channel; the dimension from the top edge to the bottom edge is the *width* of the channel (see Fig. 23.8). Since there are no terminals on the left and right edges, the width is often taken to be variable, and the goal is to find routing paths achieving the connections specified by the nets and minimizing the width of the channel. In this case, the space needed for the wires determines the width of the channel. The length of the channel is more often viewed as fixed, although there are channel routing models in which routes are allowed to cross outside the left and right edges of the channel.

We can now discuss the problem of interfacing routes at channel edges. There are two main approaches to handling the interfacing of channels. One is to define the channels so that all adjacent channels form '$\top$'s (no '+'s). Then if the channel routing is done for the base of the '$\top$' first, the positions of paths leaving the base of the '$\top$' and entering the cross piece of the '$\top$' are fixed by the routing of the base and can be treated as terminal positions for the cross piece of the '$\top$'. Using this approach places constraints on the routing order of the channels. We can model these constraints using a directed graph: there is a vertex, v_C, for each channel C and an edge from v_A to v_B if channel A and channel B abut with channel A as the base of the '$\top$' and channel B as the cross piece of the '$\top$'. The edge from v_A to v_B represents that channel A must be routed before channel B. This graph must be acyclic for the set of constraints on the order of routing to be feasible. If the graph is not acyclic, another method must be used to deal with some

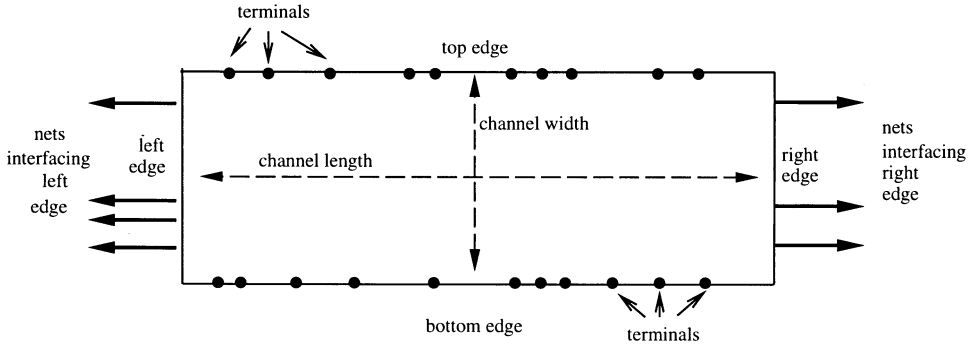

FIGURE 23.8 A channel. Nets interfacing at the left and right edges are not in a given order.

of the channel interfaces. Slicing floor plans are very good for this approach because if each slice is defined to be a channel, then the channel order constraint graph will be acyclic.

The second alternative for handling the interfaces of channels is to define a special kind of channel, called a **switch box,** that is constrained by terminal locations on all four sides. In this alternative, some or all of the standard channels abut switch boxes. Special algorithms are used to do the switch box routing, since, practically speaking, this is a more difficult problem than standard channel routing.

23.6 Global Routing

Since global routing need not produce actual paths for wires, the channels can be modeled by a graph, called the *channel intersection graph.* For each channel, project the terminals lying on the top and bottom of the channel onto the midline of the channel. Each channel can be divided into segments by the positions of these projected terminals. The channel intersection graph is an undirected graph with one vertex for each projected terminal and one vertex for each intersection of channels. There is one edge for each segment of a channel, which connects the pair of vertices representing the terminals and/or channel intersections bounding the segment. A length and a capacity can be assigned to each edge, representing, respectively, the length between the ends of the channel segment and the width of the channel. Different versions of the global routing problem use one or both of the length and capacity parameters.

Given the channel intersection graph, the problem of finding a global routing for a set of nets becomes the problem of finding a **Steiner tree** in the channel intersection graph for the terminals of each net. Earlier in this chapter, we defined Steiner trees for points in the plane. For a general graph $G = (V, E)$, a Steiner tree for a subset of vertices $U \subset V$ is a set of edges of G that form a tree in G and whose set of endpoints contains the set U. Various versions of the global routing problem are produced by the constraints and optimization criteria used. For example, one can simply ask for the minimum length Steiner tree for each net, or one can ask for a set of Steiner trees that does not violate capacity constraints and has total minimum length. For each edge, the capacity used by a set of Steiner trees is the number of Steiner trees containing that edge; this must be no greater than the capacity of the edge. Another choice is not to have constraints on the capacity of edges but to minimize the maximum capacity used for any edge. In general, any combination of constraints and cost functions on length and capacity can be used. However, regardless of the criteria, the global routing problem is invariably NP-complete. A more detailed discussion of variations of the problem and their complexity can be found in [19]. There, a number of sophisticated algorithms for Steiner tree problems are also discussed. Here we will only discuss two techniques based on basic graph algorithms: breadth-first search and Dijkstra's single-source shortest path algorithm.

The minimum Steiner tree problem is itself NP-complete (see pages 208-209 in [7]). Therefore, one approach to global routing is to avoid finding Steiner trees by breaking up each net into a collection of point-to-point connections. One way to do this is to find the minimum Euclidean or rectilinear spanning

tree for the terminals belonging to each net (ignoring the channel structure), and use the edges of this tree to define the point-to-point connections. Then one can use Dijkstra's single-source shortest path algorithm on the channel intersection graph to find a shortest path for each point-to-point connection. Paths for connections of the same net that share edges can then be merged, yielding a Steiner tree. If there are no capacity constraints on edges, the quality of this solution is only limited by the quality of the approximation of a minimum Steiner tree by the chosen collection of point-to-point paths. If there are capacity constraints, then after solving each shortest path problem, one must remove from the channel intersection graph the edges whose used capacity already equals the edge capacity. In this case, the order in which nets and terminals within a net are routed is significant. Heuristics are used to choose this order. One can better approximate Steiner trees for the nets by, at each iteration for connections within one net, choosing a terminal not yet connected to any other terminals in the net as the source of Dijkstra's algorithm. Since this algorithm computes the shortest path to every other vertex in the graph from the source, the shortest path which connects to any other vertex in the channel intersection graph that is already on a path connecting terminals of the net can be used. Of course there are variations on this idea.

For any graph, breadth-first search from a vertex v will find a shortest path from v to every other vertex in the graph when the length of each edge is 1. Breadth-first search takes time $O(|V| + |E|)$ compared to the best worst-case running time known for Dijkstra's algorithm: $O(|V| \log |V| + |E|)$ time. It is also very straightforward to implement. It is easy to incorporate heuristics that take into account the capacity of an edge already used and bias the search towards edges with little capacity used. Furthermore, breadth-first search can be started from several vertices simultaneously, so that all terminals of a net could be starting points of the search simultaneously. If it is adequate to view all channel segments as being of equal length, then the edge lengths can all be assigned value 1 and breadth-first search can be used. This might occur when the terminals are uniformly distributed and so divide channels into approximately equal-length segments. Alternatively, one can add new vertices to the channel intersection graph to further decompose the channel segments into unit-length segments. This can substantially increase $|V|$ and $|E|$ so that they are proportional to the dimensions of the underlying grid defining the unit of length rather than the number of channels and terminals in the problem. However, this allows one to use breadth-first search to compute shortest paths while modeling the actual lengths of channels. In fact, breadth-first search was developed by Lee [16][7] for routing of circuit boards in exactly this manner. He modeled the entire board by a grid graph, and modeled obstacles to routing paths as grid vertices that were missing from the graph. Each wire route was found by doing a breadth-first search in the grid graph.

23.7 Channel Routing

Channel routing is not one single problem, but rather a family of problems based on the allowable paths for wires in the channel. We will limit our discussion to grid-based routing. While both grid-free rectilinear and nonrectilinear routing techniques exist, the most basic techniques are grid-based. We assume that there is a grid underlying the channel, the sides of the channel lie on grid edges, terminals lie on grid points, and all routing paths must follow edges in the grid. For ease of discussion, we shall refer to channel directions as though the channel were oriented with its length running horizontally. The vertical segments of the grid that run from the top to the bottom of the channel are referred to as *columns.* The horizontal segments of the grid that run from the left edge to the right edge of the channel are referred to as *tracks.* We will consider channel routing problems that allow the width of the channel to vary. Therefore, the

[7] The first published description of breadth-first search was by E. F. Moore for finding a path in a maze. Lee developed the algorithm for routing in grid graphs under a variety of path costs. See the discussion on page 394 of [19].

number of columns, determining the channel length, will be fixed, but the number of tracks, determining the channel width, will be variable. The goal is to minimize the number of tracks used to route the channel.

The next distinction is based on how many routing layers are presumed. If there are ℓ routing layers, then there are ℓ overlaid copies of the grid, one for each layer. Routes that use the same edge on different layers do not interact and are considered disjoint. Routes change layer at grid points. The exact rules for how routes can change layers vary, but the most common is to view a route that goes from layer i to layer j ($j > i$) at a grid point as using layers $i + 1, \ldots, j - 1$ as well at the grid point.

One can separate the channel routing problem into two subproblems: finding Steiner trees in the grid that achieve the interconnections, and finding a **layer assignment** for each edge in each Steiner tree so that the resulting set of routes is legal. One channel routing model for which this separation is made is knock-knee routing. (See Section 9.5 of [19].) Given any set of trees in the grid (not only those for knock-knee routes), a legal layer assignment can be determined efficiently for two layers. Maximal single-layer segments in each tree can be represented as vertices of a conflict graph, with segments that must be on different layers related by conflict edges. Then finding a legal two-layer assignment is equivalent to two-coloring the conflict graph. A more challenging problem is **via minimization,** which is to find a legal layer assignment that minimizes the number of grid points at which layer change occurs. This problem is also solvable in polynomial time as long as none of the Steiner trees contain a four-way split (a technical limitation of the algorithm). For more than two layers, both layer assignment and via minimization are NP-complete. (See Section 9.5.3 of [19]).

We have chosen to discuss two routing models in detail: single-layer routing and two-layer **Manhattan routing.** Routing models that allow more than two layers, called multilayer models, are becoming more popular as technology is able to provide more layers for wires. However, many of the multilayer routing techniques are derived from single-layer or two-layer Manhattan techniques (e.g.,[8]), so we focus this restricted discussion on those models. A more detailed review of channel routing algorithms can be found in [15]. Neither model requires layer assignment. In single-layer routing there is no issue of layer assignment; in Manhattan routing, the model is such that the layer assignment is automatically derived from the paths. Therefore, for each model, our discussion need only address how to find a collection of Steiner trees that satisfy the restrictions of the routing model.

Manhattan Routing

Manhattan routing is the dominant 2-layer routing model. It dates back to printed circuit boards [10]. It dominates because it finesses the issue of layer assignment by defining all vertical wire segments to be on one layer and all horizontal wire segments to be on the other layer. Therefore, a horizontal routing path and a vertical routing path can cross without interacting, but any path that bends at a grid point is on both layers at that point and no path for a disjoint net can use the same point. Thus, under the Manhattan model, the problem of routing can be stated completely in terms of finding a set of paths such that paths for distinct nets may cross but do not share edges or bend points.

Although Manhattan routing provides a simple model of legal routes, the resulting channel routing problem is NP-complete. An important lower bound on the width of a channel is the **channel density.** The density at any vertical line cutting the channel (not necessarily a column) is the number of nets that have terminals both to the left and right of the vertical line. The interpretation is that each net must have at least one wire crossing the vertical line, and thus a number of tracks equal to the density at the vertical line is necessary. For columns, nets that contain a terminal on the column are counted in the density unless the net contains exactly two terminals and these are at the top and bottom of the column. (Such a net can be routed with a vertical path the extent of the column.) The channel density is the maximum density of any vertical cut of the channel. In practice, the channel routing problem is solved with heuristic algorithms that find routes giving a channel width within one or two of density, although such performance is not provably achievable.

If a channel routing instance has no top terminal and bottom terminal on the same column, then a number of tracks equal to the channel density suffices and a route achieving this density can be solved in $O(m + n \log n)$ time, where n is the number of nets and m is the number of terminals. Under this restriction, the channel routing problem becomes equivalent to the problem of **interval graph coloring.** The equivalence is based on the observation that if no column contains terminals at its top and bottom, then any terminal can connect to any track by a vertical segment that does not conflict with any other path (see Fig. 23.9). Each net can use one horizontal segment that spans all the columns containing its terminals. The issue is to pack these horizontal segments into the minimum number of tracks so that no segments intersect. Equivalently, the goal is to color the segments (or intervals) with the minimum number of colors so that no two segments that intersect are the same color. Hence we have the relationship to interval graphs, which have a set of vertices that represent intervals on a line and edges between vertices of intersecting intervals.

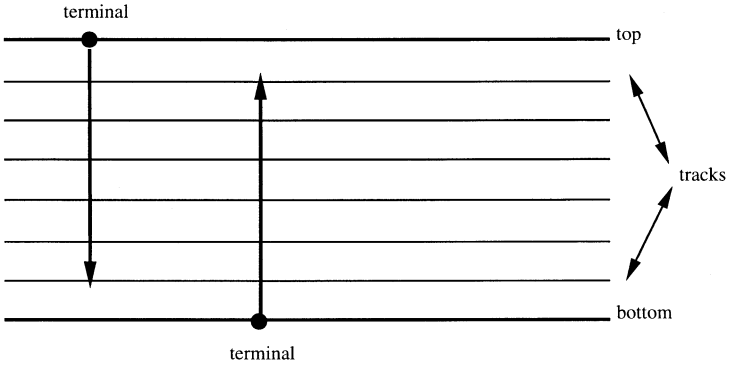

FIGURE 23.9 Connecting to tracks without conflicts. Each of the nets can reach any of the tracks with a vertical segment in the column containing the terminal.

A classic greedy algorithm can assign a set I of intervals to d tracks, where d is the **channel density.** Intervals are placed in tracks in order of their left endpoints; all tracks are filled with intervals from left to right concurrently (the actual position of each track does not matter). The set of interval endpoints is first sorted so that the combined order of left (starting) endpoints and right (ending) endpoints is known. At any point in the algorithm, there are tracks containing intervals that have not yet ended and tracks that are free to receive new intervals. A queue F is used to hold the free tracks; the function FREE inserts (enqueues) a track in F. The unprocessed endpoints are stored in a queue of points, P, sorted from left to right. The function DEQUEUE is the standard deletion operation for a queue [3]. (See Chapter 4.) The algorithm starts with only one track and adds tracks as needed; variable t holds the number of tracks used.

INTERVAL-BY-INTERVAL ASSIGNMENT (I)

```
1  Sort the endpoints of the intervals in I and build queue P
2  t ← 1
3  FREE track 1
4  while P is not empty
5     do p ← DEQUEUE(P)
6        if p is the left endpoint of an interval i
7           then do  if F is empty
```

8 **then do** $t \leftarrow t + 1$
9 Put i in track t
10 **else do** $track \leftarrow$ DEQUEUE(F)
11 Put i in $track$
12 **else do** FREE the track containing the interval whose right endpoint is p

To see that this algorithm never uses more than a number of tracks equal to the density d of the channel, note that when t is increased at line 8 it is because the current t tracks all contain intervals that have not yet ended when the left endpoint p obtained in line 5 is considered. Therefore, when t is increased for the last time to value w, all tracks numbered less than w contain intervals that span the current p; hence $d \geq w$. Since no overlapping intervals are places in the same track, $w = d$. Therefore, the algorithm finds an optimal track assignment. Preprocessing to find the interval for each net takes time $O(m)$ and INTERVAL-BY-INTERVAL ASSIGNMENT has running time $O(|I| \log |I|) = O(n \log n)$, due to the initial sorting of the endpoints of I.

Once one allows terminals at both the top and bottom of a column (except when all such pairs of terminals belong to the same net), one introduces a new set of constraints called *vertical constraints.* These constraints capture the fact that if net i has a terminal at the top of column c and net j has a terminal at the bottom of column c, then to connect these terminals to horizontal segments using vertical segments at column c, the horizontal segment for i must be above the horizontal segment for j. On can construct a vertical constraint graph that has a vertex v_i for each net i and a directed edge between v_i and v_j if there is a column that contains a terminal in i at the top and a terminal in j at the bottom. If one considers only routes that use at most one horizontal segment per net, then the constraint graph represents order constraints on the tracks used by the horizontal segments. If the vertical constraint graph is cyclic, then the routing cannot be done with one horizontal segment per net. If the vertical constraint graph is acyclic, it is NP-complete to determine if the routing can be achieved in a given number of tracks (see [19, p. 547]). Furthermore, even if an optimal or good routing using one horizontal segment per net is found, the number of tracks required is often substantially larger than what could be obtained using more horizontal segments. For these reasons, practical channel routing algorithms allow the route for each net to traverse portions of several tracks. Each time a route changes from one track to another, it uses a section of a column; this is called a **jog** (see Fig. 23.10).

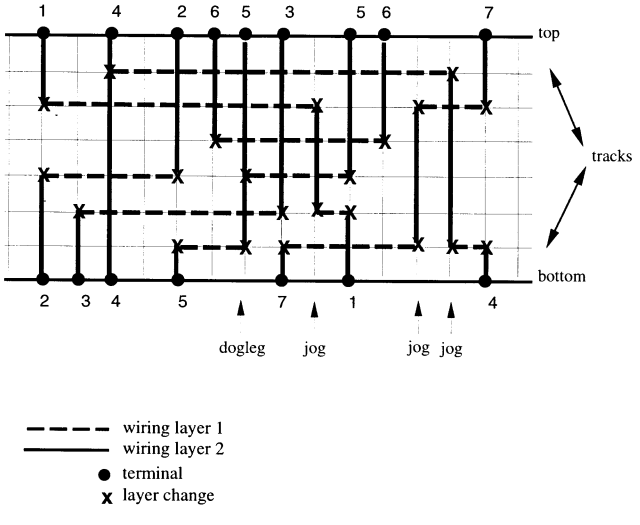

FIGURE 23.10 A channel routing in the 2-layer Manhattan model showing jogs.

Manhattan channel routing remains NP-complete even if unrestricted jogs are allowed (see [19, p. 541]). Therefore, the practical routing algorithms for this problem use heuristics. The earliest of these is by Deutsch [4]. Deutsch allows the route for a net to jog only in a column that contained a terminal of the net; he calls these jogs "doglegs" (see Fig. 23.10). This approach effectively breaks up each net into two-point subnets, and one can then define a vertical constraint graph in which each vertex represents a subnet. Deutsch's algorithm is based on a modification of INTERVAL-BY-INTERVAL ASSIGNMENT called *track-by-track assignment*. Track-by-track assignment also fills tracks greedily from left to right but fills one track to completion before starting the next. Deutsch's basic algorithm does track-by-track assignment but does not assign an interval for a subnet to a track if the assignment would violate a vertical constraint. Embellishments on the basic algorithm try to improve its performance and minimize the number of doglegs. Others have also modified the approach. (See the discussion in Section 9.6.1.4 of [19].) The class of algorithms based on greedy assignment of sorted intervals is also known as "left-edge algorithms."

Manhattan channel routing is arguably the most widely used detailed routing model and many algorithms have been developed. The reader is referred to [31] or [15] for a survey of algorithms. In this chapter, we will discuss only one more algorithm—an algorithm that proceeds column-by-column in contrast to the track-by-track algorithm. The column-by-column algorithm was originally proposed by Rivest and Fiduccia [28] and was called by them a "greedy" router. This algorithm routes all nets simultaneously. It starts at the leftmost column of the channel and proceeds to the right, considering each column in order. As it proceeds left to right it creates, destroys and continues horizontal segments for nets in the channel. Using this approach, it is easy to introduce a jog for a net in any column. At each column, the algorithm connects terminals at the top and bottom to horizontal segments for their nets, starting new segments when necessary, and ending segments when justified. At each column, for each continuing net with terminals to the right, it may also create a jog to bring a horizontal segment of the route closer to the channel edge containing the next terminal to the right. Thus, the algorithm employs some "look ahead" in determining what track to use for each net at each column. The algorithm is actually a framework with many parameters that can be adjusted. It may create, for one net, multiple horizontal segments that cross the same column and may extend routes beyond the left and right edges of the channel. It is a very flexible framework that allows many competing criteria to be considered and allows the interaction of nets more directly than strategies that route one net at a time. Many routing tools have adopted this approach.

Single-Layer Routing

Although single-layer channel routing plays a role in the routing of multilayer channels (e.g.,[8]), its greatest significance comes from the fact that even in its most general form, it can be solved optimally in polynomial time. There is a rich theory of single-layer detailed routing that has been developed not only for channel routing, but for routing in more general regions (see [22]). The first algorithmic results for single-layer channel routing were by Tompa [34], who considered **river routing** problems. A river routing problem is a single-layer channel routing problem in which each net contains exactly two terminals, one at the top edge of the channel and one at the bottom edge of the channel. The nets have terminals in the same order along the top and bottom—a requirement if the problem is to be routable in one layer. Tompa considered unconstrained (versus rectilinear) wire paths and gave a $O(n^2)$-time algorithm for n nets to test routability and find the route that minimizes both the individual wire lengths and the total wire length when the width of the channel is fixed. This algorithm can be used as a subroutine within binary search to find the minimum-width channel in $O(n^2 \log n)$ time. Tompa also suggested how to modify his algorithm for the rectilinear case. Dolev et al. [5] built upon Tompa's theory for the rectilinear case and presented an $O(n)$-time algorithm to compute the minimum width of the channel and an $O(n^2)$-time algorithm to actually produce the rectilinear routing. The difference in running times comes from the fact that the routing may actually have n segments per net, and thus would take $O(n^2)$-time to generate (see Fig. 23.11). In contrast, the testing for routability can be done by examining a set of constraints for the

channel. The results were generalized to multi-terminal nets by Greenberg and Maley [9], where the time to calculate the minimum width remains linear in the number of terminals.

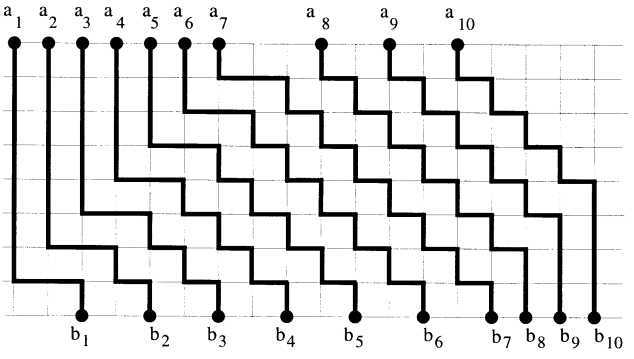

FIGURE 23.11 A river routing. The route for a single net may bend $O(n)$ times.

We now present the theory that allows the width of a river-routing channel to be computed in linear time. Our presentation is an amalgam of the presentations in [5] and [18]. The heart of the theory is the observation that for river routing, cut lines other than the vertical lines that define channel density also contribute to a lower bound for the width of the channel. This lower bound is then shown to be an upper bound as well. Indexing from left to right, let the ith net of a routing channel, $1 \leq i \leq n$, be denoted by the pair (a_i, b_i) where a_i is the horizontal position of its terminal on the top of the channel and b_i is the horizontal position of its terminal on the bottom of the channel. Consider a line from b_i to a_{i+k}, $k > 0$, cutting the channel. There are $k + 1$ nets that must cross this line. Measuring slopes from 0° to 180°, if the line has slope $\geq 90^\circ$, then $k + 1$ nets must cross the vertical (90°) line at b_i, and there must be $k + 1$ tracks. If the line has slope $< 90^\circ$ and $> 45^\circ$, then each vertical grid segment that crosses the line can be paired with a horizontal grid segment that must also cross the line and which cannot be used by a different net. Therefore, the line must cross $k + 1$ tracks. Finally, if the line has slope $\leq 45^\circ$, then each horizontal grid segment that crosses the line can be paired with a vertical grid segment that must also cross the line and which cannot be used by a different net. Therefore, there must be $k + 1$ columns crossing the line, i.e., $a_{i+k} - b_i \geq k$. Similarly, by considering a line from b_{i+k} to a_i, we conclude $k + 1$ tracks are necessary unless $b_{k+i} - a_i \geq k$. In the case of $k = 0$, a_i must equal b_i for no horizontal track to be required. Based on this observation, it can be proved that the minimum number of tracks t required by an instance of river routing is the least t such that for all $1 \leq i \leq n - t$

$$b_{i+t} - a_i \geq t \tag{23.14}$$

and

$$a_{i+t} - b_i \geq t \; . \tag{23.15}$$

To find the minimum such t in linear time, observe that $a_{i+k+1} \geq a_{i+k} + 1$ and $b_{i+k+1} \geq b_{i+k} + 1$. Therefore,

$$\text{if } b_{i+k} - a_i \geq k \text{ then } b_{i+k+1} - a_i \geq b_{i+k} + 1 - a_i \geq k + 1 \tag{23.16}$$

and

$$\text{if } a_{i+k} - b_i \geq k \text{ then } a_{i+k+1} - b_i \geq a_{i+k} + 1 - b_i \geq k + 1 \; . \tag{23.17}$$

Therefore, we can start with $t = 0$ and search for violated constraints from $i = 1$ to $n - t$; each time a constraint of the form of (23.14) or (23.15) above is violated, we increase t by one and continue the search; t can be no larger than n. Let N denote the set of nets in a river routing channel, $|N| = n$. The following algorithm calculates the minimum number of tracks needed to route this channel.

RIVER-ROUTING WIDTH (N)

```
1  i ← 1
2  t ← 0
3  while i ≤ |N| − t
4     do if b_{i+t} − a_i ≥ t and a_{i+t} − b_i ≥ t
5        then do i ← i + 1
6        else do t ← t + 1
7  return t
```

The actual routing for a river-routing channel can be produced in greedy fashion by routing one net at a time from left to right, and routing each net beginning with its left terminal. The route of any net travels vertically whenever it is not blocked by a previously routed net, travels horizontally right until it can travel vertically again or until it reaches the horizontal position of the right terminal of the net. This routing takes worst-case time $O(n^2)$, as the example in Fig. 23.11 illustrates.

23.8 Research Issues and Summary

This chapter has given an overview of the design problems arising from the computer-aided layout of VLSI circuits and some of the algorithmic approaches used. The algorithms presented in this chapter draw upon the theoretical foundations discussed in other chapters. Graph models are predominant and are frequently used to capture constraints. Since many of the problems are NP-complete, heuristics are used. Research continues in this field, both to find better methods of solving these difficult problems—both in efficiency and quality of solution—and to model and solve new layout problems arising from the ever-changing technology of VLSI fabrication and packaging. Layout techniques particular to increasingly popular technologies such as field-programmable gate arrays (FPGAs) and multichip modules (MCMs) have been and continue to be developed.

A major theme of current research in VLSI layout is the consideration of circuit performance as well as layout area. As feature sizes continue to shrink, wire delay is becoming an increasingly large fraction of total circuit delay. Therefore, the delay introduced by routing is increasingly important. The consideration of performance has necessitated new techniques, not only for routing but for partitioning and placement as well. In some cases, the techniques for area-based layout have been extended to consider delay. For example, the simulated annealing approach to placement has been modified to consider delay on critical paths. However, many researchers are developing new approaches for performance-based layout. For example, one finds the use of the techniques of linear programming, integer programming, and even specialized higher-order programming (see Chapters 31 and 32) in recent work on performance-driven layout. Clock-tree routing, to minimize clock delay and clock skew, is also receiving attention as an important component of performance-driven layout.

The reader is referred to the references given in *Further Information* for broader descriptions of the field and, in particular, for more thorough treatments of current research.

23.9 Defining Terms

Channel: A rectangular region for routing wires, with terminals lying on two opposite edges, called the "top" and "bottom." The other two edges contain no terminals, but wires may cross these edges for nets that enter the channel from other channels. The routing area of a layout is decomposed into several channels.

Channel density: Orient a channel so that the top and bottom are horizontal edges. Then the density at any vertical line cutting the channel is the number of nets that have terminals both to the left and right of the vertical line. Nets with a terminal on the vertical line contribute to the density unless all of the terminals of the net lie on the vertical line. The channel density is the maximum density of any vertical cut of the channel.

Channel routing: The problem of determining the routes, i.e., paths and layers, for wires in a routing channel.

Compaction: The process of modifying a given layout to remove extra space between features of the layout.

Floor plan: An approximate layout of a circuit that is made before the layouts of the components composing the circuit have been completely determined.

Floor plan sizing: Given a floor plan and a set of components, each with a shape function, finding an assignment of specific shapes to the components so that the area of the layout is minimized.

Floor planning: Designing a floor plan.

General cell layout: A style of layout in which the components may be of arbitrary height and width and functional complexity.

Global routing: When a layout area is decomposed into channels, global routing is the problem of choosing which channels will be used to make the interconnections for each net.

Graph partitioning: Given a graph with weights on its vertices and costs on its edges, the problem of partitioning the vertices into some given number k of approximately equal-weight subsets such that the cost of the edges that connect vertices in different subsets is minimized.

Interval graph coloring: Given a finite set of n intervals $\{[l_i, r_i], 1 \leq i \leq n\}$, for integer l_i and r_i, color the intervals with a minimum number of colors so that no two intervals that intersect are the same color. The graph representation is direct: each vertex represents an interval, and there is an edge between two vertices if the corresponding intervals intersect. Then coloring the interval graph corresponds to coloring the intervals.

Jog: In a rectilinear routing model, a vertical segment in a path that is generally running horizontally, or vice versa.

Layer assignment: Given a set of trees in the plane, each interconnecting the terminals of a net, an assignment of a routing layer to each segment of each tree so that the resulting wiring layout is legal under the routing model.

Manhattan routing: A popular rectilinear channel routing model in which paths for disjoint nets can cross (a vertical segment crosses a horizontal segment) but cannot contain segments that overlap in the same direction at even a point.

Net: A set of terminals to be connected together.

Rectilinear: With respect to layouts, describes a layout for which there is an underlying pair of orthogonal axes defining "horizontal" and "vertical;" the features of the layout, such as the sides of the components and segments of the paths of wires, are horizontal and vertical line segments.

River routing: a single-layer channel routing problem in which each net contains exactly two terminals, one at the top edge of the channel and one at the bottom edge of the channel. The nets have terminals in the same order along the top and bottom—a requirement if the problem is to be routable in one layer.

Shape function: A function that gives the possible dimensions of the layout of a component with a flexible (or not yet completely determined) layout. For a shape function $s : [w_{min}, \infty] \rightarrow [h_{min}, \infty]$ with $[w_{min}, \infty]$ and $[h_{min}, \infty]$ subsets of $\Re^+$, $s(w)$ is the minimum height of any rectangle of width w that contains a layout of the component.

Slicing floor plan: A floor plan which can be obtained by the recursive bipartitioning of a rectangular layout area using vertical and horizontal line segments.

Steiner tree: Given a graph $G = (V, E)$ a Steiner tree for a subset of vertices U of V is a subset of edges of G that form a tree and contain among their endpoints all the vertices of U. The tree may contain other vertices than those in U. For a Euclidean Steiner tree, U is a set of points in the Euclidean plane, and the tree interconnecting U can contain arbitrary points and line segments in the plane.

Switch box: A rectangular routing region containing terminals to be connected on all four sides of the rectangle boundary and for which the entire interior of the rectangle can be used by wires (contains no obstacles).

Terminal: A position within a component where a wire attaches. Usually a terminal is a single point on the boundary of a component, but a terminal can be on the interior of a component and may consist of a set of points, any of which may be used for the connection. A typical set of points is an interval along the component boundary.

Topological sort: Given a directed, acyclic graph, a topological sort of the vertices of the graph is a total ordering of the vertices such that if vertex u comes before vertex v in the ordering, there is no directed path from v to u.

Via minimization: Given a set of trees in the plane, each interconnecting the terminals of a net, determining a layer assignment that minimizes the number of points (vias) at which a layer change occurs.

Acknowledgments

I would like to thank Ron Pinter for his help in improving this chapter.

Further Information

This chapter has given several examples of the successful application of the theory of combinatorial algorithms to problems in VLSI layout. It is by no means a survey of all the important problems and algorithms in the area. Several textbooks have been written on algorithms for VLSI layout, such as [19, 27, 29, 31], and the reader is referred to these for more complete coverage of the area. Other review articles of interest are [26] on placement, [2] on geometric algorithms for layout, [14] on layout, [15] on channel routing, [12] on layer assignment, and [1] on netlist partitioning. There are many conferences and workshops on computer-aided design that contain papers presenting algorithms for layout. The *ACM/IEEE Design Automation Conference* and the *IEEE/ACM International Conference on Computer-Aided Design* are the richest sources of algorithms among these conferences. The premier journal on the topic is *IEEE Transactions on Computer-Aided Design of Integrated Circuits and Systems.* Other journals include *Integration, the VLSI Journal* published by North-Holland Publishing and *IEEE Transaction on VLSI Systems.* The ACM has just begun a journal *Transactions on Design Automation of Electronic Systems* that has the potential to become another good source of papers on layout algorithms. Layout algorithms also appear in journals focusing on general algorithm development such as *SIAM Journal on Computing,* published by the Society of Industrial and Applied Mathematics, *Journal of Algorithms,* published by Academic Press, and *Algorithmica,* published by Springer-Verlag.

24.1 Introduction

Computational complexity is aimed at measuring how complex a computational solution is. There are many ways to measure the complexity of a solution: how hard it is to understand it, how hard to express it, how long the solution process will take, and more. The last criterion—time—is most widely taken as the definition of complexity. This is because the agent that implements an **algorithm** is usually a computer—and from a user's point of view, the most important issue is how long one should wait to see the solution. However, there are other important measures of complexity, such as the amount of memory, hardware, information, communication, knowledge, or energy needed for the solution. Complexity theory is aimed at quantifying these resources precisely and studying the amounts of them required to accomplish computational tasks.

This technical sense of the word "complexity" did not take root until the mid-1960s. Today, complexity theory is not only a vibrant subfield of computer science, but also has direct or metaphoric impact on other fields such as dynamical systems and chaos theory. The seed of computational complexity is the formalization of the concept of an **algorithm.** Algorithms in turn must be planted in some *computational model,* ideally one that abstracts important features of real computing machines and processes. In this chapter we consider the **Turing machine,** a computer model created and studied by the British mathematician Alan Turing in the 1930s [39]. Chapter 26 will discuss different (and equivalent) ways of formalizing algorithms.

With the advent of commercial computers in the 1950s and 1960s, when processor speed was much lower and memory cost unimaginably higher than today, it became critical to design *efficient* algorithms for solving large classes of problems. Just knowing that a problem was solvable, which had been the main concern of computability theory since the 1930s, was no longer enough. Turing machines provided a basis

for Hartmanis and Stearns [14] to formally define the measures of **time complexity** and **space complexity** for computations. The latter refers to the amount of memory needed to execute the computation. They defined measures for other resources as well, and Blum [1] found a precise definition of *complexity measure* that was not tied to any particular resource or machine model. Together with earlier work by Rabin [30], these papers marked the beginning of *computational complexity theory* as an important new discipline. A closely related development was drawn together by Knuth, whose work on algorithms and data structures [19] created the field of *algorithm design and analysis.* All of this work has been recognized in annual Turing Awards given by the Association for Computing Machinery. Hartmanis' Turing Award lecture [13] recounts the origins of computational complexity theory and speculates on its future development.

The power of a computing machine depends on its internal structure as well as on the amount of time, space, or other resources it is allowed to consume. Restricting our model of choice, the Turing machine, in various internal ways yields progressively simpler and weaker computing machines. These machines correspond to a natural hierarchy of grammars defined and advanced by Chomsky [5], which we describe in Chapter 25. In this chapter we present the most basic computational models, and use these models to classify problems first by solvability and then by complexity.

Central issues studied by researchers in computational complexity include the following.

- For a given amount of resources, or for a given type of resource, what problems can and cannot be solved?
- What is the relationship between problems requiring essentially the same amount of the resource or resources? May they be equivalent in some intrinsic sense?
- What connections are there between different kinds of resources? Given more time, can we reduce the demand on memory storage, or vice-versa?
- What general limits can be set on the kind of problems that can be solved when resources are limited?

The end thrust of Turing's famous paper [39] was to demonstrate rigorously that several fundamental problems in logic cannot be solved by algorithms at all. Complexity theory aims to show similar results for many more problems in the presence of resource limits. Such an unsolvability result, although "bad news" in most contexts (cryptographic security is an exception) can have practical benefits: it may lead to alternative models, goals, or solution strategies. As will come out in Chapters 27 and 28, complexity theory has so far been much more successful at drawing relative conclusions and relationships between problems than in proving absolute statements about (un)solvability.

24.2 Computational Models

Throughout this chapter, Σ denotes a finite alphabet of symbols; unless otherwise specified, $\Sigma = \{0, 1\}$. Then Σ^* denotes the set of all finite strings, including the empty string ϵ, over Σ. A **language** over Σ is simply a subset of Σ^*.

We use **regular expressions** in specifying some languages. In advance of the formal definition to come in Chapter 25, we define them as one kind of "patterns" for strings to "match." The basic patterns are ϵ and the characters in Σ, which match only themselves. The null pattern $\emptyset$ matches no strings. Two patterns joined by "$+$" match any string that matches either of them. Two or more patterns written in sequence match any string composed of substrings that match the respective patterns. A pattern followed by a "$*$" matches any string that can be divided into zero or more successive substrings, each of which matches the pattern—here the "zero" case applies to ϵ, which matches any starred pattern. For example, the pattern $0(0+1)^*1$ matches any string that begins with a 0 and ends with a 1, with zero or more binary characters in between. The pattern can be used as a *name* for the language of strings that match it. In like manner, the pattern $(0^*10^*1)^*0^*$ stands for the language of binary strings that have an even number of 1s. This

pattern *says* that trailing 0s are immaterial to any such string, and the rest of the string can be broken into zero or more substrings, each of which ends in a 1 and has exactly one previous 1.

Finite Automata

The **finite automaton** (in its **deterministic** version) was introduced by McCulloch and Pitts in 1943 as a logical model for the behavior of neural systems [28]. Rabin and Scott introduced the **nondeterministic** finite automaton (NFA) in [31], and showed that NFAs are equivalent to deterministic finite automata, in the sense that they recognize the same class of languages. This class of languages, called the **regular languages,** had already been characterized by Kleene [18] and Chomsky and Miller [6] in terms of regular expressions and regular grammars, which will be described formally in Chapter 25.

In addition to their original role in the study of neural nets, finite automata have enjoyed great success in many fields such as the design and analysis of sequential circuits [21], asynchronous circuits [3], text-processing systems [23], and compilers. They also led to the design of more efficient algorithms. One excellent example is the development of linear-time string-matching algorithms, as described in [20]. Other applications of finite automata can be found in computational biology [35], natural language processing, and distributed computing [27].

A **finite automaton,** pictured in Fig. 24.1, consists of an *input tape* and a *finite control.* The input tape contains a finite string of input symbols, and is read one symbol at a time from left to right. The finite control is connected to an *input head* that reads each symbol, and can be in one of a finite number of *states.* The input head is *one-way,* meaning that it cannot "backspace" to the left, and *read-only,* meaning that it cannot alter the tape. At each *step,* the finite control may change its state according to its current state and the symbol read, and the head advances to the next tape cell. In an NFA there may be more than one choice of next state in a step. Figure 24.1 also shows the second step of a computation on an input string beginning *aabab* . . . When the input head reaches the right end of the input tape, if the machine is in a state designated "final" (or "accepting"), we say that the input string is *accepted;* else we say it is *rejected.* The following is the formal definition.

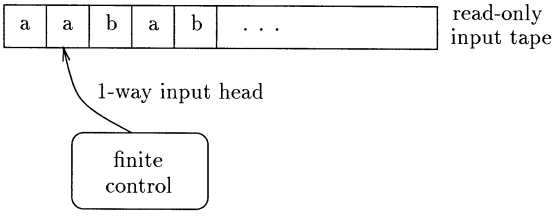

FIGURE 24.1 A finite automaton.

DEFINITION 24.1 A **nondeterministic finite automaton** (NFA) is a quintuple $(Q, \Sigma, \delta, q_0, F)$, where

- Q is a finite set of *states;*
- Σ is a finite set of *input symbols;*
- δ, the *state transition function,* is a mapping from $Q \times \Sigma$ to subsets of Q;
- $q_0 \in Q$ is the *start state* of the NFA;
- $F \subseteq Q$ is the set of *final states.*

If δ maps $|Q| \times \Sigma$ to singleton subsets of Q, then we call such a machine a **deterministic finite automaton** (DFA).

Note that a DFA is treatable as a special case of an NFA, where the next state is always uniquely determined by the current state and the symbol read. On any input string $x \in \Sigma^*$, a DFA follows a unique *computation path,* starting in state q_0. If the final state in the path is in F, then x is *accepted,* and the path is an *accepting path.* An NFA, however, may have multiple computation paths on the same input x. It is useful to imagine that when an NFA has more than one next state, all options are taken in parallel, so that the "super-computation" is a tree of branching computation paths. Then the NFA is said to *accept* x if at least *one* of those paths is an accepting path.
