Preface

Forty years ago (1966), Ronald L. Graham formally introduced approximation algorithms. The idea was to generate near-optimal solutions to optimization problems that could not be solved efficiently by the computational techniques available at that time. With the advent of the theory of NP-completeness in the early 1970s, the area became more prominent as the need to generate near optimal solutions for NP-hard optimization problems became the most important avenue for dealing with computational intractability. As it was established in the 1970s, for some problems one can generate near optimal solutions quickly, while for other problems generating provably good suboptimal solutions is as difficult as generating optimal ones. Other approaches based on probabilistic analysis and randomized algorithms became popular in the 1980s. The introduction of new techniques to solve linear programming problems started a new wave for developing approximation algorithms that matured and saw tremendous growth in the 1990s. To deal, in a practical sense, with the inapproximable problems there were a few techniques introduced in the 1980s and 1990s. These methodologies have been referred to as metaheuristics. There has been a tremendous amount of research in metaheuristics during the past two decades. During the last 15 or so years approximation algorithms have attracted considerably more attention. This was a result of a stronger inapproximability methodology that could be applied to a wider range of problems and the development of new approximation algorithms for problems in traditional and emerging application areas.

As we have witnessed, there has been tremendous growth in field of approximation algorithms and metaheuristics. The basic methodologies are presented in Parts I–III. Specifically, Part I covers the basic methodologies to design and analyze efficient approximation algorithms for a large class of problems, and to establish inapproximability results for another class of problems. Part II discusses local search, neural networks and metaheuristics. In Part III multiobjective problems, sensitivity analysis and stability are discussed.

Parts IV–VI discuss the application of the methodologies to classical problems in combinatorial optimization, computational geometry and graphs problems, as well as for large-scale and emerging applications. The approximation algorithms discussed in the handbook have primary applications in computer science, operations research, computer engineering, applied mathematics, bioinformatics, as well as in engineering, geography, economics, and other research areas with a quantitative analysis component.

Chapters 1 and 2 present an overview of the field and the handbook. These chapters also cover basic definitions and notation, as well as an introduction to the basic methodologies and inapproximability. Chapters 1–8 discuss methodologies to develop approximation algorithms for a large class of problems. These methodologies include restriction (of the solution space), greedy methods, relaxation (LP and SDP) and rounding (deterministic and randomized), and primal-dual methods. For a minimization problem P these methodologies provide for every problem instance I a solution with objective function value that is at most $(1+\epsilon) \cdot f^*(I)$, where ϵ is a positive constant (or a function that depends on the instance size) and $f^*(I)$ is the optimal solution value for instance I. These algorithms take polynomial time with respect to the size of the instance I being solved. These techniques also apply to maximization problems, but the guarantees are different. Given as input a value for ϵ and any instance I for a given problem P, an approximation scheme finds a solution with objective function value at most $(1+\epsilon) \cdot f^*(I)$. Chapter 9 discusses techniques that have been used to design approximation schemes. These approximation schemes take polynomial time with respect to the size of the instance I (PTAS). Chapter 10 discusses different methodologies for designing fully polynomial approximation schemes (FPTAS). These schemes take polynomial time with respect to the size of the instance I and $1/\epsilon$. Chapters 11–13 discuss asymptotic and randomized approximation schemes, as well as distributed and randomized approximation algorithms. Empirical analysis is covered in Chapter 14 as well as in chapters in Parts IV–VI. Chapters 15–17 discuss performance measures, reductions that preserve approximability, and inapproximability results.

Part II discusses deterministic and stochastic local search as well as very large neighborhood search. Chapters 21 and 22 present reactive search and neural networks. Tabu search, evolutionary computation, simulated annealing, ant colony optimization and memetic algorithms are covered in Chapters 23–27. In Part III, I discuss multiobjective optimization problems, sensitivity analysis and stability of approximations.

Part IV covers traditional applications. These applications include bin packing and extensions, packing problems, facility location and dispersion, traveling salesperson and generalizations, Steiner trees, scheduling, planning, generalized assignment, and satisfiability.

Computational geometry and graph applications are discussed in Part V. The problems discussed in this part include triangulations, connectivity problems in geometric graphs and networks, dilation and detours, pair decompositions, partitioning (points, grids, graphs and hypergraphs), maximum planar subgraphs, edge disjoint paths and unsplittable flow, connectivity problems, communication spanning trees, most vital edges, and metaheuristics for coloring and maximum disjoint paths.

Large-scale and emerging applications (Part VI) include chapters on wireless ad hoc networks, sensor networks, topology inference, multicast congestion, QoS multimedia routing, peer-to-peer networks, data broadcasting, bioinformatics, CAD and VLSI applications, game theoretic approximation, approximating data streams, digital reputation and color quantization.

Readers who are not familiar with approximation algorithms and metaheuristics should begin with Chapters 1–6, 9–10, 18–21, and 23–27. Experienced researchers will also find useful material in these basic chapters. We have collected in this volume a large amount of this material with the goal of making it as complete as possible. I apologize in advance for omissions and would like to invite all of you to suggest to me chapters (for future editions of this handbook) to keep up with future developments in the area. I am confident that research in the field of approximations algorithms and metaheuristics will continue to flourish for a few more decades.

About the Cover

The four objects in the bottom part of the cover represent scheduling, bin packing, traveling salesperson, and Steiner tree problems. A large number of approximation algorithms and metaheuristics have been designed for these four fundamental problems and their generalizations.

The seven objects in the middle portion of the cover represent the basic methodologies. Of these seven, the object in the top center represents a problem by its solution space. The object to its left represents its solution via restriction and the one to its right represents relaxation techniques. The objects in the row below represent local search and metaheuristics, problem transformation, rounding, and primal-dual methods.

The points in the top portion of the cover represent solutions to a problem and their height represents their objective function value. For a minimization problem, the possible solutions generated by an approximation scheme are the ones inside the bottommost rectangle. The ones inside the next rectangle represent the one generated by a constant ratio approximation algorithm. The top rectangle represents the possible solution generated by a polynomial time algorithm for inapproximable problems (under some complexity theoretic hypothesis).

About the Editor

Dr. Teofilo F. Gonzalez received the B. S. degree in computer science from the Instituto Tecnológico de Monterrey (1972). He was one of the first handful of students to receive a computer science degree in Mexico. He received his Ph.D. degree from the University of Minnesota, Minneapolis (1975). He has been member of the faculty at Oklahoma University, Penn State, and University of Texas at Dallas, and has spent sabbatical leaves at Utrecht University (Netherlands) and the Instituto Tecnológico de Monterrey (ITESM, Mexico). Currently he is professor of computer science at the University of California, Santa Barbara. Professor Gonzalez's main area of research activity is the design and analysis of efficient exact and approximation algorithms for fundamental problems arising in several disciplines. His main research contributions fall in the areas of resource allocation and job scheduling, message dissemination in parallel and distributed computing, computational geometry, graph theory, and VLSI placement and wire routing.

His professional activities include chairing conference program committees and membership in journal editorial boards. He has served as an accreditation evaluator and has been a reviewer for numerous journals and conferences, as well as CS programs and funding agencies.

University of California, Santa Barbara

1.1 Introduction

Approximation algorithms, as we know them now, were formally introduced in the 1960s to generate near-optimal solutions to optimization problems that could not be solved efficiently by the computational techniques available at that time. With the advent of the theory of NP-completeness in the early 1970s, the area became more prominent as the need to generate near-optimal solutions for NP-hard optimization problems became the most important avenue for dealing with computational intractability. As established in the 1970s, for some problems one can generate near-optimal solutions quickly, while for other problems generating provably good suboptimal solutions is as difficult as generating optimal ones. Other approaches based on probabilistic analysis and randomized algorithms became popular in the 1980s. The introduction of new techniques to solve linear programming problems started a new wave for developing approximation algorithms that matured and saw tremendous growth in the 1990s. To deal, in a practical sense, with the inapproximable problems, there were a few techniques introduced in the 1980s and 1990s. These methodologies have been referred to as metaheuristics and include simulated annealing (SA), ant colony optimization (ACO), evolutionary computation (EC), tabu search (TS), and memetic algorithms (MA). Other previously established methodologies such as local search, backtracking, and branch-and-bound were also explored at that time. There has been a tremendous amount of research in metaheuristics during the past two decades. These techniques have been evaluated experimentally and have demonstrated their usefulness for solving practical problems. During the past 15 years or so, approximation algorithms have attracted considerably more attention. This was a result of a stronger inapproximability methodology that could be applied to a wider range of problems and the development of new approximation algorithms for problems arising in established and emerging application areas. Polynomial time approximation schemes (PTAS) were introduced in the 1960s and the more powerful fully polynomial time approximation schemes (FPTAS) were introduced in the 1970s. Asymptotic PTAS and FPTAS, and fully randomized approximation schemes were introduced later on.

Today, approximation algorithms enjoy a stature comparable to that of algorithms in general and the area of metaheuristics has established itself as an important research area. The new stature is a by-product of a natural expansion of research into more practical areas where solutions to real-world problems are expected, as well as by the higher level of sophistication required to design and analyze these new procedures. The goal of approximation algorithms and metaheuristics is to provide the best possible solutions and to guarantee that such solutions satisfy certain important properties. This volume houses these two approaches and thus covers all the aspects of approximations. We hope it will serve as a valuable reference for approximation methodologies and applications.

Approximation algorithms and metaheuristics have been developed to solve a wide variety of problems. A good portion of these results have only theoretical value due to the fact that their time complexity is a high-order polynomial or have huge constants associated with their time complexity bounds. However, these results are important because they establish what is possible, and it may be that in the near future these algorithms will be transformed into practical ones. Other approximation algorithms do not suffer from this pitfall, but some were designed for problems with limited applicability. However, the remaining approximation algorithms have real-world applications. Given this, there is a huge number of important application areas, including new emerging ones, where approximation algorithms and metaheuristics have barely penetrated and where we believe there is an enormous potential for their use. Our goal is to collect a wide portion of the approximation algorithms and metaheuristics in as many areas as possible, as well as to introduce and explain in detail the different methodologies used to design these algorithms.

1.2 Overview

Our overview in this section is devoted mainly to the earlier years. The individual chapters discuss in detail recent research accomplishments in different subareas. This section will also serve as an overview of Parts I, II, and III of this handbook. Chapter 2 discusses some of the basic methodologies and applies them to simple problems. This prepares the reader for the overview of Parts IV, V, and VI presented in Chapter 2.

Even before the 1960s, research in applied mathematics and graph theory had established upper and lower bounds for certain properties of graphs. For example, bounds had been established for the chromatic number, achromatic number, chromatic index, maximum clique, maximum independent set, etc. Some of these results could be seen as the precursors of approximation algorithms. By the 1960s, it was understood that there were problems that could be solved efficiently, whereas for other problems all their known algorithms required exponential time. Heuristics were being developed to find quick solutions to problems that appeared to be computationally difficult to solve. Researchers were experimenting with heuristics, branch-and-bound procedures, and iterative improvement frameworks and were evaluating their performance when solving actual problem instances. There were many claims being made, not all of which could be substantiated, about the performance of the procedures being developed to generate optimal and suboptimal solutions to combinatorial optimization problems.

1.2.1 Approximation Algorithms

Forty years ago (1966), Ronald L. Graham [1] formally introduced approximation algorithms. He analyzed the performance of list schedules for scheduling tasks on identical machines, a fundamental problem in scheduling theory.

Problem: Scheduling tasks on identical machines.

Instance: Set of n tasks $(T_1, T_2, \ldots, T_n)$ with processing time requirements $t_1, t_2, \ldots, t_n$, partial order C defined over the set of tasks to enforce task dependencies, and a set of m identical machines.

Objective: Construct a schedule with minimum makespan. A *schedule* is an assignment of tasks to time intervals on the machines in such a way that (1) each task T_i is processed continuously for t_i units of time by one of the machines; (2) each machine processes at most one task at a time; and (3) the precedence constraints are satisfied (i.e., machines cannot commence the processing of a task until all its predecessors have been completed). The *makespan* of a schedule is the time at which all the machines have completed processing the tasks.

The *list scheduling* procedure is given an ordering of the tasks specified by a list L. The procedure finds the earliest time t when a machine is idle and an unassigned task is *available* (i.e., all its predecessors have been completed). It assigns the leftmost available task in the list L to an idle machine at time t and this step is repeated until all the tasks have been scheduled.

The main result in Ref. [1] is proving that for every problem instance I, the schedule generated by this policy has a makespan that is bounded above by $(2 - 1/m)$ times the optimal makespan for the instance. This is called the *approximation ratio* or *approximation factor* for the algorithm. We also say that the algorithm is a $(2 - 1/m)$-approximation algorithm. This criterion for measuring the quality of the solutions generated by an algorithm remains one of the most important ones in use today. The second contribution in Ref. [1] is establishing that the approximation ratio $(2 - 1/m)$ is the best possible for list schedules, i.e., the analysis of the approximation ratio for this algorithm cannot be improved. This was established by presenting problem instances (for all m and $n \geq 2m - 1$) and lists for which the schedule generated by the procedure has a makespan equal to $2 - 1/m$ times the optimal makespan for the instance. A restricted version of the list scheduling algorithm is analyzed in detail in Chapter 2.

The third important result in Ref. [1] is showing that list scheduling procedures schedules may have anomalies. To explain this, we need to define some terms. The makespan of the list schedule, for instance, I, using list L is denoted by $f_L(I)$. Suppose that instance I' is a slightly modified version of instance I. The modification is such that we intuitively expect that $f_L(I') \leq f_L(I)$. But that is not always true, so there is an *anomaly*. For example, suppose that I' is I, except that I' has an additional machine. Intuitively, $f_L(I') \leq f_L(I)$ because with one additional machine tasks should be completed earlier or at the same time as when there is one fewer machine. But this is not always the case for list schedules, there are problem instances and lists for which $f_L(I') > f_L(I)$. This is called an *anomaly*. Our expectation would be valid if list scheduling would generate minimum makespan schedules. But we have a procedure that generates suboptimal solutions. Such guarantees are not always possible in this environment. List schedules suffer from other anomalies. For example, relaxing the precedence constraints or decreasing the execution time of the tasks. In both these cases, one would expect schedules with smaller or the same makespan. But, that is not always the case. Chapter 2 presents problem instances where anomalies occur. The main reason for discussing anomalies now is that even today numerous papers are being published and systems are being deployed where "common sense"-based procedures are being introduced without any analytical justification or thorough experimental validation. Anomalies show that since we live for the most part in a "suboptimal world," the effect of our decisions is not always the intended one.

Other classical problems with numerous applications are the traveling salesperson, Steiner tree, and spanning tree problems, which will be defined later on. Even before the 1960s, there were several well-known polynomial time algorithms to construct minimum-weight spanning trees for edge-weighted graphs [2]. These simple greedy algorithms have low-order polynomial time complexity bounds. It was well known at that time that the same type of procedures do not always generate an optimal tour for the traveling salesperson problem (TSP), and do not always construct optimal Steiner trees. However, in 1968 E. F. Moore (see Ref. [3]) showed that for any set of points P in metric space $L_M < L_T \leq 2L_S$, where L_M, L_T, and L_S are the weights of a minimum-weight spanning tree, a minimum-weight tour (solution) for the TSP and minimum-weight Steiner tree for P, respectively. Since every spanning tree is a Steiner tree, the above bounds show that when using a minimum-weight spanning tree to approximate a minimum weight Steiner tree we have a solution (tree) whose weight is at most twice the weight of an optimal Steiner tree. In other words, any algorithm that generates a minimum-weight spanning tree is a 2-approximation algorithm for the Steiner tree problem. Furthermore, this approximation algorithm takes the same time as an algorithm that constructs a minimum-weight spanning tree for edge-weighted graphs [2], since such an algorithm can be used to construct an optimal spanning tree for a set of points in metric space. The above bound is established by defining a transformation from any minimum-weight Steiner tree into a TSP tour with weight at most $2L_S$. Therefore, $L_T \leq 2L_S$ [3]. Then by observing that the deletion of an edge in an optimum tour for the TSP results in a spanning tree, it follows that $L_M < L_T$. Chapter 3 discusses this approximation algorithm in detail. The Steiner ratio is defined as L_S/L_M. The above arguments show that the Steiner ratio is at least $\frac{1}{2}$. Gilbert and Pollak [3] conjectured that the Steiner ratio in the Euclidean plane equals $\frac{\sqrt{3}}{2}$ (the 0.86603 . . . conjecture). The proof of this conjecture and improved approximation algorithms for different versions of the Steiner tree problem are discussed in Chapters 42.

The above constructive proof can be applied to a minimum-weight spanning tree to generate a tour for the TSP. The construction takes polynomial time and results in a 2-approximation algorithm for the TSP. This approximation algorithm for the TSP is also referred to as the *double spanning tree algorithm* and is discussed in Chapters 3 and 31. Improved approximation algorithms for the TSP as well as algorithms for its generalizations are discussed in Chapters 3, 31, 40, 41, and 51. The approximation algorithm for the Steiner tree problem just discussed is explained in Chapter 3 and improved approximation algorithms and applications are discussed in Chapters 42, 43, and 51. Chapter 59 discusses approximation algorithms for variations of the spanning tree problem.

In 1969, Graham [4] studied the problem of scheduling tasks on identical machines, but restricted to independent tasks, i.e., the set of precedence constraints is empty. He analyzes the longest processing time (LPT) scheduling rule; this is list scheduling where the list of tasks L is arranged in nonincreasing order of their processing requirements. His elegant proof established that the LPT procedure generates a schedule with makespan at most $\frac{4}{3}-\frac{1}{3m}$ times the makespan of an optimal schedule, i.e., the LPT scheduling algorithm has a $\frac{4}{3}-\frac{1}{3m}$ approximation ratio. He also showed that the analysis is best possible for all m and $n \geq 2m + 1$. For $n \leq 2m$ tasks, the approximation ratio is smaller and under some conditions LPT generates an optimal makespan schedule. Graham [4], following a suggestion by D. Kleitman and D. Knuth, considered list schedules where the first portion of the list L consists of k tasks with the longest processing times arranged by their starting times in an optimal schedule for these k tasks (only). Then the list L has the remaining $n - k$ tasks in any order. The approximation ratio for this list schedule using list L is $1 + \frac{1-1/m}{1+\lceil k/m \rceil}$. An optimal schedule for the longest k tasks can be constructed in $O(km^k)$ time by a straightforward branch-and-bound algorithm. In other words, this algorithm has approximation ratio $1 + \epsilon$ and time complexity $O(n \log m + m^{(m-1-\epsilon m)/\epsilon})$. For any fixed constants m and ϵ, the algorithm constructs in polynomial (linear) time with respect to n a schedule with makespan at most $1 + \epsilon$ times the optimal makespan. Note that for a fixed constant m, the time complexity is polynomial with respect to n, but it is not polynomial with respect to $1/\epsilon$. This was the first algorithm of its kind and later on it was called a *polynomial time approximation scheme*. Chapter 9 discusses different PTASs. Additional PTASs appear in Chapters 42, 45, and 51. The proof techniques presented in Refs. [1,4] are outlined in Chapter 2, and have been extended to apply to other problems. There is an extensive body of literature for approximation algorithms and metaheuristics for scheduling problems. Chapters 44, 45, 46, 47, 73, and 81 discuss interesting approximation algorithms and heuristics for scheduling problems. The recent scheduling handbook [5] is an excellent source for scheduling algorithms, models, and performance analysis.

The development of NP-completeness theory in the early 1970s by Cook [6] and Karp [7] formally introduced the notion that there is a large class of decision problems (the answer to these problems is a simple yes or no) that are computationally equivalent. By this, it is meant that either every problem in this class has a polynomial time algorithm that solves it, or none of them do. Furthermore, this question is the same as the $P = NP$ question, an open problem in computational complexity. This question is to determine whether or not the set of languages recognized in polynomial time by deterministic Turing machines is the same as the set of languages recognized in polynomial time by nondeterministic Turing machines. The conjecture has been that $P \neq NP$, and thus the hardest problems in *NP* cannot be solved in polynomial time. These computationally equivalent problems are called *NP-complete* problems. The scheduling on identical machines problem discussed earlier is an optimization problem. Its corresponding decision problem has its input augmented by an integer value B and the yes-no question is to determine whether or not there is a schedule with makespan at most B. An optimization problem whose corresponding decision problem is NP-complete is called an *NP-hard* problem. Therefore, scheduling tasks on identical machines is an NP-hard problem. The TSP and the Steiner tree problem are also NP-hard problems. The minimum-weight spanning tree problem can be solved in polynomial time and is not an NP-hard problem under the assumption that $P \neq NP$. The next section discusses NP-completeness in more detail. There is a long list of practical problems arising in many different fields of study that are known to be NP-hard problems [8]. Because of this, the need to cope with these computationally intractable problems was recognized earlier on. This is when approximation algorithms became a central area of research activity. Approximation algorithms offered a way to circumvent computational intractability by paying a price when it comes to the quality of the solution generated. But a solution can be generated quickly. In other words and another language, “no te fijes en lo bien, fijate en lo rápido.” Words that my mother used to describe my ability to play golf when I was growing up.

In the early 1970s Garey et al. [9] as well as Johnson [10,11] developed the first set of polynomial time approximation algorithms for the bin packing problem. The analysis of the approximation ratio for these algorithms is asymptotic, which is different from those for the scheduling problems discussed earlier. We will define this notion precisely in the next section, but the idea is that the ratio holds when the optimal solution value is greater than some constant. Research on the bin packing problem and its variants has attracted very talented investigators who have generated more than 650 papers, most of which deal with approximations. This work has been driven by numerous applications in engineering and information sciences (see Chapters 32–35).

Johnson [12] developed polynomial time algorithms for the sum of subsets, max satisfiability, set cover, graph coloring, and max clique problems. The algorithms for the first two problems have a constant ratio approximation, but for the other problems the approximation ratio is ln n and n^{ϵ}. Sahni [13,14] developed a PTAS for the knapsack problem. Rosenkrantz et al. [15] developed several constant ratio approximation algorithms for the TSP. This version of the problem is defined over edge-weighted complete graphs that satisfy the triangle inequality (or simply metric graphs), rather than for points in metric space as in Ref. [3]. These algorithms have an approximation ratio of 2.

Sahni and Gonzalez [16] showed that there were a few NP-hard optimization problems for which the existence of a constant ratio polynomial time approximation algorithm implies the existence of a polynomial time algorithm to generate an optimal solution. In other words, for these problems the complexity of generating a constant ratio approximation and an optimal solution are computationally equivalent problems. For these problems, the approximation problem is NP-hard or simply inapproximable (under the assumption that $P \neq NP$). Later on, this notion was extended to mean that there is no polynomial time algorithm with approximation ratio r for a problem under some complexity theoretic hypothesis. The approximation ratio r is called the *in-approximability ratio*, and r may be a function of the input size (see Chapter 17).

The k-min-cluster problem is one of these inapproximable problems. Given an edge-weighted undirected graph, the k-min-cluster problem is to partition the set of vertices into k sets so as to minimize the sum of the weight of the edges with endpoints in the same set. The k-maxcut problem is defined as the k-min-cluster problem, except that the objective is to maximize the sum of the weight of the edges with endpoints in different sets. Even though these two problems have exactly the same set of feasible and optimal solutions, there is a linear time algorithm for the k-maxcut problem that generates k-cuts with weight at least $\frac{k-1}{k}$ times the weight of an optimal k-cut [16], whereas approximating the k-min-cluster problem is a computationally intractable problem. The former problem has the property that a near-optimal solution may be obtained as long as partial decisions are made optimally, whereas for the k-min-cluster an optimal partial decision may turn out to force a terrible overall solution.

Another interesting problem whose approximation problem is NP-hard is the TSP [16]. This is not exactly the same version of the TSP discussed above, which we said has several constant ratio polynomial time approximation algorithms. Given an edge-weighted undirected graph, the TSP is to find a least weight tour, i.e., find a least weight (simple) path that starts at vertex 1, visits each vertex in the graph *exactly* once, and ends at vertex 1. The weight of a path is the sum of the weight of its edges. The version of the TSP studied in Ref. [15] is limited to metric graphs, i.e., the graph is complete (all the edges are present) and the set of edge weights satisfies the triangle inequality (which means that the weight of the edge joining vertex i and j is less than or equal to the weight of any path from vertex i to vertex j). This version of the TSP is equivalent to the one studied by E. F. Moore [3]. The approximation algorithms given in Refs. [3,15] can be adapted easily to provide a constant-ratio approximation to the version of the TSP where the tour is defined as visiting each vertex in the graph *at least* once. Since Moore’s approximation algorithms for the metric Steiner tree and metric TSP are based on the same idea, one would expect that the Steiner tree problem defined over arbitrarily weighted graphs is NP-hard to approximate. However, this is not the case. Moore’s algorithm [3] can be modified to be a 2-approximation algorithm for this more general Steiner tree problem.

As pointed out in Ref. [17], Levner and Gens [18] added a couple of problems to the list of problems that are NP-hard to approximate. Garey and Johnson [19] showed that the max clique problem has the property that if for some constant r there is a polynomial time r-approximation algorithm, then there is a polynomial time r'-approximation algorithm for any constant r' such that $0 < r' < 1$. Since at that time researchers had considered many different polynomial time algorithms for the clique problem and none had a constant ratio approximation, it was conjectured that none existed, under the assumption that $P \neq NP$. This conjecture has been proved (see Chapter 17).

A PTAS is said to be an FPTAS if its time complexity is polynomial with respect to n (the problem size) and $1/\epsilon$. The first FPTAS was developed by Ibarra and Kim [20] for the knapsack problem. Sahni [21] developed three different techniques based on rounding, interval partitioning, and separation to construct FPTAS for sequencing and scheduling problems. These techniques have been extended to other problems and are discussed in Chapter 10. Horowitz and Sahni [22] developed FPTAS for scheduling on processors with different processing speed. Reference [17] discusses a simple $O(n^3/\epsilon)$ FPTAS for the knapsack problem developed by Babat [23,24]. Lawler [25] developed techniques to speed up FPTAS for the knapsack and related problems. Chapter 10 presents different methodologies to design FPTAS. Garey and Johnson [26] showed that if any problem in a class of NP-hard optimization problems that satisfy certain properties has a FPTAS, then $P = NP$. The properties are that the objective function value of every feasible solution is a positive integer, and the problem is *strongly* NP-hard. Strongly *NP*-hard means that the problem is NP-hard even when the magnitude of the maximum number in the input is bounded by a polynomial on the input length. For example, the TSP is strongly NP-hard, whereas the knapsack problem is not, under the assumption that $P \neq NP$ (see Chapter 10).

Lin and Kernighan [27] developed elaborate heuristics that established experimentally that instances of the TSP with up to 110 cities can be solved to optimality with 95% confidence in $O(n^2)$ time. This was an iterative improvement procedure applied to a set of randomly selected feasible solutions. The process was to perform k pairs of link (edge) interchanges that improved the length of the tour. However, Papadimitriou and Steiglitz [28] showed that for the TSP no local optimum of an efficiently searchable neighborhood can be within a constant factor of the optimum value unless $P = NP$. Since then, there has been quite a bit of research activity in this area. Deterministic and stochastic local search in efficiently searchable as well as in very large neighborhoods are discussed in Chapters 18–21. Chapter 14 discusses issues relating to the empirical evaluation of approximation algorithms and metaheuristics.

Perhaps the best known approximation algorithm is the one by Christofides [29] for the TSP defined over metric graphs. The approximation ratio for this algorithm is $\frac{3}{2}$, which is smaller than the approximation ratio of 2 for the algorithms reported in Refs. [3,15]. However, looking at the bigger picture that includes the time complexity of the approximation algorithms, Christofides algorithm is not of the same order as the ones given in Refs. [3,15]. Therefore, neither set of approximation algorithms dominates the other as one set has a smaller time complexity bound, whereas the other (Christofides algorithm) has a smaller worst-case approximation ratio.

Ausiello et al. [30] introduced the differential ratio, which is another way of measuring the quality of the solutions generated by approximation algorithms. The differential ratio destroys the artificial dissymmetry between "equivalent" minimization and maximization problems (e.g., the k-max cut and the k-min-cluster discussed above) when it comes to approximation. This ratio uses the difference between the worst possible solution and the solution generated by the algorithm, divided by the difference between the worst solution and the best solution. Cornuejols et al. [31] also discussed a variation of the differential ratio approximations. They wanted the ratio to satisfy the following property: "A modification of the data that adds a constant to the objective function value should also leave the error measure unchanged." That is, the "error" by the approximation algorithm should be the same as before. Differential ratio and its extensions are discussed in Chapter 16, along with other similar notions [30]. Ausiello et al. [30] also introduced *reductions that preserve approximability*. Since then, there have been several new types of approximation preserving reductions. The main advantage of these reductions is that they enable us to define large classes of optimization problems that behave in the same way with respect to approximation. Informally, the class of NP-optimization problems, **NPO**, is the set of all optimization problems Π that can be "recognized" in polynomial time (see Chapter 15 for a formal definition). An **NPO** problem Π is said to be in **APX**, if it has a constant approximation ratio polynomial time algorithm. The class **PTAS** consists of all **NPO** problems that have PTAS. The class **FPTAS** is defined similarly. Other classes, **Poly-APX**, **Log-APX**, and **Exp-APX**, have also been defined (see Chapter 15).

One of the main accomplishments at the end of the 1970s was the development of a polynomial time algorithm for linear programming problems by Khachiyan [32]. This result had a tremendous impact on approximation algorithms research, and started a new wave of approximation algorithms. Two subsequent research accomplishments were at least as significant as Khachiyan's [32] result. The first one was a faster polynomial time algorithm for solving linear programming problems developed by Karmakar [33]. The other major accomplishment was the work of Grötschel et al. [34,35]. They showed that it is possible to solve a linear programming problem with an exponential number of constraints (with respect to the number of variables) in time which is polynomial in the number of variables and the number of bits used to describe the input, given a *separation oracle* plus a bounding ball and a lower bound on the volume of the feasible solution space. Given a solution, the separation oracle determines in polynomial time whether or not the solution is feasible, and if it is not it finds a constraint that is violated. Chapter 11 gives an example of the use of this approach. Important developments have taken place during the past 20 years. The books [35,36] are excellent references for linear programming theory, algorithms, and applications.

Because of the above results, the approach of formulating the solution to an NP-hard problem as an integer linear programming problem and then solving the corresponding linear programming problem became very popular. This approach is discussed in Chapter 2. Once a fractional solution is obtained, one uses rounding to obtain a solution to the original NP-hard problem. The rounding may be deterministic or randomized, and it may be very complex (metarounding). LP rounding is discussed in Chapters 2, 4, 6–9, 11, 12, 37, 45, 57, 58, and 70.

Independently, Johnson [12] and Lovász [37] developed efficient algorithms for the set cover with approximation ratio of $1 + \ln d$, where d is the maximum number of elements in each set. Chvátal [38] extended this result to the weighted set cover problem. Subsequently, Hochbaum [39] developed an algorithm with approximation ratio f, where f is the maximum number of sets containing any of the elements in the set. This result is normally inferior to the one by Chvátal [38], but is more attractive for the weighted vertex cover problem, which is a restricted version of the weighted set cover. For this subproblem, it is a 2-approximation algorithm. A few months after Hochbaum's initial result,[1] Bar-Yehuda and Even [40] developed a primal-dual algorithm with the same approximation ratio as the one in [39]. The algorithm in [40] does not require the solution of an LP problem, as in the case of the algorithm in [39], and its time complexity is linear. But it uses linear programming theory. This was the first primal-dual approximation algorithm, though some previous algorithms may also be viewed as falling into this category. An application of the primal-dual approach, as well as related ones, is discussed in Chapter 2. Chapters 4, 37, 39, 40, and 71 discuss several primal-dual approximation algorithms. Chapter 13 discusses "distributed" primal-dual algorithms. These algorithms make decisions by using only "local" information.

In the mid 1980s, Bar-Yehuda and Even [41] developed a new framework parallel to the primal-dual methods. They call it *local ratio*; it is simple and requires no prior knowledge of linear programming. In Chapter 2, we explain the basics of this approach, and recent developments are discussed in [42].

Raghavan and Thompson [43] were the first to apply randomized rounding to relaxations of linear programming problems to generate solutions to the problem being approximated. This field has grown tremendously. LP randomized rounding is discussed in Chapters 2, 4, 6–8, 11, 12, 57, 70, and 80 and deterministic rounding is discussed in Chapters 2, 6, 7, 9, 11, 37, 45, 57, 58, and 70. A disadvantage of LP-rounding is that a linear programming problem needs to be solved. This takes polynomial time with

[1] Here, we are referring to the time when these results appeared as technical reports. Note that from the journal publication dates, the order is reversed. You will find similar patterns throughout the chapters. To add to the confusion, a large number of papers have also been published in conference proceedings. Since it would be very complex to include the dates when the initial technical report and conference proceedings were published, we only include the latest publication date. Please keep this in mind when you read the chapters and, in general, the computer science literature.

respect to the input length, but in this case it means the number of bits needed to represent the input. In contrast, algorithms based on the primal-dual approach are for the most part faster, since they take polynomial time with respect to the number of "objects" in the input. However, the LP-rounding approach can be applied to a much larger class of problems and it is more robust since the technique is more likely to be applicable after changing the objective function or constraints for a problem.

The first APTAS (asymptotic PTAS) was developed by Fernandez de la Vega and Lueker [44] for the bin packing problem. The first AFPTAS (Asymptotic FPTAS) for the same problem was developed by Karmakar and Karp [45]. These approaches are discussed in Chapter 16. Fully polynomial randomized approximation schemes (FPRAS) are discussed in Chapter 12.

In the 1980s, new approximation algorithms were developed as well as PTAS and FPTAS based on different approaches. These results are reported throughout the handbook. One difference was the application of approximation algorithms to other areas of research activity (very large-scale integration (VLSI), bioinformatics, network problems) as well as to other problems in established areas.

In the late 1980s, Papadimitriou and Yannakakis [46] defined *MAXSNP* as a subclass of NPO. These problems can be approximated within a constant factor and have a nice logical characterization. They showed that if MAX3SAT, vertex cover, MAXCUT, and some other problems in the class could be approximated in polynomial time with an arbitrary precision, then all MAXSNP problems have the same property. This fact was established by using *approximation preserving* reductions (see Chapters 15 and 17). In the 1990s, Arora et al. [47], using complex arguments (see Chapter 17), showed that MAX3SAT is hard to approximate within a factor of $1 + \epsilon$ for some $\epsilon > 0$ unless $P = NP$. Thus, all problems in MAXSNP do not admit a PTAS unless $P = NP$. This work led to major developments in the area of approximation algorithms, including inapproximability results for other problems, a bloom of approximation preserving reductions, discovery of new inapproximability classes, and construction of approximation algorithms achieving optimal or near optimal approximation ratios.

Feige et al. [48] showed that the clique problem could not be approximated to within some constant value. Applying the previous result in Ref. [26] showed that the clique problem is inapproximable to within any constant. Feige [49] showed that the set cover is inapproximable within ln n. Other inapproximable results appear in Refs. [50,51]. Chapter 17 discusses all of this work in detail.

There are many other very interesting results that have been published in the past 15 years. Goemans and Williamson [52] developed improved approximation algorithms for the maxcut and satisfiability problems using *semidefinite programming* (SDP). This seminal work opened a new venue for the design of approximation algorithms. Chapter 15 discusses this work as well as recent developments in this area. Goemans and Williamson [53] also developed powerful techniques for designing approximation algorithms based on the primal-dual approach. The dual-fitting and factor revealing approach is used in Ref. [54]. Techniques and extensions of these approaches are discussed in Chapters 4, 13, 37, 39, 40, and 71.

In the past couple of decades, we have seen approximation algorithms being applied to traditional combinatorial optimization problems as well as problems arising in other areas of research activity. These areas include VLSI design automation, networks (wired, sensor and wireless), bioinformatics, game theory, computational geometry, and graph problems. In Section 2, we elaborate further on these applications.

1.2.2 Local Search, Artificial Neural Networks, and Metaheuristics

Local search techniques have a long history; they range from simple constructive and iterative improvement algorithms to rather complex methods that require significant fine-tuning, such as evolutionary algorithms (EAs) or SA. Local search is perhaps one of the most natural ways to attempt to find an optimal or suboptimal solution to an optimization problem. The idea of local search is simple: start from a solution and improve it by making local changes until no further progress is possible. Deterministic local search algorithms are discussed in Chapter 18. Chapter 19 covers stochastic local search algorithms. These are local search algorithms that make use of randomized decisions, for example, in the context of generating initial solutions or when determining search steps. When the neighborhood to search for the next solution is very large, finding the best neighbor to move to is many times an NP-hard problem. Therefore, a suboptimal solution is needed at this step. In Chapter 20, the issues related to very large-scale neighborhood search are discussed from the theoretical, algorithmic, and applications point of view.

Reactive search advocates the use of simple sub symbolic machine learning to automate the parameter tuning process and make it an integral (and fully documented) part of the algorithm. Parameters are normally tuned through a feedback loop that many times depends on the user. Reactive search attempts to mechanize this process. Chapter 21 discusses issues arising during this process.

Artificial neural networks have been proposed as a tool for machine learning and many results have been obtained regarding their application to practical problems in robotics control, vision, pattern recognition, grammatical inferences, and other areas. Once trained, the network will compute an input/output mapping that, if the training data was representative enough, will closely match the unknown rule that produced the original data. Neural networks are discussed in Chapter 22.

The work of Lin and Kernighan [27] as well as that of others sparked the study of modern heuristics, which have evolved and are now called *metaheuristics*. The term metaheuristics was coined by Glover [55] in 1986 and in general means “to find beyond in an upper level.” Metaheuristics include Tabu Search (TS), Simulated Annealing (SA), Ant Colony Optimization, Evolutionary Computation (EC), iterated local search (ILC), and Memetic Algorithms (MA). One of the motivations for the study of metaheuristics is that it was recognized early on that constant ratio polynomial time approximation algorithms are not likely to exist for a large class of practical problems [16]. Metaheuristics do not guarantee that near-optimal solutions will be found quickly for all problem instances. However, these complex programs do find near-optimal solutions for many problem instances that arise in practice. These procedures have a wide range of applicability. This is the most appealing aspect of metaheuristics.

The term Tabu Search (TS) was coined by Glover [55]. TS is based on *adaptive memory* and *responsive exploration*. The former allows for the effective and efficient search of the solution space. The latter is used to guide the search process by imposing restraints and inducements based on the information collected. Intensification and diversification are controlled by the information collected, rather than by a random process. Chapter 23 discusses many different aspects of TS as well as problems to which it has been applied.

In the early 1980s Kirkpatrick et al. [56] and, independently, Černý [57] introduced Simulated Annealing (SA) as a randomized local search algorithm to solve combinatorial optimization problems. *SA* is a local search algorithm, which means that it starts with an initial solution and then searches through the solution space by iteratively generating a new solution that is “near” it. Sometimes, the moves are to a worse solution to escape local optimal solutions. This method is based on statistical mechanics (Metropolis algorithm). It was heavily inspired by an analogy between the physical annealing process of solids and the problem of solving large combinatorial optimization problems. Chapter 25 discusses this approach in detail.

Evolutionary Computation (EC) is a metaphor for building, applying, and studying algorithms based on Darwinian principles of natural selection. Algorithms that are based on evolutionary principles are called *evolutionary algorithms* (EA). They are inspired by nature’s capability to evolve living beings well adapted to their environment. There has been a variety of slightly different EAs proposed over the years. Three different strands of EAs were developed independently of each other over time. These are *evolutionary programming* (EP) introduced by Fogel [58] and Fogel et al. [59], *evolutionary strategies* (ES) proposed by Rechenberg [60], and *genetic algorithms* (GAs) initiated by Holland [61]. GAs are mainly applied to solve discrete problems. *Genetic programming* (GP) and *scatter search* (SS) are more recent members of the EA family. EAs can be understood from a unified point of view with respect to their main components and the way they explore the search space. EC is discussed in Chapter 24.

Chapter 17 presents an overview of Ant Colony Optimization (ACO)—a metaheuristic inspired by the behavior of real ants. ACO was proposed by Dorigo and colleagues [62] in the early 1990s as a method for solving hard combinatorial optimization problems. ACO algorithms may be considered to be part of *swarm intelligence*, the research field that studies algorithms inspired by the observation of the behavior of *swarms*. Swarm intelligence algorithms are made up of simple individuals that cooperate through self-organization.

Memetic Algorithms (MA) were introduced by Moscato [63] in the late 1980s to denote a family of metaheuristics that can be characterized as the hybridization of different algorithmic approaches for a given problem. It is a population-based approach in which a set of cooperating and competing agents are engaged in periods of individual improvement of the solutions while they sporadically interact. An important component is *problem and instance-dependent knowledge*, which is used to speed-up the search process. A complete description is given in Chapter 27.

1.2.3 Sensitivity Analysis, Multiobjective Optimization, and Stability

Chapter 30 covers *sensitivity analysis*, which has been around for more than 40 years. The aim is to study how variations affect the optimal solution value. In particular, parametric analysis studies problems whose structure is fixed, but where cost coefficients vary continuously as a function of one or more parameters. This is important when selecting the model parameters in optimization problems. In contrast, Chapter 31 considers a newer area, which is called *stability*. By this we mean how the complexity of a problem depends on a parameter whose variation alters the space of allowable instances.

Chapters 28 and 29 discuss *multiobjective combinatorial optimization*. This is important in practice since quite often a decision is rarely made with only one criterion. There are many examples of such applications in the areas of transportation, communication, biology, finance, and also computer science. Approximation algorithms and a FPTAS for multiobjective optimization problems are discussed in Chapter 28. Chapter 29 covers stochastic local search algorithms for multiobjective optimization problems.

1.3 Definitions and Notation

One can use many different criteria to judge approximation algorithms and heuristics. For example the quality of solution generated, and the time and space complexity needed to generate it. One may measure the criteria in different ways, e.g., we could use the worst case, average case, median case, etc. The evaluation could be analytical or experimental. Additional criteria include characterization of data sets where the algorithm performs very well or very poorly; comparison with other algorithms using benchmarks or data sets arising in practice; tightness of bounds (for quality of solution, time and space complexity); the value of the constants associated with the time complexity bound including the ones for the lower order terms; and so on. For some researchers, the most important aspect of an approximation algorithm is that it is complex to analyze, but for others it is more important that the algorithm be complex and involve the use of sophisticated data structures. For researchers working on problems directly applicable to the "real world," experimental evaluation or evaluation on benchmarks is a more important criterion. Clearly, there is a wide variety of criteria one can use to evaluate approximation algorithms. The chapters in this handbook use different criteria to evaluate approximation algorithms.

For any given optimization problem P, let $A_1, A_2, \ldots$ be the set of current algorithms that generate a feasible solution for each instance of problem P. Suppose that we select a set of criteria C and a way to measure it that we feel is the most important. How can we decide which algorithm is best for problem P with respect to C? We may visualize every algorithm as a point in multidimensional space. Now, the approach used to compare feasible solutions for multiobjective function problems (see Chapters 28 and 29) can also be used in this case to label some of the algorithms as current Pareto optimal with respect to C. Algorithm A is said to be *dominated* by algorithm B with respect to C, if for each criterion $c \in C$ algorithm B is "not worse" than A, and for at least one criterion $c \in C$ algorithm B is "better" than A. An algorithm is said to be a *current Pareto optimal* algorithm with respect to C if none of the current algorithms dominates it.

In the next subsections, we define time and space complexity, NP-completeness, and different ways to measure the quality of the solutions generated by the algorithms.

1.3.1 Time and Space Complexity

There are many different ways one can use to judge algorithms. The main ones we use are the time and space required to solve the problem. This can be expressed in terms on n, the input size. It can be evaluated empirically or analytically. For the analytical evaluation, we use the time and space complexity of the algorithm. Informally, this is a way to express the time the algorithm takes to solve a problem of size n and the amount of space needed to run the algorithm.

It is clear that almost all algorithms take different time to execute with different data sets even when the input size is the same. If you code it and run it on a computer you will see more variation depending on the different hardware and software installed in the system. It is impossible to characterize exactly the time and space required by an algorithm. We need a short cut. The approach that has been taken is to count the number of "operations" performed by the algorithm in terms of the input size. "Operations" is not an exact term and refers to a set of "instructions" whose number is independent of the problem size. Then we just need to count the total number of operations.

Counting the number of operations exactly is very complex for a large number of algorithms. So we just take into consideration the "highest"-order term. This is the O notation.

Big "oh" notation: A (positive) function $f(n)$ is said to be $O(g(n))$ if there exist two constants $c \geq 1$ and $n_0 \geq 1$ such that $f(n) \leq c \cdot g(n)$ for all $n \geq n_0$.

The function $g(n)$ is the highest-order term. For example, if $f(n) = n^3 + 20n^2$, then $g(n) = n^3$. Setting $n_0 = 1$ and $c = 21$ shows that $f(n)$ is $O(n^3)$. Note that $f(n)$ is also $O(n^4)$, but we like $g(n)$ to be the function with the smallest possible growth. The function $f(n)$ cannot be $O(n^2)$ because it is impossible to find constants c and n_0 such that $n^3 + 20n^2 \leq cn^2$ for all $n \geq n_0$.

The time and space complexity of an algorithm is expressed in the O notation and describes their growth rate in terms of the problem size. Normally, the problem size is the number of vertices and edges in a graph, the number of tasks and machines in a scheduling problem, etc. But it can also be the number of bits used to represent the input.

When comparing two algorithms expressed in O notation, we have to be careful because the constants c and n_0 are hidden. For large n, the algorithm with the smallest growth rate is the better one. When two algorithms have similar constants c and n_0, the algorithm with the smallest growth function has a smaller running time. The book [2] discusses in detail the O notation as well as other notation.

1.3.2 NP-Completeness

Before the 1970s, researchers were aware that some problems could be computationally solved by algorithms with (low) polynomial time complexity ($O(n)$, $O(n^2)$, $O(n^3)$, etc.), whereas other problems had exponential time complexity, for example, $O(2^n)$ and $O(n!)$. It was clear that even for small values of n, exponential time complexity equates to computational intractability if the algorithm actually performs an exponential number of operations for some inputs. The convention of computational tractability being equated to polynomial time complexity does not really fit well, as an algorithm with time complexity $O(n^{100})$ is not really tractable if it actually performs n^{100} operations. But even under this relaxation of "tractability," there is a large class of problems that does not seem to have computationally tractable algorithms.

We have been discussing optimization problems. But NP-completeness is defined with respect to decision problems. A decision problem is simply one whose answer is "yes" or "no." The scheduling on identical machines problems discussed earlier is an optimization problem. Its corresponding decision problem has its input augmented by an integer value B and the yes-no question is to determine whether or not there is a schedule with makespan at most B. Every optimization problem has a corresponding decision problem. Since the solution of an optimization problem can be used directly to solve the decision problem, we say that the optimization problem is at least as hard to solve as the decision problem. If we show that the decision problem is a computationally intractable problem, then the corresponding optimization problem is also intractable.

The development of NP-completeness theory in the early 1970s by Cook [6] and Karp [7] formally introduced the notion that there is a large class of decision problems that are computationally equivalent. By this we mean that either every problem in this class has a polynomial time algorithm that solves it, or none of them do. Furthermore, this question is the same as the $P = NP$ question, an open problem in computational complexity. This question is to determine whether or not the set of languages recognized in polynomial time by deterministic Turing machines is the same as the set of languages recognized in polynomial time by nondeterministic Turing machines. The conjecture has been that $P \neq NP$, and thus the problems in this class do not have polynomial time algorithms for their solution. The decision problems in this class of problems are called *NP-complete* problems. Optimization problems whose corresponding decision problems are NP-complete are called *NP-hard* problems.

Scheduling tasks on identical machines is an NP-hard problem. The TSP and Steiner tree problem are also NP-hard problems. The minimum-weight spanning tree problem can be solved in polynomial and it is not an NP-hard problem, under the assumption that $P \neq NP$. There is a long list of practical problems arising in many different fields of study that are known to be NP-hard problems. In fact, almost all the optimization problems discussed in this handbook are NP-hard problems. The book [8] is an excellent source of information for NP-complete and NP-hard problems.

One establishes that a problem Q is an NP-complete problem by showing that the problem is in NP and giving a polynomial time transformation from an NP-complete problem to the problem Q.

A problem is said to be in *NP* if one can show that a yes answer to it can be verified in polynomial time. For the scheduling problem defined above, you may think of this as providing a procedure that given any instance of the problem and an assignment of tasks to machines, the algorithm verifies in polynomial time, with respect to the problem instance size, that the assignment is a schedule and its makespan is at most B. This is equivalent to the task a grader does when grading a question of the form "Does the following instance of the scheduling problem have a schedule with makespan at most 300? If so, give a schedule." Just verifying that the "answer" is correct is a simple problem. But solving a problem instance with 10,000 tasks and 20 machines seems much harder than simply grading it. In our oversimplification, it seems that $P \neq NP$. Polynomial time verification of a yes answer does not seem to imply polynomial time solvability.

A polynomial time transformation from decision problem P_1 to decision problem P_2 is an algorithm that takes as input any instance I of problem P_1 and constructs an instance $f(I)$ of P_2. The algorithm must take polynomial time with respect to the size of the instance I. The transformation must be such that $f(I)$ is a yes-instance of P_2 if, and only if, I is a yes-instance of P_1.

The implication of a polynomial transformation $P_1 \alpha P_2$ is that if P_2 can be solved in polynomial time, then so can P_1, and if P_1 cannot be solved in polynomial time, then P_2 cannot be solved in polynomial time.

Consider the partition problem. We are given n items $1, 2, \ldots, n$. Item j has size $s(j)$. The problem is to determine whether or not the set of items can be partitioned into two sets such that the sum of the size of the items in one set equals the sum of the size of the items in the other set. Now let us polynomially transform the partition problem to the decision version of the identical machines scheduling problem. Given any instance I of partition, we define the instance $f(I)$ as follows. There are n tasks and $m = 2$ machines. Task i represents item i and its processing time is $s(i)$. All the tasks are independent and $B = \sum_{i=1}^{i=n} s(i)/2$. Clearly, $f(I)$ has a schedule with maskespan B iff the instance I has a partition.

A decision problem is said to be *strongly NP-complete* if the problem is NP-complete even when all the "numbers" in the problem instance are less than or equal to $p(n)$, where p is a polynomial and n is the "size" of the problem instance. Partition is not NP-complete in the strong sense (under the assumption that $P \neq NP$) because there is a polynomial time dynamic programming algorithm to solve this problem when $\sum s(i) \leq p(n)$ (see Chapter 10). An excellent source for NP-completeness information is the book by Garey and Johnson [8].

1.3.3 Performance Evaluation of Algorithms

The main criterion used to compare approximation algorithms has been the quality of the solution generated. Let us consider different ways to compare the quality of the solutions generated when measuring the worst case. That is the main criterion discussed in Section 1.2.

For some problems, it is very hard to judge the quality of the solution generated. For example, approximating colors, can only be judged by viewing the resulting images and that is subjective (see Chapter 86). Chapter 85 covers digital reputation schemes. Here again, it is difficult to judge the quality of the solution generated. Problems in the application areas of bioinformatics and VLSI fall into this category because, in general, these are problems with multiobjective functions.

In what follows, we concentrate on problems where it is possible to judge the quality of the solution generated. At this point, we need to introduce additional notation. Let P be an optimization problem and let A be an algorithm that generates a feasible solution for every instance I of problem P. We use $\hat{f}_A(I)$ to denote the objective function value of the solution generated by algorithm A for instance I. We drop A and use $\hat{f}(I)$ when it is clear which algorithm is being used. Let $f^*(I)$ be the objective function value of an optimal solution for instance I. Note that normally we do not know the value of $f^*(I)$ exactly, but we have bounds that should be as tight as possible.

Let G be an undirected graph that represents a set of cities (vertices) and roads (edges) between a pair of cities. Every edge has a positive number called the weight (or cost) and represents the cost of driving (gas plus tolls) between the pair of cities it joins. A *shortest path* from vertex s to vertex t in G is an st-path (path from s to t) such that the sum of the weight of the edges in it is the "'least possible among all possible st-paths." There are well-known algorithms that solve this shortest-path problem in polynomial time [2]. Let A be an algorithm that generates a feasible solution (st-path) for every instance I of problem P. If for every instance I, algorithm A generates an st-path such that

$$\hat{f}(I) \leq f^*(I) + c$$

where c is some fixed constant, then A is said to be an *absolute* approximation algorithm for problem P with (additive) approximation bound c. Ideally, we would like to design a linear (or at least polynomial) time approximation algorithm with the smallest possible approximation bound. It is not difficult to see that this is not a good way of measuring the quality of a solution. Suppose that we have a graph G and we are running an absolute approximation algorithm for the shortest path problem concurrently in two different countries with the edge weight expressed in the local currency. Furthermore, assume that there is a large exchange rate between the two currencies. Any approximation algorithm solving the weak currency instance will have a much harder time finding a solution within the bound of c, than when solving the strong currency instance. We can take this to the extreme. We now claim that the above absolute approximation algorithm A can be used to generate an optimal solution for every problem instance within the same time complexity bound.

The argument is simple. Given any instance I of the shortest-path problem, we construct an instance I_{c+1} using the same graph, but every edge weight is multiplied by $c + 1$. Clearly, $f^*(I_{c+1}) = (c + 1) f^*(I)$. The st-path for I_{c+1} constructed by the algorithm is also an st-path in I with weight $\hat{f}(I) = \hat{f}(I_{c+1})/(c + 1)$. Since $\hat{f}(I_{c+1}) \leq f^*(I_{c+1}) + c$, then by substituting the above bounds we know that

$$\hat{f}(I) = \frac{\hat{f}(I_{c+1})}{(c+1)} \leq \frac{f^*(I_{c+1})}{c+1} + \frac{c}{c+1} = f^*(I) + \frac{c}{c+1}$$

Since all the edges have integer weights, it then follows that the algorithm solves the problem optimally. In other words, for the shortest path problem any algorithm that generates a solution with (additive) approximation bound c can be used to generate an optimal solution within the same time complexity bound. This same property can be established for almost all NP-hard optimization problems. Because of this, the use of absolute approximation has never been given a serious consideration.

Sahni [14] defines as an ϵ-approximation algorithm for problem P an algorithm that generates a feasible solution for every problem instance I of P such that

$$|\frac{\hat{f}(I) - f^*(I)}{f^*(I)}| \leq \epsilon$$

It is assumed that $f^*(I) > 0$. For a minimization problem, $\epsilon > 0$ and for a maximization problem, $0 < \epsilon < 1$. In both cases, ϵ represents the percentage of error. The algorithm is called an ϵ-approximation algorithm and the solution is said to be an ϵ-approximate solution. Graham's list scheduling algorithm [1] is a $1-1/n$-approximation algorithm, and Sahni and Gonzalez [16] algorithm for the k-maxcut problem is a $\frac{1}{k}$-approximation algorithm (see Section 1.2). Note that this notation is different from the one discussed in Section 1.2. The difference is 1 unit, i.e., the ϵ in this notation corresponds to $1+\epsilon$ in the other.

Johnson [12] used a slightly different, but equivalent notation. He uses the approximation ratio ρ to mean that for every problem instance I of P, the algorithm satisfies $\frac{\hat{f}(I)}{f^*(I)} \leq \rho$ for minimization problems, and $\frac{f^*(I)}{\hat{f}(I)} \leq \rho$ for maximization problems. The one for minimization problems is the same as the one given in Ref. [1]. The value for ρ is always greater than 1, and the closer to 1, the better the solution generated by the algorithm. One refers to ρ as the *approximation ratio* and the algorithm is a ρ-approximation algorithm. The list scheduling algorithm in the previous section is a $(2-\frac{1}{m})$-approximation algorithm and the algorithm for the k-maxcut problem is a $(\frac{k}{k-1})$-approximation algorithm. Sometimes, $1/\rho$ is used as the approximation ratio for maximization problems. Using this notation, the algorithm for the k-maxcut problem in the previous section is a $1-\frac{1}{k}$-approximation algorithm.

All the above forms are in use today. The most popular ones are ρ for minimization and $1/\rho$ for maximization. These are referred to as approximation ratios or approximation factors. We refer to all these algorithms as ϵ-approximation algorithms. The point to remember is that one needs to be aware of the differences and be alert when reading the literature. In the above discussion, we make ϵ and ρ look as if they are fixed constants. But, they can be made dependent on the size of the problem instance I. For example, it may be $\ln n$, or n^{ϵ} for some problems, where n is some parameter of the problem that depends on I, e.g., the number of nodes in the input graph, and ϵ depends on the algorithm being used to generate the solutions.

Normally, one prefers an algorithm with a smaller approximation ratio. However, it is not always the case that an algorithm with smaller approximation ratio always generates solutions closer to optimal than one with a larger approximation ratio. The main reason is that the notation is for the worst-case ratio and the worst case does not always occur. But there are other reasons too. For example, the bound for the optimal solution value used in the analysis of two different algorithms may be different. Let P be the shortest-path minimization problem and let A be an algorithm with approximation ratio 2. In this case, we use d as the lower bound for $f^*(I)$, where d is some parameter of the problem instance. Algorithm B is a 1.5-approximation algorithm, but $f^*(I)$ used to establish it is the exact optimal solution value. Suppose that for problem instance I the value of d is 5 and $f^*(I) = 8$. Algorithm A will generate a path with weight at most 10, whereas algorithm B will generate one with weight at most $1.5 \times 8 = 12$. So the solution generated by Algorithm B may be worse than the one generated by A even if both algorithms generate the worst values for the instance. One can argue that the average "error" makes more sense than worst case. The problem is how to define and establish bounds for average "error." There are many other pitfalls when using worst-case ratios. It is important to keep all this in mind when making comparisons between algorithms. In practice, one may run several different approximation algorithms concurrently and output the best of the solutions. This has the disadvantage that the running time of this compound algorithm will be the one for the slowest algorithm.

There are a few problems for which the worst-case approximation ratio applies only to problem instances where the value of the optimal solution is small. One such problem is the bin packing problem discussed in Section 1.2. Informally, ρ_A^{∞} is the smallest constant such that there exists a constant $K < \infty$ for which

$$\hat{f}(I) \leq \rho_A^{\infty} f^*(I) + K$$

The *asymptotic approximation ratio* is the multiplicative constant and it hides the additive constant K. This is most useful when K is small. Chapter 32 discusses this notation formally. The asymptotic notation is mainly used for bin packing and some of its variants.

Ausiello et al. [30] introduced the *differential ratio*. Informally, an algorithm is said to be a δ differential ratio approximation algorithm if for every instance I of P

$$\frac{\omega(I) - \hat{f}(I)}{\omega(I) - f^*(I)} \leq \delta$$

where $\omega(I)$ is the value of a worst solution for instance I. Differential ratio has some interesting properties for the complexity of the approximation problems. Chapter 16 discusses differential ratio approximation and its variations.

As said earlier, there are many different criteria to compare algorithms. What if we use both the approximation ratio and time complexity? For example, the approximation algorithms in Ref. [15] and the one in Ref. [29] are current Pareto optimal with respect to these criteria for the TSP defined over metric graphs. Neither of the algorithms dominates the others in both time complexity and approximation ratio. The same can be said about the simple linear time approximation algorithm for the k-maxcut problem in Ref. [16] and the complex one given in Ref. [52] or the more recent ones that apply for all k.

The best algorithm to use also depends on the instance being solved. It makes a difference whether we are dealing with an instance of the TSP with optimal tour cost equal to a billion dollars and one with optimal cost equal to just a few pennies. Though, it also depends on the number of such instances being solved.

More elaborate approximation algorithms have been developed that generate a solution for any fixed constant ϵ. Formally, a PTAS for problem P is an algorithm A that given any fixed constant $\epsilon > 0$, it constructs a solution to problem P such that $|\frac{\hat{f}(I) - f^*(I)}{f^*(I)}| \leq \epsilon$ in polynomial time with respect to the length of the instance I. Note that the time complexity may be exponential with respect to $1/\epsilon$. For example, the time complexity could be $O(n^{(1/\epsilon)})$ or $O(n + 4^{O(1/\epsilon)})$. Equivalent PTAS are also defined using different notation, for example, based on $\frac{\hat{f}(I)}{f^*(I)} \leq 1 + \epsilon$ for minimization problems.

One would like to design PTAS for all problems, but that is not possible unless $P = NP$. Clearly, with respect to approximation ratios, the PTAS is better than the ϵ-approximation algorithms for some ϵ. But their main drawback is that they are not practical because the time complexity is exponential on $1/\epsilon$. This does not preclude the existence of a practical PTAS for "natural" occurring problems. However, a PTAS establishes that a problem can be approximated for all fixed constants. Different types of PTAS are discussed in Chapter 9. Additional PTAS are presented in Chapters 42, 45, and 51.

A PTAS is said to be an FPTAS if its time complexity is polynomial with respect to n (the problem size) and $1/\epsilon$. FPTAS are for the most part practical algorithms. Different methodologies for designing FPTAS are discussed in Chapter 10.

Approximation schemes based on asymptotic approximation and on randomized algorithms have been developed. Chapters 11 and 45 discuss asymptotic approximation schemes and Chapter 12 discusses randomized approximation schemes.

Basic Methodologies and Applications

Teofilo F. Gonzalez
University of California, Santa Barbara

2.1 Introduction

In Chapter 1 we presented an overview of approximation algorithms and metaheuristics. This serves as an overview of Parts I, II, and III of this handbook. In this chapter we discuss in more detail the basic methodologies and apply them to simple problems. These methodologies are restriction, greedy methods, LP rounding (deterministic and randomized), α vector, local ratio and primal dual. We also discuss in more detail inapproximability and show that the "classical" version of the traveling salesperson problem (TSP) is constant ratio inapproximable. In the last three sections we present an overview of the application chapters in Parts IV, V, and VI of the handbook.

2.2 Restriction

Chapter 3 discusses *restriction* which is one of the most basic techniques to design approximation algorithms. The idea is to generate a solution to a given problem P by providing an optimal or suboptimal solution to a subproblem of P. A subproblem of a problem P means restricting the solution space for P by disallowing a subset of the feasible solutions. The idea is to restrict the solution space so that it has some structure, which can be exploited by an efficient algorithm that solves the problem optimally or suboptimally. For this approach to be effective the subproblem must have the property that, for every problem instance, its optimal or suboptimal solution has an objective function value that is "close" to the optimal one for P. The most common approach is to solve just one subproblem, but there are algorithms where more than one subproblem is solved and then the best of the solutions computed is the solution generated. Chapter 3 discusses this methodology and shows how to apply it to several problems. Approximation algorithms based on this approach are discussed in Chapters 35, 36, 42, 45, 46, 54, and 73. Let us now discuss a scheduling application in detail. This is the scheduling problem studied by Graham [1,2].

2.2.1 Scheduling

A set of n tasks denoted by $T_1, T_2, \ldots, T_n$ with processing time requirements $t_1, t_2, \ldots, t_n$ have to be processed by a set of m identical machines. A partial order C is defined over the set of tasks to enforce a set of precedence constraints or task dependencies. The partial order specifies that a machine cannot commence the processing of a task until all of its predecessors have been completed. Each task T_i has to be processed for t_i units of time by one of the machines. A (nonpreemptive) schedule is an assignment of tasks to time intervals on the machines in such a way that (1) each task T_i is processed continuously for t_i units of time by one of the machines; (2) each machine processes at most one task at a time; and (3) the precedence constraints are satisfied. The *makespan* of a schedule is the latest time at which a task is being processed. The scheduling problem discussed in this section is to construct a minimum makespan schedule for a set of partially ordered tasks to be processed by a set of identical machines. Several limited versions of this scheduling problem has been shown to be NP-hard [3].

Example 2.1

The number of tasks, n, is 8 and the number of machines, m, is 3. The processing time requirements for the tasks, and the precedence constraints are given in Figure 2.1, where a directed graph is used to represent the task dependencies. Vertices represent tasks and the directed edges represent task dependencies. The integers next to the vertices represent the task processing requirements. Figure 2.2 depicts two schedules for this problem instance.

In the next subsection, we present a simple algorithm based on restriction to generate provable good solutions to this scheduling problem. The solution space is restricted to schedules without forced "idle time," i.e., each feasible schedule does not have idle time from the time at which all the predecessors of task T_i (in C) are completed to the time when the processing of task T_i begins, for each i.

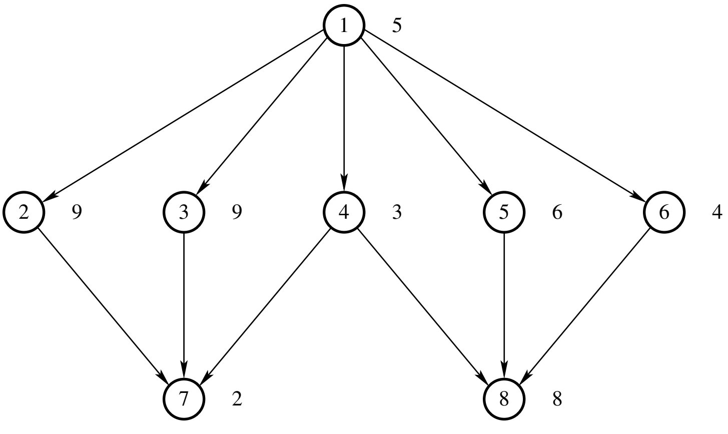

FIGURE 2.1 Precedence constraints and processing time requirements for Example 2.1.

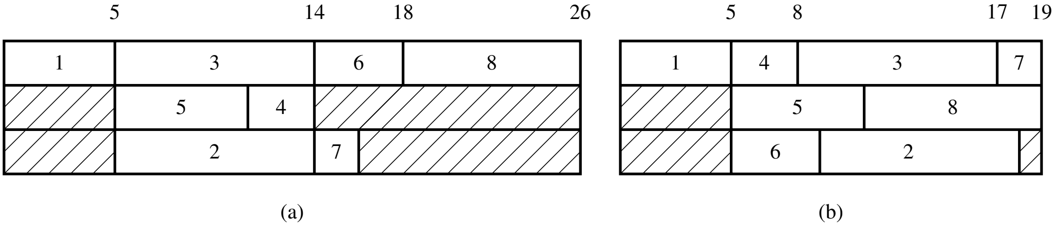

FIGURE 2.2 (a) and (b) represent two different AAT schedules for Example 2.1. Schedule (b) is a minimum makespan schedule.

2.2.2 Partially Ordered Tasks

Let us further restrict the scheduling policy to construct a schedule from time zero till all the tasks have been assigned. The scheduling policy is: whenever a machine becomes idle we assign one of the unassigned tasks that is ready to commence execution, i.e., we have completed all its predecessors. Any scheduling policy in this category can be referred to as a *no-additional-delay* scheduling policy. The simplest version of this scheduling policy is to assign any of the tasks (AAT) ready to be processed. A schedule generated by this policy is called an AAT schedule. These schedules are like the list schedules [1] discussed in Chapter 1. The difference is that list schedules have an ordered list of tasks, which is used to break ties. The analysis for both types of algorithms is the same since the list could be any list.

In Figure 2.2 we give two possible AAT schedules. The two schedules were obtained by breaking ties differently. The schedule in Figure 2.2(b) is a minimum makespan schedule. The reason for this is that the machines can only process one of the tasks T_1, T_5, or T_8 at a time, because of the precedence constraints.

Figure 2.2 suggests that an optimal schedule can be generated by just finding a clever method to break ties. Unfortunately, one cannot prove that this is always the case because there are problem instances for which all minimum makespan schedules are not AAT schedules.

The makespan of an AAT schedule is never greater than $2 - \frac{1}{m}$ times the one of an optimal schedule for the instance. This is expressed by

$$\frac{\hat{f}_I}{f_I^*} \leq 2 - \frac{1}{m}$$

where $\hat{f}_I$ is the makespan of any possible AAT schedule for problem instance I and f_I^* is the makespan of an optimal schedule for I. We establish this property in the following theorem:

Theorem 2.1

For every instance I of the identical machine scheduling problem, and every AAT schedule, $\frac{\hat{f}_I}{f_I^*} \leq 2 - \frac{1}{m}$.

Proof

Let S be any AAT schedule for problem instance I with makespan $\hat{f}_I$. By construction of the AAT schedules it cannot be that at some time $0 \leq t \leq \hat{f}_I$ all machines are idle. Let i_1 be the index of a task that finishes at time $\hat{f}_I$. For $j = 2, 3, \ldots,$ if task $T_{i_{j-1}}$ has at least one predecessor in C, then define i_j as the index of a task with latest finishing time that is a predecessor (in C) of task $T_{i_{j-1}}$. We call these tasks a *chain* and let k be the number of tasks in the chain. By the definition of task T_{i_j}, it cannot be that there is an idle machine from the time when task T_{i_j} completes its processing to the time when task $T_{i_{j-1}}$ begins processing. Therefore, a machine can only be idle when another machine is executing a task in the chain. From these two observations we know that

$$m\hat{f}_I \leq (m-1)\sum_{j=1}^{k} t_{i_j} + \sum_{j=1}^{n} t_j$$

Since no machine can process more than one task at a time, and since not two tasks, one of which precedes the other in C, can be processed concurrently, we know that an optimal makespan schedule satisfies

$$f_I^* \geq \frac{1}{m}\sum_{j=1}^{n} t_j \quad \text{and} \quad f_I^* \geq \sum_{j=1}^{k} t_{i_j}$$

Substituting in the above inequality, we know that $\frac{\hat{f}_I}{f_I^*} \leq 2 - \frac{1}{m}$. □

The natural question to ask is whether or not the approximation ratio $2 - \frac{1}{m}$ is the best possible for AAT schedules. The answer to this question is affirmative, and a problem instance for which this bound is tight is given in Example 2.2.

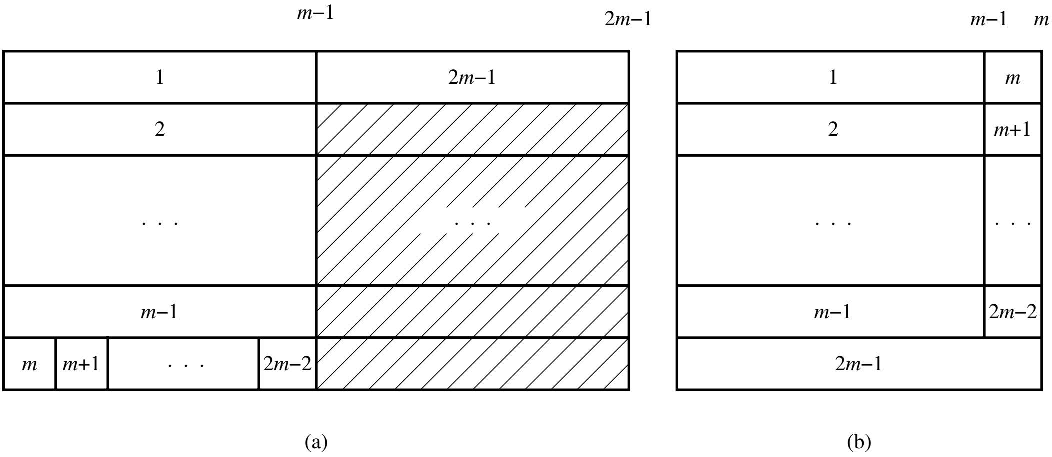

FIGURE 2.3 (a) AAT schedule. (b) Optimal schedule for Example 2.2.

Example 2.2

There are $2m - 1$ independent tasks. The first $m - 1$ tasks have processing time requirement $m - 1$, the next $m - 1$ tasks have processing time requirement one, and the last task has processing time requirement equal to m. An AAT schedule with makespan $2m - 1$ is given in Figure 2.3(a), and in Figure 2.3(b) we give a minimum makespan schedule.

Note that these results also hold for the list schedules [1] defined in Chapter 1. These type of schedules are generated by a no-additional-delay scheduling rule that is augmented by a list that is used to decide which of the ready-to-process tasks is the one to be assigned next.

Let us now consider the case when ties (among tasks that are ready) are broken in favor of the task with smallest index (T_i is selected before T_j if both tasks are ready to be processed and $i < j$). The problem instance I_A given in Figure 2.4 has three machines and eight tasks. Our scheduling procedure (augmented with a tie-breaking list) generates a schedule with makespan 14. In Chapter 1, we say that list schedules (which are this type of schedules) have anomalies. To verify this, apply the scheduling algorithm to instance I_A, but now there are four machines. One would expect a schedule for this new instance to have makespan at most 14, but you can easily verify that this is not the case. Now apply the scheduling algorithm to the instance I_A where every task has a processing requirement decreased by one unit. One would expect a schedule for this new instance to have makespan at most 14, but you can easily verify that is not the case. Apply the scheduling algorithm to the problem instance I_A without the precedence constraints from task

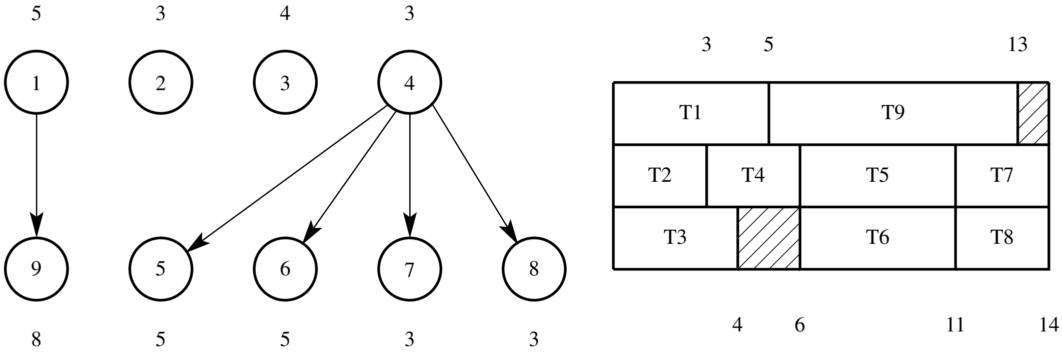

FIGURE 2.4 (a) Problem instance with anomalous behavior. (b) AAT schedule with tie-breaking list.

4 to 5 and task 4 to 6. One would expect a schedule for this instance to have makespan at most 14, but that is not the case. These are anomalies. Approximation algorithms suffer from this type of anomalous behavior. We need to be aware of this fact when using approximation algorithms.

As in the case of Example 2.2, the worst case behavior arises when the task with longest processing time is being processed while the rest of the machines are idle. Can a better approximation bound be established for the case when ties are broken in favor of a task with longest processing time (LPT)? The schedules generated by this rule are called *LPT schedules.* Any LPT schedule for the problem instance in Figure 2.3 is optimal. Unfortunately, this is not always the case and the approximation ratio in general is the same as the one for the AAT schedules. To see this just partition task $2m-1$ in Example 2.2 (see Figure 2.3[a]) into a two-task chain. The first one has processing requirement of ϵ, for some $0 < \epsilon < 1$, and the second one $m-\epsilon$. The schedule generated by the LPT rule will schedule first all the tasks with processing requirement greater than 1 and then the two tasks in the chain.

The problem with the LPT rule is that it only considers the processing requirements of the tasks ready to process, but ignores the processing requirements of the tasks that follow it. We define the *weight of a directed path* as the sum of the processing time requirements of the tasks in the path. Any directed path that starts at task t with maximum weight among all paths that start at task t is called a *critical path for task t.* The critical-path (CP) schedule is defined as a no-additional-delay schedule where the decision of which task to process next is a task whose CP weight is largest among the ready-to-be processed tasks. The CP schedule is optimal for the problem instance that was generated by replacing the last task in Example 2.2 by two tasks. However, Graham constructed problem instances for which the makespan of the CP schedule is $2 - 1/m$ times the length of an optimal schedule.

It is not known whether or not a polynomial-time algorithm exists with a smaller approximation ratio even when the processing time requirements for all the tasks are identical and $m \geq 3$. There is a polynomial-time algorithm that generates an optimal schedule when $m = 2$, but the problem with different task processing times is NP-hard. In the next subsection we present an algorithm with a smaller approximation ratio for scheduling independent task.

2.3 Greedy Methods

Another way to generate suboptimal solutions is to apply greedy algorithms. The idea is to generate a solution by making a sequence of irrevocable decisions. Each of these decisions is a best possible choice at that point, for example, select an edge of least weight, select the vertex of highest degree, or select the task with longest processing time. Chapter 4 discusses greedy methods. The discussion also includes primal-dual approximation algorithms falling into this category. Chapter 5 discusses the recursive greedy method. This methodology is for the case when making the best possible decision is an NP-hard problem. A large portion of the bin packing algorithms are greedy algorithms. Bin packing and its variants are discussed in Chapters 32–35. Other greedy methods appear in Chapters 36, 38, 39, 44–46, 49, 50, 58, 59, and 69. Let us now discuss the LPT scheduling rule for scheduling independent tasks on identical machines.

2.3.1 Independent Tasks

Another version of this scheduling problem that has received considerable attention is when the tasks are independent, i.e., the partial order between the tasks is empty. Graham's [2] elegant analysis for LPT scheduling has become a classic. In fact, the analysis of quite a few subsequent exact and approximation scheduling algorithms follow the same approach.

First, we analyze the LPT scheduling rule. For this case there is only one possible schedule, modulo the relabeling of the tasks. We call this a "greedy method" because of the ordering of the tasks with respect to their processing requirements. This tends to generate schedules where the shortest tasks end up being processed last and the resulting schedules tend to have near-optimal makespan. However as we shall see, one may obtain the same approximation ratio by just scheduling the tasks using a list where the $2m$ task with longest processing time appear first (in sorted order) and the remaining tasks appear next in any order. This approach could be called "limited greedy." We discuss other approximation algorithms for this problem after presenting the analysis for LPT schedules.

Let I be any problem instance with n independent tasks and m identical machines. We use $\hat{f}_I$, as the makespan for the LPT schedule for I and f_I^* as the one for an optimal schedule. In the next theorem we establish the approximation ratio for LPT schedules.

Theorem 2.2

For every scheduling problem instance I with n independent tasks and m identical machines, every LPT schedule satisfies $\frac{\hat{f}_I}{f_I^*} \leq \frac{4}{3} - \frac{1}{3m}$.

Proof

It is clear that LPT schedules are optimal for $m = 1$. Assume that $m \geq 2$. The proof is by contradiction. Suppose the above bound does not hold. Let I be a problem instance with the least number of tasks for which $\frac{\hat{f}_I}{f_I^*} > \frac{4}{3} - \frac{1}{3m}$. Let n the number of tasks in I, m the number of machines, and assume that $t_1 \geq t_2 \geq \cdots \geq t_n$. Let k be the smallest index of a task that finishes at time $\hat{f}_I$. It cannot be that $k < n$, as otherwise the problem instance $T_1, T_2, \ldots, T_k$ is also a counterexample and it has fewer tasks than instance I, but by assumption problem instance I is a counterexample with the least number of tasks. Therefore, k must be equal to n.

By the definition of LPT schedules, we know that there cannot be idle time before task T_n begins execution. Therefore,

$$\sum_{i=1}^{n} t_i + (m-1)t_n \geq m\hat{f}_I$$

This is equivalent to

$$\hat{f}_I \leq \frac{1}{m}\sum_{i=1}^{n} t_i + \left(1 - \frac{1}{m}\right)t_n$$

Since each machine cannot process more than one task at a time, we know that $f_I^* \geq \sum_{i=1}^{n} t_i/m$. Combining these two bounds we have

$$\frac{\hat{f}_I}{f_I^*} \leq 1 + \left(1 - \frac{1}{m}\right)\frac{t_n}{f_I^*}$$

Since I is a counterexample for the theorem, this bound must be greater than $\frac{4}{3} - \frac{1}{3m}$. Simplifying we know that $f_I^* < 3t_n$. Since t_n is the task with smallest processing time requirement it must be that in an optimal schedule, for instance, I none of the machines can process three or more tasks. Therefore, the number of tasks n is at most $2m$.

For problem instance I, let S^* be an optimal schedule with least $\sum f_i^2$, where f_i is the makespan in S^* for machine i. Assume without loss of generality that the tasks assigned to each machine are arranged from largest to smallest with respect to their processing times. All machines have at most two tasks, as S^* is an optimal schedule for I which by definition is a counterexample for the theorem.

Let i and j be two machines in schedule S^* such that $f_i > f_j$, machine i has two tasks and machine j has at least one task. Let a and b be the task index for the last task processed by machine i and j, respectively. It cannot be that $t_a > t_b$, as otherwise applying the interchange given in Figure 2.5(a) results

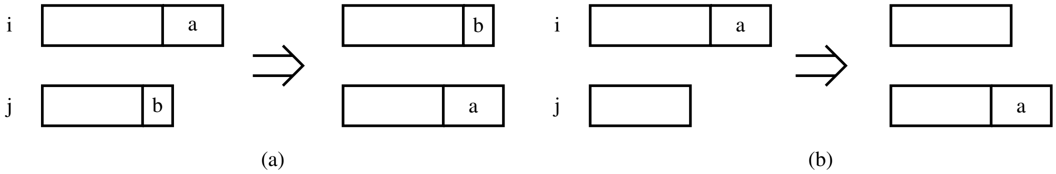

FIGURE 2.5 Schedule transformations.

in an optimal schedule with smaller $\sum f_i^2$. This contradicts the fact that S^* is an optimal schedule with least $\sum f_i^2$. Let i and j be two machines in schedule S^* such that machine i has two tasks. Let a be the task index for the last task processed by machine i. It cannot be that $f_i - t_a > f_j$ as otherwise applying the interchange given in Figure 2.5(b) results in an optimal schedule with smaller $\sum f_i^2$. This contradicts the fact that S^* is an optimal schedule with least $\sum f_i^2$.

Since the transformations given in Figure 2.5(a) and Figure 2.5(b) cannot apply, the schedule S^* must be of the form shown in Figure 2.6 after renaming the machines, i.e., machine i is assigned task T_i (if $i \leq n$) and task T_{2m-i+1} (if $2m - i + 1 \leq n$). But this schedule is an LPT schedule and $\hat{f} = f^*$. Therefore, there cannot be any counterexamples to the theorem. This completes the proof of the theorem. □

For all m there are problem instances for which the ratio given by Theorem 2.2 is tight. In Figure 2.7 we give one of such problem instance for three machines.

The important properties needed to prove Theorem 2.2 are that the longest $2m$ tasks need to be scheduled via LPT, and either the schedule will be optimal for the $2m$ task or at least three tasks will be assigned to a machine. The first set of m tasks, the ones with longest processing time, will be assigned to one machine each, so the order in which they are assigned is not really important. The next set of m tasks need to be assigned from longest to shortest processing times as in the LPT schedule. The remaining tasks can be assigned in any order as long as whenever a machine finishes a task the next task in the list is assigned to that machine. Any list schedule whose list follows the above ordering can be shown to have makespan at most $\frac{4}{3} - \frac{1}{3m}$ times the one of an optimal schedule. These type of schedules form a restriction on the solution space.

It is interesting to note that the problem of scheduling $2m$ independent tasks is an NP-hard problem. However, in polynomial time we can find out if there is an optimal schedule in which each machine has at most two tasks. And this is all that is needed to establish the $\frac{4}{3} - \frac{1}{3m}$ approximation ratio. One of the first

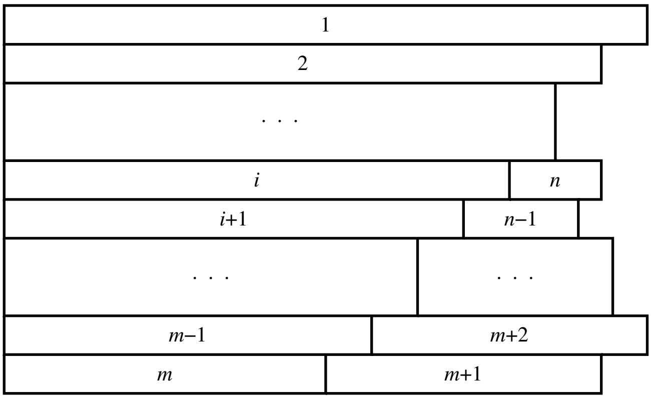

FIGURE 2.6 Optimal schedule.

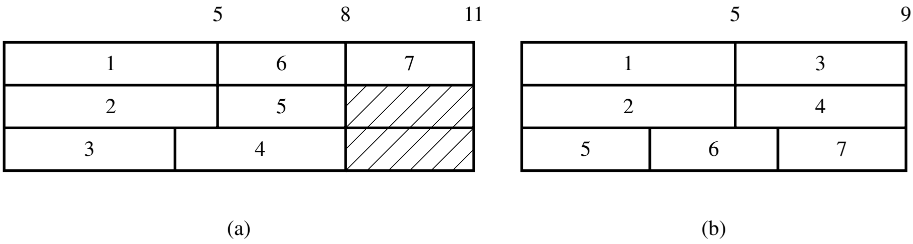

(a)

(b)

FIGURE 2.7 (a) LPT schedule. (b) Optimal schedule.

avenues of research explored was to see if the same approach would hold for the longest $3m$ tasks. That is, give a polynomial-time algorithm that finds an optimal schedule in which each machine has at most three tasks. If such an algorithm exists, we could use it to generate schedules that are within $\frac{5}{4} - \frac{1}{4m}$ times the makespan of an optimal schedule. This does not seem possible as Garey and Johnson [3] established that this problem is NP-hard.

Other approximation algorithms with improved performance were subsequently developed. Coffman et al. [4] introduced the multifit (MF) approach. A k attempt MF approach is denoted by MF_k. The MF_k procedure performs k binary search steps to find the smallest capacity c such that all the tasks can be packed into a set of m bins when packing using first fit with the tasks sorted in nondecreasing order of their processing times. The tasks assigned to bin i correspond to machine i and c is the makespan of the schedule. The approximation ratio has been shown to be $1.22 + 2^{-k}$ and the time complexity of the algorithm is $O(n \log n + kn \log m)$. Subsequent improvements to $1.2 + 2^{-k}$ [5] and $\frac{72}{61} + \frac{1}{2^k}$ [6] were possible within the same time complexity bound. However, the latter algorithm has a very large constant associated with the big "oh" bound.

Following a suggestion by D. Kleitman and D. E. Knuth, Graham [2] was led to consider the following scheduling strategy. For any $k \geq 0$ an optimal schedule for the longest k tasks is constructed and then the remaining tasks are scheduled in any order using the no-additional-delay policy. He shows that this algorithm has an approximation ratio $1 + \frac{1-1/m}{1+\lceil k/m \rceil}$ and takes $O(n \log m + km^k)$ time when there is a fixed number of machines. This was the first polynomial-time approximation scheme for any problem. This polynomial-time approximation scheme, as well as the ones for other problems are explained in more detail in Chapter 9. Fully polynomial-time approximation schemes are not possible for this problem unless $P = NP$ [3].

2.4 Relaxation: Linear Programming Approach

Let us now consider the minimum-weight vertex cover, which is a fundamental problem in the study of approximation algorithms. This problem is defined as follows

Problem: Minimum-weight vertex cover.

Instance: Given a vertex weighted undirected graph G with the set of vertices $V = \{v_1, v_2, \ldots, v_n\}$, edges $E = \{e_1, e_2, \ldots, e_m\}$ and a positive real number (weight) w_i assigned to each vertex v_i.

Objective: Find a minimum-weight vertex cover, i.e., a subset of vertices $C \subset V$ such that every edge is incident to at least one vertex in C. The weight of the vertex cover C is the sum of the weight of the vertices in C.

It is well known that the minimum-weight vertex cover problem is an NP-hard problem. Now consider the following simple greedy algorithm to generate a vertex cover. Assume without loss of generality that the graph G does not have isolated vertices, i.e., vertices without any edges. An edge is said to be *uncovered* with respect to a set of vertices C if both of its endpoints are vertices in $V \backslash C$, i.e., if both endpoints are not in C.

```
Algorithm Min-Weight($G$)
    Let $C = \emptyset$;
    while there is an uncovered edge do
        Let $U$ be the set of vertices adjacent to at least one uncovered edge;
        Add to $C$ a least weight vertex in set $U$;
    endwhile
end
```

Algorithm `Min-Weight` is not a constant-ratio approximation algorithm for the vertex cover problem. Consider the family of star graphs $\mathcal{K}$ each with $l + 1$ nodes, l edges, the center vertex having weight k and the l leaves having weight 1, for any positive integers $k \geq 2$ and $l \geq 3$. For each of these graphs Algorithm `Min-Weight` generates a vertex cover that includes all the leaves in the graph and the weight of the cover is l. For all graphs in $\mathcal{K}$ with $k = 2$, an optimal cover has weight 2 and includes only the center vertex. Therefore, Algorithm `Min-Weight` has an approximation ratio of at least $l/2$, which cannot be bounded above by any fixed constant.

Algorithm `Max-Weight` is identical to Algorithm `Min-Weight`, but instead of selecting the vertex in set U with least weight, it selects one with largest weight. Clearly, this algorithm constructs an optimal cover for the graphs identified above where Algorithm `Min-Weight` performs badly. For every graph in $\mathcal{K}$, this algorithm selects as its vertex cover the center vertex which has weight k. Now for all graphs in $\mathcal{K}$ with $l = 2$, an optimal cover consists of both leaf vertices and it has weight 2. Therefore, the approximation ratio for Algorithm `Max-Weight` is at least $k/2$, which cannot be bounded above by any fixed constant.

All of the graphs identified above, where one of the algorithms performs badly, have the property that the other algorithm constructs an optimal solution. A compound algorithm that runs both algorithms and then selects the better of the two vertex covers may be a constant-ratio algorithm for the vertex cover problem. However, this compound algorithm can also be easily fooled by just using a graph consisting of two stars, where each of the individual algorithms failed to produce good solutions. Therefore, this compound algorithm fails to generate constant-ratio approximate solutions. One may now argue that we could partition the graph into connected components and apply both algorithms to each component. For these "two-star" graphs the new compound algorithm will generate an optimal solution. But in general this new approach fails to produce a constant-ratio approximate solution for all possible graphs. Adding an edge between the center vertex in the "two-star" graphs gives rise to problem instances for which the new compound algorithm fails to provide a constant ratio approximate solution.

A more clever approach is a modified version of Algorithm `Min-Weight`, where instead of selecting a vertex of least possible weight in set U, one selects a vertex v in set U with least $w(v)/u(v)$, where $u(v)$ is the number of uncovered edges incident to vertex v. This seems to be a better strategy because when vertex v is added to C it covers $u(v)$ edges at a total cost of $w(v)$. So the cost (weight) per edge of $w(v)/u(v)$ is incurred when covering the uncovered edges incident to vertex v. This strategy solves optimally the star graphs in $\mathcal{K}$ defined above. However, even when all the weights are equal, one can show that this is not a constant ratio approximation algorithm for the weighted vertex cover problem. In fact, the approximation ratio for this algorithm is about $\log n$. Instances with a simple recursive structure that asymptotically achieve this bound as the number of vertices increases can be easily constructed. Chapter 3 gives an example of how to construct problem instances where an approximation algorithm fails to produce a good solution.

Other approaches to solve the problem can also be shown to fail to provide a constant-ratio approximation algorithm for the weighted vertex cover. What type of algorithm can be used to guarantee a constant-ratio solution to this problem? Let us try another approach.

Another way to view the minimum-weight vertex cover is by defining a 0/1 variable x_i for each vertex v_i in the graph. The 0/1 vector X defines a subset of vertices C as follows. Vertex v_i is in C if and only if $x_i = 1$. The set of vertices C defined by X is a vertex cover if and only if for every edge $\{i, j\}$ in the graph $x_i + x_j \geq 1$. The vertex cover problem is expressed as an instance of the 0/1 integer linear programming (ILP) as follows:

$$\text{minimize} \quad \sum\nolimits_{i \in V} w_i x_i \tag{2.1}$$

$$\text{subject to} \quad x_i + x_j \geq 1 \;\; \forall \{i, j\} \in E \tag{2.2}$$

$$x_i \in \{0, 1\} \quad \forall i \in V \tag{2.3}$$

The 0/1 ILP is also an NP-hard problem.

An important methodology for designing approximation algorithms is relaxation. In this case one relaxes the integer constraints for the x_i values. That is, we replace constraint (2.3) ($x_i = \{0, 1\}$) by $0 \leq x_i \leq 1$ (or simply $x_i \geq 0$, which in this case is equivalent). This means that we are augmenting the solution space by adding solutions that are not feasible for the original problem. This approach will at least provide us with what appears to be a good lower bound for the value of an optimal solution of the original problem, since every feasible solution to the original problem is a feasible solution to the relaxed problem (but the converse is not true). This relaxed problem is an instance of the linear programming (LP) problem which can be solved in polynomial time. Let X^* be an optimal solution to the LP problem. Clearly, X^* might not be a vertex cover as the x_i^* values may be noninteger. The previous interpretation for the X^* values has been lost because it does not make sense to talk about a fractional part of a vertex being part of a vertex cover. To circumvent this situation, we need to use the X^* vector to construct a 0/1 vector $\hat{X}$ that represents a vertex cover. For a vector $\hat{X}$ to represent a vertex cover it needs to satisfy inequality (2.2) (i.e., $\hat{x}_i + \hat{x}_j \geq 1$), for every edge $e_k = \{i, j\} \in E$. Clearly, the inequalities hold for X^*. This means that for each edge $e_k = \{i, j\} \in E$ at least one of x_i^* or x_j^* has value at least greater than or equal to $\frac{1}{2}$. So the vector $\hat{X}$ defined from X^* as $\hat{x}_i = 1$ if $x_i^* \geq \frac{1}{2}$ (rounding up) and $\hat{x}_i = 0$ if $x_i^* < \frac{1}{2}$ (rounding down) represents a vertex cover. Furthermore, because of the rounding up the objective function value for the vertex cover $\hat{X}$ is at most $2 \sum w_i x_i^*$. Since $\sum w_i x_i^*$ value is a lower bound for an optimal solution to the weighted vertex cover problem, we know that this procedure generates a vertex cover whose weight is at most twice the weight of an optimal cover, i.e., it is a 2-approximation algorithm. This process is called (deterministic) *LP rounding*. Chapters 6, 7, 9, 11, 37, 45, 57, 58, and 70 discuss and apply this methodology to other problems.

Another way to round is via randomization, which means in this case that we flip a biased coin (with respect to x_i^* and perhaps other factors) to decide the value for $\hat{x}_i$. The probability of $\hat{X}$ is a vertex cover and its expected weight can be computed. By repeating this randomization process several times, one can show that a cover with weight at most twice the optimal one will be generated with very high probability. In this case it is clear that randomization is not needed. However, for other problems it is justified. Chapters 4, 6, 7, 11, 12, 57, 70, and 80 discuss LP randomized rounding, and Chapter 8 discusses more complex randomized rounding for semidefinite programming (SDP).

The above rounding methods have the disadvantage that an LP problem needs to be solved. Experimental evaluations over several decades have shown that the Simplex method solves quickly (in poly time) the LP problem. But the worst-case time complexity is exponential with respect to the problem size. In Chapter 1 we have discussed the Ellipsoid algorithm and more recent ones that solve LP problems. Even though these algorithms have polynomial-time complexity, there is a term that depends on the number of bits needed to represent the input. Much progress has been made in speeding up these procedures, but the algorithms are not competitive with typical $O(n^2)$ time algorithms for other problems.

Let us now discuss another approximation algorithm for the minimum vertex cover problem that it is "independent" of LP, and then we discuss a local-ratio and a primal-dual approach to this problem.

We call this approach the *α-vector* approach. For every vertex $i \in V$, we define $\delta(i)$ as the set of edges incident to vertex i. Let $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_m)$ be any vector of m nonnegative real values, where $m = |E|$ is the number of edges in the graph. For all k multiply the kth edge inequality by α_k,

$$\alpha_k x_i + \alpha_k x_j \geq \alpha_k \quad \forall e_k = \{i, j\} \in E \tag{2.4}$$

The total sum of these inequalities can be expressed as

$$\sum_{i \in V} \sum_{e_k \in \delta(i)} \alpha_k x_i \geq \sum_{e_k \in E} \alpha_k \tag{2.5}$$

Define $\beta_i = \sum_{e_k \in \delta(i)} \alpha_k$ for every vertex $i \in V$. In other words, β_i be the sum of the α values of all the edges incident to vertex i. Substituting in the above inequality we know that

$$\sum_{i \in V} \beta_i x_i \geq \sum_{e_k \in E} \alpha_k \tag{2.6}$$

Suppose that the α vector is such that $w_i \geq \beta_i$ for all i. Then it follows that

$$\sum_{i \in V} w_i x_i \geq \sum_{i \in V} \beta_i x_i \geq \sum_{e_k \in E} \alpha_k \tag{2.7}$$

In other words any vector α such that the resulting vector β computed from it satisfies $w_i \geq \beta_i$ provides us with the lower bound $\sum_{e_k \in E} \alpha_k$ for the objective function value of every vector X that represents a vertex cover. In other words, if we assign a positive weight to each edge in such a way that the sum of the weight of the edges incident to each vertex i is at most w_i, then the sum of the weight of the edges is a lower bound for an optimum solution.

This is a powerful lower bound. To get maximum strength we need to find a vector α such that $\sum_{e_k \in E} \alpha_k$ is maximum. But finding this vector is as hard as solving the LP problem described earlier. What if we find a maximal vector α, i.e., a vector that cannot possibly be increased in any of its components? This is a simple task. It is just a matter of starting with an α vector with all entries being zero and then increasing one of its components until it is no longer possible to do so. We keep on doing this until there are no edges whose α value can be increased. In this maximal solution, we know that for each edge in the graph at least one of its endpoints has the property that $\beta_i = w_i$, as otherwise the maximality of α is contradicted. Define the vector $\hat{X}$ from the α vector as follows: $x_i = 1$ if $\beta_i = w_i$, and $x_i = 0$, otherwise. Clearly, $\hat{X}$ represents a vertex cover because for every edge in the graph we know that at least one of its vertices has $\beta_i = w_i$. What is the weight of the vertex cover represented by $\hat{X}$? We know that $\sum w_i \hat{x}_i = \sum \beta_i \hat{x}_i \leq 2 \sum \alpha_k$ because each α_k can contribute its value to at most two β_is. Therefore, we have a simple 2-approximation algorithm for the weighted vertex cover problem. Furthermore, the procedure to construct the vertex cover takes linear time with respect to the number of vertices and edges in the graph.

This algorithm was initially developed by Bar-Yehuda and Even [7] using the LP relaxation and its dual. This approach is called the *primal-dual* approach. It will be discussed later in this section. The above algorithm can be proven to be a 2-approximation algorithm without using the ILP formulation. That is, the same result can be established by just using simple combinatorial arguments [8].

Another related approach, called *local ratio*, was developed by Bar-Yehuda and Even [9]. Initially, each vertex is assigned a cost which is simply its weight and it is referred to as the *remaining cost*. At each step the algorithm makes a "down payment" on a pair of vertices. This has the effect of decreasing the remaining cost of each of the two vertices. Label the edges in the graph $\{e_1, e_2, \ldots, e_m\}$. The algorithm considers one edge at a time using this ordering. When the kth edge $e_k = \{i, j\}$ is considered, define γ_k as the minimum of the remaining cost of vertex i and vertex j. The edge makes a down payment of γ_k to each of its two endpoints and each of the two vertices has its remaining cost decreased by γ_k. The procedure stops when we have considered all the edges. All the vertices whose current cost is zero have been paid for completely and they are yours to keep. The remaining ones have not been paid for and there are "no refunds" (not even if you talk to the store manager). The vertices that have been paid for completely form a vertex cover. The weight of all the vertices in the cover generated by the procedure is at most twice $\sum_{e_k \in E} \gamma_k$, which is simply the sum of the down payments made. What is the weight of an optimal vertex cover? The claim is it is equal to $\sum_{e_k \in E} \gamma_k$. The reason is simple. Consider the first step when we introduce γ_1 for edge e_1. Let I_0 be the initial problem instance and I_1 be the resulting instance after deleting edge e_1 and reducing the cost of the two endpoints of edge e_1 by γ_1. One can prove that $f^*(I_0) = f^*(I_1) + \gamma_1$, and inductively that $f^*(I_0) = \sum_{e_k \in E} \gamma_k$ [10]. The algorithm is a 2-approximation algorithm for the weighted vertex cover. The approach is called *local ratio* because at each step one adds $2\gamma_k$ to the value of the solution generated and one accounts for γ_k value of an optimal solution. This local-ratio approach has been successfully applied to quite a few problems. The best feature of this approach is that it is very simple to understand and does not require any LP background.

The primal-dual approach is similar to the previous ones, but it uses the foundations of LP theory. The LP relaxation problem is

$$\text{minimize} \quad \sum_{i \in V} w_i x_i \tag{2.8}$$

$$\text{subject to} \quad x_i + x_j \geq 1 \quad \forall e_k = \{i, j\} \in E \tag{2.9}$$

$$x_i \geq 0 \qquad \forall i \in V. \tag{2.10}$$

The LP problem is called the *primal* problem. The corresponding dual problem is

$$\text{maximize} \quad \sum_{e_k \in E} y_k \tag{2.11}$$

$$\text{subject to} \quad \sum_{e_k \in \delta(i)} y_k \leq w_i \quad \forall i \in V \tag{2.12}$$

$$y_k \geq 0 \qquad \forall e_k \in E \tag{2.13}$$

As you can see the Y vector is simply the α vector defined earlier, and the dual is to find a Y vector with maximum $\sum_{i \in V} y_i$. Linear programming theory [11,12] states that any feasible solution X to the primal problem and any feasible solution Y to the dual problem are such that

$$\sum_{e_k \in E} y_k \leq \sum_{i \in V} w_i x_i$$

This is called *weak duality. Strong duality* states that

$$\sum_{e_k \in E} y_i^* = \sum_{i \in V} w_i x_i^*$$

where X^* is an optimal solution to the primal problem and Y^* is an optimal solution to the dual problem. Note that the dual variables are multiplied by weights which are the right-hand side of the constraints in the primal problem. In this case all of them are one.

The primal-dual approach is based on the weak duality property. The idea is to first construct a feasible solution to the dual problem. That solution will give us a lower bound for the value of an optimal vertex cover, in this case. Then we use this solution to construct a solution to the primal problem. The idea is that the difference of the objective function value between the primal and dual solutions we constructed is "small." In this case we construct a maximal vector Y (as we did with the α vector before). Then we note that since the Y vector is maximal, then for at least one of the endpoints (say i) of every edge must satisfy Inequality 2.12 tight, i.e., $\sum_{e_k \in \delta(i)} y_k = w_i$. Now define vector X with $x_i = 1$ if inequality (2.12) is tight in the dual solution. Clearly, X represents a feasible solution to the primal problem and its objective function value is at most $2 \sum_k y_k$. It then follows by weak duality that an optimal weighted vertex cover has value at least $\sum_k y_k$ and we have a 2-approximation algorithm for the weighted vertex cover. It is simple to see that the algorithm takes linear time (with respect to the number of vertices and edges in the graph) to solve the problem.

There are other ways to construct a solution to the dual problem. In Chapters 4 and 13 another method is discussed for finding a solution to the dual problem. Note the difference in the time required to construct the solution. Chapter 13 discusses a "distributed" version of this algorithm. This algorithm makes decisions by using only "local" information. Chapters 37, 39, 40, and 71 discuss several approximation algorithms based on variations of the primal dual approach. Some of these methods are not exactly primal dual, but may be viewed this way.

Linear programming has also been used as a tool to compute the approximation ratio of some algorithms. This type of research may eventually be called the *automatic analysis of approximation algorithms.* Chapter 3 discusses an early approach to compute the approximation ratio, and Chapter 39 discusses a more recent one. In the former case, a set of LP needed to be solved. Once this was computed it gave the necessary insight on how to prove it analytically. In the latter case, one just formulates the problem and finds bounds for the value of an optimal solution to the LP problem.

2.5 Inapproximability

Sahni and Gonzalez [13] established that constant-ratio polynomial time approximation algorithms exist for some problems only if $P = NP$. In other words, finding a suboptimal solution to some problems is as hard as finding an optimal solution. Any polynomial-time algorithm that generates k-approximate solution can be used to find an optimal solution to the problem in polynomial-time. One of these problems is the "classical" version of the TSP defined in Chapter 1, not the restricted one defined over metric graphs. To prove this result we show that an NP-complete problem, called the Hamiltonian Cycle (HC) problem, can be solved in polynomial time if there is a polynomial-time algorithm for the TSP that generates a k-approximate solution, for any fixed constant k. The HC problem is given an undirected graph, $G = (V, E)$, determine whether on not the graph has a HC. A HC for an undirected graph G is a path that starts at vertex 1, visits each vertex *exactly* once, and ends at vertex 1.

To prove this result a polynomial transformation (Chapter 1 and [3]) is used. Let $G = (V, E)$ be any instance of the HC problem with $n = |V|$. Now construct an instance $G' = (V', E', W')$ of the TSP as follows. The graph G' has n vertices and it is complete (all the edges are present). The edge $\{i, j\}$ in E' has weight 1 if the edge $\{i, j\}$ is in E, and weight Z otherwise. The value of Z is $(k-1)n + 2 > 1$. It will be clear later on why it was defined this way. If the graph G has a HC, then we know that the graph G' has a tour with weight n. However, if G does not have a HC, then all tours for the graph G' have weight greater than or equal to $n - 1 + Z$. A k-approximate solution (tour) when $f^*(G') = n$ must have weight at most $\hat{f}(G') \leq kf^*(G') = kn$. When G does not have a HC, the best possible tour that can be found by the approximation algorithm is one with weight at least $n - 1 + Z = kn + 1$. Therefore, if the approximation algorithm returns a tour with weight at most kn, then G has a HC, otherwise (the tour returned has weight $> kn$) G does not have a HC. Since the algorithm takes polynomial-time with respect to the number of vertices and edges in the graph, it then follows that the algorithm solves in polynomial time the HC problem. So we say that the TSP is inapproximable with respect to any constant ratio. It is inapproximable in the sense that a polynomial-time constant-ratio approximation algorithm implies the solution to a computational complexity question. In this case it is the $P = NP$ question.

In the last 15 years there have been new inapproximability results. These results have been for constant, $\ln n$, and n^ϵ approximation ratios. The techniques to establish some of these results are quite complex, but an important component continues to be reducibility. Chapter 17 discusses all of this work in detail.

2.6 Traditional Applications

We have used the label “traditional applications” to refer to the more established combinatorial optimization problems. Although some of the problems falling into the other categories also fall into this category and vice versa. The problems studied in this part of the handbook fall into the following categories: bin packing, packing, facility dispersion and location, traveling salesperson, Steiner tree, scheduling, planning, generalized assignment, and satisfiability. Let us briefly discuss these categories.

One of the fundamental problems in approximations is the bin packing problem. Chapter 32 discusses online and offline algorithms for one-dimensional bin packing. Chapters 33 and 34 discuss variants of the bin packing problem. This include variations that fall into the following type of problems: the number of items packed is maximized while keeping the number of bins fixed; there is a bound on the number of items that can be packed in each bin; dynamic bin packing, where each item has an arrival and departure time; the item sizes are not known, but the ordering of the weights is known; items may be fragmented while packing them into fixed capacity bins, but certain items cannot be assigned to the same bin; bin stretching; variable sized bin packing problem; and the bin covering problem.

Chapter 35 discusses several ways to generalize the bin packing problem to more dimensions. Two- and three-dimensional strip packing, bin packing in dimensions two and higher, vector packing, and several other variations are discussed. Primal-dual approximation algorithms for packing and stabbing (or covering) problems are covered in Chapter 37. Cutting and packing problems with important applications in the wood, glass, steel, and leather industries as well as in very large-scale integration (VLSI) design, newspaper paging, and container and truck loading are discussed in Chapter 36. For several decades, cutting and packing has attracted the attention of researchers in various areas including operations research, computer science, manufacturing, etc.

Facility dispersion problems are covered in Chapter 38. Dispersion problems arise in a number of applications, such as locating obnoxious facilities, choosing sites for business franchises, and selecting dissimilar solutions in multiobjective optimization. The facility location problem that model the placement of “desirable” facilities such as warehouses, hospitals, and fire stations are discussed in Chapter 39. These algorithms are called “dual fitting and factor revealing.”

Very interesting approximation algorithms for the prize collecting TSP is studied in Chapter 40. In this problem a salesperson has to collect a certain amount of prizes (the quota) by visiting cities. A known prize can be collected in every city. Chapter 41 discusses branch-and-bound algorithms for the TSP. These algorithms have been implemented to run in a multicomputer environment. A general software tool for running branch and bound algorithms in a distributed environment is discussed. This framework may be used for almost any divide-and-conquer computation. With minor adjustments, this tool can take any algorithm defined as a computation over directed acyclic graph, where the nodes refer to computations and the edges specify a precedence relation between computations, and run in a distributed environment.

Approximation algorithms for the Steiner tree problem are discussed in Chapter 42. This problem has applications in several research areas. One of these areas is VLSI physical design. In Chapter 43, practical approximations for a restricted Steiner tree problem are discussed.

Meeting deadline constraints is of great importance in real-time systems. In situations when this is not possible, it is often more desirable to execute some parts of every task, than to give up completely the execution of some tasks. This model allows for the trade-off of the quality of computations in favor of meeting the deadline constraints. Every task is logically decomposed into two subtasks, mandatory and optional. This type of scheduling problems fall under the imprecise computation model. These problems are discussed in Chapter 44. Chapter 45 discussed approximation algorithms for the *malleable task* scheduling problem. In this model, the processing time of a task depends on the number of processors allotted to it. A generalization of both the bin packing and TSP is the vehicle scheduling problem. Approximation algorithms for this problem are discussed in Chapter 46.

Automated planning consists of finding a sequence of actions that transforms an initial state into one of the goal states. Planning is widely applicable, and has been used in such diverse application domains as spacecraft control, planetary rover operations, automated nursing aides, image processing, computer security, and automated manufacturing. Chapter 47 discusses approximation algorithms and heuristics for problems falling into this category.

Chapter 48 presents heuristics and metaheuristics for the generalized assignment problem. This problem is a natural generalization of combinatorial optimization problems including bipartite matching, knapsack and bin packing problems; and has many important applications in flexible manufacturing systems, facility location, and vehicle routing problems.

Chapter 49 examines probabilistic greedy heuristics for maximization and minimization versions of the satisfiability problem.

2.7 Computational Geometry and Graph Applications

The problems falling into this category have applications in several fields of study, but can be viewed as computational geometry and graph problems. The problems studied in this part of the handbook fall into the following categories: 2D and 3D triangulations, connectivity problems, design and evaluation of geometric networks, pair decompositions, minimum edge length partitions, digital geometry, disjoint path problems, graph partitioning, graph coloring, finding subgraphs or trees with certain properties, etc.

Triangulation is not only an interesting theoretical problem in computational geometry, it also has many important applications, such as finite element methods for computer-aided design (CAD) and physical simulations. Chapter 50 discusses approximation algorithms for triangulations in two and three dimensions.

Chapter 51 examines approximation schemes for various geometric minimum-cost k-connectivity problems and for geometric survivability problems, giving a detailed tutorial of the novel techniques developed for these algorithms.

Geometric networks arise in many applications. Road networks, railway networks, telecommunication, pattern matching, bioinformatics—any collection of objects in space that have some connections between them can be modeled as a geometric network. Chapter 52 considers the problem of designing a "good" network and the dual problem, i.e., evaluating how "good" a given network is. Chapter 53 gives an overview of several proximity problems that can be solved efficiently using the well-separated pair decomposition (WSPD). A WSPD may be regarded as a "small" set of edges that approximates the dense complete Euclidean graph.

Approximation algorithms for minimum edge length partitions of rectangles with interior points are discussed in Chapter 54. This problem has applications in the area of CAD of integrated circuits and systems. Chapter 55 considers partitions of finite d-dimensional integer grids by lines in two-dimensional space or by hyperplanes and hypersurfaces in an arbitrary dimension. Some of these problems arise in the areas of digital image processing (analysis) and neural networks. Chapter 56 discusses the problem of finding a planar subgraph of maximum weight in a given graph. Problems of this form have applications in circuit layout, facility layout, and graph drawing.

Finding disjoint paths in graphs is a problem that has attracted considerable attention from at least three perspectives: graph theory, VLSI design, and network routing/flow. The corresponding literature is extensive. Chapter 57 explores offline approximation algorithms for problems on general graphs as influenced from the network flow perspective.

Chapter 58 surveys approximation algorithms and hardness results for different versions of the generalized Steiner network problem in which we seek to find a low-cost subgraph that satisfies prescribed connectivity requirements. These problems include the following well-known problems: min-cost k-flow, min-cost spanning tree, traveling salesman, directed/undirected Steiner tree, Steiner forest, k-edge/node-connected spanning subgraph, and others.

Besides numerous network design applications, spanning trees also play an important role in several newly established research areas, such as biological sequence alignments and evolutionary tree construction. Chapter 59 explores the problem of designing approximation algorithms for spanning-tree problems under different objective functions. It focuses on approximation algorithms for constructing efficient communication spanning trees.

Graph partitioning problem arises in a wide range of applications. Due to the complexity of the problem, heuristics have to be applied to partition large graphs in a reasonable amount of time. Chapter 60 discusses different approaches to the graph partitioning problem. The k-way partitioning of a hypergraph problem seeks to minimize a given cost function of such an assignment. A standard cost function is *net cut*, which is the number of hyperedges that span more than one partition, or, more generally, the sum of weight of such edges. Constraints are typically imposed on the solution, and make the problem difficult. Several heuristics for this problem are discussed in Chapter 61.

In many applications such as design of transportation networks, one often needs to identify a set of regions/sections whose damage will cause the greatest increase in transportation cost within the network. Once identified, extra protection can be deployed to prevent them from being damaged. A version of this problem is finding the most vital edges whose removal will cause the greatest damage to a particular property of the graph. The problems are traditionally referred to as prior analysis problems in sensitivity analysis and it is discussed in Chapter 62.

Stochastic local search algorithms for the classical graph coloring problem are discussed in Chapter 63. This problem arises in many real-life applications like register allocation, air traffic flow management, frequency assignment, light wavelengths assignment in optical networks, or timetabling. Chapter 64 discusses ant colony optimization (ACO) for solving the maximum disjoint paths problems. This problem has many applications including the establishment of routes for connection requests between physically separated network endpoints.

2.8 Large-Scale and Emerging Applications

The problems arising in the areas of wireless and sensor networks, multicasting, multimedia, bioinformatics VLSI CAD, game theory, data analysis, digital reputation, and color quantization may be referred to as problems in "emerging" applications and normally involve large-scale problems instances. Some of these problems also fall in the other application areas.

Chapter 65 describes existing multicast routing protocols for ad hoc and sensor networks, and analyze the issue of computing minimum cost multicast trees. The multicast routing problem, and approximation algorithms for mobile ad hoc networks (MANETs) and wireless sensor networks (WSNs) are presented.

Since flat networks do not scale, it is important to overlay a virtual infrastructure on a physical network. The design of the virtual infrastructure should be general enough so that it can be leveraged by a multitude of different protocols. Chapter 66 proposes a novel clustering scheme based on a number of properties of diameter-2 graphs. Extensive simulation results have shown the effectiveness of the clustering scheme when compared to other schemes proposed in the literature.

Ad hoc networks are formed by collections of nodes which communicate with each other through radio propagation. Topology control problems in such networks deal with the assignment of power values to the nodes so that the power assignment leads to a graph topology satisfying some specified properties. The problem is to minimize a specified function of the powers assigned to the nodes. Chapter 67 discusses some known approximation algorithms for this type of problems. The focus is on approximation algorithms with proven performance guarantees.

An important requirement of wireless ad hoc networks is that they should be self-organizing. Energy conservation and network performance are probably the most critical issues in wireless ad hoc networks, because wireless devices are usually powered by batteries only and have limited computing capability and memory. Many proposed methods apply computational geometry technique (specifically, geometrical spanner) to achieve power efficiency. In Chapter 68, approximation algorithms of power spanner for ad hoc networks are reviewed.

As networks continue to grow explosively both in size and internal complexity, the ever-increasing tremendous traffic load and applications drive researchers to develop techniques for analyzing network performance and managing network resources. To accomplish this, one needs to know the current internal structure of the network. Discovery of internal information such as topology and localized lossy links plays an important role in resource management, loss recovery, and congestion control. Chapter 69 proposes a way to identify this via message multicasting.

Due to the recently rapid development of multimedia applications, multicast has become the critical technique in many network applications. In multicasting routing, the main objective is to send data from one or more sources to multiple destinations to minimize the usage of resources such as bandwidth, communication time, and connection costs. Chapter 70 discusses contemporary research concerning multicast congestion problems in different type of networks.

Recent progress in audio, video, and data storage technologies has given rise to a host of high-bandwidth real-time applications such as video conferencing. These applications require Quality of Service (QoS) guarantees from the underlying networks. Thus, multicast routing algorithms, which manage network resources efficiently and satisfy the QoS requirements, have come under increased scrutiny in recent years. Chapter 71 considers the problem of finding an optimal multicast tree with certain special characteristics. This problem is a generalization of the classical Steiner tree problem.

Scalability is especially critical for peer-to-peer systems. The basic idea of peer-to-peer systems is to have an open self-organizing system of peers that does not rely on any central server and where peers can join and leave, at will. This has the benefit that individuals can cooperate without fees or an investment in additional high-performance hardware. Also, peer-to-peer systems can make use of the tremendous amount of resources (such as computation and storage) that otherwise sit idle on individual computers when they are not in use by their owners. Chapter 72 seeks ways of implementing join, leave, and route operations so that for any sequence of join, leave, and route requests can be executed quickly; the degree, diameter, and stretch factor of the resulting network are as small as possible; and the *expansion* of the resulting network is as large as possible. Good approximate solutions to this multiobjective optimization problem are discussed in Chapter 72.

Scheduling problems modeling the broadcasting of data items over wireless channels are discussed in Chapter 73. The chapter covers exact and heuristic solutions for variants of this problem.

Microarrays have been evolving rapidly, and are among the most novel and revolutionary new biotechnologies. They allow us to monitor the expression of thousands of genes at once. With a single experiment billions of individual hypotheses can be tested. Chapter 74 presents three illustrative examples in the analysis of microarray data sets.

Chapter 75 considers two problems from computational biology, namely, primer selection and planted motif search. The closest string and the closest substring problems are closely related to the planted motif search problem. Representative approximation algorithms for these problems are discussed.

There are interesting algorithmic issues that arise when length constraints are taken into account in the formulation of a variety of problems on string similarity, particularly in the problems related to local alignment. Chapter 76 discusses these types of problems which have their roots and most striking applications in computational biology. Chapter 77 discusses approximation algorithms for the selection of robust tag single nucleotide polymorphisms (SNPs). This is a problem in human genomics that arises in the current experimental environment. Chapter 78 considers a sphere packing problem. Recent interest on this problem was motivated by medical applications in radiosurgery. Radiosurgery is a minimally invasive surgical procedure that uses radiation to destroy tumors inside the human body.

VLSI has produced some of the largest combinatorial optimization problems ever considered. Placement is one of the most difficult of these problems. Placement problems with over 10 million variables and constraints are not unusual, and problem sizes continue to grow with Moore's law. Realistic objectives and constraints for placement incorporate complex models of signal timing, power consumption, wiring routability, manufacturability, noise, temperature, etc. Chapter 79 considers VLSI placement algorithms.

Due to delay scaling effects in deep-submicron technologies, interconnect planning and synthesis are becoming critical to meeting VLSI chip performance targets with reduced design turnaround time. In particular, the global routing phase of the design cycle is receiving renewed interest, as it must efficiently handle increasingly more complex constraints for increasingly larger designs. Chapter 80 presents an integrated approach for congestion and timing-driven global routing, buffer insertion, pin assignment, and buffer/wire sizing. This is a multiobjective optimization problem.

Chapters 81–83 discuss game theory problems related to the Internet and scheduling. They deal with ways of achieving equilibrium. Issues related to algorithmic game theory, approximate economic equilibrium and algorithm mechanism design are discussed.

Over the last decade, the size of data seen by a computational problem has grown immensely. There appears to be more web pages than human beings, and web pages have been successfully indexed. Routers generate huge traffic logs, in the order of terabytes, in a short time. The same explosion of data is felt in observational sciences because our capabilities of measurement have grown significantly. Chapter 84 considers a processing mode where input items are not explicitly stored and the algorithm just passes over the data once.

A virtual community can be defined as a group of people sharing a common interest or goal who interact over a virtual medium, most commonly the Internet. Virtual communities are characterized by an absence of face-to-face interaction between participants which makes the task of measuring the trustworthiness of other participants harder than in nonvirtual communities. This is because of the anonymity that the Internet provides, coupled with the loss of audiovisual cues that help in the establishment of trust. As a result, digital reputation management systems are an invaluable tool for measuring trust in virtual communities. Chapter 85 discusses various systems which can be used to generate a good solution to this problem.

Chapter 86 considers the problem of approximating "colors." Several algorithmic methodologies are presented and evaluated experimentally. These algorithms include dimension weighted clustering approximation algorithms.

Restriction Methods

Teofilo F. Gonzalez
University of California, Santa Barbara

3.1 Introduction

Restriction is one of the most basic techniques to design approximation algorithms. The idea is to generate a solution to a given problem P by providing an optimal or suboptimal solution to a subproblem of P. By a subproblem of a problem P we mean restricting the solution space for P by disallowing a subset of the feasible solutions. The most common approach is to solve one subproblem, but there are algorithms that first solve several subproblems and the algorithm outputs the best of these solutions. An optimal or suboptimal solution to the subproblem(s) is generated by any of the standard methodologies.

This approach is in a sense the opposite of "relaxing a problem," i.e., augmenting the feasible solution space by including previously infeasible solutions. In this case one needs to solve a superproblem of P. An approximation algorithm for P solves the superproblem (optimally or suboptimally) and then transforms such solution to one that is feasible for P. Approximation algorithms based on the linear programming methodology fall under this category. There are many different conversion techniques including rounding, randomized rounding, etc. Chapters 4, 6, 7, and 12 discuss this approach in detail. Approximation algorithms based on both restriction and relaxation exist. These algorithms first restrict the solution space and then relaxes it. The resulting solution space is different from the original one.

In this chapter we discuss several approximation algorithms based on restriction. When designing algorithms of this type the question that arises is which of the many subproblems should be selected to provide an approximation for a given problem? One would like to select a subproblem that "works best." But what do we mean by a subproblem that works best? The one that works best could be a subproblem, which results in an approximation algorithm with smallest possible approximation ratio, or it could be a subproblem whose solution can be computed the fastest, or one may use some other criteria, for example, any of the ones discussed in Chapter 1. Perhaps "works best" should be with respect to a combination of different criteria. But even when using the approximation ratio as the only evaluation criteria for an algorithm, it is not at all clear how to select a subproblem that can be solved quickly and from which a best possible solution could be generated. These are the two most important properties when choosing a subproblem. By studying several algorithms based on restriction one learns why it works for these cases and then it becomes easier to find ways to approximate other problems.

The problems that we will discuss in this chapter to illustrate "restriction" are Steiner trees, the traveling salesperson, covering points by squares, rectangular partitions, and routing multiterminal nets. The Steiner tree and traveling salesperson problems (TSPs) are classical problems in combinatorial optimization. The algorithms that we discuss for the TSPs are among the best known approximation algorithms for any problem.

A closely related approach to restriction is *transformation-restriction.* The idea is to transform the problem instance to a restricted instance of the same problem. The difference is that the restricted problem instance is not a subproblem of original problem instance as in the case of restriction, but it is a "simpler" problem of the same type. In Section 3.5 we present algorithms based on this approach for routing multiterminal nets and embedding hyperedges in a cycle. The fully polynomial-time approximation scheme for the knapsack problem, based on rounding discussed in Chapter 10, is based on transformation-restriction. In Section 3.8 we summarize the chapter, and briefly discuss other algorithms based on restriction for path problems arising in computational geometry.

3.2 Steiner Trees

The Steiner tree problem is a classical problem in combinatorial optimization. Let us define the Steiner tree problem over an edge-weighted complete metric graph $G = (V, E, w)$, where V is the set of n vertices, E the set of $m = \frac{n^2-n}{2}$ edges, and $w : E \rightarrow R^+$ the weight function for the edges. Since the graph is metric the set of weights satisfies the triangle inequality, i.e., for every pair of vertices i, j, $w(i, j)$ is less than or equal to the sum of the weight of the edges in any path from vertex i to vertex j. The Steiner tree problem consists of a metric graph $G = (V, E, W)$ and a subset of vertices $T \subseteq V$. The problem is to find a tree that includes all the vertices in T plus some other vertices in the graph such that the sum of the weight of the edges in the tree is least possible. The Steiner tree problem in an NP-hard problem.

When $T = V$ the problem is called the minimum-weight (cost) spanning tree problem. By the 1960s there were several well-known polynomial-time algorithms to construct a minimum-weight spanning tree for edge-weighted graphs [1]. These simple greedy algorithms have low-order polynomial-time complexity bounds.

Given an instance of the metric graph Steiner tree problem ($G = (V, E, W)$, T) one may construct a minimum-weight spanning tree for the subgraph $G' = (T, E', W')$, where E' and W' include only the edges joining vertices in T. Clearly, this minimum-weight spanning tree is a restricted version of the Steiner tree problem and it seems a natural way to approximate the Steiner tree problem. This approach was analyzed in 1968 by E. F. Moore (see Ref. [2]) for the Steiner tree problem defined in metric space. The metric graph problem, we just defined, includes only a subset of all the possible points in metric space. E. F. Moore presented an elegant proof of the fact that in metric space (and also for metric graphs) $L_M < L_T \leq 2L_S$, where L_M, L_T, and L_S are the weight of a minimum-weight spanning tree, a minimum-weight tour (solution) for the TSP and minimum-weight Steiner tree for any set of points P, respectively. We will define the TSP in the next section. Since every spanning tree is a Steiner tree, the above bounds show that when using a minimum-weight spanning tree to approximate the Steiner tree results in a solution whose weight is at most twice the weight of an optimal Steiner tree. In other words, any algorithm that generates a minimum-weight spanning tree is a 2-approximation algorithm for the Steiner tree problem. Furthermore, this approximation algorithm takes the same time as an algorithm that constructs a minimum-weight spanning trees for edge-weighted graphs [1], since such an algorithm can be used to construct an optimal spanning tree for a set of points in metric space. The above bound is established by defining a transformation from any minimum-weight Steiner tree into a TSP tour in such a way that $L_T \leq 2L_S$ [2]. Then by observing that the deletion of an edge in an optimum tour to the TSP results in a spanning tree, one has $L_M < L_T$. The proof is identical to the one given in the next section where we show this result, but starting from a minimum-weight spanning tree.

3.3 Traveling Salesperson Tours

The TSP has been studied for several decades [3]. There are many variations of this problem. One of the simplest versions of the problem consists of an edge-weighted complete graph and the problem is to find a minimum-weight tour that starts and ends at vertex one and visits every vertex *exactly* once. The weight of a tour is the sum of the weight of the edges in the tour. Sahni and Gonzalez [4] (see Chapter 1) show that the constant-ratio approximation problem is NP-hard, i.e., if for any constant c there is a polynomial-time algorithm with approximation ratio c then $P = NP$. In this section we discuss approximation algorithms for the TSP defined over complete metric graphs. These algorithms are among the best known approximation algorithms for any problem. The "double-minimum-weight spanning tree" (DMWST) approximation algorithm that we discuss in this section is widely known, and it is based on the constructive proof for the approximation algorithm discussed in the previous section developed for the Steiner tree problem by E. F. Moore. Additional constant-ratio approximation algorithms for this version of the TSP were developed by Rosenkrantz et al. [5]. These algorithms as well the DMWST algorithm have an approximation ratio of $2 - 1/n$ and take $O(n^2)$ time. Since the graph is complete, the time complexity is linear with respect to the number of edges in the graph. After presenting this result we discuss the improved approximation algorithm by Christofides [6]. This algorithm has a smaller approximation ratio, but its time complexity grows faster than that of the previous algorithms.

In the literature you will find that the TSP is also defined with tours visiting each vertex *at least* once. We now show that both versions of the TSP defined over metric graphs are equivalent problems. Consider any optimal tour R where some vertices are visited more than once. Let vertex i be a vertex visited more than once. Let vertices j and k be visited just before and just after vertex i. Delete from the tour the edges $\{j, i\}$ and $\{i, k\}$ and add edge $\{j, k\}$. Because the graph is metric the tour weight will stay the same or decrease. If it decreases, then it contradicts the optimality of R. So the weight of the tour must be the same as before. After applying this transformation until it is no longer possible we obtain a tour R' in which every vertex is visited exactly once and the weight of R' is identical to that of R. Since every tour that visits every vertex exactly once also visits every vertex at least once, it follows that both versions of the problem for metric graphs have the same optimal tour weight, i.e., both problems are equivalent. Since for the TSP defined over metric graphs both versions of the problem are equivalent, for convenience we use the definition of tours to visit each vertex at least once.

Now suppose that you have an optimal tour S for an instance I of the TSP. Applying the above transformation we obtain an optimal tour S' in which every vertex is visited exactly once. Deleting an edge from the tour results in a spanning tree. Therefore, the weight of a minimum-weight spanning tree is a lower bound for the weight of an optimal tour. The questions are: How good of a lower bound is it? How can one construct a tour from a spanning tree?

How can we find a tour from a spanning tree T? Just draw the spanning tree in the plane with a vertex as its root and construct a tour by visiting each edge in the tree T twice as illustrated in Figure 3.1. A more

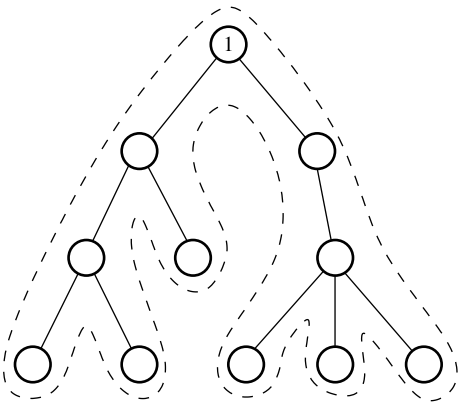

FIGURE 3.1 Spanning tree (solid lines) and tour constructed (broken lines).

formal approach is to construct an *Euler circuit* in the multigraph (graph with multiple edges between vertices) consisting of two copies of the edges in T. An Euler tour (or circuit) is a path that starts and ends at the same vertex and visits every edge in the multigraph once. An Euler tour always exists for the multigraphs we have defined because these multigraphs are connected and all their nodes are of even degree (the number of edges incident to each vertex is even). These multigraphs are called *Eulerian*, and an Euler tour can be constructed in linear time with respect to the number of nodes and edges in the multigraph [7].

The approximation algorithm, which we refer to as *DMWST*, constructs a minimum weight spanning tree, makes a copy of all the edges in the tree, and then generates a tour from this tree with weight equal to twice the weight of a minimum weight spanning tree. We established before that an optimal tour has weight greater than the weight of a minimum weight spanning tree, it then follows that the weight of the tour that the DMWST algorithm generates is at most twice the weight of an optimal tour for G. Therefore, algorithm DMWST generates 2-approximate solution. Actually the ratio is $2-1/n$, which can be established when the edge deleted for an optimal tour to obtain a spanning tree is one with largest weight. The time complexity of the algorithm is bounded by the time complexity for generating a minimum weight spanning tree, since an Euler tour can be constructed in linear time with respect to the number of edges in the spanning tree. We formalize these results in the following theorem.

Theorem 3.1

For the metric traveling salesperson problem, algorithm DMWST generates a tour with weight at most $(2-1/n)$ *times the weight of an optimal tour. The time complexity of the algorithm is* $O(n^2)$ *time, which is linear time with respect to the number of edges in the graph.*

Proof

The proof for the approximation ratio follows from the above discussion. As Fredman and Tarjan [8] point out, implementing Prim's minimum weight spanning tree algorithm by using Fibonacci heaps results in a minimum weight spanning tree algorithm that takes $O(n \log\, n + m)$ time. Since the graph is complete, the time complexity is $O(n^2)$, which is linear with respect to the number of edges in the graph. □

So what is the restriction in the above algorithms? We are actually *restricting* tours for the TSP to traverse the least possible number of *different* edges, though a tour may traverse some of these edges more than once. The minimum number of different edges in G is $n-1$ and they form a spanning tree. It is therefore advantageous to select the edges in a spanning tree of least possible total weight. This justifies the use of a minimum-weight spanning tree. This is another way to think about the design of the DMWST algorithm.

Christofides [6] modified the above approach so that the tours generated have total weight within 1.5 times the weight of an optimal tour. However, the currently fastest implementation of this procedure takes $O(n^3)$ time. His modification is very simple. First observe that there are many different ways to transform a spanning tree into an Eulerian multigraph. All possible augmentations must include at least one edge incident to every odd degree vertex in the spanning tree. Let N be the set of odd degree vertices in the spanning tree. Christofides, idea is to transform the spanning tree into an Eulerian multigraph by adding the least number of edges with the least possible total weight. He showed that such set of edges is a minimum weight complete matching on the graph G_N induced by the set of vertices N in G. A *matching* is a subset of the edges in a multigraph, no two of which are incident upon the same vertex. A matching is *complete* if every node has an edge in the matching incident to it, and the weight of a matching is the sum of the weights of the edges in it. A minimum weight complete matching can be constructed in polynomial time. The edges in the complete matching plus the ones in the spanning tree form an Eulerian multigraph, and Christofides' algorithm generates as its solution an Euler tour of this multigraph.

To establish the 1.5 approximation bound we observe that an optimal tour can be transformed without increasing its total weight into another tour that visits only the vertices in N because the graph is metric. One can partition the edges in this restricted tour into two sets such that each set is a complete matching for the restricted graph. One set contains the even-numbered edges in the tour and the other set the odd-numbered edges. Since a minimum weight complete matching for G_N has total weight smaller than the above two matchings, it then follows that the minimum weight complete matching has total weight at most half of the weight of an optimal tour. Therefore, the edges in the tour constructed by Christofides' algorithm have weight at most 1.5 times the weight of an optimal tour. The time complexity for Christofides' algorithm is $O(n^3)$ and it is dominated by the time required to construct a minimum weight complete matching [9,10]. We formalize this result in the following theorem whose proof follows from the above discussion.

Theorem 3.2 [6]

For the metric traveling salesperson problem, Christofides' algorithm generates a tour with weight at most 1.5 *times the weight of an optimal tour. The time complexity of the algorithm is* $O(n^3)$.

This approach is similar to the one employed by Edmonds and Johnson [11] for the *Chinese Postman Problem.* Given an edge-weighted connected undirected graph, the Chinese Postman problem is to construct a minimum-weight cycle, possibly with repeated edges, which contains every edge in the graph. The currently best algorithm to solve this problem takes $O(n^3)$ time, and it uses shortest paths and weighted matching algorithms. There are asymptotically faster algorithms when the graphs are sparse and weight of the edges are integers.

3.4 Covering Points by Squares

Given a set of n points, $P = \{(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)\}$, in two-dimensional space and an integer D, the CS_2 problem is to find the least number of $D \times D$ squares to cover P. The CS_2 problem as well as the problem of covering by disks have been shown to be NP-hard [12]. Approximation algorithm for these problems as well as their generalizations to multidimensional space have been developed [13,14]. All of these problems find applications in several research areas [12,15,16]. The most popular application is to find the least number of emergency facilities such that every potential patient lives at a distance at most D from at most one facility. This application corresponds to covering by the least number of disks with radius D.

We discuss in this section a simple approximation algorithm based on restriction for the CS_2 problem. Assume without loss of generality that $x_i \geq 0$ and $y_i \geq 0$ and that at least one of the points has x-coordinate value of zero. Define the function $I_x(P_i) = \lfloor x_i/D \rfloor$. For $k \geq 0$, *band k* consists of all the points with $I_x(P_i) = k$.

The restriction to the solution space is to only allow feasible solutions where each square covers points from only one band. Note that an optimal solution to the CS_2 problem does not necessarily satisfy this property. For example, the instance with $P_1 = (0.1, 1.0)$, $P_2 = (0.1, 2.0)$, $P_3 = (1.1, 0.9)$, $P_4 = (1.1, 2.1)$, and $D = 1$ has two squares in optimal cover. The first square covers points P_1 and P_3, and the second covers P_2 and P_4. However an optimal cover for the points in band 0 (i.e., P_1 and P_2) is one square and the one for the points in band 1 (i.e., P_3 and P_4) is two squares. So an optimal cover to the restricted problem has three squares, but an optimal cover for the CS_2 problem has two squares.

One reason for restricting the solution space in this way is that an optimal cover for any given band can be easily generated by a greedy procedure in $O(n \log n)$ time [14]. A greedy approach places a square as high as possible provided it includes the bottommost point in the band as well as all other points in the band at a vertical distance at most 1 from a bottommost point. All the points covered by this square are removed and the procedure is repeated until all the points have been covered. One can easily show that this is an optimal cover by transforming any optimal solution for the band, without increasing the number of squares, to the cover generated by the greedy algorithm. By using elaborate data structures, Gonzalez [14] showed that the greedy algorithm can be implemented to take $(n \log s)$, where s is the number of squares in an optimal solution. Actually a method that uses considerable more space can be used to solve the problem in $O(n)$ time [14].

The solution generated by our algorithm for the whole problem is the union of the covers for each of the bands generated by the greedy method. Let $\hat{f} = E + O$ be the total number of squares, where $E(O)$ is the number of squares for the even (odd-)-numbered bands. We claim that an optimal solution to the CS_2 problem has at least $max\{E, O\}$ squares. This follows from the fact that an optimal solution for the even (odd-)-numbered bands is $E(O)$ because it is not possible for a square to cover points from two different even (odd-)-numbered bands. Therefore, $\frac{\hat{f}_I}{f_I^*} \leq 2$, where f_I^* is the number of squares in an optima solution for problem instance I. This result is formalized in the following theorem whose proof follows from the above discussion.

Theorem 3.3

For the CS_2 problem the above procedure generates a cover such that $\frac{\hat{f}_I}{f_I^*} \leq 2$ in $O(n \log s)$ time, where s is the number of squares in an optimal solution.

A polynomial-time approximation scheme for the generalization of the CS_2 to d dimensions (the CS_d problem) is discussed in Chapter 9. The idea is to generate a set of solutions by shifting the bands by different amounts and then selecting as the solution the best cover computed by the algorithm. This approach is called *shifting* and was introduced by Hochbaum and Maass [13].

3.5 Rectangular Partitions

The minimum edge-length rectangular partition, RG_P problem has applications in the area of computer-aided design of integrated circuits and systems. Given a rectangle R with interior points P, the RG_P problem is to introduce a set of interior lines segments with least total length such that every point in P is in at least one of the partitioning line segments, and R is partitioned into rectangles. Figure 3.2(a) shows a problem instance I and Figure 3.2(b) shows an optimal rectangular partition for the problem instance I.

A rectangular partition E is said to have a *guillotine cut* if one of the vertical or horizontal line segments partitions the rectangle into two rectangles. A rectangular partition E is said to be a *guillotine partition* if either E is empty, or E has a guillotine cut and each of the two resulting rectangular partitions is a guillotine partition.

Finding an optimal rectangular partition is an NP-hard problem [17]. However, an optimal guillotine partition can be constructed in polynomial time. Therefore, it is natural to restrict the solution space to guillotine partitions when approximating rectangular partitions.

In Chapter 54 we prove that an optimal guillotine partition has total edge length, which is at most twice the length of an optimal rectangular partition. Gonzalez and Zheng [18] presented a complex proof that shows that bound is just 1.75. In Chapter 54 we also explain the basic ideas behind the proof of the approximation ratio of 1.75. This approach has been extended to the multidimensional version of this problem by Gonzalez et al. [19].

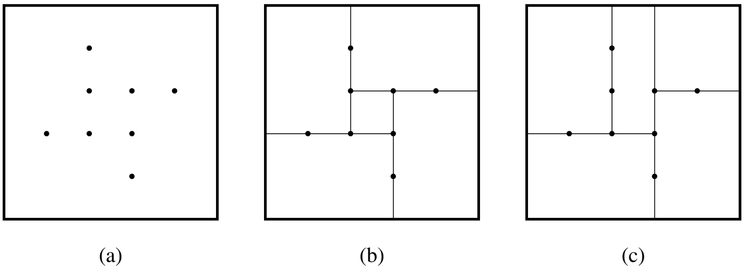

FIGURE 3.2 (a) Instance I of the RG_P problem. (b) Rectangular partition for the instance I. (c) Guillotine partition for the instance I.

An optimal guillotine partition can be constructed in $O(n^5)$ time via dynamic programming. When n is large this approach is not practical. Gonzalez et al. [20] showed that suboptimal guillotine partitions that can be constructed in $O(n \log n)$ time generate solutions with total edge length at most four times the length of an optimal rectangular partition. As in the case of optimal guillotine partitions this result has been extended to the multidimensional version of the problem [20]. Clearly, neither of the methods dominates the other when considering both the approximation ratio and the time complexity bound.

Chapter 42 discusses how more general guillotine cuts can be used to develop a polynomial time approximation scheme (PTAS) for the TSP in two-dimensional space. Chapter 51 discusses this approach for the TSP and Steiner tree problems.

3.6 Routing Multiterminal Nets

Let R be a rectangle whose sides lie on the two-dimensional integer grid. A subset of grid points on the boundary of R that do not include the corners of R is denoted by S and its grid points are called *terminal points*. Let n be the number of terminal points, i.e., the cardinality of set S, and let $N_1, N_2, \ldots, N_m$ a partition of S such that each set N_i includes at least two terminal points. Each set N_i is called a *net* and the problem is to make all the terminal points electrically common by introducing a set wire segments. Terminal points from different nets should not be made electrically common. The wire segment must be along the grid lines outside R with at most one wire segment assigned to each grid edge. When the grid edges incident to a grid point belong to wire segments from two nets, the two wires must cross. In other words, dog-legs (wires from two nets bending at a grid point) are not allowed. The main reasons are that dog-legs would complicate the layer assignment without improving the layout area.

There are two layers available for the wires. Since dog-legs are not allowed, the layer assignment for the wire segments is straightforward. All horizontal wire segments are assigned to one layer and all the vertical ones are assigned to the other. A vertical and horizontal wire segment with a common grid point can be made electrically common by introducing a via for the connection of the wires at that grid point.

The Multiterminal net routing Around a Rectangle (*MAR*) problem is given a rectangle R and a set of nets, find a layout, subject to the constraints defined above, that fits inside a rectangle with least possible area. Constructing a layout in this case reduces to just finding the wire segments for each net along the grid lines (without dog-legs) outside R, since the layer assignment is straightforward.

Developing a constant-ratio approximation algorithm for this problem is complex because the objective function depends on the product of two values, rather than just one value as in most other problems. Gonzalez and Lee [21] developed a linear-time algorithms for the *MAR* problem when every net consists of two terminal points. It is conjectured that the problem is NP-hard when the nets have three terminal points each. Gonzalez and Lee [21,22] developed constant-ratio approximation algorithms for the *MAR* problem [22,23]. The approximation ratios for these algorithms are 1.69 [22] and 1.6 [23]. The approach is to partition the set of nets into groups and then route each group of nets independently of each other. Some of the groups are routed optimally. Since the analysis of the approximation ratio for these algorithms is complex, in this section we only analyze the case when the nets contain one terminal point on the top side of R and one or more terminal points on the bottom side of R. The set of these nets is called N_{TB}. The algorithm to route the N_{TB} nets is based on restriction and it is quite interesting. Readers interested in additional details are referred to Refs. [22,23].

Let n_{TB} be the number of N_{TB} nets. Let E be an optimal area layout for all the nets and let D be E except that the set of nets in N_{TB} are all connected by a path that crosses the left side of R. In this case the layout for the nets N_{TB} is restricted (only paths that cross the left side of R are allowed). We use $H_E(TB)$ ($H_D(TB)$) to denote the height of the layout $E(D)$ on the top plus the corresponding height on the bottom side of R. To simplify the analysis, let us assume that every net in N_{TB} is connected in E by a path that either crosses the left or right (but not both) sides of R. Gonzalez and Lee [23] explain how to modify the analysis when some of these nets are connected by paths that cross both the left and right sides of R.

By *reversing* the connecting path for a net in N_{TB} we mean to connect the net by a path that crosses the opposite side of R, i.e., if it crossed the left side of R it will now cross the right side, or vice versa. When we reverse the connecting path for a net the height on the top side plus the bottom side of R increases by at most two. We say that connecting paths for two N_{TB} nets *cross on the top side* of R when their contribution to the height of the assignment is two for at least one point in between two terminal points. When we *interchange* the connecting paths for two N_{TB} nets that cross on the top side of R we mean reversing both connecting paths. An interchange increases by at most two the height on the top side plus the bottom side of R.

We transform E to D by reversals to quantify the difference in heights between E and D. The largest increase in height is when all the N_{TB} nets are connected in E by paths that cross the right side of R. In this case we need to reverse all the connecting paths for the N_{TB} nets, so $H_D(TB) \leq H_E(TB) + 2n_{TB}$. When one plugs this in the analysis for the whole problem it results in an algorithm with an approximation ratio greater than 2.

A better approach is to use the following restriction. All the connecting paths for the N_{TB} nets are identical, and either they cross the left or the right side of R. In this case we construct two different layouts. Let $D_l(D_r)$ be E except that all the nets in N_{TB} are connected by a path crossing the left (right) side of R. Let M be a minimum area layout between D_l and D_r. In E let $l(r)$ be the number of N_{TB} nets connected by a path crossing the left (right) side of R. By reversing the minimum of $\{l, r\}$ paths it is possible to transform E to D_l or D_r. Therefore, $H_M(TB) \leq H_E(TB) + n_{TB}$, which is better by 50% than for the assignment D defined above.

It is obvious that by trying more alternatives one can obtain better solutions. Let us partition the set of nets N_{TB} into two groups, S_l and S_r. The set S_l contains the $\frac{n_{TB}}{2}$ nets in N_{TB} whose terminal point on the top side of R is closest to the left side of R, and set S_r contains the remaining ones. For $i, j \in \{l, r\}$ let D_{ij} be E except that all the nets in S_l are connected by paths that cross the "i" side of R and all the nets in S_r are connected by paths that cross the "j" side of R. Let P be a minimum area layout among D_{ll}, D_{lr}, D_{rl}, and D_{rr}. Let $l_1(r_1)$ be the number of nets in S_l connected by a path that crosses the left side of R. We define l_2 and r_2 similarly, but using set S_l. We show in the following lemma that $H_P(TB) \leq H_E(TB) + \frac{3}{4}n_{TB}$.

Lemma 3.1

Let P and E be the assignments defined above. Then $H_P(TB) \leq H_E(TB) + \frac{3}{4}n_{TB}$.

Proof

The proof is by contradiction. Suppose that $H_P(TB) > H_E(TB) + \frac{3}{4}n_{TB}$. There are two cases depending on the values of r_1 and l_2.

Case 1: $r_1 \geq l_2$. To transform assignment E to D_{lr} we need to interchange l_2 connecting paths that cross on the top side of R and reverse $r_1 - l_2$ connecting paths. Therefore, $H_{D_{lr}}(TB) \leq H_E(TB) + 2r_1$. Since $H_{D_{lr}}(TB) \geq H_P(TB) > H_E(TB) + \frac{3}{4}n_{TB}$, we know that $2r_1 > \frac{3}{4}n_{TB}$, which is equivalent to $r_1 > \frac{3}{8}n_{TB}$. Since $r_1 + l_1 = \frac{1}{2}n_{TB}$, we know that $l_1 < \frac{1}{8}n_{TB}$.

To transform assignment E to D_{rr} we need to reverse $l_1 + l_2$ connecting paths. Therefore, $H_{D_{rr}}(TB) \leq H_E(TB) + 2l_1 + 2l_2$. Since $H_{D_{rr}}(TB) \geq H_P(TB) > H_E(TB) + \frac{3}{4}n_{TB}$, we know that $l_1 + l_2 > \frac{3}{8}n_{TB}$. Applying the same argument to assignment D_{rl}, we know $l_1 + r_2 > \frac{3}{8}n_{TB}$. Adding these two last inequalities and substituting the fact that $l_2 + r_2 = \frac{1}{2}n_{TB}$, we know that $l_1 > \frac{1}{8}n_{TB}$. This contradicts our previous finding that $l_1 < \frac{1}{8}n_{TB}$.

Case 2: $r_1 < l_2$. A contradiction in this case can be obtained applying similar arguments.

It must then be that $H_P(TB) \leq H_E(TB) + \frac{3}{4}n_{TB}$. □

For three groups, rather than two, Gonzalez and Lee [22] showed that $H_P(TB) \leq H_E(TB) + \frac{2}{3}n_{TB}$, where P is the best of the eight assignments generated. This is enough to prove the approximation ratio of 1.69 for the *MAR* problem. If instead of three groups one uses six, one can prove $H_P(TB) \leq H_E(TB) + 0.6n_{TB}$, where P is the best of the 64 assignments generated. In this case, the approximation ratio for the *MAR* problem is 1.6. Interestingly, partitioning into more groups results in smaller bounds for this group, but does not reduce the approximation ratio for the *MAR* problem because the routing of other nets becomes the bottleneck. We state Gonzalez and Lee's theorem without a proof. Readers interested in the proof are referred to Ref. [23].

Theorem 3.4

For the MAR problem the procedure given in Ref. [23] generates a layout with area at most 1.6 *times the area of an optimal layout in* $O(nm)$ *time.*

An interesting observation is that the proof that the bound $H_P(TB) \leq H_E(TB) + (1.6)n_{TB}$ holds can be carried out automatically by solving a set of linear programming problems. The linear programming problems find the ratios for l_i and r_i such that the minimum increase from E to one of the layouts is maximized. Note that some of the "natural" constraints of the problem are in terms $\max\{r_1, l_2\}$, which makes the solution space nonconvex. However by replacing it with inequalities of the form $r_1 \leq l_2$ and $r_1 > l_2$ we partition the optimization region into several convex regions. By solving a set of linear programming problems (one for each convex region) the maximum possible increase can be computed.

3.7 Variations on Restriction

A closely related approach to restriction is to generate a solution by solving a restricted problem instance constructed from the original instance. We call this approach *transformation-restriction*. For example, consider the routing multiterminal nets around a rectangle discussed in Section 3.6. Remember that there are n terminal points and m nets. Suppose that we break every net i with k_i points into k_i nets with two terminal points each. The k nets consist of adjacent terminal points of the net. In order for these k_i nets to have different terminal points we make a copy of each terminal point at half-integer points next to the old ones. Note that a new grid needs to be redefined to include the half-integer points without introducing more horizontal (vertical) routing tracks above or below (to the left or right) of R. Figure 3.3(b) shows the details. The resulting 2-terminal net problems can be solved in linear time using the optimal algorithm developed by Gonzalez and Lee [21]. A solution to this problem can be easily transformed into a solution to the original problem after deleting the added terminal points as well as some superfluous connections. This algorithm generates a layout whose total area is at most 4 times the area of an optimal layout. Furthermore, the layout can be constructed in $O(n)$ time. With respect to the approximation ratio Gonzalez and Lee's algorithms [22,23] are better, but these algorithms take $O(nm)$ time, whereas the simple algorithm in this section takes linear time.

3.7.1 Embedding Hyperedges in a Cycle

In this subsection we present an approximation algorithm for Embedding Hyperedges in a Cycle so as to Minimize the Congestion (EHCMC). As pointed out in Chapter 70, this problem has applications in the area of design automation and parallel computing. As input we are given a hypergraph $G = (V, H)$, where $V = \{v_1, v_2, \ldots, v_n\}$ is the set vertices and $H = \{h_1, h_2, \ldots, h_m\}$ the set of hyperedges (or subsets with at least two elements of the set V). Traversing the vertices $v_1, v_2, \ldots, v_n$ in the clockwise direction

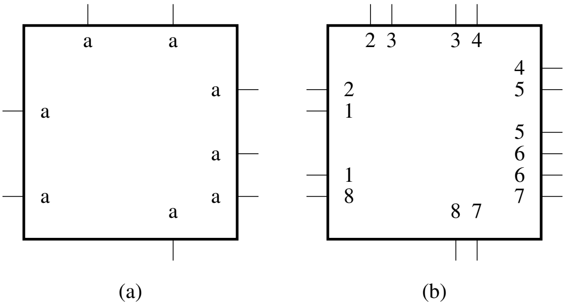

FIGURE 3.3 (a) Net with k-terminal points. (b) Resulting k 2-terminal nets.

forms a cycle, which we call C. Let v_t and v_s be two vertices in h_i such that v_s is the next vertex in h_i in clockwise direction from v_t. Then the pair (v_s, v_t) for hyperedge h_i defines the connecting path for h_i that begins at vertex v_s then proceeds in the clockwise direction along the cycle until reaching vertex v_t. Every edge e in the cycle that is visited by the connecting path formed by pair (v_s, v_t) is said to be *covered* by the connecting path. The EHCMC problem consists of finding a connecting path c_i for every hyperedge h_i such that the maximum congestion of an edge in C is least possible, where the congestion of an edge e in cycle C is the number of connecting paths that include edge e.

Ganley and Cohoon [24] showed that when the maximum congestion is bounded by a fixed constant k, the EHCMC problem is solvable in polynomial time. But, the problem is NP-hard when there is no constant bound for k. Frank et al. [25] showed that when the hypergraph is a graph the EHCMC problem can be solved in polynomial time. We call this problem the Embedding Edges in a Cycle to Minimize Congestion (EECMC). In this section we present the simple linear-time algorithm with an approximation ratio of 2 for the EHCMC problem developed by Gonzalez [26].

The algorithm based on *transformation-restriction* for this problem is simple and uses the same approach as in the previous subsection. This general approach also works for other routing problems. A hyperedge with k vertices $x_1, x_2, \ldots, x_k$, appearing in that order around the cycle C is decomposed into the following k edges $\{x_1, x_2\}, \{x_2, x_3\}, \ldots, \{x_{k-1}, x_k\}, \{x_k, x_1\}$. Note that in this case we do not need to introduce additional vertices as in the previous subsection because a vertex may be part of several hyperedges. The decomposition transforms the problem into an instance of the EECMC problem, which can be solved by the algorithm given in Ref. [25]. From this embedding we can construct an embedding for the original problem instance after deleting some superfluous edges in the embedding. The resulting embedding can be easily shown to have congestion of at most twice the one in an optimal solution X. This is because there is a solution S to the EECMC problem instance in which every connecting path Y in X can be mapped to a set of connecting paths in S with the property that if the connecting path Y contributes one unit to the congestion of an edge e, then the set of connecting paths in S contributes 2 units to the congestion of edge e. Furthermore, each connecting path in S appears in one mapping. The time complexity of the algorithm is $O(n)$.

3.8 Concluding Remarks

We have seen several approximation algorithms based on restriction. As we have seen the restricted problem may be solved optimally or suboptimally as in Section 3.5. One generates solutions closer to optimal, whereas the other generates the solutions faster. These are many more algorithms based on this technique. For example, some computational geometry problems where the objective function is in terms of distance have been approximated via restriction [27–30]. These type of problems allow feasible solutions to be any set of points along a given set of line segments. A restricted problem allows only a set of points (called *artificial points*) to be part of a feasible solution. The more artificial points, the smaller the approximation ratio of the solution; however, it will take longer to solve the restricted problem.

There are problems for which it is not known whether or not there is a constant-ratio approximation algorithm. However, heuristics based on restriction are used to generate good solutions in practice. One such problems is discussed in Chapter 73.

A closely related approach to restriction is *transformation-restriction.* The idea is to transform the problem instance to a restricted instance of the same problem. The difference is that the restricted problem instance is not a subproblem of original problem instance as in the case of restriction. In this chapter we applied this approach to a couple of problems.

Approximations algorithms that are based on restriction and relaxation exist. These algorithms first restrict the solution space and then relaxes it resulting in a solution space that is different from the original one. Gonzalez and Gonzalez [31] have applied this approach successfully to the minimum edge length corridor problem.

4.1 Introduction

Greedy algorithms can be used to solve many optimization problems exactly and efficiently. Examples include classical problems such as finding minimum spanning trees and scheduling unit length jobs with profits and deadlines. These problems are special cases of finding a maximum- or minimum-weight basis of a *matroid*. This well-studied problem can be solved exactly and efficiently by a simple greedy algorithm [1,2].

Greedy methods are also useful for designing efficient *approximation* algorithms for intractable (i.e., NP-hard) combinatorial problems. Such algorithms find solutions that may be suboptimal, but still satisfy some performance guarantee. For a minimization problem, an algorithm has *approximation ratio* α, if, for every instance I, the algorithm delivers a solution whose cost is at most $\alpha \times \text{OPT}(I)$, where $\text{OPT}(I)$ is the cost of an optimal solution for instance I. An α-approximation algorithm is a polynomial-time algorithm with an approximation ratio of α.

In this chapter, we survey several NP-hard problems that can be approximately solved via greedy algorithms. For a couple of fundamental problems, we sketch the proof of the approximation ratio. For most of the other problems that we survey, we give brief descriptions of the algorithms and citations to the articles where these results were reported.

4.2 Set Cover

We start with SET COVER, perhaps one of the most elementary of the NP-hard problems. The problem is defined as follows. The input is a set $X = \{x_1, x_2, \ldots, x_n\}$ of elements and a collection of sets $\mathcal{S} = \{S_1, S_2, \ldots, S_m\}$ whose union is X. Each set S_i has a weight of $w(S_i)$. A *set cover* is a subset $\mathcal{S}' \subseteq \mathcal{S}$ such that $\bigcup_{S_j \in \mathcal{S}'} S_j = X$. Our goal is to find a set cover $\mathcal{S}' \subseteq \mathcal{S}$ so as to minimize $w(\mathcal{S}') = \sum_{S_i \in \mathcal{S}'} w(S_i)$. In other words, we wish to choose a minimum-weight collection of subsets that covers all the elements.

Intuitively, for a given weight, one prefers to choose a set that covers most of the elements. This suggests the following algorithm: Start with an empty collection of sets, then repeatedly add sets to the collection, each time adding a set that minimizes the cost per newly covered element (i.e., the set that minimizes the weight of the set divided by the number of its elements that are not yet in any set in the collection).

4.2.1 Algorithm for Set Cover

Next we prove that this algorithm has approximation ratio $H(|S_{\max}|)$, where $S_{\max}$ is the largest set in $\mathcal{S}$ and H the harmonic function, defined as $H(d) = \sum_{i=1}^{d} 1/i$. For simplicity, assume each set has weight 1.

We use the following charging scheme: *when the algorithm adds a set S to the collection, let u denote the number of not-yet-covered elements in S and charge $1/u$ to each of those elements.* Clearly, the weight of the chosen sets is at most the total amount charged. To finish, we observe that the total amount charged is at most OPT × $H(|S_{\max}|)$. To see why this is so, let $S^* = \{e_s, e_{s-1}, \ldots, e_1\}$ be any set in OPT. Assume that when the greedy algorithm chooses sets to add to its collection, it covers the elements in S^* in the order given (each e_i is covered by the time e_{i-1} is). When the charge for an element e_i is computed (i.e., when the greedy algorithm chooses a set S containing e_i for the first time) at least i elements $(e_i, e_{i-1}, e_{i-2}, \ldots, e_1)$ in S^* are not yet covered. Since the greedily chosen set S contains at least as many not-yet-covered elements as S^*, the charge to e_i is at most $1/i$. Thus, the total charge to elements in S^* is at most

$$\frac{1}{s} + \frac{1}{s-1} + \cdots + \frac{1}{2} + 1 = H(s) \leq H(|S_{\max}|)$$

Thus, the total charge to elements covered by OPT is at most OPT × $H(|S_{\max}|)$. Since every element is covered by OPT, this means that the total charge is at most OPT × $H(|S_{\max}|)$. This implies that the greedy algorithm is an $H(|S_{\max}|)$-approximation algorithm.

These results were first reported in the mid-1970s [3–6]. Since then, it has been proven that no polynomial-time approximation algorithm for set cover has a significantly better approximation ratio unless P = NP [7].

The algorithm and approximation ratio extend to a fairly general class of problems called *minimizing a linear function subject to a submodular constraint.* This problem generalizes set cover as follows. Instead of asking for a set cover, we ask for a collection of sets C such that some function $f(C) \geq f(X)$. The function $f(C)$ should be increasing as we add sets to C and it should have the following property: if $C \subset C'$, then for any set S, $f(C' \cup \{S'\}) - f(C') \leq f(C \cup \{S\}) - f(C)$. In terms of the greedy algorithm, this means that adding a set S to the collection now increases f at least as much as adding it later. (For set cover, take $f(C)$ to be the number of elements covered by sets in C.) See Ref. [8] for details.

4.2.2 Shortest Superstring Problem

We consider an application of the set cover problem, SHORTEST SUPERSTRING problem. Given an alphabet Σ, and a collection of n strings $S = \{s_1, \ldots, s_n\}$, where each s_i is a string from the alphabet Σ, find a shortest string s that contains each s_i as a substring. There are several constant-factor approximation algorithms for this problem [9]; here we simply want to illustrate how to reduce this problem to the set cover problem. The reduction is such that an optimal solution to the set cover problem has weight at most twice the length of a shortest superstring.

For each $s_i, s_j \in S$ and for each value $0 < k < \min(|s_i|, |s_j|)$, we first check to see if the last k symbols of s_i are identical to the first k symbols of s_j. If so, we define a new string β_{ijk} obtained by concatenating s_i with s_j^k, the string obtained from s_j by deleting the first k characters of s_j. Let $\mathcal{C}$ be the set of strings β_{ijk}. For a string π we define $S(\pi) = \{s \in S | s \text{ is a substring of } \pi\}$. The underlying set of elements of the set cover is S. The specified subsets of S are the sets $S(\pi)$ for each $\pi \in S \cup \mathcal{C}$. The weight of each set $S(\pi)$ is $|\pi|$, the length of the string.

We can now apply the greedy set cover algorithm to find a collection of sets $S(\pi_i)$ and then simply concatenate the strings π_i to find a superstring. The approximation factor of this algorithm can be shown to be $2H(n)$.

4.3 Steiner Trees

The STEINER TREE problem is defined as follows. Given an edge-weighted graph $G = (V, E)$ and a set of terminals $S \subseteq V$, find a minimum-weight tree that includes all the nodes in S. (When $S = V$, then this is the problem of finding a minimum-weight *spanning* tree. There are several very fast greedy algorithms that can be used to solve this problem optimally.) The Steiner tree problem is NP-hard and several greedy algorithms have been designed that give a factor 2 approximation [10,11]. We briefly describe the idea behind one of the methods. Let $T_1 = \{s_1\}$ (an arbitrarily chosen terminal from S). At each step, T_{i+1} is computed from T_i as follows: attach the vertex from $S - T_i$ that is the "closest" to T_i by a path to T_i and call the newly added special vertex s_{i+1}. Thus T_i always contains the vertices $s_1, s_2, \ldots, s_i$. It is clear that the solution produces a Steiner tree. It is possible to prove that the weight of this tree is at most twice the weight of an optimal Steiner tree.

Zelikovsky [12] developed a greedy algorithm with an approximation ratio of 11/6. This bound has been further improved subsequently, but by using more complex methods.

A generalization of Steiner trees called NODE-WEIGHTED STEINER TREES is defined as follows. Given a node-weighted graph $G = (V, E)$ and a set of terminals $S \subset V$, find a minimum-weight tree that includes all the nodes in S. Here, the weight of a tree is the sum of the weights of its nodes. It can be shown that this problem is at least as hard as the set cover problem to approximate [13]. Interestingly, this problem is solved via a greedy algorithm similar to the one for the set cover problem with costs. We define a "spider" as a tree on ℓ terminals, where there is at most one vertex with degree more than 2. Each leaf in the tree corresponds to a terminal. The weight of the spider is simply the weight of the nodes in the spider. The algorithm at each step greedily picks a spider with minimum ratio of weight to number of terminals in it. It collapses all the terminals spanned by the spider into a single vertex, makes this new vertex a terminal and repeats until one terminal remains. The approximation guarantee of this algorithm is $2 \ln |S|$. Further improvements appear in Ref. [14]. For more on the Steiner tree problem, see the book by Hwang et al. [15].

4.4 *K*-Centers

The K-CENTER problem is a fundamental facility location problem and is defined as follows: given an edge-weighted graph $G = (V, E)$, find a subset $S \subseteq V$ of size at most K such that each vertex in V is close to some vertex in S. More formally, the objective function is defined as follows:

$$\min_{S \subseteq V} \max_{u \in V} \min_{v \in S} d(u, v)$$

where d is the distance function. For example, one may wish to install K fire stations and minimize the maximum distance (response time) from a location to its closest fire station.

Gonzalez [16] describes a very simple greedy algorithm for the basic K-center problem and proves that it gives an approximation factor of 2. The algorithm works as follows. Initially, pick any node v_0 as a center and add it to the set C. Then for $i = 1$ to K do the following: in iteration i, for every node $v \in V$, compute its distance $d^i(v, C) = \min_{c \in C} d(v, c)$ to the set C. Let v_i be a node that is farthest away from C, i.e., a node for which $d^i(v_i, C) = \max_{v \in V} d(v, C)$. Add v_i to C. Return the nodes $v_0, v_1, \ldots, v_{K-1}$ as the solution.

The above greedy algorithm is a 2-approximation for the K-center problem. First note that the radius of our solution is $d^K(v_K, C)$, since by definition v_K is the node that is farthest away from our set of centers. Now consider the set of nodes $v_0, v_1, \ldots, v_K$. Since this set has cardinality $K + 1$, at least two of these nodes, say v_i and v_j, must be covered by the same center c in the optimal solution. Assume without loss of generality that $i < j$. Let R^* denote the radius of the optimal solution. Observe that the distance from each node to the set C does not increase as the algorithm progresses. Therefore $d^K(v_K, C) \leq d^j(v_K, C)$. Also we must have $d^j(v_K, C) \leq d^j(v_j, C)$, otherwise we would not have selected node v_j in iteration j. Therefore,

$$d(c, v_i) + d(c, v_j) \geq d(v_i, v_j) \geq d^j(v_j, C) \geq d^K(v_K, C)$$

by the triangle inequality and the fact that v_i is in the set C at iteration j. But since $d(c, v_i)$ and $d(c, v_j)$ are both at most R^*, we have the radius of our solution $= d^K(v_K, C) \leq 2R^*$.

4.5 Connected Dominating Sets

The connected dominating set (CDS) problem is defined as follows. Given a graph $G = (V, E)$, find a minimum size subset S of vertices, such that the subgraph induced by S is connected and S forms a dominating set in G. Recall that a dominating set is one in which each vertex is either in the dominating set or adjacent to some vertex in the dominating set. The CDS problem is known to be *NP*-hard.

We describe a greedy algorithm for this problem [17]. The algorithm runs in two phases. At the start of the first phase all nodes are colored white. Each time we include a vertex in the dominating set, we color it black. Nodes that are dominated are colored gray (once they are adjacent to a black node). In the first phase, the algorithm picks a node at each step and colors it black, coloring all adjacent white nodes gray. A *piece* is defined as a white node or a black connected component. *At each step we pick a node to color black that gives the maximum (nonzero) reduction in the number of pieces.*

It is easy to show that at the end of this phase if no vertex gives a nonzero reduction to the number of pieces, then there are no white nodes left.

In the second phase, we have a collection of black connected components that we need to connect. Recursively, connect pairs of black components by choosing a chain of vertices, until there is one black connected component. Our final solution is the set of black vertices that form the connected component.

Key Property: At the end of the first phase if there is more than one black component, then there is always a pair of black components that can be connected by choosing a chain of two vertices.

It can be shown that the CDS found by the algorithm is of size at most $(\ln \Delta + 3) \cdot |OPT_{CDS}|$, where Δ is the maximum degree of a node.

Let a_i be the number of pieces left after the *i*th iteration, and $a_0 = n$. Since a node can connect up to Δ pieces, $|OPT_{CDS}| \geq \frac{a_0}{\Delta}$. (This is true if the optimal solution has at least two nodes.) Consider the $(i+1)^{\text{th}}$ iteration. An optimal solution can connect a_i pieces. Hence, the greedy procedure is guaranteed to pick a node which connects at least $\lceil \frac{a_i}{|OPT_{CDS}|} \rceil$ pieces. Thus, the number of pieces will reduce by at least $\lceil \frac{a_i}{|OPT_{CDS}|} \rceil - 1$. This gives us the recurrence relation

$$a_{i+1} \leq a_i - \left\lceil \frac{a_i}{|OPT_{CDS}|} \right\rceil + 1 \leq a_i \left(1 - \frac{1}{|OPT_{CDS}|}\right) + 1$$

Its solution is

$$a_{i+1} \leq a_0 \left(1 - \frac{1}{|OPT_{CDS}|}\right)^i + \sum_{j=i}^{i-1} \left(1 - \frac{1}{|OPT_{CDS}|}\right)^j$$

Notice after $|OPT_{CDS}| \ln \frac{a_0}{|OPT_{CDS}|}$ iterations, the number of pieces left is less than $2|OPT_{CDS}|$. After this, for each node we choose, we will decrease the number of pieces by at least one until the number of black components is at most $|OPT_{CDS}|$, thus at most $|OPT_{CDS}|$ more vertices are picked. So after $|OPT_{CDS}| \ln \frac{a_0}{|OPT_{CDS}|} + |OPT_{CDS}|$ iterations at most $|OPT_{CDS}|$ pieces are left to connect. We connect the remaining pieces choosing chains of at most two vertices in the second phase. The total number of nodes chosen is at most $|OPT_{CDS}| \ln \frac{a_0}{|OPT_{CDS}|} + |OPT_{CDS}| + 2|OPT_{CDS}|$, and since $\Delta \geq \frac{a_0}{|OPT_{CDS}|}$, the solution found has at most $|OPT_{CDS}|(\ln \Delta + 3)$ nodes.

4.6 Scheduling

We consider the following simple scheduling problem [18]. There are k identical machines. We are given a collection of n jobs. Job J_i is specified by the vector: (r_i, d_i, p_i, w_i). The job has a *release* time of r_i, a *deadline* of d_i and a *processing time* of p_i. The weight of the job is w_i. Our goal is to schedule a subset of the jobs such that each job starts after its release time and is completed by its deadline. If S is a subset of jobs that are scheduled, then the total profit due to set S is $\sum_{J_i \in S} w_i$. We do not get any profit if the job is not completed by its deadline. Our objective is to find a maximum-profit subset of jobs that can be scheduled on the k machines. The jobs are scheduled on one machine, with no preemption. In other words, if job J_i starts on machine j at time s_i, then $r_i \leq s_i$ and $s_i + p_i \leq d_i$. Moreover, each machine can be executing at most one job at any point of time.

A number of algorithms for the problem are based on linear program (LP) rounding [18]. A special case of interest is when all jobs have unit weight (or identical weight). In this case, we simply wish to maximize the number of scheduled jobs. The following greedy algorithm has the property that it schedules a set of jobs such that the total number of scheduled jobs is at least ρ_k times the number of jobs in an optimal schedule. Here $\rho_k = 1 - \frac{1}{(1+\frac{1}{k})^k}$. Observe that when $k = 1$, then $\rho_k = \frac{1}{2}$, and this bound is tight for the greedy algorithm.

The algorithm considers each machine in turn and finds a maximal set of jobs to schedule for the machine; it removes these jobs from the collection of remaining jobs, then recurses on the remaining set of jobs. Now we discuss how a maximal set of jobs is chosen for a single machine. The idea is to pick a job that can be finished as quickly as possible. After we pick this job, we schedule it, starting it at the earliest possible time. Making this choice might force us to reject several other jobs. We then consider starting a job after the end of the last scheduled job, and again pick one that we can finish at the earliest possible time. In this way, we construct the schedule for a single machine.

4.7 Minimum-Degree Spanning Trees

In this problem, the input is a graph $G = (V, E)$, with nonnegative weights $w : E \mapsto R^+$ on its edges. We are also given an integer $d > 1$. The objective of the problem is to find a minimum-weight spanning tree of G in which the degree of every node is at most d. It is a generalization of the Hamiltonian path problem, and is therefore NP-hard. It is known that the problem is not approximable to any ratio unless $P = NP$ or the approximation algorithm is allowed to output a tree whose degree is greater than d. Approximation algorithms try to find a tree whose degree is as close to d as possible, but whose weight is not much more than an optimal degree-d tree.

Greedy algorithms usually select one edge at a time, and once an edge is chosen, that decision is never revoked and the edge is part of the output. Here we add a subset S of edges at a time (e.g., a spanning forest), where S is chosen to minimize a relaxed version of the objective function. We get an iterative solution and the output is a union of the edges selected in each of the steps. This approach typically provides a logarithmic approximation. For minimum-degree spanning trees (MDST), the algorithm finds a tree of degree $O(d \log n)$, whose weight is within $O(\log n)$ of an optimal degree-d tree, where the graph has n vertices. The ideas have appeared in Refs. [19,20]. Such algorithms in which two objectives (degree and weight) are approximated are called *bicriteria* approximation algorithms.

A minimum-weight subgraph in which each node has degree at most d and at least 1 can be computed using algorithms for matching. Except for possibly being disconnected, this subgraph satisfies the other properties of an MDST: degree constraints and weight at most OPT. A greedy algorithm for MDST works by repeatedly finding d-forests, where each d-forest is chosen to connect the connected components left from the previous stages. The number of components decreases by a constant factor in each stage, and, in $O(\log n)$ stages, we get a tree of degree at most $d \log n$.

4.8 Maximum-Weight b-Matchings

In this problem, we are interested in computing a maximum-weight subgraph of a given graph G in which each node has degree at most b. The classical matching problem is a b-matching with $b = 1$. This problem can be solved optimally in polynomial time, but the algorithms take about $O(n^3)$ time. We discuss a 1/2-approximation algorithm that runs in $O(bE + E \log E)$ time. The edges are sorted by weight, with the heaviest edges considered first. Start with an empty forest as the initial solution. When an edge is considered, we see if adding it to the solution violates the degree bound of its end vertices. If not, we add it to our solution. Intuitively, each edge of our solution can displace at most 2 edges of an optimal solution, one incident to each of its end vertices, but of lesser weight.

4.9 Primal-Dual Methods

In this section we study a powerful technique, namely the primal-dual method, for designing approximation algorithms [21]. Duality provides a systematic approach for bounding OPT, a key task in proving any approximation ratio. The approach underlies many approximation algorithms. In this section, we illustrate the basic method via a simple example.

A closely related method, one that we do not explore here, is the "local-ratio" method developed by Bar-Yehuda [22]. It seems that most problems that have been solved by the primal-dual method, appear amenable to attack by the local-ratio method as well.

We use as our example another fundamental NP-hard problem, the VERTEX COVER problem. Given a graph $G = (V, E)$ with weights on the vertices given by $w(v)$, we wish to find a minimum-weight vertex cover. A vertex cover is a subset of vertices, $S \subseteq V$, such that for each edge $(u, v) \in E$, either $u \in S$ or $v \in S$ or both. This problem is equivalent to the special case of the set cover problem, where each set contains exactly two elements.

We describe a 2-approximation algorithm. First, write an integer linear program (ILP) for this problem. For each vertex v in the given graph, the program has a binary variable $x_v \in \{0, 1\}$. Over this space of variables, the problem is to find

$$\min \Big\{ \sum_{v \in V} w(v) x_v : x_u + x_v \geq 1 \quad (\forall (u, v) \in E) \Big\}$$

It is easy to see that an optimal solution to this integer program gives an optimal solution to the original vertex cover problem. Thus, the integer program is NP-hard to solve. Instead of solving it directly, we relax ILP to an LP, which is to optimize the same objective function over the same set of constraints, but with real-valued variables $x_v \in [0, 1]$.

Each LP has a dual. Let $N(v)$ denote the neighbor set of v. The dual of LP has a variable $y_{(u,v)} \geq 0$ for each edge $(u, v) \in E$. Over this space of variables, the dual of LP is to find

$$\max \Big\{ \sum_{(u,v) \in E} y_{u,v} : \sum_{u \in N(v)} y_{(u,v)} \leq w(v) \quad (\forall v \in V) \Big\}$$

The key properties of these programs are the following:

1. Weak duality: The cost of any feasible solution to the dual is a lower bound on the cost of any feasible solution to LP. Consequently, the cost of any feasible solution to the dual is a lower bound on the cost of any feasible solution to ILP.
2. If we can find feasible solutions for ILP and the dual, where the cost of our solution to ILP is at most α times the cost of our solution to the dual, then our solution to ILP has cost at most α OPT.

One way to get an approximate solution is to solve the vertex cover LP optimally (e.g., using a network flow algorithm [23]), and then round the obtained fractional solution to an integral solution. Here we describe a different algorithm—a greedy algorithm that computes solutions to both ILP and the dual. The solutions are not necessarily optimal, but will have costs within a factor of 2.

The dual solution is obtained by the following simple heuristic: *Initialize all dual variables to 0, then simultaneously and uniformly raise all dual variables, except those dual variables that occur in constraints that are currently tight. Stop when all constraints are tight.* The solution to ILP is obtained as follows: *Compute the dual solution above. When the constraint for a vertex v becomes tight, add v to the cover.* (Thus, the vertices in the cover are those whose constraints are tight.)

The constraint for vertex v is tight if $\sum_{u\in N(v)} y_{(u,v)} = w(v)$. When we start to raise the dual variables, the sum increases at a rate equal to the degree of the vertex. Thus, the first vertices to be added are those minimizing $\frac{w(v)}{d(v)}$. These vertices and their edges are effectively deleted from the graph, and the process continues.

The algorithm returns a vertex cover because, in the end, for each edge (u, v) at least one of the two vertex constraints is tight. By weak duality, to see that the cost of the cover is at most 2OPT, it suffices to see that the cost of the cover S is at most twice the cost of the dual solution. This is true because each node's weight can be charged to the dual variables corresponding to the incident edges, and each such dual variable is charged at most twice:

$$\sum_{v\in S} w(v) = \sum_{v\in S}\sum_{u\in N(v)} y_{(u,v)} \le 2 \sum_{(u,v)\in E} y_{(u,v)}$$

The equality above follows because $w(v) = \sum_{u\in N(v)} y_{(u,v)}$ for each vertex added to the cover. The inequality follows because each dual variable $y_{(u,v)}$ occurs at most twice in the sum.

To implement the algorithm, it suffices to keep track of the current degree $D(v)$ of each vertex v as well as the slack $W(v)$ remaining in the constraint for v. In fact, with a little bit of effort the reader can see that the following pseudocode implements the algorithm described above, without explicitly keeping track of dual variables. This algorithm was first described by Clarkson [24]:

```
GREEDY-VERTEX-COVER($G$, $S$)
for all $v \in V$ do $W(v) \leftarrow w(v)$; $D(v) \leftarrow deg(v)$
$S \leftarrow \emptyset$
while $E \neq \emptyset$ do
    Find $v \in V$ for which $\frac{W(v)}{D(v)}$ is minimized.
    for all $u \in N(v)$ do
        $E \leftarrow E \setminus (u, v)$
        $W(u) \leftarrow W(u) - \frac{W(v)}{D(v)}$ and $D(u) \leftarrow D(u) - 1$
    end
    $S \leftarrow S \cup \{v\}$ and $V \leftarrow V \setminus \{v\}$
end
```

More sophisticated applications of the primal-dual method require more sophisticated proofs. In some cases, the algorithm starts with a greedy phase, but then has a final round in which some previously added elements are discarded. The key idea is to develop the primal solution hand in hand with the dual solution in a way that allows the cost of the primal solution to be "charged" to the cost of the dual.

Because the vertex cover problem is a special case of the set cover problem, it is also possible to solve the problem using the greedy set cover algorithm. This gives an approximation ratio of at most $H(|V|)$, and in fact there are vertex cover instances for which that greedy algorithm produces a solution of cost $\Omega(H(|V|))$ OPT. The greedy algorithm described above is almost the same; it differs only in that it modifies the weights of the neighbors of the chosen vertices as it proceeds. This slight modification yields a significantly better approximation ratio.

4.10 Greedy Algorithms via the Probabilistic Method

In their book on the probabilistic method, Alon et al. [25] describe probabilistic proofs as follows:

> In order to prove the existence of a combinatorial structure with certain properties, we construct an appropriate probability space and show that a randomly chosen element in the space has the desired properties with positive probability.

The *method of conditional probabilities* is used to convert those proofs into efficient algorithms [26].

For some problems, elementary probabilistic arguments easily prove that good solutions exist. In some cases (especially when the proofs are based on iterated random sampling), the probabilistic proof can be converted into a greedy algorithm. This is a fairly general approach for designing greedy algorithms. In this section we give some examples.

4.10.1 Max Cut

Given a graph $G = (V, E)$, the MAX-CUT problem is to partition the vertices into two sets S and $\overline{S}$ so as to maximize the number of edges "cut" (crossing between the two sets). The problem is NP-hard.

Consider the following randomized algorithm: *For each vertex, choose the vertex to be in S or $\overline{S}$ independently with probability* 1/2. We claim this is a 1/2-approximation algorithm, in expectation. To see why, note that the probability when any given edge is cut is 1/2. Thus, by linearity of expectation, in expectation $|E|/2$ edges are cut. Clearly an optimal solution cuts at most twice this many edges.

Next, we apply the *method of conditional probabilities* [25,26] to convert this randomized algorithm into a deterministic one. We replace each random choice made by the algorithm by a deterministic choice that does "as well" in a precise sense. Specifically, we modify the algorithm to maintain the following invariant:

> *After each step, if we were to take the remaining choices randomly, then the expected number of edges cut in the end would be at least* |E|/2*.*

Suppose decisions have been made for vertices $V_t = \{v_1, v_2, \ldots, v_t\}$, but not yet for vertex v_{t+1}. Let S_t denote the vertices in V_t chosen to be in S. Let $\overline{S}_t = V_t - S_t$ denote the vertices in V_t chosen to be in $\overline{S}$. Given these decisions, the status of each edge in $V_t \times V_t$ is known, while the rest still have a 1/2 probability of being cut. Let $x_t = |E \cap (S_t \times \overline{S}_t)|$ denote the number of those edges that will definitely cross the cut. Let $e_t = |E - V_t \times V_t|$ denote the number of edges which are not yet determined. Then, given the decisions made so far, the expected number of edges that would be cut if all remaining choices were to be taken randomly would be

$$\phi_t \doteq x_t + e_t/2$$

The x_t term counts the edges cut so far, while the $e_t/2$ term counts the e_t edges with at least one undecided endpoint: each of those edges will be cut with probability 1/2.

Our goal is to replace the random decisions for the vertices with deterministic decisions that guarantee $\phi_{t+1} \geq \phi_t$ at each step. If we can do this, then we will have $|E|/2 = \phi_0 \leq \phi_1 \leq \cdots \leq \phi_n$, and, since ϕ_n is the number of edges finally cut, this will ensure that at least $|E|/2$ edges are cut.

Consider deciding whether the vertex v_{t+1} goes into S_{t+1} or $\overline{S}_{t+1}$. Let s be the number of v_{t+1}'s neighbors in S_t. Let $\overline{s}$ be the number of v_{t+1}'s neighbors in $\overline{S}_{t+1}$. By calculation

$$\phi_{t+1} - \phi_t = \begin{cases} s/2 - \overline{s}/2 & \text{if } v_{t+1} \text{ is added to } \overline{S}_{t+1} \\ \overline{s}/2 - s/2 & \text{otherwise} \end{cases}$$

Thus, the following strategy ensures $\phi_{t+1} \geq \phi_t$: *if $s \leq \overline{s}$, then put v_{t+1} in S_{t+1}; otherwise put v_t in $\overline{S}_{t+1}$*. By doing this at each step, the algorithm guarantees that $\phi_n \geq \phi_{n-1} \geq \cdots \geq |E|/2$.

We have derived the following greedy algorithm: *Start with $S = \overline{S} = \emptyset$. Consider the vertices in turn. For each vertex v, put the vertex v in S or $\overline{S}$, whichever has fewer of v's neighbors.* We know from the derivation that this is a 1/2-approximation algorithm.

4.10.2 Independent Set

Although the application of the method of conditional probabilities is somewhat technical, it is routine, in the sense that it follows a similar form in every case. Here is another example.

The problem of finding a MAXIMUM INDEPENDENT SET in a graph $G = (V, E)$ is one of the most basic problems in graph theory. An independent set is defined as a subset S of vertices such that there are no edges between any pair of vertices in S. The problem is NP-hard. Turan's theorem states the following: *Any graph G with n nodes and average degree d has an independent set I of size at least $n/(d+1)$*. Next, we sketch a classic proof of the theorem using the probabilistic method. Then we apply the method of conditional probabilities to derive a greedy algorithm.

Let $\hat{N}(v) = N(v) \cup \{v\}$ denote the neighbor set of v, including v. Consider this randomized algorithm: *Start with $I = \emptyset$. Consider the vertices in a random order. When considering v, add it to I if $\hat{N}(v) \cap I = \emptyset$.*

For a vertex v to be added to I, it suffices for v to be considered before any of its neighbors. This happens with probability $|\hat{N}(v)|^{-1}$. Thus, by linearity of expectation, the expected number of vertices added to I is at least

$$\sum_{v} |\hat{N}(v)|^{-1}$$

A standard convexity argument shows this is at least $n/(d+1)$, completing the proof of Turan's theorem.

Now we apply the method of conditional probabilities. Suppose the first t vertices $V_t = \{v_1, v_2, \ldots, v_t\}$ have been considered. Let $I_t = V_t \cap I$ denote those that have been added to I. Let $R_t = V \setminus (V_t \cup \hat{N}(I_t))$ denote the remaining vertices that might still be added to I and let $\hat{N}_t(v) = \hat{N}(v) \cap R_t$ denote the neighbors of v that might still be added. If the remaining vertices were to be chosen in random order, the expected number of vertices in I by the end would be at least

$$\phi_t \doteq |I_t| + \sum_{v \in R_t} |\hat{N}_t(v)|^{-1}$$

We want the algorithm to choose vertex v_{t+1} to ensure $\phi_{t+1} \geq \phi_t$. To do this, it suffices to choose the vertex $w \in R_t$ minimizing $|\hat{N}_t(w)|$, for then

$$\phi_{t+1} - \phi_t \geq 1 - \sum_{v \in \hat{N}_t(w)} |\hat{N}_t(v)|^{-1} \geq 1 - \sum_{v \in \hat{N}_t(w)} |\hat{N}_t(w)|^{-1} = 0$$

This gives us the following greedy algorithm: *Start with $I = \emptyset$. Repeat until no vertices remain: Choose a vertex v of minimum degree in the remaining graph; add v to I and delete v and all of its neighbors from the graph. Finally, return I.* It follows from the derivation that this algorithm ensures $n/(d+1) \leq \phi_0 \leq \phi_1 \leq \cdots \leq \phi_n$, so that the algorithm returns an independent set of size at least $n/(d+1)$, where d is the average degree of the graph.

As an exercise, the reader can give a different derivation leading to the following greedy algorithm (with the same performance guarantee): *Order the vertices by increasing degree, breaking ties arbitrarily. Let I consist of those vertices that precede all their neighbors in the ordering.*

4.10.3 Unweighted Set Cover

Next we illustrate the method on the set cover problem.

We start with a randomized rounding scheme that uses iterated random sampling to round a fractional set cover (a solution to the relaxed problem) to a true set cover. We prove an approximation ratio for the randomized algorithm, then apply the method of conditional probabilities to derive a deterministic greedy algorithm.

We emphasize that, in applying the method of conditional probabilities, we remove the explicit dependence of the algorithm on the fractional set solution. Thus, the final algorithm does not in fact require solving the relaxed problem first.

Recall the definition of the set cover problem from the beginning of the chapter. For this section, we will assume all weights $w(S_i)$ are 1.

Consider the following relaxation of the problem: assign a value $z_i \in [0, 1]$ to each set S_i so as to minimize $\sum_i z_i$ subject to the constraint that, for every element x_j, $\sum_{i:x_j \in S_i} z_i \geq 1$. We call a z meeting these constraints a *fractional set cover*.

The optimal set cover gives one possible solution to the relaxed problem, but there may be other fractional set covers that give a smaller objective function value. However, not too much smaller. We claim the following: *Let z be any fractional set cover. Then there exists an actual set cover C of size at most $T = \lceil \ln(n)|z| \rceil$, where $|z| = \sum_i z_i$.*

To prove this, consider the following randomized algorithm: given z, *draw T sets at random from the distribution p defined by $p(S_i) = z_i/|z|$*. With nonzero probability, this random experiment yields a set cover. Here is why. A calculation shows that, with each draw, the chance that any given element e is covered is at least $1/|z|$. Thus, the expected number of elements left uncovered after T draws is at most

$$n(1 - 1/|z|)^T \; < \; n \exp(-T/|z|) \; \leq \; 1$$

Since on average less than one element is left uncovered, it must be that some outcome of the random experiment covers all elements.

Next we apply the method of conditional probabilities. Suppose that t sets have been chosen so far, and let n_t denote the number of elements not yet covered. Then the conditional expectation of the number of elements left uncovered at the end is at most

$$\phi_t \; \doteq \; n_t(1 - 1/|z|)^{T-t}$$

We want the algorithm to choose each set to ensure $\phi_t \leq \phi_{t-1}$, so that in the end $\phi_T \leq \phi_0 < 1$ and the chosen sets form a cover.

Suppose the first t sets have been chosen, so that ϕ_t is known. A calculation shows that, if the next set is chosen at random according to the distribution p, then $E[\phi_{t+1}] \leq \phi_t$. Thus, choosing the next set to *minimize* ϕ_{t+1} will ensure $\phi_{t+1} \leq \phi_t$. By inspection, choosing the set to minimize ϕ_{t+1} is the same as choosing the set to minimize n_{t+1}.

We have derived the following greedy algorithm: *Repeat T times: add a set to the collection so as to minimize the number of elements remaining uncovered.* In fact, it suffices to do the following: *Repeat until all elements are covered: add a set to the collection so as to minimize the number of elements remaining uncovered.* (This suffices because we know from the derivation that a cover will be found within T rounds.)

We have proven the following fact: *The above greedy algorithm returns a cover of size at most* $\min_z \lceil \ln(n)|z| \rceil$, *where z ranges over all fractional set covers.* Since the minimum-size set cover OPT corresponds to a z with $|z| = |\text{OPT}|$, we have the following corollary: *The above greedy algorithm returns a cover of size at most* $\lceil \ln(n)\text{OPT} \rceil$.

This algorithm can be generalized to weighted set cover, and slightly stronger performance guarantees can be shown [3–6]. This particular greedy approach applies to a general class of problems called "minimizing a linear function subject to a submodular constraint" [8].

Comment: In many cases, applying the method of conditional probabilities will not yield a greedy algorithm, because the conditional expectation ϕ_t will depend on the fractional solution in a nontrivial way. In that case, the derandomized algorithm will first have to compute the fractional solution (typically by solving a linear program). That is Raghavan and Thompson's standard method of *randomized rounding* [27]. The variant we see here was first observed in Ref. [28]. Roughly, to get a greedy algorithm, we should apply the method of conditional probabilities to a probabilistic proof based on *repeated random sampling* from the distribution defined by the fractional optimum.

4.10.4 Lagrangian Relaxation for Fractional Set Cover

The algorithms described above fall naturally into a larger and technically more complicated class of algorithms called *Lagrangian relaxation algorithms*. Typically, such an algorithm is used to find a structure meeting a given set of constraints. The algorithm constructs a solution in small steps. Each step is made so as to minimize (or keep from increasing) a *penalty function* that approximates some of the underlying constraints. Finally, the algorithm returns a solution that approximately meets the underlying constraints.

These algorithms typically have a greedy outer loop. In each iteration, they solve a subproblem that is simpler than the original problem. For example, a multicommodity flow algorithm may solve a sequence of shortest-path subproblems, routing small amounts of flow along paths chosen to minimize the sum of edge penalties that grow exponentially with the current flow on the edge.

Historical examples include algorithms by von Neumann, Ford and Fulkerson, Dantzig-Wolfe decomposition, Benders' decomposition, and Held and Karp. In 1990, Shahrokhi and Matula proved a polynomial time bound for such an algorithm for multicommodity flow. This sparked a long line of work generalizing and strengthening this result (e.g., [29–31]). See the recent text by Bienstock [32]. These works focus mainly on *packing and covering problems*—LPs and ILPs with nonnegative coefficients.

As a rule, the problems in question can also be solved by standard linear programming algorithms such as the simplex, the ellipsoid, or interior-point algorithms. The primary motivation for studying Lagrangian relaxation algorithms has been that, like other greedy algorithms, they can often be implemented without explicitly constructing the full underlying problem. This can make them substantially faster.

As an example, here is a Lagrangian relaxation algorithm for fractional set cover (given an instance of the set cover problem, find a fractional set cover z of minimum size $|z| = \sum_i z_i$; see the previous subsection for definitions). Given a set cover instance and $\varepsilon \in [0, 1/2]$, the algorithm returns a fractional set cover of size at most $1 + O(\varepsilon)$ times the optimum:

1. Let $N = 2\ln(n)/\varepsilon^2$, where n is the number of elements.
2. Repeat until all elements are sufficiently covered ($\min_j c(j) \geq N$).
3. Choose a set S_i maximizing $\sum_{x_j \in S_i} (1-\varepsilon)^{c(j)}$, where $c(j)$ denotes the number of times any set containing element x_j has been chosen so far.
4. Return z, where z_i is the number of times S_i was chosen divided by N.

The naive implementation of this algorithm runs in $O(nM\log(n)/\varepsilon^2)$ time, where $M = \sum_i |S_i|$ is the size of the input. With appropriate modifications, the algorithm can be implemented to run in $O(M\log(n)/\varepsilon^2)$ time.

For readers who are interested, we sketch how this algorithm may be derived using the probabilistic framework. To begin, we imagine that we have in hand any fractional set cover z^*, to which we apply the following randomized algorithm: *Define probability distribution p on the sets by $p(S_i) = z^*_i/|z^*|$. Draw sets randomly according to p until every element has been covered (in a drawn set) at least $N = 2\ln(n)/\varepsilon^2$ times. Return z, where z_i is the number of times set S_i was drawn, divided by N.* (The reader should keep in mind that the dependence on z^* will be removed when we apply the method of conditional probabilities.)

Claim: *With nonzero probability, the algorithm returns a fractional set cover of size at most* $(1 + O(\varepsilon))|z^*|$.

Next we prove the claim. Let $T = |z^*|N/(1-\varepsilon)$. We will prove that, with nonzero probability, within T draws each set will be covered at least N times. This will prove the claim because then the size of z is at most $T/N = |z^*|/(1-\varepsilon)$.

Fix a given element x_j. With each draw, the chance that x_j is covered is at least $1/|z^*|$. Thus, the expected number of times x_j is covered in T draws is at least $T/|z^*| = N/(1-\varepsilon)$. By a standard Chernoff bound, the probability that x_j is covered less than N times in T rounds is at most $\exp(-\varepsilon^2 N/2(1-\varepsilon)) < 1/n$.

By linearity of expectation, the expected number of elements that are covered less than N times in T rounds is less than 1. Thus, with nonzero probability, all elements are covered at least N times in T rounds.

This proves the claim. Next we apply the method of conditional probabilities to derive a greedy algorithm.

Let X_{jt} be an indicator variable for the event that x_j is covered in round t, so that for any j the X_{jt}'s are independent with $E[X_{jt}] \geq 1/|z^*|$. Let $\mu = N/(1-\varepsilon)$. The proof of the Chernoff-bound bounds $\Pr[\sum_t X_{jt} \leq (1-\varepsilon)\mu]$ by the expectation of the following quantity:

$$\frac{(1-\varepsilon)^{\sum_t X_{jt}}}{(1-\varepsilon)^{(1-\varepsilon)\mu}} = \frac{(1-\varepsilon)^{\sum_t X_{jt}}}{(1-\varepsilon)^N}$$

Thus, the proof of our claim above implicitly bounds the probability of failure by the expectation of

$$\phi = \sum_j \frac{(1-\varepsilon)^{\sum_t X_{jt}}}{(1-\varepsilon)^N}$$

Furthermore, the proof shows that the expectation of this quantity is less than 1.

To apply the method of conditional probabilities, we will *choose each set to keep the conditional expectation of the above quantity ϕ below 1.*

After the first t sets have been drawn, the random variables X_{js} for $s \leq t$ are determined, while X_{js} for $s > t$ are not yet determined. Using the inequalities from the proof of the Chernoff bound, the conditional expectation of ϕ given the choices for the first t sets is at most

$$\phi_t \doteq \sum_j \frac{\prod_{s \leq t}(1-\varepsilon)^{X_{js}} \times \prod_{s>t}(1-\varepsilon/|z^*|)}{(1-\varepsilon)^N}$$

This quantity is initially less than 1, so it suffices to *choose each set to ensure* $\phi_{t+1} \leq \phi_t$. If the $t+1$st set is chosen randomly according to p, then $E[\phi_{t+1}] \leq \phi_t$. Thus, to ensure $\phi_{t+1} \leq \phi_t$, it suffices to choose the set to minimize ϕ_{t+1}. By a straightforward calculation, this is the same as choosing the set S_i to maximize $\sum_{x_j \in S_i}(1-\varepsilon)^{\Sigma_{s \leq t} X_{jt}}$. This gives us the algorithm in question (at the top of this section). From the derivation, we know the following fact: *The algorithm above returns a fractional set cover of size at most* $(1+O(\varepsilon)) \min_{z^*} |z^*|$, *where z^* ranges over all the fractional set covers.*

4.11 Conclusions

In this chapter we surveyed a collection of problems and described simple greedy algorithms for several of these problems. In several cases, the greedy algorithms described do not represent the state of the art for these problems. The reader is referred to other chapters in this handbook to read in more detail about the specific problems and the techniques that yield the best worst-case approximation guarantees. In many instances, the performance of greedy algorithms may be better than their worst-case bounds suggest. This and their simplicity make them important in practice.

For some problems (e.g., set cover), it is known that a greedy algorithm gives the best possible approximation ratio unless $NP \subset \mathrm{DTIME}(n^{\log\log n})$. But for some problems no such intractability results are yet known. In these cases, instead of proving hardness of approximation for all polynomial-time algorithms, one may try something easier: to prove that no *greedy* algorithm gives a good approximation. Of course this requires a formal definition of the class of algorithms. (A similar approach has been fruitful in competitive analysis of online algorithms.) Such a formal study of greedy algorithms with an eye toward lower bound results has been the subject of several recent papers [33].

For additional information on combinatorial optimization, the reader is referred to books by Papadimitriou and Steiglitz [2], Cook et al. [34], and a series of three books by Schrijver [35]. For more on approximation algorithms, there is a book by Vazirani [23], lecture notes by Motwani [36], and a book edited by Hochbaum [37]. There is a chapter on greedy algorithms in several textbooks, such as Kleinberg and Tardos [38], and Cormen et al. [39]. More on randomized algorithms can be found in a book by Motwani and Raghavan [40], and a survey by Shmoys [41].

Recursive Greedy Methods

Guy Even
Tel Aviv University

5.1 Introduction

Greedy algorithms are often the first algorithms that one considers for various optimization problems, and, in particular, covering problems. The idea is very simple: try to build a solution incrementally by augmenting a partial solution. In each iteration, select the "best" augmentation according to a simple criterion. The term greedy is used because the most common criterion is to select an augmentation that minimizes the ratio of "cost" to "advantage." We refer to the cost-to-advantage ratio of an augmentation as the *density* of the augmentation.

In the set-cover (SC) problem, every set S has a weight (or cost) $w(S)$. The "advantage" of a set S with respect to a partial cover $\{S_1, \ldots, S_k\}$ is the number of new elements covered by S, i.e., $|S \setminus (S_1 \cdots S_k)|$. In each iteration, a set with a minimum density is selected and added to the partial solution until all the elements are covered. In the SC problem, it is easy to find an augmentation with minimum density simply by recomputing the density of every set in every iteration.

In this chapter, we consider problems for which it is NP-hard to find an augmentation with minimum density. From a covering point of view, this means that there are exponentially many sets. However, these sets are succinctly represented using a structure with polynomial complexity. For example, the sets can be paths or trees in a graph. In such problems, applying the greedy algorithm is a nontrivial task. One way to deal with such a difficulty is to try to approximate a minimum density augmentation. Interestingly, the augmentation itself is computed using a greedy algorithm, and this is why the algorithm is called the recursive greedy algorithm.

The recursive greedy algorithm was presented by Zelikovsky [1] and Kortsarz and Peleg [2]. In Ref. [1], the directed Steiner tree (DST) problem in acyclic graphs was considered. In the DST problem, the input consists of a directed graph $G = (V, E)$ with edge weights $w(e)$, a subset $X \subseteq V$ of terminals, and a root $r \in V$. The goal is to find a minimum-weight subgraph that contains directed paths from r to every terminal in X. In Ref. [2], the bounded diameter Steiner tree (BDST) problem was considered. In the BDST problem, the input consists of an undirected graph $G = (V, E)$ with edge costs $w(e)$, a subset of terminals $X \subseteq V$, and a diameter parameter d. The goal is to find a minimum-weight tree that spans

X with diameter bounded by d. In both papers, it is proved that, for every $\varepsilon > 0$, the recursive greedy algorithm achieves an $O(|X|^{\varepsilon})$ approximation ratio in polynomial time. The recursive greedy algorithm is still the only nontrivial approximation algorithm known for these problems.

The presentation of the recursive greedy algorithm was simplified and its analysis was perfected by Charikar et al. [3]. In Ref. [3], the recursive greedy algorithm was used for the DST problem. The improved analysis gave a poly-logarithmic approximation ratio in quasi-polynomial time (i.e., running time is $O(n^{c \log n})$, for a constant c).

The recursive greedy algorithm is a combinatorial algorithm (i.e., no linear programming or high precision arithmetic is used). The algorithm's description is simple and short. The analysis captures the intuition regarding the segments during which the greedy approach performs well. The running time of the algorithm is exponential in the depth of the recursion, and hence, reducing its running time is an important issue.

We present modifications of the recursive greedy algorithm that enable reducing the running time. Unfortunately, these modifications apply only to the restricted case in which the graph is a tree. We demonstrate these methods on the Group Steiner (GS) problem [4] and its restriction to trees [5]. Following Ref. [6], we show that for the GS problem over trees, the recursive greedy algorithm can be modified to give a poly-logarithmic approximation ratio in polynomial time. Better poly-logarithmic approximation algorithms were developed for the GS problem; however, these algorithms rely on linear programming [5,7].

5.1.1 Organization

In Section 5.2, we review the greedy algorithm for the SC problem. In Section 5.3, we present three versions of DST problems. We present simple reductions that allow us to focus on only one version. Section 5.4 constitutes the heart of this chapter; in it the recursive greedy algorithm and its analysis are presented. In Section 5.5, we consider the GS problem over trees. We outline modifications of the recursive greedy algorithm that enable a poly-logarithmic approximation ratio in polynomial time. We conclude in Section 5.6 with open problems.

5.2 A Review of the Greedy Algorithm

In this section we review the greedy algorithm for the SC problem and its analysis.

In the SC problem we are given a set of elements, denoted by $U = \{1, \ldots, n\}$ and a collection $\mathcal{R}$ of subsets of U. Each subset $S \in \mathcal{R}$ is also given a nonnegative weight $w(S)$. A subset $\mathcal{C} \subseteq \mathcal{R}$ is an SC if $\bigcup_{S' \in \mathcal{C}} S' = \{1, \ldots, n\}$. The *weight* of a subset of $\mathcal{R}$ is simply the sum of the weights of the sets in $\mathcal{R}$. The goal in the SC problem is to find a cover of minimum weight. We often refer to a subset of $\mathcal{R}$ that is not a cover as a *partial cover*.

The greedy algorithm starts with an empty partial cover. A cover is constructed by iteratively asking an *oracle* for a set to be added to the partial cover. This means that no backtracking takes place; every set that is added to the partial cover is kept until a cover is obtained. The oracle looks for a set with the lowest *residual density*, defined as follows.

Definition 5.1

Given a partial cover $\mathcal{C}$, the residual density of a set S is the ratio

$$\rho_{\mathcal{C}}(S) \triangleq \frac{w(S)}{|S \setminus \bigcup_{S' \in \mathcal{C}} S'|}$$

Note that the residual density is nondecreasing (and may even increase) as the greedy algorithm accumulates sets. The performance guarantee of the greedy algorithm is summarized in the following theorem (see Chapter 4).

Theorem 5.1

The greedy algorithm computes a cover whose cost is at most $(1 + \ln\ n) \cdot w(C^*)$, *where* C^* *is a minimum-weight cover.*

There are two main questions that we wish to ask about the greedy algorithm:

Question 1: What happens if the oracle is approximate? Namely, what if the oracle does not return a set with minimum residual density, but a set whose residual density is at most α times the minimum residual density? How does such an approximate oracle affect the approximation ratio of the greedy algorithm? In particular, we are interested in the case that α is not constant (e.g., α depends on the number of uncovered elements). We note that in the SC problem, an exact oracle is easy to implement. But we will see a generalization of the SC problem in which the task of an exact oracle is NP-hard, and hence we will need to consider an approximate oracle.

Question 2: What happens if we stop the execution of the greedy algorithm before a complete cover is obtained? Suppose that we stop the greedy algorithm when the partial cover covers $\beta \cdot n$ elements in U. Can we bound the weight of the partial cover? We note that one reason for stopping the greedy algorithm before it ends is that we simply run out of "budget" and cannot "pay" for additional sets.

The following lemma helps answer both questions. Let x denote the number of elements that are not covered by the partial cover. We say that the oracle is $\alpha(x)$-approximate if the residual density of the set it finds is at most $\alpha(x)$ times the minimum residual density.

Lemma 5.1 (Charikar et al. [3])

Suppose that the oracle of the greedy algorithm is $\alpha(x)$*-approximate and that* $\alpha(x)/x$ *is a nonincreasing function. Let* $\mathcal{C}_i$ *denote partial cover accumulated by the greedy algorithm after adding i sets. Then,*

$$\frac{w(\mathcal{C}_i)}{w(\mathcal{C}^*)} \leq \int_{n-|\cup_{S'\in\mathcal{C}_i} S'|}^{n} \frac{\alpha(x)}{x}\, dx$$

Proof

The proof is by induction on n. When $n = 1$, the algorithm simply returns a set S such that $w(S) \leq \alpha(1) \cdot w(\mathcal{C}^*)$. Since $\alpha(x)/x$ is nonincreasing, we conclude that $\alpha(1) \leq \int_0^1 \frac{\alpha(x)}{x}\, dx$, and the induction basis follows.

The induction step for $n > 1$ is proved as follows. Let $\mathcal{C}_i = \{S_1, \ldots, S_i\}$. When the oracle computes S_1, its density satisfies: $w(S_1)/|S_1| \leq \alpha(n) \cdot w(\mathcal{C}^*)/n$. Hence, $w(S_1) \leq |S_1| \cdot \frac{\alpha(n)}{n} \cdot w(\mathcal{C}^*)$. Since $\alpha(x)/x$ is nonincreasing, $|S_1| \cdot \frac{\alpha(n)}{n} \leq \int_{n-|S_1|}^{n} \frac{\alpha(x)}{x}\, dx$. We conclude that

$$w(S_1) \leq \int_{n-|S_1|}^{n} \frac{\alpha(x)}{x} dx \cdot w(\mathcal{C}^*) \tag{5.1}$$

Now consider the residual set system over the set of elements $\{1, \ldots, n\} \setminus S_1$ with the sets $S' = S \setminus S_1$. We keep the set weights unchanged, i.e., $w(S') = w(S)$. The collection $\{S'_2, \ldots, S'_i\}$ is the output of the greedy algorithm when given this residual set system. Let $n' = |S'_2 \cup \cdots \cup S'_i|$. Since $\mathcal{C}^*$ induces a cover of the residual set with the same weight as $w(\mathcal{C}^*)$, the induction hypothesis implies that

$$w(S'_2) + \cdots + w(S'_i) \leq \int_{n-(n'+|S_1|)}^{n-|S_1|} \frac{\alpha(x)}{x} dx \cdot w(\mathcal{C}^*). \tag{5.2}$$

The lemma follows now by adding Eq. (5.1) and Eq. (5.2). □

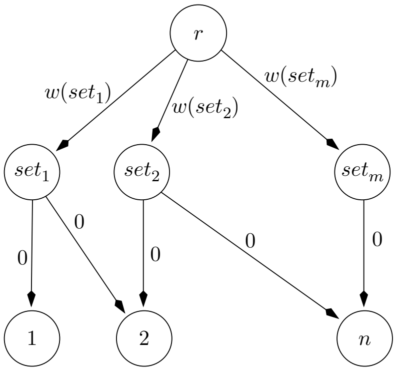

FIGURE 5.1 Reduction of SC instance to DST instance.

We remark that for a full cover, since $\int_0^1 dx/x$ is not bounded, one could bound the ratio by $\alpha(1) + \int_1^n \frac{\alpha(x)}{x}\,dx$. Note that for an exact oracle $\alpha(x) = 1$, this modification of Lemma 5.1 implies Theorem 5.1.

Lemma 5.1 shows that the greedy algorithm also works with approximate oracles. If $\alpha(x) = O(\log x)$, then the approximation ratio of the greedy algorithm is simply $O(\alpha(n) \cdot \log n)$. But, for example, if $\alpha(x) = x^{\varepsilon}$, then the lemma "saves" a factor of $\log n$ and shows that the approximation ratio is $\frac{1}{\varepsilon} \cdot n^{\varepsilon}$. So this settles the first question.

Lemma 5.1 also helps settle the second question. In fact, it proves that the greedy algorithm (with an exact oracle) is a bicriteria algorithm in the following sense.

Claim 5.1

If the greedy algorithm is stopped when $\beta \cdot n$ elements are covered, then the cost of the partial cover is bounded by $\ln\left(\frac{1}{1-\beta}\right) \cdot w(C^*)$.

The greedy algorithm surly does well with the first set it selects, but what can we say about the remaining selections? Claim 5.1 quantifies how well the greedy algorithm does as a function of the portion of the covered elements. For example, if $\beta = 1 - 1/e$, then the partial cover computed by the greedy algorithm weighs no more than $w(C^*)$. (We ignore here the knapsack-like issue of how to cover "exactly" $\beta \cdot n$ elements, and assume that, when we stopped the greedy algorithm, the partial cover covers $\beta \cdot n$ elements.) The lesson to be remembered here is that the greedy algorithm performs "reasonably well" as long as "few" elements have been covered.

The DST problem is a generalization of the SC problem. In fact, every SC instance can be represented as a DST instance over a layered directed graph with three vertex layers (see Figure 5.1). The top layer contains only a root, the middle layer contains a vertex for every set, and the bottom layer contains a vertex for every element. The weight of an edge from the root to a set is simply the weight of the set. The weight of all edges from sets to elements are zero. The best approximation algorithm for SC is the greedy algorithm. What form could a greedy algorithm have for the DST problem?

5.3 Directed Steiner Problems

In this section, we present three versions of DST problems. We present simple reductions that allow us to focus on only the last version.

Notation and Terminology

We denote the vertex set and edge set of a graph G by $V(G)$ and $E(G)$, respectively. An *arborescence* T rooted at r is a directed graph such that (i) the underlying graph of T is a tree (i.e., if edge directions are ignored in T, then T is a tree), and (ii) there is a directed path in T from the root r to every node in T. If an arborescence T is a subgraph of G, then we say that T *covers* (or *spans*) a subset of vertices X if $X \subseteq V(T)$. If edges have weights $w(e)$, then the weight of a subgraph G' is simply $\sum_{e \in E(G')} w(e)$. We denote by T_v the subgraph of T that is induced by all the vertices reachable from v (including v).

5.3.1 The Problems

The DST Problem

In the DST problem the input consists of a directed graph G, a set of terminals $X \subseteq V(G)$, positive edge weights $w(e)$, and a root $r \in V(G)$. An arborescence T rooted at r is a DST if it spans the set of terminals X. The goal in the DST problem is to find a minimum-weight DST.

The k-DST Problem

Following Ref. [3], we consider a version of the DST problem, called k-DST, in which only part of the terminals must be covered. In the k-DST problem, there is an additional parameter k, often called the *demand.* An arborescence T rooted at r is a k*-partial* DST (k-DST) if $|V(T) \cap X| \geq k$. The goal in the k-DST problem is to find a minimum-weight k-partial DST. We denote the weight of an optimal k-partial DST by $DS^*(G, X, k)$. (Formally, the root r should be a parameter, but we omit it to shorten the notation.) We encode DST instances as k-DST instances simply by setting $k = |X|$.

The ℓ-Shallow k-DST Problem

Following Ref. [2], we consider a version of the k-DST problem in which the length of the paths from the root to the terminals is bounded by a parameter ℓ. A rooted arborescence in which every node is at most ℓ edges away from the root is called an ℓ*-layered tree.* (Note that we count the number of layers of edges; the number of layers of nodes is $\ell + 1$.) In the ℓ-shallow k-DST problem, the goal is to compute a minimum k-DST among all ℓ-layered trees.

5.3.2 Reductions

Obviously, the k-DST problem is a generalization of the DST problem. Similarly, the ℓ-shallow k-DST problem is a generalization of the k-DST problem (i.e., simply set $\ell = |V| - 1$). The only nontrivial approximation algorithm we know is for the ℓ-shallow k-DST problem; this approximation algorithm is a recursive greedy algorithm. Since its running time is exponential in ℓ, we need to consider reductions that result with as small as possible values of ℓ.

For this purpose we consider two well-known transformations: transitive closure and layering. We now define each of these transformations.

Transitive Closure

The *transitive closure* of G is a directed graph $TC(G)$ over the same vertex set. For every $u, v \in V$, the pair (u, v) is an edge in $E(TC(G))$ if there is a directed path from u to v in G. The weight $w'(u, v)$ of an edge in $E(TC(G))$ is the minimum weight of a path in G from u to v.

The weight of an optimal k-DST is not affected by applying transitive closure namely,

$$DS^*(G, X, k) = DS^*(TC(G), X, k) \tag{5.3}$$

This means that replacing G by its transitive closure does not change the weight of an optimal k-DST. Hence, we may assume that G is transitively closed, i.e., $G = TC(G)$.

Layering

Let ℓ denote a positive integer. We reduce the directed graph G into an ℓ-layered directed acyclic graph LG_ℓ as follows (see Figure 5.2). The vertex set $V(LG_\ell)$ is simply $V(G) \times \{0, \ldots, \ell\}$. The jth layer in $V(LG_\ell)$ is the subset of vertices $V(G) \times \{j\}$. We refer to $V(G) \times \{0\}$ as the *bottom layer* and to $V(G) \times \{\ell\}$ as the *top layer.* The graph LG_ℓ is layered in the sense that $E(LG_\ell)$ contains only edges from the $V(G) \times \{j + 1\}$ to $V(G) \times \{j\}$, for $j < \ell$. The edge set $E(LG_\ell)$ contains two types of edges: *regular* edges and *parallel* edges. For every $(u, v) \in E(G)$ and every $j < \ell$, there is a regular

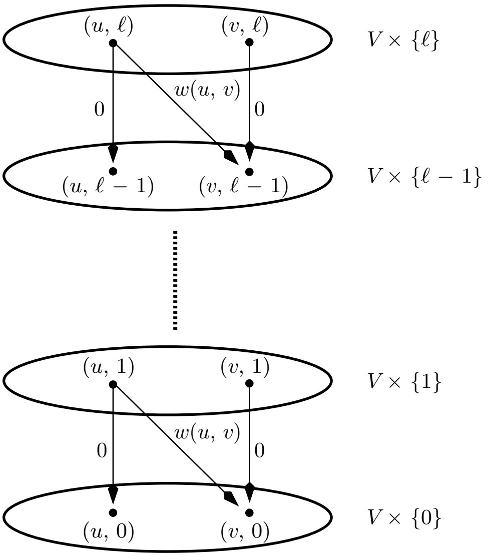

FIGURE 5.2 Layering of a directed graph G. Only parallel edges incident to images of $u, v \in V(G)$ and regular edges corresponding to $(u, v) \in E(G)$ are depicted.

edge $(u, j + 1) \rightarrow (v, j) \in E(LG_\ell)$. For every $u \in V$ and every $j < \ell$, there is a parallel edge $(u, j + 1) \rightarrow (u, j) \in E(LG_\ell)$. All parallel edges have zero weight. The weight of a regular edge is inherited from the original edge, namely, $w((u, j + 1) \rightarrow (v, j)) = w(u, v)$. The set of terminals X' in $V(LG_\ell)$ is simply $X \times \{0\}$, namely, images of terminals in the bottom layer. The root in LG_ℓ is the node (r, ℓ). The following observation shows that we can restrict our attention to layered graphs.

Observation 5.1

There is a weight- and terminal-preserving correspondence between ℓ-layered r-rooted trees in G and (r, ℓ)-rooted trees in LG_ℓ. In particular, $w(LT^*_\ell) = DS^*(LG_\ell, X', k)$, where LT^*_ℓ denotes a minimum-weight k-DST among all ℓ-layered trees.

Observation 5.1 implies that if we wish to approximate LT^*_ℓ, then we may apply layering and assume that the input graph is an ℓ-layered acyclic graph in which the root is in the top layer and all the terminals are in the bottom layer.

Limiting the Number of Layers

As we pointed out, the running time of the recursive greedy algorithm is exponential in the number of layers. It is therefore crucial to be able to bound the number of layers. The following lemma bounds the penalty incurred by limiting the number of layers in the Steiner tree. The proof of the lemma appears in Appendix A and uses notation introduced in Section 5.4. (A slightly stronger version appears in Ref. [8], with the ratio $2^{1-1/\ell} \cdot \ell \cdot k^{1/\ell}$.)

Lemma 5.2 (Zelikovsky [1], corrected in Helvig et al. [8])

If G is transitively closed, then $w(LT^*_\ell) \leq \frac{\ell}{2} \cdot k^{2/\ell} \cdot DS^*(G, X, k)$.

It follows that an α-approximate algorithm for an ℓ-shallow k-DST is also an $\alpha\beta$-approximation algorithm for k-DST, where $\beta = \frac{\ell}{2} \cdot k^{2/\ell}$. We now focus on the development of an approximation algorithm for the ℓ-shallow k-DST problem.

5.4 A Recursive Greedy Algorithm for ℓ-Shallow k-DST

This section presents a recursive greedy algorithm for the ℓ-shallow k-DST problem. Based on the layering transformation, we assume that the input graph is an ℓ-layered acyclic directed graph G. The set of terminals, denoted by X, is contained in the bottom layer. The root, denoted by r, belongs to the top layer.

5.4.1 Motivation

We now try to extend the greedy algorithm to the ℓ-shallow k-DST problem. Suppose we have a directed tree $T \subseteq G$ that is rooted at r. This tree only covers part of the terminals. Now we wish to augment T so that it covers more terminals. In other words, we are looking for an r-rooted augmenting tree T_{aug} to be added to the T. We follow the minimum density heuristic, and define the residual density of T_{aug} by

$$\rho_T(T_{aug}) \triangleq \frac{w(T_{aug})}{|(T_{aug} \cap X) \setminus (T \cap X)|}$$

All we need now is an algorithm that finds an augmenting tree with the minimum residual density. Unfortunately, this problem is by itself NP-hard. Consider the following reduction: Let G denote the two-layered DST instance mentioned above to represent an SC instance. Add a layer with a single node r' that is connected to the root r of G. The weight of the edge (r', r) should be large (say, n times the sum of the weights of the sets). It is easy to see that every minimum density subtree must span all the terminals. Hence, every minimum density subtree induces a minimum-weight SC, and finding a minimum density subtree in a three-layered graph is already NP-hard. We show in Section 5.4.3 that for two or less layers, one can find a minimum density augmenting tree in polynomial time.

We already showed that the greedy algorithm also works well with an approximate oracle. So we try to approximate a subtree with minimum residual density. The problem is how to do it? The answer is by applying a greedy algorithm recursively!

Consider an ℓ-layered directed graph and a root r. The algorithm finds a low-density ℓ-layered augmenting tree by accumulating low-density $(\ell - 1)$-layered augmenting trees that hang from the children of r. These trees are found by augmenting low-density trees that hang from grandchildren of r, and so on. We now formally describe the algorithm.

5.4.2 The Recursive Greedy Algorithm

Notation

We denote the number of terminals in a subgraph G' by $k(G')$ (i.e., $k(G') = |X \cap V(G')|$). Similarly, for a set of vertices U, $k(U) = |X \cap U|$. We denote the set of vertices reachable in G from u by *desc*(u). We denote the layer of a vertex u by *layer*(u) (e.g., if u is a terminal, then *layer*$(u) = 0$).

Description

A listing of the algorithm DS(u, k, X) appears as Algorithm 5.1. The stopping condition is when u belongs to the bottom layer or when the number of uncovered terminals reachable from u is less than the demand k (i.e., the instance is infeasible). In either case, the algorithm simply returns the root $\{r\}$.

The algorithm maintains a partial cover T that is initialized to the single vertex u. The augmenting tree T_{aug} is selected as the best tree found by the recursive calls to the children of u (together with the edge from u to its child). Note that the recursive calls are applied to all the children of u and all the possible demands k'. After T_{aug} is added to the partial solution, the terminals covered by T_{aug} are erased from the set of terminals so that the recursive calls will not attempt to cover terminals again. Once the demand is met, namely, k terminals are covered, the accumulated cover T is returned.

The algorithm is invoked with the root r, the demand k, and the set of terminals X. Note that if the instance is feasible (namely, at least k terminals are reachable from the root), then the algorithm never encounters infeasible subinstances during its execution.

Algorithm 5.1 DS(u, k, X)—A recursive greedy algorithm for the Directed Steiner Tree Problem. The graph is layered and all the vertices in the bottom layer are terminals. The set of terminals is denoted by X. We are searching for a tree rooted at u that covers k terminals.

```
stopping condition: if $layer(u) = 0$ or $k(desc(u)) < k$ then return $(\{u\})$.
initialize: $T \leftarrow \{u\}$; $X^{res} \leftarrow X$.
while $k(T) < k$ do
    recurse: for every $v \in children(u)$ and every $k' \leq \min\{k - k(T), |desc(v) \cap X^{res})|\}$
                    $T_{v,k'} \leftarrow \mathrm{DS}(v, k', X^{res})$.
    select: Let $T_{aug}$ be a lowest residual density tree among the trees $T_{v,k'} \cup \{(u, v)\}$, where
        $v \in children(u)$ and $k' \leq k - k(T)$.
    augment & update: $T \leftarrow T \cup T_{aug}$; $X^{res} \leftarrow X^{res} \setminus V(T_{aug})$.
end while
return $(T)$.
```

5.4.3 Analysis

Minimum Residual Density Subtree

Consider a partial solution T rooted at u accumulated by the algorithm. A tree T' rooted at u is a *candidate tree* for augmentation, if (i) every vertex $v \in V(T')$ in the bottom layer of G is in X^{res} (i.e., T' covers only new terminals) and (ii) $0 < k(T') \leq k - k(T)$ (i.e., T' does not cover more terminals than the residual demand). We denote by T'_u a tree with minimum residual density among all the candidate trees.

We leave the proof of the following lemma as an exercise.

Lemma 5.3

Assume that $w_i, k_i > 0$, *for every* $0 \leq i \leq n$. *Then,* $\min_i \frac{w_i}{k_i} \leq \frac{\sum_i w_i}{\sum_i k_i} \leq \max_i \frac{w_i}{k_i}$.

Corollary 5.1

If u is not a terminal, then we may assume that u has a single child in T'_u.

Proof

We show that we could pick a candidate tree with minimum residual density in which u has a single child. Suppose that u has more than one child in T'_u. To every edge $e_j = (u, v_j) \in E(T'_u)$ we match a subtree A_{e_j} of T'_u. The subtree A_{e_j} contains u, the edge (u, v_j), and the subtree of T'_u hanging from v_j. The subtrees $\{A_{e_j}\}_{e_j}$ form an edge-disjoint decomposition of T'_u. Let $w_j = w(A_{e_j})$ and $k_j = k(A_{e_j} \setminus T)$. Since u is not a terminal, the subtrees $\{A_{e_j}\}_{e_j}$ partition the terminals in $V(T'_u)$, and $k(T'_u) = \sum_j k_j$. Similarly, $w(T'_u) = \sum_j w_j$. By Lemma 5.3, it follows that one of the trees A_{e_j} has a residual density that is not greater than the residual density of T'_u. Use this minimum residual density subtree instead of T'_u, and the corollary follows. □

Density

Note that edge weights are nonnegative and already covered terminals do not help in reducing the residual density. Therefore, every augmenting tree T_{aug} covers only new terminals and does not contain terminals already covered by T. It follows that every terminal in T_{aug} belongs to X^{res} and, therefore, $k(T_{aug}) = |T_{aug} \cap X^{res}|$. We may assume that the same holds for T'_u; namely, T'_u does not contain already covered terminals. Therefore, where possible, we ignore the "context" T in the definition of the residual density and simply refer to *density*, i.e., the density of a tree T' is $\rho(T') = w(T')/|V(T') \cap X|$.

Notation and Terminology

A *directed star* is a one-layered rooted directed graph (i.e., there is a center out of which directed edges emanate to the leaves). We abbreviate and refer to a directed star simply as a star. A *flower* is a two-layered rooted graph in which the root has a single child.

Bounding the Density of Augmenting Trees

When *layer* $(u) = 1$, if u has least k terminal neighbors, then the algorithm returns a star centered at u. The number of edges emanating from r in the star equals k, and these k edges are the k lightest edges emanating from r to terminals. It is easy to see that in this case the algorithm returns an optimal k-DST.

The analysis of the algorithm is based on the following claim that bounds the ratio between the densities of the augmenting tree and T'_u.

Claim 5.2 **(Charikar et al. [3])**

If layer $(u) \geq 2$*, then, in every iteration of the while loop in an execution of* $DS(u, k)$*, the subtree* T_{aug} *satisfies*

$$\rho(T_{aug}) \leq (layer(u) - 1) \cdot \rho(T'_u)$$

Proof

The proof is by induction on *layer* (u). Suppose that *layer* $(u) = 2$. By Corollary 5.1, T'_u is a flower that consists of a star S_v centered at a neighbor v of u, the node u, and the edge (u, v). Moreover, S_v contains the $k(T'_u)$ closest terminals to v. When the algorithm computes T_{aug} it considers all stars centered at children v' of u consisting of the $k' \leq k - k(T)$ closest terminals to v'. In particular, it considers the star S_v together with the edge (u, v). Hence, $\rho(T_{aug}) \leq \rho(T'_u)$, as required.

We now prove the induction step for *layer* $(u) > 2$. Let $i =$ *layer* (u). The setting is as follows: During an execution of $DS(u, X)$, a partial cover T has been accumulated, and now an augmenting tree T_{aug} is computed. Our goal is to bound the density of T_{aug}.

By Corollary 5.1, u has a single child in T'_u. Denote this child by u'. Let $B_{u'}$ denote the subtree of T'_u that hangs from u' (i.e., $B_{u'} = T'_u \backslash \{u, (u, u')\}$). Let $k' = k(T'_u)$.

We now analyze the selection of T_{aug} while bearing in mind the existence of the "hidden candidate" T'_u that covers k' terminals. Consider the tree $T_{u',k'}$ computed by the recursive call DS(u', k', X^{res}). We would like to argue that $T_{u',k'}$ should be a good candidate. Unfortunately, that might not be true! However, recall that the greedy algorithm does "well" as long as "few" terminals are covered. So we wish to show that a "small prefix" of $T_{u',k'}$ is indeed a good candidate. We now formalize this intuition.

The tree $T_{u',k'}$ is also constructed by a sequence of augmenting trees, denoted by $\{A_j\}_j$. Namely, $T_{u',k'} = \bigcup_j A_j$. We identify the smallest index ℓ for which the union of augmentations $A_1 \cup \cdots \cup A_\ell$ covers at least $k'/(i - 1)$ terminals (recall that $i =$ *layer* (u)). Formally,

$$k\left(\bigcup_{j=1}^{\ell-1} A_j\right) < \frac{k'}{(i-1)} \leq k\left(\bigcup_{j=1}^{\ell} A_j\right)$$

Our goal is to prove the following two facts. Fact (1): Let $k'' = k(\bigcup_{j=1}^{\ell} A_j)$, then the candidate tree $T_{u',k''} =$ DS(u', k'', X^{res}) equals the prefix $\bigcup_{j=1}^{\ell} A_j$. Fact (2): The density of $T_{u',k''}$ is small, i.e., $\rho(T_{u',k''}) \leq (i - 1) \cdot \rho(B_{u'})$.

The first fact is a "simulation argument" since it claims that the union of the first ℓ augmentations computed in the course of the construction of $T_{u',k'}$ is actually one of the candidate trees computed by the algorithm. This simulation argument holds because, as long as the augmentations do not meet the demand, the same prefix of augmentations is computed. Note that k'' is the formalization of "few" terminals (compared to k'). Using $k'/(i-1)$ as an exact measure for a few terminals does not work because the simulation argument would fail.

The second fact states that the density of the candidate $T_{u',k''}$ is smaller than $(i - 1) \cdot \rho(B_{u'})$. Note that $B_{u'}$ and $A_1 \cup \cdots \cup A_{\ell-1}$ may share terminals (in fact, we would "like" the algorithm to "imitate"

$B_{u'}$ as much as possible). Hence, the residual density of $B_{u'}$ may increase as a result of adding the trees $A_1, \ldots, A_{\ell-1}$. However, since $k(A_1 \cup \cdots \cup A_{\ell-1}) < k'/(i-1)$, it follows that even after accumulating $A_1 \cup \cdots \cup A_{\ell-1}$, the residual density of $B_{u'}$ does not grow much. Formally, the residual density of $B_{u'}$ after accumulating $A_1 \cup \cdots \cup A_{\ell-1}$ is bounded as follows:

$$\begin{aligned}\rho_{(T \cup A_1 \cup \cdots \cup A_{\ell-1})}(B_{u'}) &= \frac{w(B_{u'})}{k' - k(A_1 \cup \cdots A_{\ell-1})}\\ &\leq \frac{w(B_{u'})}{k' \cdot (1 - \frac{1}{i-1})}\\ &= \left(\frac{i-1}{i-2}\right) \cdot \rho(B_{u'}) \end{aligned} \tag{5.4}$$

We now apply the induction hypothesis to the augmenting trees A_j (for $j \leq \ell$), and bound their residual densities by ($layer(u') - 1$) times the "deteriorated" density of $B_{u'}$. Formally, the induction hypothesis implies that when A_j is selected as an augmentation tree its density satisfies:

$$\begin{aligned}\rho(A_j) &\leq (i-2) \cdot \rho_{(T \cup A_1 \cdots \cup A_{j-1})}(B_{u'})\\ &\leq (i-1) \cdot \rho(B_{u'}) \quad \text{(by Eq. (5.4))}\end{aligned}$$

By Lemma 5.3, $\rho(\bigcup_{j=1}^{\ell} A_j) \leq \max_{j=1 \ldots \ell} \rho(A_j)$. Hence, $\rho(T_{u',k''}) \leq (i-1) \cdot \rho(B_{u'})$, and the second fact follows.

To complete the proof, we need to deal with the addition of the edge (u, u').

$$\begin{aligned}\rho(\{(u,u')\} \cup T_{u',k''}) &= \frac{w(u,u') + w(T_{u',k''})}{k''}\\ &\leq \frac{w(u,u')}{k'} \cdot (i-1) + \rho(T_{u',k''}) \quad \left(\text{since } k'' \geq \frac{k'}{i-1}\right)\\ &\leq (i-1) \cdot \rho(\{(u,u')\} \cup B_{u'}) \quad \text{(by fact [2])}\\ &= (i-1) \cdot \rho(T'_u)\end{aligned}$$

The claim follows since $\{(u, u')\} \cup T_{u',k''}$ is only one of the candidates considered for the augmenting tree T_{aug} and hence $\rho(T_{aug}) \leq \rho(\{(u,u')\} \cup T_{u',k''})$. □

Approximation Ratio

The approximation ratio follows immediately from Lemma 5.1.

Claim 5.3

Suppose that G is ℓ-layered. Then, the approximation ratio of Algorithm $DS(r, k, X)$ is $O(\ell \cdot \log k)$.

Running Time

For each augmenting tree, Algorithm $DS(u, k, X)$ invokes at most $n \cdot k$ recursive calls from children of u. Each augmentation tree covers at least one new terminal, so there are at most k augmenting trees. Hence, there are at most $n \cdot k^2$ recursive calls from the children of u. Let $time(\ell)$ denote the running time of $DS(u, k, X)$, where $\ell = layer(u)$. Then the following recurrence holds: $time(\ell) \leq (n \cdot k^2) \cdot time(\ell - 1)$. We conclude that the running time is $O(n^{\ell} \cdot k^{2\ell})$.

5.4.4 Discussion

Approximation of k-DST

The approximation algorithm is presented for ℓ-layered acyclic graphs. In Section 5.3.2, we presented a reduction from the k-DST problem to the ℓ-shallow k-DST problem. The reduction is based on layering and its outcome is an ℓ-layered acyclic graph. We obtain the following approximation result from this reduction.

Theorem 5.2 **(Charikar et al. [3])**

For every ℓ, there an $O(\ell^3 \cdot k^{2/\ell})$-approximation algorithm for the k-DST problem with running time $O(k^{2\ell} \cdot n^{\ell})$.

Proof

The preprocessing time is dominated by the running time of $DS(r, k, X)$ on the graph after it is transitively closed and layered into ℓ layers.

Let R^* denote a minimum residual density augmenting tree in the transitive closure of the graph (without the layering). Let T'_{k^*} denote a minimum residual subtree rooted at u in the layered graph among the candidate trees that cover $k(R^*)$ terminals. By Lemma 5.2, $w(T'_{k^*}) \leq \ell/2 \cdot k(R^*)^{\ell/2} \cdot w(R^*)$, and hence, $\rho(T'_{k^*}) \leq \ell/2 \cdot k(R^*)^{\ell/2} \cdot \rho(R^*)$. Since $\rho(T'_u) \leq \rho(T'_{k^*})$, by Claim 5.2 it follows that $\rho(T_{aug}) \leq (\ell - 1) \cdot \ell/2 \cdot k^{2/\ell} \cdot \rho(R^*)$.

We now apply Lemma 5.1. Note that $\int \frac{x^{2/\ell}}{x} dx = \frac{\ell}{2} \cdot x^{2/\ell}$. Hence, $w(T) = O(\ell^3 \cdot k^{2/\ell})$, where T is the tree returned by the algorithm, and the theorem follows. □

We conclude with the following result.

Corollary 5.2

For every constant $\varepsilon > 0$, there exists a polynomial-time $O(k^{1/\varepsilon})$-approximation algorithm for the k-DST problem. There exists a quasi-polynomial-time $O(\log^3 k)$-approximation algorithm for the k-DST problem.

Proof

Substitute $\ell = 2/\varepsilon$ and $\ell = \log k$ in Theorem 5.2. □

Preprocessing

Computing the transitive closure of the input graph is necessary for the correctness of the approximation ratio. Recall that Lemma 5.2 holds only if G is transitively closed.

Layering, on the other hand, is used to simplify the presentation. Namely, the algorithm can be described without layering (see Refs. [2,3]). The advantage of using layering is that it enables a unified presentation of the algorithm (i.e., there is no need to deal differently with one-layered trees). In addition, the layered graph is acyclic, so we need not consider multiple "visits" of the same node. Finally, for a given node u, we know from its layer what the recursion level is (i.e., the recursion level is $\ell - \mathit{layer}(u)$) and what the height of the tree we are looking for is (i.e., current height is $\mathit{layer}(u)$).

Suggestions for Improvements

One might try to reduce the running time by not repeating computations associated with the computations of candidate trees. For example, when computing the candidate $T_{v,k-k(T)}$ the algorithm computes a sequence of augmenting trees that is used to build also other candidates rooted at v that cover fewer terminals (we relied on this phenomenon in the simulation argument used in the proof of Claim 5.2). However, such improvements do not seem to reduce the asymptotic running time; namely, the running time would still be exponential in the number of layers and the basis would still be polynomial. We discuss other ways to reduce the running time in the next section.

Another suggestion to improve the algorithm is to zero the weight of edges when they are added to the partial cover T (see Ref. [1]). Unfortunately, we do not know how to take advantage of such a modification in the analysis and, therefore, keep the edge weights unchanged even after we pay for them.

5.5 Improving the Running Time

In this section, we consider a setting in which the recursive greedy algorithm can be modified to obtain a poly-logarithmic approximation ratio in polynomial time. The setting is with a problem called the GS problem, and only part of the modifications are applicable also to the k-DST problem. (Recall that the problem of finding a polynomial-time poly-logarithmic approximation algorithm for k-DST is still open.)

Motivation

We saw that the running time of the recursive greedy algorithm is $O((nk^2)^\ell)$, where k is the demand (i.e., number of terminals that needs to be covered), the degree of a vertex can be as high as $n-1$ (since transitive closure was applied), and ℓ is the bound on the number of layers we allow in the k-DST.

To obtain polynomial running times, we first modify the algorithm and preprocess the input so that its running time is $\log(n)^{O(\ell)}$. We then set $\ell = \log n / \log\log n$. Note that

$$(\log n)^{\frac{\log n}{\log\log n}} = n$$

Hence, a polynomial running time is obtained.

Four modifications are required to make this idea work:

1. Bound the number of layers—we already saw that the penalty incurred by limiting the number of layers can be bounded. In fact, according to Lemma 5.2, the penalty incurred by $\ell = \log n / \log\log n$ is poly-logarithmic (since $\ell \cdot k^{2/\ell} = (\log n)^{O(1)}$).
2. Degree reduction—we must reduce the maximum degree so that it is poly-logarithmic, otherwise too many recursive calls are invoked. Preprocessing of GS instances over trees achieves such a reduction in the degree.
3. Avoid small augmenting trees—we must reduce the number of iterations of the while loop. The number of iterations can be bounded by $(\log n)^c$ if we require that every augmenting tree must cover at least a poly-logarithmic fraction of the residual demand.
4. Geometric search—we must reduce the number of recursive calls. Hence, instead of considering all demands below the residual demand, we consider only demands that are powers of $(1+\varepsilon)$.

The GS Problem over Trees

We now present a setting where all four modifications can be implemented. In the GS problem over trees, the input consists of: (1) an undirected tree T rooted at r with nonnegative edge edges w(e), and (2) groups $g_i \subseteq V(T)$ of terminals. A subtree $T' \subseteq T$ rooted at r covers k groups if $V(T')$ intersects at least k groups. We refer to a subtree that covers k groups as a k-GS tree. The goal is to find a minimum-weight k-GS tree.

We denote the number of vertices by n and the number of groups by m. For simplicity, assume that every terminal is leaf of T and that every leaf of T is a terminal. In addition, we assume that the groups g_i are disjoint. Note that the assumption that the groups are disjoint implies that $\sum_{i=1}^{m} |g_i| \leq n$.

Bounding the Number of Layers

Lemma 5.2 applies also to GS instances over trees, provided that transitive closure is used. Before transitive closure is used, we direct the edges from the node closer to the root to the node farther away from the root. As mentioned above, limiting the number of layers to $\ell = \log n / \log\log n$ incurs a poly-logarithmic penalty.

However, there is a problem with bounding the number of layers according to Lemma 5.2. The problem is that we need to transitively close the tree. This implies that we lose the tree topology and end up with an directed acyclic graph instead. Unfortunately, we only know how to reduce the maximum degree of trees, not of directed acyclic graphs. Hence, we need to develop a different reduction that keeps the tree topology.

In Ref. [6], a height reduction for trees is presented. This reduction replaces T by an ℓ-layered tree T'. The penalty incurred by this reduction is $O(n^{c/\ell})$, where c is a constant. The details of this reduction appear in Ref. [6].

Reducing the Maximum Degree

We now sketch how to preprocess the tree T to obtain a tree $\nu(T)$ such that: (i) There is a weight preserving correspondence between k-GS trees in T and in $\nu(T)$. (ii) The maximum number of children of a vertex in $\nu(T)$ is bounded by an integer $\beta \geq 3$. (iii) The number of layers in $\nu(T)$ is bounded by the number of layers in T plus $\lfloor \log_{\beta/2} n \rfloor$. We set $\beta = \lceil \log n \rceil$, and obtain the required reduction.

We define a node $v \in V(T)$ to be *β-heavy* if the number of terminals that are descendents of v is at least n/β; otherwise v is *β-light*.

Given a tree T rooted at u and a parameter β, the tree $\nu(T)$ is constructed recursively as follows. If u is a leaf, then the algorithm returns u. Otherwise, the star induced by u and its children is locally transformed as follows. Let $v_1, v_2, \ldots, v_k$ denote the children of u.

1. Edges between u and β-heavy children v_i of u are not changed.
2. The β-light children of u are grouped arbitrarily into minimal bunches such that each bunch (except perhaps for the last) is β-heavy. Note that the number of leaves in each bunch (except perhaps for the last bunch) is in the half-closed interval $[n_u/\beta, 2n_u/\beta)$. For every bunch B, a new node b is created. An edge (u, b) is added as well as edges between b and the children of u in the bunch B. The edge weights are set as follows: (a) $w(u, b) \leftarrow 0$, and (b) $w(b, v_i) \leftarrow w(u, v_i)$.

After the local transformation, let $v'_1, v'_2, \ldots, v'_j$ be the new children of u. Some of these children are the original children and some are the new vertices introduced in the bunching. The tree $\nu(T)$ is obtained by recursively processing the subtrees $T_{v'_i}$, for $1 \leq i \leq j$, in essence replacing $T_{v'_i}$ by $\nu(T_{v'_i})$.

The maximum number of children after processing is at most β because the subtrees $\{T_{v'_i}\}_i$ partition the nodes of $V(T_u) - \{u\}$ and each tree except, perhaps one, is β-heavy. The recursion is applied to each subtree $T_{v'_i}$, and hence $\nu(T)$ will satisfies the degree requirement, as claimed. The weight preserving correspondence between k-GS trees in T and in $\nu(T)$ follows from the fact that the "shared" edges (u, b) that were created for bunching together β-light children of u have zero weight.

We now bound the height of $\nu(T)$. Consider a path p in $\nu(T)$ from the root r to a leaf v. All we need to show is that p contains at most $\log_{\beta/2} n$ new nodes (i.e., nodes corresponding to bunches of β-light vertices). However, the number of terminals hanging from a node along p decreases by a factor of at least $\beta/2$ every time we traverse such a new node, and the bound on the height of $\nu(T)$ follows.

The Modified Algorithm

We now present the modified recursive greedy algorithm for GS over trees. A listing of the modified recursive greedy algorithm appears as Algorithm 5.2.

Algorithm 5.2 Modified-GS(u, k, $\mathcal{G}$)—Modified recursive greedy algorithm for k-GS over trees.

```
stopping condition: if $u$ is a leaf then return $(\{u\})$.
Initialize: $cover \leftarrow \{u\}$ and $\mathcal{G}^{res} \leftarrow \mathcal{G}$.
while $k(cover) < k$ do
    recurse: for every $v \in$ children($u$) and
    for every $k'$ $\underline{\text{power of } (1+\lambda) \text{ in } [\gamma_r \cdot (k - k(cover)), k - k(cover)]}$

        $T_{v,k'} \leftarrow$ Modified-GS($v$, $k'$, $\mathcal{G}^{res}$).

    select: (pick the lowest density tree)

        $T_{aug} \leftarrow \text{MIN-DENSITY}\left\{T_{v,k'} \cup \{(u, v)\}\right\}$.

    augment & update: $cover \leftarrow cover \cup T_{aug}$; $\mathcal{G}^{res} \leftarrow \mathcal{G}^{res} \setminus \{g_i : T_{aug}$ intersects $g_i\}$.
    keep $k/h(T_u)$-cover: $\underline{\text{if first time } k(cover) \geq k/h(T_u) \text{ then } cover_h \leftarrow cover.}$
end while
return $\underline{\text{(lowest density tree} \in \{cover, cover_h\})}$.
```

The following notation is used in the algorithm. The input is a rooted undirected tree T that does not appear as a parameter of the input. Instead, a node u is given, and we consider the subtree of T that hangs from u. We denote this subtree by T_u. The partial cover accumulated by the algorithm is denoted by *cover*. The set of groups of terminals is denoted by $\mathcal{G}$. The set of groups of terminals not covered by *cover* is denoted by $\mathcal{G}^{res}$. The number of groups covered by *cover* is denoted by $k(cover)$. The height of a tree T_u is the maximum number of edges along a path from u to a leaf in T_u. We denote the height of T_u by $h(T_u)$.

Two parameters λ and γ_v appear in the algorithm. The parameter λ is set to equal $1/h(T)$. The parameter γ_v satisfies $1/\gamma_v = |children(v)| \cdot (1 + 1/\lambda) \cdot (1 + \lambda)$.

Lines that are significantly modified (compared to Algorithm 5.1) are underlined. In line 4, two modifications take place. First, the smallest demand is not one, but a poly-logarithmic fraction of the residual demand (under the assumption that the maximum degree and the height is poly-logarithmic). Second, only demands that are powers of $(1+\lambda)$ are considered. In line 7, the algorithm also stores the partial cover that first covers at least $1/h(T_u)$ of the initial demand k. This change is important for the simulation argument in the proof. Since the algorithm does not consider all the demands, we need to consider also the partial cover that the simulation argument points to. Finally, in line 9, we return the partial cover with the best density among *cover* and $cover_h$. Again, this selection is required for the simulation argument.

Note that modified-GS$(u, k, \mathcal{G})$ may return now a cover that covers less than k groups. If this happens in the topmost call, then one needs to iterate until a k-GS cover is accumulated.

The following claim is proved in Ref. [6]. It is analogous to Claim 5.2 and is proved by rewriting the proof while taking into account error terms that are caused by the modifications. Due to lack of space, we omit the proof.

Claim 5.4 **(Chekuri et al. [6])**

The density of every augmenting tree T_{aug} *satisfies*

$$\rho(T_{aug}) \le (1+\lambda)^{2h(T_u)} \cdot h(T_u) \cdot \rho(T'_u)$$

The following theorem is proved in Ref. [6]. The assumptions on the height and maximum degree are justified by the reduction discussed above.

Theorem 5.3

Algorithm modified-GS$(r, k, \mathcal{G})$ *is a poly-logarithmic approximation algorithm with polynomial running time for GS instances over trees with logarithmic maximum degree and* $O(\log n/\log\log n)$ *height.*

5.6 Discussion

In this chapter, we presented the recursive greedy algorithm and its analysis. The algorithm is designed for problems in which finding a minimum density augmentation of a partial solution is an NP-hard problem. The main advantages of the algorithm are its simplicity and the fact that it is a combinatorial algorithm. The analysis of the approximation ratio of the recursive greedy algorithm is nontrivial and succeeds in bounding the density of the augmentations.

The recursive greedy algorithm has not been highlighted as a general method, but rather as an algorithm for Steiner tree problems. We believe that it can be used to approximate other problems as well.

Open Problems

The quasi-polynomial-time $O(\log^3 k)$-approximation algorithm for DST raises the question of finding a polynomial-time algorithm with a poly-logarithmic approximation ratio for DST. In particular, the question is whether the running time of the recursive greedy algorithm for DST can be reduced by modifications or preprocessing.

Acknowledgments

I would like to thank Guy Kortsarz for introducing me to the recursive greedy algorithm and sharing his understanding of this algorithm with me. Guy also volunteered to read a draft. I thank Chandra Chekuri for many discussions related to this chapter. Lotem Kaplan listened and read drafts and helped me in

the search for simpler explanations. Thanks to the Max-Planck-Institut für Informatik where I had the opportunity to finish writing the chapter. Special thanks to Kurt Mehlhorn and his group for carefully listening to a talk about this chapter.

Appendix A

Proof of Lemma 5.2

We prove that given a k-DST T in a transitive closed directed graph G, there exists a k-DST T' such that: (i) T' is ℓ-layered and (ii) $w(T') \leq \frac{\ell}{2} \cdot k^{2/\ell} \cdot w(T)$. The proof uses the notation introduced in Section 5.4.

Notation

Consider a rooted tree T. The subtree of T that consists of the vertices hanging from v is denoted by T_v. Let $\alpha = k^{2/\ell}$. We say that a node $v \in V(T)$ is *α-heavy* if $k(T_v) \geq k(T)/\alpha$. A node v is *α-light* if $k(T_v) < k(T)/\alpha$. A node v is *minimally α-heavy* if v is α-heavy and all its children are α-light. A node v is *maximally α-light* if v is α-light and its parent is α-heavy.

Promotion

We now describe an operation called promotion of a node (and hence the subtree hanging from the node). Let G denote a directed graph that is transitively closed. Let T denote a rooted tree at r that is a subgraph of G. *Promotion* of $v \in V(T)$ is the construction of the rooted tree T' over the same vertex set with the edge set: $E(T') \triangleq E(T) \cup \{(r, v)\} \backslash \{(p(v), v)\}$. The promotion of v simply makes v a child of the root.

Height Reduction

The height reduction procedure is listed as Algorithm 5.3. The algorithm iteratively promotes minimally α-heavy nodes that are not children of the root, until every α-heavy node is a child of the root. The algorithm then proceeds with recursive calls for every maximally α-light node. There are two types of maximally α-light nodes: (1) children of promoted nodes, and (2) α-light children of the root (that have not been promoted).

Algorithm 5.3 HR(T, r, α)—A recursive height reduction algorithm. T is a tree rooted at r, and $\alpha > 1$ is a parameter.

```
stopping condition: if $V(T) = \{r\}$ then return $(\{r\})$.
$T' \leftarrow T$.
while $\exists v \in V(T') : v$ is minimally $\alpha$-heavy & $dist(r, v) > 1$ do
    $T' \leftarrow promote(T', v)$
end while
for all maximally $\alpha$-light nodes $v \in V(T')$ do
    $T' \leftarrow$ tree obtained from $T'$ after replacing $T'_v$ by HR$(T'_v, v, \alpha)$.
end for
return $(T')$.
```

The analysis of the algorithm is as follows. Let $h_\alpha(k(T))$ denote an upper bound on the height of the returned tree as a function of the number of terminals in T. The recursion is applied only to maximally α-light trees that are one or two edges away from the current root. It follows that $h_\alpha(k(T))$ satisfies the recurrence

$$h_\alpha(k') \leq h_\alpha(k'/\alpha) + 2$$

Therefore, $h_\alpha(k') \leq 2 \log_\alpha k'$.

Bounding the Weight

We now bound the weight of the tree T' returned by the height reduction algorithm. Note that every edge $e' \in E(T')$ corresponds to a path $path(e') \in T$. We say that an edge $e \in E(T)$ is *charged* by an edge $e' \in E(T')$ if $e \in path(e')$. If we can prove that every edge $e \in E(T)$ is charged at most β times, then $w(T') \leq \beta \cdot w(T)$.

We now prove that every edge $e \in E(T)$ is charged at most $\alpha \cdot \log_\alpha k(T)$ times. It suffices to show that every edge is charged at most α times in each level of the recursion. Since the number of terminals reduces by a factor of at least α in each level of the recursion, the recursion depth is bounded by $\log_\alpha k(T)$. Hence, the bound on the number of times that an edge is charged follows.

Consider an edge $e \in E(T)$ and one level of the recursion. During this level of the recursion, α-heavy nodes are promoted. The subtrees hanging from the promoted nodes are disjoint. Since every such subtree contains at least $k(T)/\alpha$ terminals, it follows that the number of promoted subtrees is at most α. Hence, the number of new edges $(r, v) \in E(T')$ from the root r to a promoted node v is at most α. Each such new edge charges every edge in $E(T)$ at most once, and hence every edge in $E(T)$ is charged at most α times in each recursive call. Note also that the recursive calls in the same level of the recursion are applied to disjoint subtrees. Hence, for every edge $e \in E(T)$, the recursive calls that charge e belong to a single path in the recursion tree.

We conclude that the recursion depth is bounded by $\log_\alpha k(T)$ and an edge is charged at most α times in each recursive call. Set $\ell = 2\log_\alpha k(T)$, and then $\alpha \log_\alpha k(T) = \frac{\ell}{2} \cdot k^{2/\ell}$. The lemma follows. □

Linear Programming

Yuval Rabani
Technion—Israel Institute of Technology

6.1 Introduction

In this chapter we discuss the role of linear programming (LP) in the design and analysis of combinatorial approximation algorithms. Our emphasis is on NP-hard problems in combinatorial optimization. One aspect of their computational hardness is that such problems lack a good characterization of optimal solutions. Thus, approximating the optimum often involves finding a tight-as-possible bound on the optimal value that can be computed efficiently. LP is a powerful tool in deriving such bounds. The starting point is usually a formulation of the combinatorial optimization problem as an integer linear program. As a concrete example, consider the problem of VERTEX COVER. Given an undirected graph $G = (V, E)$ with nonnegative weights on the vertices $w : V \to \mathbb{N}$, we wish to find a minimum-weight set of vertices $V' \subset V$ such that for every $e \in E$, $e \cap V' \neq \emptyset$. This is a well-known NP-hard problem (see Ref. [1]), and here is a natural way to express it as an integer linear program. For every $i \in V$ assign an indicator variable $x_i \in \{0, 1\}$, indicating whether or not $i \in V'$. The constraints $e \cap V' \neq \emptyset$ can be expressed as $x_i + x_j \geq 1$, where $e = \{i, j\}$. The resulting program is

$$\begin{aligned} \text{minimize} \quad & \textstyle\sum_{i \in V} w(i) x_i & & \\ \text{subject to} \quad & x_i + x_j \geq 1 & \forall \{i, j\} \in E \quad & (6.1) \\ & x_i \in \{0, 1\} & \forall i \in V \quad & (6.2) \end{aligned}$$

An ideal bound on the optimum can be derived by optimizing the same objective function over the convex hull of the integer solutions. As the vertices of the convex hull are integer solutions, this would yield an optimal solution. Unfortunately, the fact that VERTEX COVER is NP-hard implies that we are not aware of a concise representation of this linear program. In particular, the convex hull has an exponential number of facets, corresponding to an exponential number of linear constraints. A polynomial-time algorithm that, given a vector $x \in \mathbb{R}^V$, finds a violated constraint or verifies that x is in the convex hull (a so-called *separation oracle*) is unlikely to exist. However, we can compute a lower bound on the optimum by relaxing the integrality constraints (6.2). Thus we get the following *linear programming relaxation* for VERTEX COVER:

$$\begin{aligned} \text{minimize} \quad & \textstyle\sum_{i \in V} w(i) x_i & & \\ \text{subject to} \quad & x_i + x_j \geq 1 & \forall \{i, j\} \in E \quad & \\ & x_i \geq 0 & \forall i \in V \quad & (6.3) \end{aligned}$$

Notice that in an optimal solution there is no reason to set any variable x_i to a value greater than 1, so we do not have to add explicitly the inequalities $x_i \leq 1, \forall i \in V$.

There are several ways in which such a bound can be used to derive an approximation algorithm. The most straightforward method is to solve the linear program, getting an assignment of potentially fractional values to the variables, then use these values to generate an integral solution. Such a procedure is called *rounding*. This chapter's focus is on rounding procedures. Other methods merely use the LP relaxation (or its dual) as a tool for analyzing the performance of an algorithm that does not explicitly solve the linear program. The performance of the approximation algorithm is compared with the solution to the linear program, rather than to the optimal solution of the NP-hard optimization problem. We will not discuss such methods (including the *primal-dual schema* and *dual fitting*) here. These methods are discussed in Chapters 2, 4, 13, 37, 39, 40, 71, and 82. Additional LP rounding applications are discussed in Chapters 7, 9, 11, 12, 70, and 80.

An important invariant of an LP relaxation is its *integrality ratio*, which is the worst-case ratio, over all possible inputs to the combinatorial optimization problem, between the linear program's optimal value and the optimization problem's optimal value. Unless the relaxation is used in conjunction with other techniques, the integrality ratio usually determines our expectation as to the best guarantee that can be achieved by an approximation algorithm relying on the relaxation.

In the following section, we review some of the methods used to derive approximation algorithms from LP relaxations, following the example of VERTEX COVER and many other examples.

6.2 Rounding

How tight is the lower bound $\min\left\{\sum_{i\in V} w(i)x_i : \text{(6.1) and (6.3)}\right\}$? Consider the clique K_n with unit weights on the vertices. Clearly, any $n-1$ vertices form a vertex cover, and if at least two vertices are excluded from the solution, then there will be at least one edge that is not covered. Thus, the cost of an optimal vertex cover is $n-1$. In contrast, assigning $x_i = \frac{1}{2}$ to all vertices i is a feasible solution to VC-LP, and its cost is $\frac{n}{2}$. So the integrality ratio of VC-LP is at least $2-\frac{2}{n}$. The following theorem proves that this is essentially tight.

Theorem 6.1 **(Nemhauser and Trotter [2])**

Every basic feasible solution to the system of linear inequalities consisting of (6.1) *and* (6.3) *is half-integral.*

Proof

Consider a feasible solution x that is not half-integral. We may assume that no entry of x exceeds 1, otherwise it is not a basic solution. Let $V^- = \{i \in V : 0 < x_i < \frac{1}{2}\}$ and let $V^+ = \{i \in V : \frac{1}{2} < x_i < 1\}$. At least one of these sets is not empty. Let $\epsilon > 0$ be a real number such that for every $i \in V^-$, $0 < x_i \pm \epsilon < \frac{1}{2}$, and for every $i \in V^+$, $\frac{1}{2} < x_i \pm \epsilon < 1$. Put

$$x_i^- = \begin{cases} x_i + \epsilon, & i \in V^- \\ x_i - \epsilon, & i \in V^+ \\ x_i, & i \in V\setminus(V^- \cup V^+) \end{cases}$$

and

$$x_i^+ = \begin{cases} x_i - \epsilon, & i \in V^- \\ x_i + \epsilon, & i \in V^+ \\ x_i, & i \in V\setminus(V^- \cup V^+) \end{cases}$$

Both x^- and x^+ are feasible solutions, $x^- \neq x^+$, and $x = \frac{1}{2}(x^- + x^+)$. Therefore, x cannot be a basic solution. □

Theorem 6.1 immediately leads to the following approximation algorithm, due to Hochbaum [3]. Solve the above linear program obtaining a basic optimal solution x^*. Set $V' = \{i \in V : x_i^* \geq \frac{1}{2}\}$. Clearly V' is a vertex cover. (In fact, we do not even need half-integrality. Every feasible solution x has the property that for every edge $\{i, j\} \in E$, either $x_i \geq \frac{1}{2}$ or $x_j \geq \frac{1}{2}$.) Also, by the choice of V' we have that

$$\sum_{i \in V'} w(i) \leq 2 \sum_{i \in V} w(i) x_i^*$$

Therefore, the above algorithm gives a 2 approximation to VERTEX COVER.

Half-integral relaxations that can be rounded easily are rare. In most cases where rounding works, it requires far greater effort and sophistication. Consider the problem of scheduling jobs on a set of unrelated machines so as to minimize the makespan, or R||C$_{\text{max}}$ in standard scheduling theory notation. The input to this problem consists of m machines and n jobs; job j is a sequence of $p_{1j}, p_{2j}, \ldots, p_{mj}$, where $p_{ij} \in \mathbb{N} \cup \{\infty\}$ denotes the processing time of job j on machine i. The goal is to find an assignment of jobs to machines $\varphi : \{1, 2, \ldots, n\} \to \{1, 2, \ldots, m\}$ that minimizes the makespan (i.e., the maximum load on a machine), which is

$$\max_i \sum_{j \in \varphi^{-1}(i)} p_{ij}$$

Clearly, this problem can be solved by the combination of binary search on the minimum makespan M, and a procedure to decide if a solution with makespan at most M exists and provide such a solution if it exists. An obvious formulation of the decision problem as an integer solution to a set of linear constraints uses indicator variables $x_{ij} \in \{0, 1\}$, where $x_{ij} = 1$ if and only if job j is assigned to machine i. Formally, the set of constraints is

$$\sum_i x_{ij} \geq 1 \quad \forall j \tag{6.4}$$

$$\sum_j p_{ij} x_{ij} \leq M \quad \forall i \tag{6.5}$$

$$x_{ij} \in \{0, 1\} \quad \forall i, j \tag{6.6}$$

The first set of constraints (6.4) ensures that every job is assigned to a machine. The second set of constraints (6.5) ensures that the load on each machine is at most the target M. A 0–1 vector x that satisfies all of the above constraints corresponds to a solution with makespan at most M. As R||C$_{\text{max}}$ is NP-hard, finding a feasible solution x is NP-hard. We thus relax the integrality constraints (6.6), replacing them by the constraints

$$x_{ij} \geq 0 \quad \forall i, j \tag{6.7}$$

One last modification is necessary to make this relaxation useful. A fractional solution may assign a fraction of a job j to a machine i for which $p_{ij} > M$. This clearly cannot happen in an integer solution, but might happen in a fractional solution. We therefore eliminate from the inequalities all variables x_{ij} for which $p_{ij} > M$.

A 2-approximation algorithm for R||C$_{\text{max}}$ based on solving the resulting system of linear inequalities is a trivial consequence of the following theorem.

Theorem 6.2 (Lenstra et al. [4])

Any basic solution to the above system of linear inequalities can be rounded in polynomial time to give an assignment of jobs to machines such that the load on any machine does not exceed $2M$.

Proof

The number of constraints (6.4) and (6.5) is $n + m$, so a basic solution x has at most $n + m$ nonzero entries. Any job j that is assigned fractionally to two or more machines contributes at least two nonzero entries. Therefore, at most m jobs are assigned fractionally. To round the fractional solution, assign job j to machine i whenever $x_{ij} = 1$. Let the set of remaining jobs be J. As explained, $|J| \leq m$. Find a matching $\varphi : J \to \{1, 2, \ldots, m\}$, where a job $j \in J$ is matched to a machine $i = \varphi(j)$ such that $x_{ij} > 0$. (The proof that such a matching exists is rather involved. We do not include it here.) Assign the jobs in J according to the matching φ. The analysis of the performance guarantee is quite simple. Assume that a fractional basic solution x exists. The load due to the jobs not in J is at most the fractional load, which is at most M. A job $j \in J$ adds a load of at most M to $\varphi(j)$, because $x_{ij} > 0$ implies that $p_{ij} \le M$. Therefore, the total load on any machine is at most $2M$. □

Another useful tool is *filtering*, which is a technique to exclude some nonzero expensive entries in a fractional solution, leaving a "critical mass" that can be rounded with provable performance. This technique was first proposed by Lin and Vitter [5]. Here we demonstrate its use in getting a constant factor approximation algorithm for METRIC FACILITY LOCATION, following the work of Shmoys et al. [6]. For the sake of simplifying the presentation, we do not try to optimize the performance guarantee. In one simple version of METRIC FACILITY LOCATION we are given a finite metric space (X, d) and a cost function on the points $f : X \to \mathbb{N}$. The points represent both clients, each having a unit demand, and potential locations for facilities. The cost of constructing a facility at $i \in X$ is $f(i)$. Each client $j \in X$ is served by the closest facility i at cost $d(i, j)$. The goal is to minimize the total construction cost plus the total service cost. Here is one way to express the problem using mixed integer programming.

$$\begin{array}{lccr} \text{minimize} & \sum_{i\in X} f(i)x_i + \sum_{i,j\in X} d(i,j)y_{ij} & & \\ \text{subject to} & y_{ij} \le x_i & \forall i, j \in X & (6.8) \\ & \sum_{i\in X} y_{ij} \ge 1 & \forall j \in X & (6.9) \\ & x_i \in \{0,1\} & \forall i \in X & (6.10) \end{array}$$

The obvious LP relaxation replaces the integrality constraints (6.10) with

$$x_i \ge 0 \quad \forall i \in X \tag{6.11}$$

This relaxation can be used to derive a constant factor approximation algorithm for METRIC FACILITY LOCATION, as the following theorem states.

Theorem 6.3

There is a polynomial-time algorithm that computes, for every vectors x, y that satisfy the constraints (6.8), (6.9), *and* (6.11), *integral vectors x', y' satisfying the same constraints, such that*

$$\sum_{i\in X} f(i)x'_i + \sum_{i,j\in X} d(i,j)y'_{ij} \le 4\left(\sum_{i\in X} f(i)x_i + \sum_{i,j\in X} d(i,j)y_{ij}\right)$$

Proof

We may assume that for every $j \in X$, $\sum_{i\in X} y_{ij} = 1$, otherwise we can scale y_{*j} without violating the constraints and without increasing the cost of the solution. For every $j \in X$, let $\rho_j = \sum_{i\in X} d(i,j)y_{ij}$ be the expected service cost for client j under the distribution y_{*j}. By Markov's Inequality, at least $\frac{1}{4}$ of the mass of the distribution lies on potential facility locations i with $d(i, j) \le \frac{4}{3}\rho_j$. We would like to choose the cheapest of these facility locations to open a facility there and serve client j. However, the problem with this idea is that the sets of close facilities for different clients may overlap partially, thus we may charge the same probability mass several times. To overcome this difficulty, we consider a set of clients that have disjoint sets of close facilities. Sort the clients by nondecreasing order of ρ_j, then select a maximal sequence of clients J such that the balls $B(j, 4\rho_j/3) = \{i \in X : d(i, j) \le 4\rho_j/3\}$, for all $j \in J$, are all disjoint. In each ball, select the cheapest location i and set $x'_i = 1$ for all such i. Set $x'_i = 0$ for all other i. Finally, for every $j \in X$, set $y'_{ij} = 1$ for a location i with $x'_i = 1$ which is closest to j, and set $y'_{ij} = 0$ for all other locations i. We have that

$$\sum_{i\in X} f(i)x'_i \le 4\sum_{j\in J}\sum_{i\in B(j,\rho_j)} f(i)x_i \le 4\sum_{i\in X} f(i)x_i$$

Consider $j \in J$. Let i' be the location with $y'_{i'j} = 1$. The cost of serving j is

$$d(i', j) \leq \frac{4}{3}\rho_j = \frac{4}{3}\sum_{i \in X} d(i, j)y_{ij}$$

Finally, consider $j \notin J$. There exists $j' \in J$ such that $\rho_{j'} \leq \rho_j$ and $B(j', 4\rho_{j'}/3) \cap B(j, 4\rho_j/3) \neq \emptyset$. Let i' be the location with $y'_{i'j} = 1$. Then,

$$d(i', j) \leq \frac{4}{3}\rho_j + \frac{8}{3}\rho_{j'} \leq 4\rho_j = 4\sum_{i \in X} d(i, j)y_{ij}$$

This concludes the proof. □

We conclude this section with a brief description of Jain's iterative rounding method, which he used to derive a 2-approximation algorithm for the GENERALIZED STEINER NETWORK problem [7]. The input to this problem is an undirected graph $G = (V, E)$, edge costs $c : E \to \mathbb{N}$, and connectivity requirements $r : V \times V \to \mathbb{N}$. The goal is to find a subgraph $G' = (V, E')$ of minimum total edge cost $\sum_{e \in E'} c(e)$, such that for every $i, j \in V$ there are at least $r(i, j)$ edge-disjoint paths connecting i and j in G'. (Clearly, we may assume that r is symmetric, that is, $r(i, j) = r(j, i)$.) The basis for Jain's algorithm is the following formulation of GENERALIZED STEINER NETWORK. Let $f : 2^V \to \mathbb{Z}$ be defined by $f(S) = \max_{i \in S, j \notin S} r(i, j)$. Thus, $f(S)$ denotes the connectivity requirement across the cut $(S, V \backslash S)$. For every $e \in E$, let $x_e \in \{0, 1\}$ be an indicator variable that will be set to 1 if and only if e is included in the solution E'. Then, GENERALIZED STEINER NETWORK can be expressed as follows:

$$\begin{array}{lll} \text{minimize} & \sum_{e \in E} c(e)x_e & \\ \text{subject to} & \sum_{e : |e \cap S| = 1} x_e \geq f(S) & \forall S \subset V \qquad (6.12) \\ & x_e \in \{0, 1\} & \forall e \in E \qquad (6.13) \end{array}$$

The function f that is used here is *weakly supermodular*, which means that $f(V) = 0$, and for every $A, B \subseteq V$, either $f(A) + f(B) \leq f(A \backslash B) + f(B \backslash A)$ or $f(A) + f(B) \leq f(A \cap B) + f(A \cup B)$ (or both). In fact, Jain's approximation algorithm works for any weakly supermodular function f. It is based on the obvious LP relaxation of the above integer program, replacing the integrality constraints (6.13) by

$$0 \leq x_e \leq 1 \quad \forall e \in E \tag{6.14}$$

Note that the resulting linear program has an exponential number of constraints. However, often an efficient *separation oracle* can be designed, so the linear program can be solved in polynomial time. This is the case with GENERALIZED STEINER NETWORK; the separation oracle computes for every pair of nodes $i, j \in V$ a minimum cut in G with edge capacities x and checks if the cut capacity is at least $r(i, j)$. The approximation algorithm is based on the following theorem.

Theorem 6.4 (Jain [7])

If f is weakly supermodular, then for every basic solution x to the inequalities (6.12) *and* (6.14) *there exists $e \in E$ such that $x_e \geq \frac{1}{2}$.*

The proof of this theorem is quite complicated and is therefore not included here. Given an optimal basic solution x, we generate an integer solution x' as follows. For every $e \in E$ such that $x_e \geq \frac{1}{2}$, we set $x'_e = 1$. Let $E_1 = \left\{e \in E : x_e \geq \frac{1}{2}\right\}$. Then we recompute a basic fractional solution x^1 with the added condition that the edges in E_1 must be picked. To compute x^1, we solve the following linear program:

$$\begin{array}{lll} \text{minimize} & \sum_{e \in E \backslash E_1} c(e)x_e & \\ \text{subject to} & \sum_{e : |e \cap S| = 1} x_e \geq f(S) - |\{e \in E_1 : |e \cap S| = 1\}| & \forall S \subset V \qquad (6.15) \\ & 0 \leq x_e \leq 1 & \forall e \in E \backslash E_1 \qquad (6.16) \end{array}$$

It can be shown easily that if f is weakly supermodular then so is the function g given by $g(S) = f(S) - |\{e \in E_1 : |e \cap S| = 1\}|$, so Theorem 6.4 applies to x^1. We continue to round the solution iteratively and recompute a basic fractional solution to the remaining problem until no more edges need to be taken. This gives a 2 approximation for GENERALIZED STEINER NETWORK.

6.3 Randomized Rounding

Consider the problem of MAXIMUM COVERAGE. The input is a collection of subsets $S_1, S_2, \ldots, S_m$ over the base set $\{1, 2, \ldots, n\}$, and a positive integer $k \in \{1, 2, \ldots, m\}$. The goal is to find k subsets $S_{i_1}, S_{i_2}, \ldots, S_{i_k}$ such that their union $\bigcup_{j=1}^{k} S_{i_j}$ has maximum cardinality. The following is a standard formulation of the problem:

$$\begin{array}{lll} \text{maximize} & \sum_{j=1}^{n} z_j & \\ \text{subject to} & z_j \le \min\left\{1, \sum_{i:\, j\in S_i} x_i\right\} & \forall j \in \{1, 2, \ldots, n\} \quad (6.17) \\ & \sum_{i=1}^{m} x_i = k & \quad (6.18) \\ & x_i \in \{0, 1\} & \forall i \in \{1, 2, \ldots, m\} \quad (6.19) \end{array}$$

Here the variable x_i is the indicator for including the set S_i in the solution. The variable z_j gets set to 1 if and only if j is covered by the sets taken in the solution. In the obvious LP relaxation, these variables are set to values in the interval $[0, 1]$. One interpretation of the relaxation is that now x_i stands for the probability of including S_i in the solution and z_j for the probability of covering j. However, we have no guarantee that a sample space with the desired probabilities exists. Nevertheless, this interpretation proves to be fruitful. Consider the following probabilistic algorithm. Pick k sets at random by sampling k times independently from the distribution Pr given by $\Pr[S_i] = \frac{x_i}{k}$. (Note that $\sum_i \Pr[S_i] = 1$, so this is indeed a distribution over the sets.) Let E_j denote the event that j is covered by the random choice of k sets. We have that

$$\begin{aligned} \Pr[E_j] &= 1 - \Pr[\bar{E}_j] \\ &= 1 - \left(1 - \frac{1}{k} \sum_{i:\, j\in S_i} x_i\right)^k \\ &\ge 1 - \left(1 - \frac{z_j}{k}\right)^k \\ &\ge \frac{e-1}{e} z_j \end{aligned}$$

This implies an approximation guarantee of $\frac{e-1}{e}$ as the expected number of elements covered is $\frac{e-1}{e}\sum_j z_j$, and $\sum_j z_j$ is an upper bound on the optimal value.

Often, bounds on large deviations are useful in the context of randomized rounding. Let $X_1, X_2, X_3, \ldots, X_n$ be independent indicator random variables with $\Pr[X_i = 1] = p_i$. Let $X = \sum_{i=1}^{n} X_i$. By the linearity of expectation, $E[X] = \sum_{i=1}^{n} p_i$. The following Chernoff-like bound is attributed to Spencer (see Ref. [8]).

Lemma 6.1

For every $\epsilon > 0$,

$$\Pr\left[X > (1+\epsilon)E[X]\right] < \left(\frac{e^{\epsilon}}{(1+\epsilon)^{1+\epsilon}}\right)^{E[X]}$$

For an application, consider Raghavan and Thompson's [9] problem of integral multicommodity flow CONGESTION MINIMIZATION that we present here in its simplest unit capacities version. Given a (directed) graph $G = (V, E)$ and a list of source–destination pairs $(s_1, t_1), (s_2, t_2), \ldots, (s_k, t_k)$ (also called *commodities)*, find, for every $i \in \{1, 2, \ldots, k\}$, a path p_i in G from s_i to t_i, minimizing the maximum number of paths that cross a single arc. Consider the following equivalent integer programming formulation. For $i \in \{1, 2, \ldots, k\}$, let P_i denote the set of all simple paths in G from s_i to t_i. (Note that $|P_i|$ might be exponentially large in the input size. We will deal with this issue later.)

$$\begin{array}{llll}
\text{minimize} & u & & \\
\text{subject to} & \sum_{p \in P_i} f_p^i = 1 & \forall i \in \{1, 2, \ldots, k\} & (6.20) \\
& \sum_{i=1}^{k} \sum_{p \in P_i : p \ni e} f_p^i \le u & \forall e \in E & (6.21) \\
& f_p^i \in \{0, 1\} & \forall i \in \{1, 2, \ldots, k\}, \ \forall p \in P_i & (6.22)
\end{array}$$

If we relax the integrality constraints (6.22), we get a linear program whose solution assigns, for every commodity $i \in \{1, 2, \ldots, k\}$, a probability distribution f^i over P_i. (In other words, we get a fractional multicommodity flow solution.) As mentioned, the number of variables in this linear program is exponential in the input size. It is nevertheless possible to solve it in time polynomial in the input size using a separation oracle for the dual. A more standard approach is to replace this linear program with a polynomial-size linear program that has arc flow variables and flow conservation constraints. The computed flows can be decomposed into a polynomial number of flow paths (see, e.g., the book [10]). Either way, we will get distributions f^i that have polynomial-size support. Note that $\max\{1, u\}$ is a lower bound for MINIMUM CONGESTION, as the optimal value is at least 1. We will use this bound in analyzing the following approximation algorithm.

The algorithm applies randomized rounding. For every commodity $i \in \{1, 2, \ldots, k\}$, we choose at random a single path p according to the distribution f^i (i.e., the probability of choosing p is f_p^i). Consider an arc $e \in E$. Clearly, the probability that the path for a commodity i uses e is precisely $q_i = \sum_{p \in P_i : p \ni e} f_p^i$. Let X_i be an indicator random variable that is set to 1 if and only if commodity i uses e. Thus, the load on e is given by $X = \sum_{i=1}^{k} X_i$. We have that

$$\mathrm{E}[X] = \sum_{i=1}^{k} q_i = \sum_{i=1}^{k} \sum_{p \in P_i : p \ni e} f_p^i$$

which is exactly the load on e in the linear program. Unfortunately, if there is more than one arc in the graph we cannot guarantee that all the arcs *simultaneously* will not be loaded more than the expectation. However, by Lemma 6.1, for a constant $c > 0$,

$$\Pr\left[X > c \frac{\log |E|}{\log \log |E|} \max\{1, \mathrm{E}[X]\}\right] < \frac{1}{2|E|}$$

Therefore, with probability at least $\frac{1}{2}$, every arc carries at most $c \frac{\log |E|}{\log \log |E|} \max\{1, u\}$ paths. In fact, if u is large, then the approximation guarantee improves. For example, if $u = \log |E|$, we can apply Lemma 6.1 with a constant ϵ to get a constant factor approximation. As u grows further, the approximation guarantee approaches 1.

6.4 Metric Spaces

Some problems in combinatorial optimization, most notably problems involving cuts in undirected graphs, can be interpreted naturally as optimization over a class of metric spaces. For example, consider the MINIMUM MULTICUT problem, introduced by Klein et al. [11]. The input to this problem is a graph $G = (V, E)$ with nonnegative edge capacities $c : E \to \mathbb{N}$, a positive integer k, and a set of k pairs of nodes $T = \{\{s_1, t_1\}, \{s_2, t_2\}, \ldots, \{s_k, t_k\}\}$ called *terminal pairs*. The goal is to find a set of edges $F \subset E$ of minimum total capacity $c(F) = \sum_{e \in F} c(e)$ whose removal disconnects every pair of terminals in T. This problem can be formalized as the following integer program. Let P denote the set of paths in G connecting

s_i and t_i, for some $i \in \{1, 2, \ldots, k\}$.

$$\begin{aligned} &\text{minimize} && \textstyle\sum_{e\in E} c(e)x_e && \\ &\text{subject to} && \textstyle\sum_{e\in p} x_e \ge 1 && \forall p \in P \qquad (6.23) \\ & && x_e \in \{0, 1\} && \forall e \in E \qquad (6.24) \end{aligned}$$

As usual, an LP relaxation is derived by replacing the integrality constraints (6.24) with

$$x_e \ge 0 \quad \forall e \in E \tag{6.25}$$

Note that the resulting linear program may have an exponential number of constraints. However, this can be dealt with using the same methods explained in the discussion on CONGESTION MINIMIZATION in the previous section. Let x be any feasible solution to the linear program. One way to interpret the solution is the following. Define a semi-metric[1] d on V by setting $d(u, v)$ to be the shortest path between u and v under edge weights given by x. Then the constraints (6.23) put $d(s_i, t_i) \ge 1$ for all $i \in \{1, 2, \ldots, k\}$. In fact, every such metric d corresponds to a feasible solution x by setting, for every $e = (u, v) \in E$, $x_e = d(u, v)$. Our hope is to find a way to "round" the semi-metric d to a multicut without increasing the objective function too much. Note that a multicut F corresponds to a semi-metric δ on V that satisfies the constraints (6.23) and also has $\delta(u, v) \in \{0, 1\}$ for every $u, v \in V$. More specifically, $\delta(u, v) = 0$ if and only if u and v are in the same connected component after removing the edges in F.

Indeed, Garg et al. [12] analyzed such a rounding procedure which is based on earlier work of Leighton and Rao [13] on SPARSEST CUT, a problem that will be discussed below.

Theorem 6.5 (Garg et al. [12])

There is a polynomial-time algorithm that, given input $x \in \mathbb{R}^E$ that satisfies the constraints (6.23) *and* (6.25), *finds a multicut F such that $c(F) = O(\sum_{e\in E} c(e)x_e \log k)$.*

Proof

Let d be the semi-metric on V that is derived from x. Let $w \in V$ be a terminal (i.e., $v = s_i$ or $v = t_i$ for some $i \in \{1, 2, \ldots, k\}$). For $\rho \in [0, \infty)$, let E_ρ denote the set of edges $\{u, v\}$ such that $d(u, w) \le \rho$ and $d(v, w) > \rho$. Consider the function $f' : [0, \infty) \to \mathbb{N}$ that is given by $f'(\rho) = \sum_{e\in E_\rho} c(e)$. Let $f(\rho) = \frac{1}{k}\sum_{e\in E} c(e)x_e + \int_0^\rho f'(\xi)\, d\xi$, so $f'(\rho) = \frac{df(\rho)}{d\rho}$. Note that for every $\rho \in [0, \infty)$, $f(\rho) \le 2\sum_{e\in E} c(e)x_e$. Now,

$$\int_0^{1/3} \frac{f'(\rho)}{f(\rho)}\, d\rho = \ln\left(\frac{f(1/3)}{f(0)}\right) \le \ln k$$

Therefore, there exists $\rho \in [0, 1/3]$ such that $f'(\rho) \le 3f(\rho)\ln k$. (Such ρ is easily found in polynomial time.) Note that as $\rho \le \frac{1}{3}$, it is impossible that for any $i \in \{1, 2, \ldots, k\}$ both $d(w, s_i) \le \rho$ and $d(w, t_i) \le \rho$.

The multicut F is generated inductively as follows. Pick a terminal $w = w_1$. Find $\rho = \rho_1$ as explained above, and eliminate from G the set $\{v \in V : d(v, w_1) \le \rho_1\}$. Let $G^1 = (V^1, E^1)$ denote the remaining graph. Suppose that $w_1, w_2, \ldots, w_t$ have been picked already. Pick a terminal $w = w_{t+1}$ in G^t (i.e., $d(w_{t+1}, w_s) > \rho_s$ for all $s \in \{1, 2, \ldots, t\}$). If there is no such terminal, then output $F = \cup_{s=1}^t (E_{\rho_s} \cap E^s)$. Otherwise, find $\rho = \rho_{t+1}$ in G^t as explained above, and eliminate from G^t the set $\{v \in V^t : d(v, w_{t+1}) \le \rho_{t+1}\}$ to create G^{t+1}. Note that t never exceeds k.

[1] A semi-metric d on a set V is a function $d : V \times V \to \mathbb{R}$ that satisfies the following conditions: (i) $d(v, v) = 0$, for every $v \in V$; (ii) $\delta(u, v) = \delta(v, u)$, for every $u, v \in V$; and (iii) $\delta(u, v) + \delta(v, w) \ge \delta(u, w)$, for every $u, v, w \in V$.

By the above discussion, F is a multicut. For $\rho \in [0, \rho_s]$, let $f'_s(\rho) = \sum_{e \in E_{\rho_s} \cap E^s} c(e)$. As

$$\sum_{s=1}^{t} \left(\frac{1}{k} \sum_{e \in E} c(e)x_e + \int_0^{\rho_s} f'_s(\xi)\, d\xi \right) \leq 2 \sum_{e \in E} c(e)x_e$$

the $O(\log\, k)$ bound on the approximation guarantee follows. □

Consider the problem of SPARSEST CUT. Given an undirected graph $G = (V, E)$ with edge capacities $c : E \to \mathbb{N}$ and a demand function $h : V \times V \to \mathbb{N}$, the goal is to find a cut $(S, \bar{S})$ that minimizes the cut ratio

$$\frac{\sum_{e:\ |S \cap e| = 1} c(e)}{\sum_{u \in S \wedge v \in \bar{S}} h(u, v)}$$

Leighton and Rao [13] gave an $O(\log |V|)$ approximation algorithm for the case that h is uniform (i.e., $h(u, v) = 1$ for every pair of nodes $u, v \in V$), using the "region growing" technique discussed above in the context of MINIMUM MULTICUT. We now discuss the general case.

A cut $(S, \bar{S})$ in G partitions the node set V into two nonempty parts S and $\bar{S}$. We can associate with $(S, \bar{S})$ a *cut semi-metric* δ_S on V. The semi-metric δ_S is defined by $\delta_S(x, y) = 1$ if $x \neq y$ and $|\{x, y\} \cap S| = 1$; otherwise $\delta_S(x, y) = 0$. The cone of linear combinations of cut semi-metrics on V with nonnegative coefficients is precisely the cone of $|V|$-point subsets of L_1. Useful polytopes can be derived from this cone by adding linear constraints that normalize the maximum or average distance. In particular, SPARSEST CUT can be formalized as follows:

$$\begin{array}{lll} \text{minimize} & \sum_{\{u,v\}=e \in E} c(e) \sum_{\emptyset \neq S \subseteq V} \delta_S(u, v)\lambda_S & \\ \text{subject to} & \sum_{u,v \in V} h(u, v) \sum_{\emptyset \neq S \subseteq V} \delta_S(u, v)\lambda_S = 1 & \\ & \lambda_S \geq 0 & \forall \emptyset \neq S \subseteq V \end{array}$$

This is a linear program with an exponential number of variables. (Note that the solution might be a convex combination of optimal cuts.) In view of the NP-hardness of SPARSEST CUT, it is unlikely that this LP can be solved in time polynomial in the size of G. A polynomial-time solvable relaxation can be derived by extending the optimization over all semi-metrics, not just nonnegative linear combinations of cut semi-metrics. This gives the following LP relaxation for SPARSEST CUT:

$$\begin{array}{ll} \text{minimize} & \sum_{\{u,v\}=e \in E} c(e)d(u, v) \\ \text{subject to} & \sum_{u,v \in V} h(u, v)d(u, v) = 1 \\ & d \text{ is a semi-metric on } V \end{array} \tag{6.26}$$

The following lemma is crucial.

Lemma 6.2 (Bourgain [14])

There is a constant $\kappa > 0$ such that the following holds. Let d be a semi-metric on a finite set of points X. Then, there exists $n \in \mathbb{N}$ and a mapping $\varphi : X \to \mathbb{R}^n$ such that for every $x, y \in X$,

$$\frac{1}{\kappa \log |X|} d(x, y) \leq \|\varphi(x) - \varphi(y)\|_1 \leq d(x, y)$$

Let supp(h) denote the support of the demand function h, i.e., the set of pairs $u, v \in V$ such that $h(u, v) > 0$.

Theorem 6.6 (Aumann and Rabani [15]; Linial et al. [16])

There exists a constant $\kappa > 0$ such that the following holds. Let d be a semi-metric on V that satisfies the constraint (6.26). Then, one can find in polynomial time a cut $(S, \bar{S})$ in G such that

$$\sum_{\{u,v\}=e \in E} c(e)d(u, v) \leq \frac{\sum_{e:\ |S \cap e| = 1} c(e)}{\sum_{u \in S \wedge v \in \bar{S}} h(u, v)} \leq \kappa \cdot \sum_{\{u,v\}=e \in E} c(e)d(u, v) \log |\text{supp}(h)|$$

Proof

Use a modification of Bourgain's Lemma 6.2 to map d and L_1 semi-metric such that the distances between pairs of points in $\mathrm{supp}(h)$ do not shrink by more than a factor of $O(\log|\mathrm{supp}(h)|)$ and no distance expands. Then use the fact that any L_1 semi-metric can be expressed as a nonnegative linear combination of cut semi-metrics to find a cut with a good ratio. □

We note that the bounds in Theorems 6.5 and 6.6 asymptotically match the known integrality gaps. The bad examples are constructed using bounded degree expander graphs. See Refs. [12,13,15,16] for more details.

We conclude this section and the chapter with a discussion of spreading metrics, a class of relaxations introduced by Even et al. [17]. We will demonstrate the technique with the problem of MINIMUM LINEAR ARRANGEMENT. Given an undirected graph $G = (V, E)$, the goal is to find a bijection $\varphi: V \to \{1, 2, \ldots, |V|\}$ that minimizes $\sum_{\{u,v\}\in E} |\varphi(u) - \varphi(v)|$. Note that one property of any such bijection is that every subset of nodes $U \subseteq V$ must be "well spread" in the sense that for every $u \in U$, $\sum_{v\in U} |\varphi(u) - \varphi(v)| \geq \frac{1}{4}(|U|^2 - 1)$. This is precisely the property that the spreading metric relaxation for MINIMUM LINEAR ARRANGEMENT exploits. Rather than optimizing over all bijections (which is NP-hard), we optimize over all metrics that satisfy the spreading constraints. Formally, we solve the following LP relaxation:

$$\begin{array}{lll} \text{minimize} & \sum_{\{u,v\}\in E} d(u, v) & \\ \text{subject to} & \sum_{v\in U} d(u, v) \geq \frac{1}{4}(|U|^2 - 1) & \forall U \subseteq V, \quad \forall u \in U \\ & d \text{ is a metric on } V & \end{array} \tag{6.27}$$

Note that the number of constraints is exponential in the size of the input graph G. However, given a metric d that does not satisfy all the constraints (6.27), it is easy to find a violated constraint in polynomial time by examining all the polynomially many combinatorially distinct balls in d. Thus, the relaxation can be solved in polynomial time.

Theorem 6.7 (Rao and Richa [18])

Given a metric d on V that satisfies all the constraints (6.27), *one can find in polynomial time a bijection $\varphi: V \to \{1, 2, \ldots, |V|\}$ such that*

$$\sum_{\{u,v\}\in E} |\varphi(u) - \varphi(v)| \leq O(\log|V|) \cdot \sum_{\{u,v\}\in E} d(u, v)$$

Proof

We describe the "rounding" algorithm. If G is not connected, we can deal with each connected component separately, so we may assume without loss of generality that G is connected. Consider a node $s \in V$. Define levels with respect to s that are indexed by $i \in \mathbb{N}$. We say that an edge $\{u, v\} \in E$ is at level i if and only if $d(s, u) \leq i$ and $d(s, v) > i$. The weight w_i of level i is the total number of edges at level i. We say that level i has label k if and only if $2^k < w_i \leq 2^{k+1}$. Note that due to constraints (6.27), there are at least $\frac{1}{4}|V|$ levels with strictly positive weight. Thus, putting $D = \sum_{\{u,v\}\in E} d(u, v)$, there is a label k such that at least $\frac{1}{4\log D}|V|$ levels are labeled with k. Let these levels be $i_1, i_2, \ldots, i_m$. Let H_0 denote the subgraph induced by the nodes $v \in V$ such that $d(s, v) \leq i_1$. For $j = 1, 2, \ldots, m - 1$, let H_j denote the subgraph induced by the nodes $v \in V$ such that $i_j < d(s, v) \leq i_{j+1}$. Finally, let H_m denote the subgraph induced by the nodes $v \in V$ such that $i_m < d(s, v)$. Recursively apply the above procedure to each of the subgraphs H_j, $j \in \{0, 1, 2, \ldots, m\}$. The output linear arrangement is composed of the concatenation of the linear arrangements for these subgraphs.

The analysis of the performance guarantee follows by devising a charging scheme, stating the charged cost as a recurrence relation and bounding the recurrence solution. The analysis is rather technical and therefore it is excluded here. □

7.1 Introduction

Many combinatorial optimization problems can be cast as integer linear programming problems. A linear programming relaxation of an integer program provides a natural lower bound (in case of minimization problems) on the value of the optimal integral solution. An optimal solution to the linear programming relaxation may not necessarily be integral. If there exists a procedure to obtain an integral solution "close" to the fractional solution then we have an approximation algorithm. This process of obtaining the integral solution from the fractional one is referred to as "rounding." Our goal is to present an ensemble of rounding techniques (which is by no means complete) that have enjoyed some success. On occasion, for detailed correctness of proofs, we refer the reader to the original paper.

Rounding techniques can be broadly divided into two categories: those that round variables nondeterministically (also called as randomized rounding), and those that round variables deterministically. The randomized rounding techniques presented typically yield solutions whose expected value is bounded. At times, the rounding steps can be made deterministic (derandomized) by using the method of conditional expectation due to Erdős and Selfridge [1]. We refer the reader to Alon and Spencer ([2], Chapter 15) for the method of conditional expectation. Both randomized as well as deterministic rounding can be further classified into techniques that round the variables independently, and those that round the variables in groups (dependently). Our presentation is along similar lines; in Section 7.2 we discuss nondeterministic rounding techniques due to Raghavan and Thompson [3], Goemans and Williamson [4], Bertsimas et al. [5], Goemans and Williamson [6], and Arora et al. [7]. We discuss deterministic rounding techniques due to Lin and Vitter [8], Jain [9], Ageev and Sviridenko [10], and Gaur et al. [11] in Section 7.3. Finally we conclude with a discussion. For other applications of rounding we refer the reader to the books by Hochbaum [12] and Vazirani [13].

Next, we define the performance ratio of an approximation algorithm. Associated with every instance $\mathcal{I}$ of an NP-optimization problem $\mathcal{P}$ is a nonempty set of feasible solutions $\mathcal{S}$. To each solution $S \in \mathcal{S}$, we assign a number called its value. For a minimization (maximization) problem, the goal is to determine the solution with the minimum (maximum) value. The solution with the minimum (maximum) value is denoted as $OPT(\mathcal{I})$ or simply as OPT when there is no ambiguity. Let A be an algorithm whose running time is bounded by a polynomial in the length of the input. $ALG(\mathcal{I})$ (or simply ALG) denotes the value of the solution returned by algorithm A on problem $\mathcal{P}$. For a minimization (maximization) problem, the performance ratio of A is defined as $\alpha = \max_{\mathcal{I}}(ALG(\mathcal{I})/OPT(\mathcal{I}))$ ($\alpha = \min_{\mathcal{I}}(ALG(\mathcal{I})/OPT(\mathcal{I}))$). For minimization (maximization) problems $\alpha \geq 1$ ($\alpha \leq 1$). The other commonly used convention is to define $\alpha = \min_{\mathcal{I}}(OPT(\mathcal{I})/ALG(\mathcal{I}))$ for a minimization problem (in which case, $\alpha \leq 1$).

7.2 Nondeterministic Rounding

7.2.1 Independent Rounding

In this section we illustrate the technique due to Raghavan and Thompson [3]. They developed the first constant-factor approximation algorithm for the minimum-width routing problem in two dimensions. Here we illustrate their technique on the Set Cover problem, basing our presentation on Vazirani [13]. Given a collection $S = \{S_1, S_2, \ldots, S_m\}$ of subsets of some universe $U = \{1, 2, \ldots, n\}$, the problem is to determine the minimum number of sets from S that cover all the elements of U. Let x_j be the variable associated with set S_j. Given below is the integer program IP and the corresponding linear programming relaxation LP for the set cover problem. The first constraint in the IP ensures that each element $i \in U$ is covered by some set in S, and the second constraint stipulates that the sets are picked integrally.

$$\begin{array}{lll} \text{IP:} & \text{minimize} & \sum_{j\in[1,m]} x_j \\ & \text{subject to:} & \sum_{j:i\in S_j} x_j \geq 1 \;\; \forall i \in U \\ & & x_j \in \{0, 1\} \;\; \forall i \in U \end{array} \qquad \begin{array}{lll} \text{LP:} & \text{minimize} & \sum_{j\in[1,m]} x_j \\ & \text{subject to:} & \sum_{j:i\in S_j} x_j \geq 1 \;\; \forall i \in U \\ & & 0 \leq x_j \leq 1 \;\; \forall i \in U \end{array}$$

Let x^* be the optimal solution to the linear programming relaxation above. In each iteration, we round each variable x_j to 1 with probability x_j^* and to 0 with probability $1 - x_j^*$. Each set S_j for which $x_j = 1$ is picked in the solution. The probability that element $i \in U$ is not covered in an iteration is $\prod_{j:i\in S_j}(1-x_j^*)$. If the element $i \in U$ occurs in the k sets $S_{i_1}, S_{i_2}, \ldots, S_{i_k}$, the values $x_{i_1}^*, x_{i_2}^*, \ldots, x_{i_k}^*$ are constrained by the inequality $\sum_{j=1}^{k} x_{i_j}^* \geq 1$, since the element $i \in U$ is covered by the optimal LP solution. The probability $\prod_{j=1}^{k}(1 - x_{i_j}^*)$ is then minimized when each value $x_{i_j}^*$ takes the value $1/k$. Thus, the probability that element $i \in U$ is not covered in an iteration is at least $(1-1/k)^k \geq 1/e$. Thus the probability that $i \in U$ is not covered after $c \log n$ iterations is $(1/e)^{c \log n} \leq 1/(4n)$ for some constant c. Equivalently, the probability that the solution computed after $c \log n$ iterations is not a valid cover is at most $\sum_{i=1}^{n} 1/(4n) = 1/4$. Furthermore, the expected number of sets in the solution computed is $(\sum_{j\in[1,m]} x_j^*)c \log n$. The probability that the number of sets is more than four times this expected value is at most 1/4 (follows from the Markov inequality). Therefore, with probability at least 1/2, the algorithm returns a cover with cost at most $(\sum_{j\in[1,m]} x_j^*)4c \log n$, implying that the performance ratio is $O(\log n)$. Srinivasan [14], observing that the constraints in the set cover problem are positively correlated, showed that the performance ratio of the randomized rounding algorithm is $\log(|U|/OPT) + O(\log\log(|U|/OPT)) + O(1)$.

Next, we consider an interesting idea due to Goemans and Williamson [4], in which two randomized rounding algorithms are run on each problem instance, and the better of the two is returned as the solution. This technique is used for the maximum satisfiability problem to obtain a 3/4-approximation algorithm, though each algorithm by itself does not provide a 3/4-approximation ratio. In the weighted version of the maximum satisfiability problem, we are given a Boolean formula in conjunctive normal form with weights on the clauses, and the goal is to determine an assignment of values (true/false) to the literals, such that the sum of weights of the clauses satisfied is maximized. The simpler rounding algorithm uses a purely randomized rounding, where each variable is set to true (false) with probability 1/2. If a clause j has k literals, then the probability that this clause is not satisfied is $1/2^k$ (corresponding to the situation when each of the k variables is set to 0). Thus, the probability that the clause is satisfied equals $1 - (1/2^k)$. To illustrate the second rounding algorithm (using linear programming) for this problem, we let C_j^+ denote the unnegated literals in the jth clause and C_j^- the negated literals in the jth clause in formula C. The integer program IP and the corresponding linear programming relaxation LP for the problem are given below.

$$\begin{array}{llll}
\text{IP:} & \text{maximize} \displaystyle\sum_{j \in C} w_j z_j & \qquad \text{LP:} & \text{maximize} \displaystyle\sum_{j \in C} w_j z_j \\
& \text{subject to:} & & \text{subject to:} \\
\displaystyle\sum_{i \in C_j^+} x_i + & \displaystyle\sum_{i \in C_j^-} (1 - x_i) \geq z_j \quad \forall j \in C & \displaystyle\sum_{i \in C_j^+} x_i + & \displaystyle\sum_{i \in C_j^-} (1 - x_i) \geq z_j \quad \forall j \in C \\
& z_j, x_i \in \{0, 1\} \quad \forall i, j & & 0 \leq z_j, x_i \leq 1 \quad \forall i, j
\end{array}$$

Let x^*, z^* be the optimal solution to the linear programming relaxation LP. The rounding sets literal i to true with probability x_i^* (without loss of generality we assume clause j contains only positive literals). The probability that clause j is satisfied after this rounding is $1 - \prod_{i \in C_j^+}(1 - x_i^*)$. If clause j contains k literals, $x_{i_1}, x_{i_2}, \ldots, x_{i_k}$, the values $x_{i_1}^*, x_{i_2}^*, \ldots, x_{i_k}^*$ are constrained by the inequality $\sum_{j=1}^{k} x_{i_j}^* \geq z_j^*$, a constraint in the LP formulation. The probability $\prod_{j=1}^{k}(1 - x_{i_j}^*)$ is then maximized when each value $x_{i_j}^*$ takes the value z_j^*/k. Thus, the probability that clause j is not satisfied after the rounding is at most $(1 - z_j^*/k)^k$. Thus the probability that clause j is satisfied after the rounding is at least $1 - (1 - z_j^*/k)^k$. Observing that $1 - (1 - z_j^*/k)^k \geq z_j^*(1 - (1 - 1/k)^k)$ for $0 \leq z_j^* \leq 1$ (due to concavity), the probability that clause j is satisfied is at least $z_j^*(1 - (1 - 1/k)^k)$.

The bound of 3/4 follows from the fact that for each clause j, $\max\{(1 - 1/2^k), z_j^*(1 - (1 - 1/k)^k)\} \geq \max\{z_j^*(1 - 1/2^k), z_j^*(1 - (1 - 1/k)^k)\} \geq \frac{z_j^*}{2}\{(1 - 1/2^k) + (1 - (1 - 1/k)^k)\} \geq 3/4 z_j^*$ for every positive integer k.

7.2.2 Dependent Rounding

7.2.2.1 Simultaneous Rounding

The idea of simultaneously rounding a set of variables was used by Bertsimas et al. [5] to establish the integrality of several well-known polytopes. In particular, they established the integrality of the polytopes associated with the minimum $s - t$ cut, p-median on a cycle, uncapacitated lot sizing, and boolean optimization. Using this technique, Bertsimas et al. [5] established a bound of $2(1-1/2^k)$ for the minimum k-sat problem. A bound of 2 is established for the feasible cut problem, by showing it is equivalent to vertex cover, which is approximable within a factor of 2 [15]. Here we illustrate the technique due to Bertsimas et al. [5] on the feasible cut problem. This technique is particularly interesting as the analysis of the performance ratio is considerably simplified.

Given a graph $G = (V, E)$ with weights on the edges, M a set of pairs of nodes in G, and a source vertex s. The problem is to determine a cut of minimum weight with the additional constraints that s belongs to the cut, but for any pair $(i, j) \in M$, both i and j are not in the cut. The integer program IP for the feasible cut problem and the corresponding linear programming relaxation LP are given below.

$$\begin{array}{lll@{\qquad}lll}
\text{IP:} & \text{minimize} & \sum_{(i,j) \in E} c_{ij} x_{ij} & \text{LP:} & \text{minimize} & \sum_{(i,j) \in E} c_{ij} x_{ij} \\
& \text{subject to:} & x_{ij} \geq y_i - y_j \quad \forall (i, j) \in E & & \text{subject to:} & x_{ij} \geq y_i - y_j \quad \forall (i, j) \in E \\
& & x_{ij} \geq y_j - y_i \quad \forall (i, j) \in E & & & x_{ij} \geq y_j - y_i \quad \forall (i, j) \in E \\
& & y_i + y_j \leq 1 \quad \forall (i, j) \in M & & & y_i + y_j \leq 1 \quad \forall (i, j) \in M \\
& & y_s = 1 & & & y_s = 1 \\
& & x_{ij}, y_j \in \{0, 1\} \quad \forall i, j & & & 0 \leq x_{ij}, y_j \leq 1 \quad \forall i, j
\end{array}$$

In this technique the variables are rounded simultaneously with respect to a random variable. Let U be a random value in $[1/2, 1]$ generated uniformly. Given an optimal solution (x^*, y^*) to the linear program LP, construct the cut as follows: if $y_i^* < U$ then $y_i = 0$, and if $y_i^* > U$ then $y_i = 1$. The rounding operation gives a feasible cut, since for each $(i, j) \in M$ at most one of y_i^*, y_j^* is greater than 1/2. Let Z_{IP}

be the value of the optimal solution to IP, Z_{LP} the value of the optimal solution to LP, and $E(Z_R)$ the expected value of the solution obtained after rounding.

Theorem 7.1

Minimum feasible cut can be approximated within a factor of 2.

Proof

Clearly, $Z_{IP} \leq E(Z_R)$. We show that $E(Z_R) \leq 2Z_{LP}$. If $E(x_{ij}) \leq 2x^*_{ij}$ for all i, j, then by linearity of expectation the result holds. Without loss of generality assume that $y^*_i \leq y^*_j$. If $y^*_j \leq 1/2$ then $E(x_{ij}) = 0$. If $y^*_i \leq 1/2 \leq y^*_j$, then $E(x_{ij}) = P(U \in [1/2, y^*_j]) = 2(y^*_j - 1/2) \leq 2(y^*_j - y^*_i)$. If $y^*_i \geq 1/2$, then $E(x_{ij}) = 2(y^*_j - y^*_i)$. This implies that $E(x_{ij}) \leq 2(y^*_j - y^*_i) \leq 2x^*_{ij}$. □

7.2.2.2 Rounding against a Hyperplane

The first substantial improvement for the Max-Cut problem was made by Goemans and Williamson [6], who presented a 0.87856 factor approximation based on semidefinite programming. The above bound is also applicable to the Max 2-Sat problem. They also gave a 0.7584 factor approximation algorithm for the Max Sat problem. Here we outline their technique for the Max-Cut problem. Given a graph $G = (V, E)$ with weights on the edges, the objective is to partition the vertices of G such that the sum of weights of the cut edges is maximized. The problem is formulated first as a quadratic (nonlinear) program, and a relaxation of the quadratic program is defined in which each variable corresponds to a vector. An optimal solution to this relaxed nonlinear program is then computed. Given a random hyperplane, the vertices are partitioned into two sets, corresponding to points above and below the hyperplane. This partition has the desired bound. For details of the proof and the algorithm for computing the optimal solution to the relaxed program VP, we refer the reader to Vazirani [13] and Chapter 8 on Semidefinite Programming by Ye, So, and Zhang. Next, we describe their formulations and the randomization procedure.

$$\begin{array}{lll} \text{QP:} & \text{maximize} & 1/2\sum_{(i,j)\in E} w_{ij}(1-y_iy_j) \\ & \text{subject to:} & y_i^2 = 1 \quad \forall i \in V \\ & & y_i \in \mathcal{Z} \quad \forall i \in V \end{array} \qquad \begin{array}{lll} \text{VP:} & \text{maximize} & 1/2\sum_{(i,j)\in E} w_{ij}(1-v_iv_j) \\ & \text{subject to:} & v_i \cdot v_i = 1 \quad \forall i \in V \\ & & v_i \in \mathcal{R}^n \quad \forall i \in V \end{array}$$

Let r be a uniformly distributed vector in unit sphere S_{n-1}, then $S = \{i : v_i \cdot r \geq 0\}$ and $V \setminus S$ are the two sets defining the partition.

7.2.2.3 Extensions

Next we outline some extensions of the basic rounding technique. In all these techniques, the variables are rounded randomly in a somewhat dependent fashion. First we consider the assignment problem in the presence of covering constraints. Given a complete bipartite graph $G = (A \cup B, E)$, with $|A| = |B|$, and weights on the edges. The objective is to find a matching of minimum weight that satisfies the covering constraints. The integer program IP and the linear programming relaxation LP for the assignment problem are given below.

$$\begin{array}{ll} \text{IP: minimize} & \sum_{(i,j)\in E} c_{ij}x_{ij} \\ \quad\text{subject to:} & \sum_{j\in B} x_{ij} = 1 \ \forall i \in A \\ & \sum_{i\in A} x_{ij} = 1 \ \forall j \in B \\ & \sum_{i\in A, j\in B} a^k_{ij}x_{ij} \geq b^k \ \forall k \in [1, K] \\ & x_{ij}, y_j \in \{0, 1\} \ \forall i \in A, \ j \in B \end{array} \qquad \begin{array}{ll} \text{LP: minimize} & \sum_{(i,j)\in E} c_{ij}x_{ij} \\ \quad\text{subject to:} & \sum_{j\in B} x_{ij} = 1 \ \forall i \in A \\ & \sum_{i\in A} x_{ij} = 1 \ \forall j \in B \\ & \sum_{i\in A, j\in B} a^k_{ij}x_{ij} \geq b^k \ \forall k \in [1, K] \\ & 0 \leq x_{ij}, y_j \leq 1 \ \forall i \in A, \ j \in B \end{array}$$

In the absence of the covering constraint ($\sum_{i\in A, j\in B} a^k_{ij}x_{ij} \geq b^k$), the polytope associated with the IP is integral. But in the presence of the covering constraints we can only guarantee a fractional optimal solution to the LP in polynomial time. One possibility is to obtain an integral solution by rounding [3] the optimal fractional solution. One major difficulty with independent rounding in the presence of equality constraints is that the probability that the constraint is satisfied could be as low as $1/e$ (consider the case when all the $x_{ij}s$ have the same value $1/|A|$). Therefore, the expected number of equality constraints satisfied in one rounding iteration is low. However, the covering constraints are satisfied almost approximately. Arora et al. [7] developed a randomized rounding technique that obtains an integral solution (from the fractional solution), which satisfies $(|A| - o(|A|)$ equality constraints and all the covering constraints almost approximately $(\sum_{i\in A,\, j\in B} a^k_{ij}x_{ij} \geq b^k - O(\sqrt{|A|}\max\{a^k_{ij}\}))$. Next, we describe their rounding algorithm for the case when all the fractional values are constants. For the rounding in the general case, and for the proofs we refer the reader to the original paper. Let x^* be the optimal fractional solution. The algorithm first constructs a multigraph from the bipartite graph as follows: for each edge in G, toss a biased coin (with probability of head x^*_{ij}) $\Theta(\log^3(n))$ times. If heads show up a times then the multigraph has a copies of edge (i, j). The multigraph is a union of paths and cycles of length $O(\sqrt{n})$ (if not then we have to delete $O(\sqrt{n})$ edges). Now these paths and cycles are further divided into $\Theta(\sqrt{n})$ groups of size $O(\sqrt{n})$ each. Within each group, either all the edges of A are picked or all the edges of B are picked, and the decision is equally likely. Using a generalization of this technique, Arora et al. [7] were able to demonstrate polynomial-time approximation schemes for dense instances of minimum linear arrangement problem, minimum cut linear arrangement problem, maximum acyclic subgraph problem, and the betweenness problem.

Next we briefly mention some other techniques. Srinivasan [16] developed a rounding technique based on distributions on level sets, and established better approximation ratios for low-congestion multipath routing problem, and the maximum coverage version of set cover problem. Gandhi et al. [17] developed a new rounding scheme based on the pipage rounding method of Ageev and Sviridenko [10] (see Section 7.3.4), and the level set-based method of Srinivasan [16] to obtain better approximation algorithms for the throughput maximization problem in broadcast scheduling, the delay minimization problem in broadcast scheduling, and the capacitated vertex cover problem. Another dependent rounding technique has been developed by Doerr [18], with applications to digital halftoning. Doerr [19] developed another dependent randomized rounding technique that respects cardinality constraints.

7.3 Deterministic Rounding

7.3.1 Scaling

Scaling is an important technique that has been applied to covering problems such as Vertex Cover to obtain a simple 2-factor approximation. Our presentation is based on Hochbaum [12] (Chapter 3). Given that it is still not known whether vertex cover admits an approximation ratio strictly better (by a constant) than 2, scaling seems to be a powerful technique. Given a graph $G = (V, E)$ with weights on the vertices. The objective is to determine a minimum-weight set $S \subset V$, such that every edge has at least one endpoint in S. Given below is the integer program IP and the corresponding linear programming relaxation LP.

$$\begin{array}{llll} \text{IP:} & \text{minimize} & \sum_{i\in V} w_i x_i & \\ & \text{subject to:} & x_i + x_j \geq 1 & \forall (i, j) \in E \\ & & x_i \in \{0, 1\} & \forall i \in V \end{array} \qquad \begin{array}{llll} \text{LP:} & \text{minimize} & \sum_{i\in V} w_i x_i & \\ & \text{subject to:} & x_i + x_j \geq 1 & \forall (i, j) \in E \\ & & 0 \leq x_i \leq 1 & \forall i \in V \end{array}$$

Let x^* be the optimal solution to the linear program LP. Let S be the set of vertices j such that $x^*_j \geq 1/2$. S is a cover because for each edge (i, j) either x_i or x_j is $\geq 1/2$, and the weight of S is at most $2\sum_{i\in V} w_i x^*_i$. Interestingly, the algorithm by Gonzalez [20] is the only factor 2 approximation algorithm for vertex cover, whose proof does not rely on the theory of linear programming.

7.3.2 Filter and Round

Sahni and Gonzalez [21] showed that for certain problems including the p-median problem, the tree pruning problem, and the generalized assignment problem, finding an α-approximate solution is NP-hard. In light of the previous result, the next best thing is to find an α-approximate solution with the minimum number of constraint violations. Lin and Vitter [8] gave such approximation algorithms for the problems mentioned above. For the generalized assignment problem, we refer the reader to Chapter 48 by Yagiura and Ibaraki. Here we will illustrate their technique on the p-median problem. Our presentation is based on Lin and Vitter [8]. Given a complete graph G on n vertices with weights on the edges and an integer p, the problem is to determine p vertices (medians) so that the sum of the distances from each vertex to its closest median is minimized. The integer program IP and the corresponding linear programming relaxation LP are given below.

$$\begin{array}{lll}
\text{IP:} & \text{minimize} & \sum_{i,j\in V} c_{ij}x_{ij} \\
& \text{subject to:} & \sum_{j\in V} x_{ij} = 1 \quad \forall i \in V \\
& & x_{ij} \le y_j \quad \forall i, j \in V \\
& & \sum_{j\in V} y_j = p \\
& & x_{ij}, y_j \in \{0, 1\} \quad \forall i, j
\end{array}
\qquad
\begin{array}{lll}
\text{LP:} & \text{minimize} & \sum_{i,j\in V} c_{ij}x_{ij} \\
& \text{subject to:} & \sum_{j\in V} x_{ij} = 1 \quad \forall i \in V \\
& & x_{ij} \le y_j \quad \forall i, j \in V \\
& & \sum_{j\in V} y_j = p \\
& & 0 \le x_{ij}, y_j \le 1 \quad \forall i, j
\end{array}$$

Given an optimal solution x^*, y^* to the LP, we obtain an integer program FP (called a filtered program) by setting some variables in x to 0. The FP has the property that any integral feasible solution is at most $(1+\alpha)$ times the value of the optimal solution to LP. First, a fractional feasible solution to FP is constructed from x^*, y^*. A feasible integral solution to FP is then obtained using either randomized rounding or some greedy rounding. Here we illustrate a deterministic (greedy) rounding method. We assume certain lemmas to illustrate the technique. For the proof of the lemmas, we refer the reader to the original paper by Lin and Vitter [8].

Lemma 7.1

Given y, the optimal values for x can be computed for the linear programming problem LP.

Given an optimal solution x^*, y^* to the LP, for a vertex $i \in V$, let V_i be the set of vertices j such that $c_{ij} \le (1+\alpha)\sum_{j\in V} c_{ij}x^*_{ij}$. The FP and the reduced filtered program (RFP) necessary to compute the solution to FP by Lemma 7.1 are

$$\begin{array}{lll}
\text{FP:} & \text{minimize} & L \\
& \text{subject to:} & \sum_{j\in V_i} x_{ij} = 1 \quad \forall i \in V \\
& & x_{ij} \le Ly_j \quad \forall i, j \in V \\
& & \sum_{j\in V} y_j = p \\
& & x_{ij} = 0 \quad \forall i \in V,\ j \in V\backslash V_i \\
& & x_{ij}, y_j \in \{0, 1\} \quad \forall i, j
\end{array}
\qquad
\begin{array}{lll}
\text{RFP:} & \text{minimize} & \sum_{j\in V} y_j \\
& \text{subject to:} & \sum_{j\in V_i} y_j \ge 1 \quad \forall i \in V \\
& & y_j \in \{0, 1\} \quad \forall i, j
\end{array}$$

L corresponds to the factor by which the covering constraints are violated. The following lemma holds by construction.

Lemma 7.2

Any feasible (integral) solution to FP has value at most $(1+\alpha)$ times the value of the optimal solution to the linear programming relaxation LP.

It is the case that $\sum_{j\in V_i} y^*_j \ge \alpha/(1+\alpha)$. Therefore, a feasible fractional solution to RFP with value $(1+1/\alpha)p$ can be constructed (by assigning $y_j = y^*_j(1+\alpha)/\alpha$). RFP is nothing but set cover, and a $\log n$ approximate integral solution can be constructed using the greedy heuristic of Chvátal [22]. Therefore, by Lemma 7.2 we have a $(1+\alpha)p\log n$ approximate constraint violations with value at most $(1+\alpha)$ times the value of the optimal solution to the integer program.

7.3.3 Iterated Rounding

The technique of iterated rounding was introduced by Jain [9], who gave a 2-factor approximation algorithm for the generalized Steiner network problem. Consider the problem of finding a minimum-cost edge-induced subgraph of a graph that contains a prespecified number of edges from each cut. Formally, $G = (V, E)$ is a graph with weights on the edges. Also given is a function $f : 2^V \rightarrow \mathcal{Z}$. The problem is to determine a minimum-weight set of edges such that for every R subset of V, the number of edges is $\delta(R) \geq f(R)$, where $\delta(R)$ are the edges in the cut defined by the vertices in R. Given below are the integer program IP and the corresponding linear programming relaxation LP.

$$\begin{array}{lll} \text{IP:} & \text{minimize} & \sum_{e\in E} w_e x_e \\ & \text{subject to:} & \sum_{e\in\delta(R)} \geq f(R) \quad \forall S \subseteq V \\ & & x_e \in \{0, 1\} \quad \forall i \in E \end{array} \qquad \begin{array}{lll} \text{LP:} & \text{minimize} & \sum_{e\in E} w_e x_e \\ & \text{subject to:} & \sum_{e\in\delta(R)} \geq f(R) \quad \forall S \subseteq V \\ & & 0 \leq x_e \leq 1 \quad \forall i \in E \end{array}$$

Note that both the programs above contain exponentially many constraints. Jain [9] gives a separation oracle for the linear programming relaxation. Using this separation oracle, an optimal solution can be computed in polynomial time [23]. Furthermore, Jain establishes the following:

Theorem 7.2

Any basic feasible solution to the linear programming relaxation has at least one variable with value $\geq 1/2$.

Based on the previous theorem, one can construct a solution as follows: find an optimal solution (basic) to the LP, include all the edges with a value $\geq 1/2$ in the solution, then recursively solve the subproblem obtained by deleting the edges included in the solution.

7.3.4 Pipage Rounding

Pipage rounding was developed by Ageev and Sviridenko [10], who applied it to the maximum coverage problem, hypergraph maximum k-cut with given sizes of parts, and scheduling on unrelated parallel machines. They showed that the maximum coverage problem can be approximated within $1 - (1 - 1/k)^k$ where k is the maximum size of any subset, thereby improving the previous bound of $1 - 1/e$ due to Cornuejols et al. [24]. For the hypergraph max k-cut they obtained a bound of $1 - (1 - 1/r)^r - 1/r^r$, where r is the cardinality of the smallest edge in the hypergraph. For the scheduling problem on unrelated machines, they considered an additional constraint on the number of jobs that a given machine can process and obtained the bound of 3/2. A similar bound was also established by Skutella [25] in the absence of cardinality constraints. For the case of two machines, the current best bound is 1.2752 due to Skutella [25], obtained by rounding the semidefinite programming relaxation using the dependent rounding technique of Goemans and Williamson [6]. Ageev et al. [26] obtained a 1/2-approximation algorithm for the max-dicut problem with given sizes of parts by a refined application of the pipage rounding. Recently, Galluccio and Nobili [27] have improved the approximation ratio from 3/4 to $1 - 1/2q$ for the maximum coverage problem when all the sets are of size 2, where every clique in a clique cover of the input graph has size at least q. Note that $q \geq 2$. This problem is also known as the maximum vertex cover problem. Pipage rounding is especially suited to problems involving assignment and cardinality constraints.

Our description of the pipage rounding is based on Ageev and Sviridenko [10]. The idea is to deterministically round a fractional solution to an integral solution, while ensuring that the objective function value does not decrease in the rounding process. If the starting fractional solution was at least c times the optimal fractional solution, then the pipage rounding will guarantee a c-approximation algorithm. The rounding process converts a fractional solution into another fractional solution with less number of nonintegral components. The "δ-convexity" of the objective functions guarantees that the objective function value does not decrease in the rounding process.

Let $G = (V, E)$ be a bipartite graph with capacities c_v on the vertices. Let $f(X)$ be a polynomially computable function defined on the values $X = \{x_e : e \in E\}$ assigned to the edges of G. Consider the following integer program IP whose solution is an assignment of 0, 1 to the edges that maximizes $f(X)$

subject to the capacity constraints, and its linear programming relaxation LP:

$$\begin{array}{llll} \text{IP:} & \text{maximize} & f(X) & \\ & \text{subject to:} & \sum_{e\in N(v)} x_e \le c_v & \forall v \in V \\ & & x_e \in \{0,1\} & \forall e \in E \end{array} \qquad \begin{array}{llll} \text{LP:} & \text{maximize} & f(X) & \\ & \text{subject to:} & \sum_{e\in N(v)} x_e \le c_v & \forall v \in V \\ & & 0 \le x_e \le 1 & \forall e \in E \end{array}$$

We do not assume that the optimal solution to the LP is computable in polynomial time. Given a fractional solution X, let $G(X)$ be the subgraph induced by the edges that are assigned a nonintegral value in X. $G(X)$ either contains a path P or a cycle C. Let $P_o(C_o)$ be the odd-indexed edges in the $P(C)$. Similarly, $P_e(C_e)$ the set of even-indexed edges in $P(C)$. Given $P(C)$, let $lb = \min\{\min\{x_e : e \in P_o(C_o)\}, \min\{1 - x_e : e \in P_e(C_e)\}\}$. Similarly, define $ub = \min\{\min\{1 - x_e : e \in P_o(C_o)\}, \min\{x_e : e \in P_e(C_e)\}\}$. f is said to be δ-convex with respect to $\delta \in [lb, ub]$ if for each fractional solution and all paths and cycles it is convex in δ. Given δ-convexity, the maximum of f in $[lb, ub]$ is attained at one of the endpoints. Pipage rounding amounts to either successively adding and deleting ub, or successively deleting and adding lb, from the values assigned to the edges in $P(C)$. This process yields a solution with a reduced number of nonintegral components. Let us examine the case when all the capacities are 1, and f computes the sum of the values assigned to the edges. In this case, the solution to the IP corresponds to a maximum matching, and the solution to the linear program corresponds to the maximum fractional matching. The pipage rounding (as can be readily verified) in this case converts the fractional matching into an integral matching of same or larger size. To compute an α-approximation it remains to find a function g that approximates f within α such that maximum of g can be computed in polynomial time, subject to the constraints in the LP.

We illustrate the application of pipage rounding to the maximum coverage problem, where we are given a collection S of weighted subsets of ground set I, and an integer k. The goal is to determine $X \subseteq I$ of cardinality k such that the sum of the weights of the sets in S that intersect with X is maximized. Associated with each element $i \in I$ is a variable x_i, and associated with each element S_j of S is a variable z_j. Given below is an integer program for the maximum coverage problem.

$$\begin{array}{lll} \text{IP:} & \text{maximize} & \sum_{j=1}^{m} w_j z_j \\ & \text{subject to:} & \sum_{i\in S_j} x_i \ge z_j, \quad \forall S_j \in S \\ & & \sum_{i=1}^{n} x_i = k \\ & & x_i \in \{0,1\} \quad \forall i \in I \end{array}$$

The objective function in IP above can be replaced with $f = \sum_{j=1}^{m} w_j(1 - \prod_{i\in S_j}(1 - x_i))$ as it has the same value over all integral vectors x. Replace f by $g = \sum_{j=1}^{m} w_j \min\{1, \sum_{i\in S_j} x_i\}$. It can be shown that f and g are δ-convex and g approximates f within a factor of $1-(1-1/k)^k$, where k is the cardinality of the largest element of S. Furthermore, the fractional optimal solution to g, subject to the constraints in IP can be computed in polynomial time.

7.3.5 Decompose and Round

We next describe a deterministic technique due to Gaur et al. [11]. This technique is applicable to geometric covering problems, and can be thought of as an extension of the scaling technique. We consider covering problems of the form min cx, subject to $Ax \ge b$, $x \in \{0,1\}^n$, where A is an $m \times n$ matrix with 0, 1 entries, and c, x are vectors of dimension n and b is a vector with m entries. The geometry of the problem under consideration imposes a structure on A, and this helps us in the application of the scaling technique. We begin with a few definitions. Let $C = \{1, \ldots, n\}$ be the set of indices of the columns in A and $R = \{1, \ldots, m\}$ the set of indices of the rows in A. Denote by $\mathcal{R} = \{R_1, R_2, \ldots, R_k\}$ a partition of R, and by $\mathcal{C} = \{C_1, C_2, \ldots, C_k\}$ a partition of the columns of A. $A(R_i, C_j)$ is the matrix obtained from A by removing the columns in $C \setminus C_j$, and the rows in $R \setminus R_i$. A matrix A is *totally unimodular* if the determinant of every square submatrix of A is ±1. We say A is *partially unimodular* with respect to $\mathcal{C}$ and $\mathcal{R}$ if for all $C_i \in \mathcal{C}$, $R_j \in \mathcal{R}$, $A(R_j, C_i)$ is totally unimodular. For a partially unimodular matrix A,

$|\mathcal{C}| = |\mathcal{R}|$ is also known as the *partial width* of A. It is well known that if M is block structured and if all the blocks are totally unimodular then M is totally unimodular. This fact, with a suitable reordering of the rows and columns, implies the following:

Lemma 7.3

Let A_D be the matrix whose ith diagonal block corresponds to $A(R_i, C_i)$ (all other entries are 0) then A_D is totally unimodular, if A is partially unimodular with respect to $\mathcal{R}$, $\mathcal{C}$.

We next describe the rectangle stabbing problem, and show that its coefficient matrix is partially unimodular and has partial width 2. A $\log n$ factor approximation for the rectangle stabbing problem is due to Hassin and Megiddo [28]. Given a set of axis-aligned rectangles (in 2D), the problem is to determine the minimum number of axis-parallel lines that are needed to stab all the rectangles. Let H be the set of horizontal lines going through the horizontal edges of the rectangles, V the set of vertical lines going through the vertical edges of the rectangles, and R the set of all rectangles. Let $H_r(V_r)$ be the set of lines from $H(V)$ that intersect rectangle $r \in R$. Given below is the integer program IP and the corresponding linear programming relaxation LP.

$$\begin{array}{lll} \text{IP: minimize} & \sum_{i\in H} h_i + \sum_{j\in V} v_j \\ \text{subject to:} & \sum_{i:i\in H_r} h_i + \sum_{j:j\in V_r} v_j \geq 1 \;\; \forall r\in R \\ & h_i, v_j \in \{0, 1\} \;\; \forall i \in H,\ j \in V \end{array}$$

$$\begin{array}{lll} \text{LP: minimize} & \sum_{i\in H} h_i + \sum_{j\in V} v_j \\ \text{subject to:} & \sum_{i:i\in H_r} h_i + \sum_{j:j\in V_r} v_j \geq 1 \, \forall r\in R \\ & 0 \leq h_i, v_j \leq 1 \;\; \forall i \in H,\ j \in V \end{array}$$

Let A be the coefficient matrix corresponding to the programs above.

Lemma 7.4

A is partially unimodular with respect to $\mathcal{C} = \{H, V\}$ and $\mathcal{R} = \{R_h, R_v\}$ as computed below.

Given an optimal solution h^*, v^* to the linear programming relaxation LP, we construct a partition $\mathcal{R} = \{R_h, R_v = R \backslash R_h\}$ of the rectangles of R as follows: R_h is the set of all the rectangles r such that $\sum_{i:i\in H_r} h_i \geq 1/2$. Let A_D be the block diagonal matrix whose blocks are $A(R_h, H)$ and $A(R_v, V)$. $A(R_h, H)$ and $A(R_v, V)$ are totally unimodular as the columns can be reordered so that each row has the consecutive ones property. By Lemma 7.3, A_D is totally unimodular. Consider the program min cx subject to $A_D x \geq 1$, $x \in \{0, 1\}^n$. Conforti et al. [29] showed that the polytope associated with A_D is integral, hence the optimal integral solution has the same value as the optimal fractional solution. Note that $(2h^*, 2v^*)$ is feasible in the previous problem. Therefore, the performance ratio is 2 as $ALG \leq (2h^*, 2v^*)$ and $OPT \geq (h^*, v^*)$. Furthermore, the addition of capacity constraints on H and V does not affect the performance ratio. These results can be generalized for arbitrary weights on the lines and requirements on the rectangles in d dimensions. For recent results on the rectangle stabbing problem with soft capacities see Even et al. [30]. The case when rectangles have zero height has been studied extensively, see Chapter 37 by Kovaleva and Spieksma.

A brief comment about the technique is in order. Every matrix A is partially unimodular with respect to the following partitions: $C_1, C_2, \ldots, C_n$, where C_i is the ith column in A. Let x^* be the optimal solution to the LP. Consider the following partition of rows: rectangle r belongs to set R_i in the partition if $x_i^* A[r, i] = \max_{j\in[1,\ldots,n]}\{x_j^* A[r, j]\}$. A_D can now be constructed from the blocks $A(R_i, C_i)$. Once again, by Lemma 7.3 A_D is totally unimodular as each $A(R_i, C_i)$ is a column vector with all ones (the determinant for every square submatrix is 1) and totally unimodular. Let τ be the maximum number of nonzero entries in a row of A. The performance ratio using the algorithm and the argument above is $1/\tau$. This is similar to the bound obtained for the set cover problem using the scaling technique. In this sense, our approach can be viewed as a generalization of the scaling technique.

The arguments outlined in the preceding paragraphs lead to the following theorem.

Theorem 7.3

Given a covering problem of the form min cx, subject to $Ax \geq b$, $x \in \{0, 1\}^n$, if A is partially unimodular and has partial width $1/\alpha$, there exists an approximation algorithm with performance ratio α.

In light of the preceding theorem it is natural to study algorithms (exact and approximation) for determining the minimum cardinality partitions with respect to which A is partially unimodular. We are not aware of any existing results and pose the determination of minimum partial width as an interesting open problem, with application to the theory of approximation algorithms.

Next, we consider an application of the rectangle stabbing problem to a load balancing problem that arises in the context of scheduling on multiprocessor systems. In the rectilinear partitioning problem, the input is a matrix of integers, and the problem is to partition the matrix using h horizontal lines and v vertical lines, such that the load inside each rectangle (formed by two consecutive horizontal and vertical lines) is minimized, where the load of a rectangle is defined to be the sum of entries in the rectangle. Given an instance of the rectilinear partitioning problem we construct an instance of the rectangle stabbing problem as follows: let L be the minimum load (we can obtain this by using binary search), all the submatrices with load in excess of L correspond to rectangles in the rectangle stabbing problem. Note that if all the rectangles are stabbed then the load is at most L. As we only have a 2-factor approximation algorithm for the rectangle stabbing problem, the number of lines returned can be twice the number of lines stipulated. Therefore, a solution to the rectilinear partitioning problem is obtained by removing every second line (horizontal as well as vertical). In the process of removing the alternate lines, a new rectangle is formed whose load is at most $4L$. Therefore, the performance ratio is 4.

7.4 Discussion

Numerous techniques have been developed over the last two decades to convert an optimal fractional solution (to the linear programming relaxation of an integer program) to an approximate integral solution. These techniques can be divided into two broad categories: those that use randomized strategies and ones that use deterministic strategies. Most of the randomized strategies can be made deterministic (at the expense of increased running time) using the method of conditional expectation. The applicability of the strategies is most evident in the context of packing and covering types of problems. Some success has been obtained in the application of these techniques in the presence of cardinality constraints.

On Analyzing Semidefinite Programming Relaxations of Complex Quadratic Optimization Problems

8.1 Introduction

Following the seminal work of Goemans and Williamson [1], there has been an outgrowth in the use of semidefinite programming (SDP) for designing approximation algorithms. Recall that an α-approximation algorithm for a problem $\mathscr{P}$ is a polynomial-time algorithm such that for every instance I of $\mathscr{P}$, it delivers a solution that is within a factor of α of the optimum value [2]. It is well known that SDPs can be solved in polynomial time (up to any prescribed accuracy) via interior-point algorithms (see, e.g., Refs. [3,4]), and they have been used very successfully in the design of approximation algorithms for a host of NP-hard problems, e.g., graph partitioning, graph coloring, and quadratic optimization [1–9], just to name a few.

Before we delve into the main topics of this chapter, let us first review Goemans and Williamson's technique of analyzing SDP relaxations and point out its limitations. Consider the following (real) discrete quadratic programming (QP) problem:

$$\begin{aligned} &\text{maximize} \quad \sum_{i,j} Q_{ij}(1 - x_i x_j) \\ &\text{subject to} \quad x_k \in \{-1, 1\}, \quad k = 1, 2, \ldots, n \end{aligned} \tag{8.1}$$

where Q is an $n \times n$ symmetric, positive-semidefinite matrix. Problem (8.1) captures a wide variety of combinatorial optimization problems (e.g., MAX CUT), and is known to be NP-hard. It is thus natural to search for a relaxation of problem (8.1) that is polynomial-time solvable and yields a provably good approximation ratio. One standard approach is to relax the binary variables x_j to unit vectors v_j in some

Hilbert space $\mathscr{H}$, and to replace the product $x_i x_j$ by the inner product $v_i \cdot v_j$ in $\mathscr{H}$. This gives the following mathematical program:

$$\begin{aligned} \text{maximize} \quad & \sum_{i,j} Q_{ij}(1 - v_i \cdot v_j) \\ \text{subject to} \quad & \|v_k\| = 1, \quad k = 1, 2, \dots, n \end{aligned} \tag{8.2}$$

Problem (8.2) is an instance of an SDP and is a so-called *SDP relaxation* of problem (8.1). Now, let w_{QP} and w_{SDP} be the optimal values of problems (8.1) and (8.2), respectively. It is clear that $w_{SDP} \geq w_{QP}$, since any feasible solution to problem (8.1) is also a feasible solution to problem (8.2). Let $\{v_1^*, \dots, v_n^*\}$ be a solution to problem (8.2), which can be obtained in polynomial time (see, e.g., Refs. [3,4]). Goemans and Williamson [1] then proposed to round this solution via a *random hyperplane*. Specifically, let $r \in \mathbb{R}^n$ be a random vector drawn uniformly from the unit sphere S^{n-1} (see, e.g., Ref. [10] for how this could be done). Then, set $\hat{x}_j = \text{sgn}(v_j^* \cdot r)$, where

$$\text{sgn}(x) = \begin{cases} 1 & \text{if } x \geq 0 \\ -1 & \text{if } x < 0 \end{cases}$$

It is clear that the rounded solution $\{\hat{x}_1, \dots, \hat{x}_n\}$ is a feasible solution to problem (8.1), but how does it compare with the optimal solution? In the case where the entries of Q are nonnegative (i.e., $Q_{ij} \geq 0$ for all i, j), Goemans and Williamson [1] gave the following elegant analysis. First, using a geometric argument and some analysis, one can show that

$$\mathbb{E}\left[1 - \hat{x}_i \hat{x}_j\right] = \frac{2}{\pi} \arccos(v_i^* \cdot v_j^*) \geq c(1 - v_i^* \cdot v_j^*) \tag{8.3}$$

for some constant $c > 0$. Now, since $Q_{ij} \geq 0$ and $1 - v_i^* \cdot v_j^* \geq 0$, we have

$$Q_{ij}\mathbb{E}\left[1 - \hat{x}_i \hat{x}_j\right] \geq c \cdot Q_{ij}(1 - v_i^* \cdot v_j^*) \tag{8.4}$$

Thus, upon summing over i, j, we conclude that

$$\sum_{i,j} Q_{ij}\mathbb{E}\left[1 - \hat{x}_i \hat{x}_j\right] \geq c \sum_{i,j} Q_{ij}(1 - v_i^* \cdot v_j^*)$$

Notice that the right-hand side is simply $c \cdot w_{SDP}$, which is at least $c \cdot w_{QP}$. Thus, it follows that the above algorithm gives an $1/c$-approximation to the optimal value of problem (8.1) in expectation.

Now, consider the following related problem:

$$\begin{aligned} \text{maximize} \quad & \sum_{i,j} Q_{ij} x_i x_j \\ \text{subject to} \quad & x_k \in \{-1, 1\}, \quad k = 1, 2, \dots, n \end{aligned} \tag{8.5}$$

and its natural SDP relaxation:

$$\begin{aligned} \text{maximize} \quad & \sum_{i,j} Q_{ij}(v_i \cdot v_j) \\ \text{subject to} \quad & \|v_k\| = 1, \quad k = 1, 2, \dots, n \end{aligned} \tag{8.6}$$

It is tempting to analyze problem (8.6) using the same approach. Indeed, by using the same rounding scheme, one can show that

$$\mathbb{E}\left[\hat{x}_i \hat{x}_j\right] = \frac{2}{\pi} \arcsin(v_i^* \cdot v_j^*)$$

and that for $-1 \leq t \leq 1$, $\arcsin(x)$ and x differ only by a constant factor. However, as one readily observes, the inequality (8.3) only provides a term-by-term estimate of the objective function and not a global estimate. Thus, if we do not assume that the entries of Q are nonnegative, then the same analysis will not go through, as inequality (8.4) will no longer be valid. However, the bottleneck in the analysis lies in (8.3), where we replace the equality by an inequality. Thus, if we could express $\mathbb{E}[\hat{x}_i\hat{x}_j]$ in such a way so that equality can be preserved throughout, then we may be able to circumvent the aforementioned diffculty and establish approximation guarantees for problem (8.6).

It turns out that such an expression is possible. In his proof of Grothendieck's inequality—a well-known inequality in functional analysis—Rietz [11] has established the following identity:

$$\begin{aligned}\frac{\pi}{2}\mathbb{E}[\operatorname{sgn}(b\cdot G)\ \operatorname{sgn}(c\cdot G)] = (b\cdot c) + \mathbb{E}\Bigg[\Bigg(b\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(b\cdot G)\Bigg)\\ \times\Bigg(c\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(c\cdot G)\Bigg)\Bigg]\end{aligned} \tag{8.7}$$

where $b, c \in \mathbb{R}^n$ are unit vectors and $G = (g_1, \ldots, g_n)$ is a standard Gaussian random vector, i.e., the g_i's are i.i.d. standard normal random variables. This identity was established in 1974, but its use for analyzing SDP relaxations was not discovered until 2004, when Alon and Naor [12] used it to analyze the SDP relaxation of a certain quadratic program. To see how this identity can be used to analyze problem (8.6), we first let $G \in \mathbb{R}^n$ be a standard Gaussian random vector and set $\hat{x}_i = \operatorname{sgn}(v_i^*\cdot G)$. Then, using (8.7), we see that

$$\begin{aligned}\frac{\pi}{2}\sum_{i,j}Q_{ij}\mathbb{E}\big[\hat{x}_i\hat{x}_j\big] &= \sum_{i,j}Q_{ij}(v_i^*\cdot v_j^*)\\ &\quad+\sum_{i,j}Q_{ij}\mathbb{E}\Bigg[\Bigg(v_i^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_i^*\cdot G)\Bigg)\Bigg(v_j^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_j^*\cdot G)\Bigg)\Bigg]\\ &= w_{SDP}+\sum_{i,j}Q_{ij}\mathbb{E}\Bigg[\Bigg(v_i^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_i^*\cdot G)\Bigg)\\ &\quad\times\Bigg(v_j^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_j^*\cdot G)\Bigg)\Bigg]\end{aligned}$$

We now claim that

$$\sum_{i,j}Q_{ij}\mathbb{E}\Bigg[\Bigg(v_i^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_i^*\cdot G)\Bigg)\Bigg(v_j^*\cdot G-\sqrt{\frac{\pi}{2}}\ \operatorname{sgn}(v_j^*\cdot G)\Bigg)\Bigg] \geq 0 \tag{8.8}$$

Assuming this, we see that

$$\sum_{i,j}Q_{ij}\mathbb{E}\big[\hat{x}_i\hat{x}_j\big] \geq \frac{2}{\pi}w_{SDP}$$

thus showing that the above algorithm gives an $2/\pi$-approximation. We remark that Nesterov [8] has established the above result using a different technique, but as we shall see, the technique we presented can be applied to analyze other SDP relaxations as well.

To establish (8.8), let N be the standard Gaussian measure, i.e.,

$$dN(r) = \frac{1}{(2\pi)^{n/2}}\exp\left(-\|r\|^2/2\right)dr$$

where $\|r\|^2 = r_1^2 + \cdots + r_n^2$ and dr is the n-dimensional Lebesgue measure. Consider the Hilbert space $L^2(N)$, i.e., the space of all real-valued measurable functions f on $\mathbb{R}^n$ with $\int_{R^n}|f|^2\,dN < \infty$ (see, e.g., Ref. [13] for details). Recall that the inner product on $L^2(N)$ is given by

$$\langle f_u, f_v\rangle \equiv \int_{R^n} f_u(r)f_v(r)\,dN(r) = \mathbb{E}[f_u\overline{f_v}]$$

Now, observe that for each vector $u \in \mathbb{R}^n$, the function $h_u : \mathbb{R}^n \to \mathbb{R}$ given by

$$h_u(r) = u \cdot r - \sqrt{\frac{\pi}{2}}\, \operatorname{sgn}(u \cdot r)$$

is an element of $L^2(N)$. Thus, it follows that

$$\mathbb{E}\left[h_{v_i^*} h_{v_j^*}\right] = \mathbb{E}\left[\left(v_i^* \cdot G - \sqrt{\frac{\pi}{2}}\, \operatorname{sgn}(v_i^* \cdot G)\right)\left(v_j^* \cdot G - \sqrt{\frac{\pi}{2}}\, \operatorname{sgn}(v_j^* \cdot G)\right)\right]$$

is an inner product of two vectors in the Hilbert space $L^2(N)$. Moreover, we may consider Q as a positive-semidefinite operator defined on the n-dimensional subspace spanned by the vectors $\{h_{v_1^*}, \ldots, h_{v_n^*}\}$. These observations allow us to conclude that (8.8) holds.

It is now instructive to review what we have done. We begin with the identity (8.7), which can be written in the form

$$\gamma \mathbb{E}[f(b \cdot G) f(c \cdot G)] = (b \cdot c) + \mathbb{E}[(b \cdot G - \sqrt{\gamma} f(b \cdot G))(c \cdot G - \sqrt{\gamma} f(c \cdot G))]$$

where f is a rotational invariant rounding function and $\gamma > 0$ a constant. This suggests that by choosing different f's, we may be able to analyze various SDP relaxations. Indeed, this is the idea behind the results in Ref. [14], where the authors showed how to choose appropriate f's to analyze the SDP relaxations of a class of discrete and continuous quadratic optimization problems in complex Hermitian form. Specifically, consider the following problems:

$$\begin{aligned} &\text{maximize} && z^H Q z \\ &\text{subject to} && z_j \in \{1, \omega, \ldots, \omega^{k-1}\}, \quad j = 1, 2, \ldots, n \end{aligned} \tag{8.9}$$

and

$$\begin{aligned} &\text{maximize} && z^H Q z \\ &\text{subject to} && |z_j| = 1, \quad j = 1, 2, \ldots, n \\ &&& z \in C^n \end{aligned} \tag{8.10}$$

where $Q \in C^{n \times n}$ is a Hermitian matrix, ω the principal kth root of unity, and z^H denotes the conjugate transpose of the complex vector $z \in C^n$. The difference between problems (8.9) and (8.10) lies in the values that the decision variables are allowed to take. In problem (8.9), we have discrete decision variables, and such variables can be conveniently modeled as roots of unity. However, in problem (8.10), the decision variables are constrained to lie on the unit circle, which is a continuous domain. Such problems arise from many applications. For instance, the MAX-3-CUT problem where the Laplacian matrix is positive, semidefinite can be formulated as an instance of problem (8.9). On the other hand, problem (8.10) arises from the study of robust optimization as well as control theory [15,16].

Just like their real counterparts, both of these problems are NP-hard, and thus we will settle for approximation algorithms. In the following sections, we will present a generic algorithm and a unified treatment of the two seemingly very different problems (8.9) and (8.10) using their natural SDP relaxations, and to derive approximation guarantees using variants of the identity (8.7).

8.2 Complex Quadratic Optimization

Let $Q \in C^{n \times n}$ be a Hermitian matrix, where $n \geq 1$ is an integer. Consider the following discrete quadratic optimization problem:

$$\begin{aligned} &\text{maximize} && z^H Q z \\ &\text{subject to} && z_j \in \{1, \omega, \ldots, \omega^{k-1}\}, \quad j = 1, 2, \ldots, n \end{aligned} \tag{8.11}$$

where ω is the principal kth root of unity. We note that as k goes to infinity, the discrete problem (8.11) becomes a continuous optimization problem:

$$\begin{aligned} &\text{maximize} && z^H Qz \\ &\text{subject to} && |z_j| = 1, \quad j = 1, 2, \ldots, n \\ & && z \in C^n \end{aligned} \tag{8.12}$$

Although problems (8.11) and (8.12) are quite different in nature, the following *complex* semidefinite program provides a relaxation for both of them:

$$\begin{aligned} &\text{maximize} && Q \bullet Z \\ &\text{subject to} && Z_{jj} = 1, \quad j = 1, 2, \ldots, n \\ & && Z \succeq 0 \end{aligned} \tag{8.13}$$

As before, we use w_{SDP} to denote the optimal value of the SDP relaxation (8.13).

Our goal is to get a near-optimal solution for problems (8.11) and (8.12). Below we present a generic algorithm due to Ref. [14] that can be used to solve both problems (8.11) and (8.12). The algorithm is quite simple, and it is similar in spirit to the algorithm of Goemans and Williamson [1,7].

Algorithm

STEP 1: Solve the SDP relaxation (8.13) and obtain an optimal solution Z^*. Since Z^* is positive-semidefinite, we can obtain a Cholesky decomposition $Z^* = VV^H$, where $V = (v_1, v_2, \ldots, v_n)$.

STEP 2: Generate two independent normally distributed random vectors $x \in R^n$ and $y \in R^n$ with mean 0 and covariance matrix $\frac{1}{2}I_n$, where I_n is the $n \times n$ identity matrix. Let $r = x + yi$.

STEP 3: For $j = 1, 2, \ldots, n$, let $\hat{z}_j = f(v_j \cdot r)$, where the function $f(\cdot)$ depends on the structure of the problem and will be fixed later. Let $\hat{z} = (\hat{z}_1, \hat{z}_2, \ldots, \hat{z}_n)$ be the resulting solution.

To prove the performance guarantee of the above algorithm, we are interested in analyzing the quantity:

$$\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] = \sum_{l,m} Q_{lm}\mathbb{E}[f(v_l \cdot r)\overline{f(v_m \cdot r)}]$$

Thus, it would be sufficient to compute the quantity $\mathbb{E}[f(v_l \cdot r)\overline{f(v_m \cdot r)}]$ for any l, m, and this will be the main concern of the analysis. The analysis, of course, depends on the choice of the function $f(\cdot)$. However, the following Lemma will be useful and it is independent of the function $f(\cdot)$. Recall that for two vectors $b, c \in C^n$, we have $b \cdot c = \sum_{j=1}^n b_j\overline{c_j}$.

Lemma 8.1

For any pair of vectors $b, c \in C^n$, $\mathbb{E}[(b \cdot r)\overline{(c \cdot r)}] = b \cdot c$, where $r = x + yi$ and $x \in R^n$ and $y \in R^n$ are two independent normally distributed random vector with mean 0 and covariance matrix $\frac{1}{2}I_n$.

Proof

This follows from a straightforward computation

$$\mathbb{E}[(b \cdot r)\overline{(c \cdot r)}] = \mathbb{E}\left[\left(\sum_{j=1}^n b_j\overline{r}_j\right)\left(\sum_{k=1}^n \overline{c}_k r_k\right)\right] = \sum_{j,k=1}^n b_j\overline{c}_k\mathbb{E}[\overline{r}_j r_k] = \sum_{j=1}^n b_j\overline{c}_j$$

where the last equality follows from the fact that the entries of x and y are independent, normally distributed with mean 0 and variance 1/2. □

In the sequel, we shall use $r \sim \mathcal{N}_C(0, I_n)$ to indicate that r is an n-dimensional standard complex normal random vector, i.e., $r = x + yi$, where $x, y \in R^n$ are two independent normally distributed random vectors, each with mean 0 and covariance matrix $\frac{1}{2}I_n$.

8.3 Discrete Problems Where Q Is Positive Semidefinite

In this section, we assume that Q is Hermitian and positive semidefinite. Consider the discrete complex quadratic optimization problem (8.11). In this case, we define the function $f(\cdot)$ in the generic algorithm presented in Section 8.2 as follows:

$$f(z) = \begin{cases} 1 & \text{if } \arg(z) \in [-\pi/k, \pi/k) \\ \omega & \text{if } \arg(z) \in [\pi/k, 3\pi/k) \\ \vdots & \vdots \\ \omega^{k-1} & \text{if } \arg(z) \in [(2k-3)\pi/k, (2k-1)\pi/k) \end{cases} \tag{8.14}$$

By construction, we have $\hat{z}_j \in \{1, \omega, \ldots, \omega^{k-1}\}$ for $j = 1, 2, \ldots, n$, i.e., $\hat{z}$ is a feasible solution of problem (8.11). Now, we can establish the following lemma.

Lemma 8.2

For any pair of vectors $b, c \in C^n$ and $r \sim \mathcal{N}_C(0, I_n)$, we have

$$\mathbb{E}[(b \cdot r)\overline{f(c \cdot r)}] = \frac{k \sin(\pi/k)}{2\sqrt{\pi}}(b \cdot c)$$

Proof

By rotation invariance, we may assume without loss of generality that $b = (b_1, b_2, 0, \ldots, 0)$ and $c = (1, 0, \ldots, 0)$. Then, we have

$$\begin{aligned} \mathbb{E}[(b_1\overline{r_1} + b_2\overline{r_2})\overline{f(\overline{r_1})}] &= b_1\mathbb{E}[\overline{r_1}\,\overline{f(\overline{r_1})}] \\ &= \frac{b_1}{\pi}\int_{\mathbf{R}}\int_{\mathbf{R}}(x - iy)\overline{f(x - iy)}\exp\{-(x^2 + y^2)\}\,dx\,dy \\ &= \frac{b_1}{\pi}\int_0^{\infty}\int_0^{2\pi} \rho^2 e^{-i\theta}\overline{f(\rho e^{-i\theta})}e^{-\rho^2}\,d\theta\,d\rho \end{aligned}$$

Now, for any $j = 1, \ldots, k$, if $(2j-3)\pi/k < \theta \le (2j-1)\pi/k$, then $-(2j-1)\pi/k \le -\theta < -(2j-3)\pi/k$, or

$$\frac{2k - 2j + 1}{k}\pi \le 2\pi - \theta < \frac{2k - 2j + 3}{k}\pi$$

It then follows from the definition of $f(\cdot)$ that

$$f(\rho e^{-i\theta}) = f(\rho e^{i(2\pi-\theta)}) = \omega^{k-j+1}$$

and hence $\overline{f(\rho e^{-i\theta})} = \omega^{j-1}$. Therefore, we have

$$\int_{(2j-3)\pi/k}^{(2j-1)\pi/k} \overline{f(\rho e^{-i\theta})}e^{-i\theta}\,d\theta = \omega^{j-1}\int_{(2j-3)\pi/k}^{(2j-1)\pi/k} e^{-i\theta}\,d\theta = 2\sin(\pi/k)$$

In particular, the above quantity is independent of j. Thus, we conclude that

$$\int_0^{2\pi} \overline{f(\rho e^{-i\theta})}e^{-i\theta}\,d\theta = 2k\sin(\pi/k)$$

Moreover, since we have

$$\int_0^{\infty} \rho^2 e^{-\rho^2}\,d\rho = \frac{\sqrt{\pi}}{4}$$

it follows that

$$\mathbb{E}[(b_1\overline{r_1} + b_2\overline{r_2})\overline{f(\overline{r_1})}] = \frac{k\sin(\pi/k)}{2\sqrt{\pi}} b_1 = \frac{k\sin(\pi/k)}{2\sqrt{\pi}}(b \cdot c)$$

as desired. □

We are now ready to prove the main result of this section.

Theorem 8.1

Suppose that Q is Hermitian and positive semidefinite. Then, there exists a $\frac{(k\sin(\frac{\pi}{k}))^2}{4\pi}$ approximation algorithm for problem (8.11).

Proof

By Lemmas 8.1 and 8.2, we have

$$\begin{aligned}\mathbb{E}&\left[\left\{(b \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(b \cdot r)\right\}\left\{\overline{(c \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(c \cdot r)}\right\}\right] \\ &= -(b \cdot c) + \frac{4\pi}{(k\sin(\frac{\pi}{k}))^2}\mathbb{E}[f(b \cdot r)\overline{f(c \cdot r)}]\end{aligned}$$

It follows that

$$\begin{aligned}\mathbb{E}[\hat{z}^H Q \hat{z}] = \frac{(k\sin(\frac{\pi}{k}))^2}{4\pi} \sum_{l=1}^{n}\sum_{m=1}^{n} q_{lm}(v_l \cdot v_m) + \frac{(k\sin(\frac{\pi}{k}))^2}{4\pi} \sum_{l=1}^{n}\sum_{m=1}^{n} q_{lm} \\ \times \mathbb{E}\left[\left\{(v_l \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_l \cdot r)\right\}\left\{\overline{(v_m \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_m \cdot r)}\right\}\right]\end{aligned} \tag{8.15}$$

We now claim that

$$\sum_{l=1}^{n}\sum_{m=1}^{n} q_{lm}\mathbb{E}\left[\left\{(v_l \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_l \cdot r)\right\}\left\{\overline{(v_m \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_m \cdot r)}\right\}\right] \geq 0 \tag{8.16}$$

To see this, let G be the standard complex Gaussian measure, i.e.,

$$dG(r) = \frac{1}{\pi^n}\exp\left(-\|r\|^2\right) dr$$

where $\|r\|^2 = |r_1|^2 + \cdots + |r_n|^2$ and dr is the $2n$-dimensional Lebesgue measure. Consider the Hilbert space $L^2(G)$, i.e., the space of all complex-valued measurable functions f on C^n with $\int_{C^n} |f|^2\, dG < \infty$. Recall that the inner product on $L^2(G)$ is given by

$$\langle f_u, f_v \rangle \equiv \int_{C^n} f_u(r)\overline{f_v(r)}\, dG(r) = \mathbb{E}[f_u\overline{f_v}]$$

Now, observe that for each vector $u \in C^n$, the function $h_u : C^n \to C$ given by

$$h_u(r) = u \cdot r - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(u \cdot r)$$

is an element of $L^2(G)$. Thus, it follows that

$$\mathbb{E}\left[h_{v_l}\overline{h_{v_m}}\right] = \mathbb{E}\left[\left\{(v_l \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_l \cdot r)\right\}\left\{\overline{(v_m \cdot r) - \frac{2\sqrt{\pi}}{k\sin(\frac{\pi}{k})} f(v_m \cdot r)}\right\}\right]$$

is an inner product of two vectors in the Hilbert space $L^2(G)$. Moreover, we may consider Q as a positive semidefinite operator defined on the n-dimensional subspace spanned by the vectors $\{h_{v_1}, \ldots, h_{v_n}\}$.

These observations allow us to conclude that (8.16) holds. Finally, upon substituting (8.16) into (8.15), we obtain

$$\mathbb{E}[\hat{z}^H Q\hat{z}] \geq \frac{(k\sin(\frac{\pi}{k}))^2}{4\pi}\sum_{l=1}^{n}\sum_{m=1}^{n} q_{lm}(v_l \cdot v_m) = \frac{(k\sin(\frac{\pi}{k}))^2}{4\pi} w_{SDP}$$

i.e., our algorithm gives a $\frac{(k\sin(\frac{\pi}{k}))^2}{4\pi}$-approximation. □

It is interesting to note that the above result can be obtained via a completely different technique. In Ref. [17], the authors developed a closed-form formula for computing the probability of a complex-valued normally distributed bivariate random vector to be in a given angular region. Using this formula and the series expansions of certain trigonometric functions, they are able to establish the same result.

As an application of Theorem 8.1, we consider the MAX-3-CUT problem, which is defined as follows. We are given an undirected graph $G = (V, E)$ with V being the set of nodes and E being the set of edges. For each edge $(i, j) \in E$, there is a weight w_{ij} that could be positive or negative. For a partition of V into three subsets V_1, V_2, and V_3, we define

$$\delta(V_1, V_2, V_3) = \{(i, j) \in E : i \in V_k,\ j \in V_l \quad \text{for } k \neq l\}$$

and

$$w(\delta(V_1, V_2, V_3)) = \sum_{(i,j)\in\delta(V_1,V_2,V_3)} w_{ij}$$

Our goal is to find a tripartition (V_1, V_2, V_3) such that $w(\delta(V_1, V_2, V_3))$ is maximized. Note that the MAX-3-CUT problem is a generalization of the well-known MAX–CUT problem. In the MAX–CUT problem, we require one of the subsets, say V_3, to be empty.

Goemans and Williamson [7] have given the following complex QP formulation for the MAX-3-CUT problem:

$$\begin{array}{ll} \text{maximize} & \frac{1}{3}\sum_{(i,j)\in E} w_{ij}\left(2 - z_i \cdot z_j - z_j \cdot z_i\right) \\ \text{subject to} & z_j \in \{1, \omega, \omega^2\} \ \text{ for all } \ j \in V \end{array} \tag{8.17}$$

Based on this formulation and its SDP relaxation, Goemans and Williamson [7] were able to give an 0.836-approximation algorithm for the MAX-3-CUT problem when the weights of the edges are nonnegative, i.e., $w_{ij} \geq 0$ for all $(i, j) \in E$. (They also showed that their algorithm is actually the same as that of Frieze and Jerrum [5], and thus give a tighter analysis of the algorithm in Ref. [5].) However, their analysis does not apply if some of the edges have negative weights.

Note that since $w_{ij} = w_{ji}$, problem (8.17) is equivalent to

$$\begin{array}{ll} \text{maximize} & \frac{2}{3}z^H L z \\ \text{subject to} & z_j \in \{1, \omega, \omega^2\} \ \text{ for all } \ j \in V \end{array} \tag{8.18}$$

where L is the Laplacian matrix of the graph $G = (V, E)$, i.e., $L_{ij} = -w_{ij}$ and $L_{ii} = \sum_{j:(i,j)\in E} w_{ij}$. However, by Theorem 8.1, problem (8.18) can be approximated by a factor of $\frac{(3\sin(\frac{\pi}{3}))^2}{4\pi} \approx 0.537$. Therefore, we obtain the following result:

Corollary 8.1

There is a randomized 0.537*-approximation algorithm for the* MAX-3-CUT *problem when the Laplacian matrix is positive-semidefinite.*

8.4 Continuous Problems Where Q Is Positive-Semidefinite

Now, let us consider problem (8.12) when Q is positive-semidefinite. This problem can be seen as a special case of problem (8.11) by letting $k \to \infty$. In this case, the function $f(\cdot)$ is defined as follows:

$$f(t) = \begin{cases} \frac{t}{|t|} & \text{if } |t| > 0 \\ 0 & \text{if } t = 0 \end{cases} \tag{8.19}$$

Note that as $k \to \infty$, we have $\frac{(k \sin(\frac{\pi}{k}))^2}{4\pi} \to \pi/4$. This establishes the following result, which has been proved independently by Ben-Tal et al. [16] and Zhang and Huang [17]. However, the proof presented above is quite a bit simpler.

Corollary 8.2

Suppose that Q is positive semidefinite and Hermitian. Then, there exists a $\frac{\pi}{4}$-approximation algorithm for problem (8.12).

8.5 Continuous Problems Where Q Is Not Positive-Semidefinite

In this section, we deal with problem (8.12) where the matrix Q is not positive-semidefinite. However, for convenience, we assume that $w_{SDP} > 0$ so that the standard definition of approximation algorithm makes sense for our problem. It is clear that $w_{SDP} > 0$ as long as all the diagonal entries of Q are zeros.

Assumption 8.1

The diagonal entries of Q are all zeros, i.e., $Q_{ii} = 0$ for $i = 1, 2, \ldots, n$.

In fact, Assumption 8.1 leads to the even stronger result that follows.

Lemma 8.3

If Q satisfies Assumption 8.1, then there exists a constant $C > 0$ such that

$$w_{SDP} \geq C \sqrt{\sum_{1 \leq i, j \leq n} |q_{ij}|^2} > 0$$

Proof

It is straightforward to show that problem (8.12) is equivalent to

$$\begin{aligned} &\text{maximize} && (x^T, y^T) \begin{pmatrix} Re(Q) & Im(Q) \\ -Im(Q) & Re(Q) \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \\ &\text{subject to} && x_j^2 + y_j^2 = 1, \quad j = 1, 2, \ldots, n \\ &&& x, y \in R^n \end{aligned} \tag{8.20}$$

Moreover, the objective value of problem (8.20) is bounded below by the objective value of the following problem:

$$\begin{aligned} &\text{maximize} && (x^T, y^T) \begin{pmatrix} Re(Q) & Im(Q) \\ -Im(Q) & Re(Q) \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \\ &\text{subject to} && x_j^2 = \tfrac{1}{2}, \quad j = 1, 2, \ldots, n \\ &&& y_j^2 = \tfrac{1}{2}, \quad j = 1, 2, \ldots, n \\ &&& x, y \in R^n \end{aligned} \tag{8.21}$$

Since Q satisfies Assumption 8.1, the diagonal entries of

$$\begin{pmatrix} Re(Q) & Im(Q) \\ -Im(Q) & Re(Q) \end{pmatrix}$$

must also be zeros. It has been shown in Ref. [18] that for any real matrix $A = (a_{ij})_{n\times n}$ with a zero diagonal, the optimal objective value of

$$\begin{aligned} &\text{maximize} && x^T Ax \\ &\text{subject to} && x_j^2 = 1, \quad j = 1, 2, \ldots, n \\ & && x \in R^n \end{aligned} \tag{8.22}$$

is bounded below by $C\sqrt{2\sum_{1\le i,\, j\le n} |a_{ij}|^2}$, for some constant $C > 0$ which is independent of A. This implies that the optimal objective value of problem (8.21) is at least

$$\frac{1}{2}C\sqrt{2\sum_{1\le i,\, j\le n} 2(|Re(q_{ij})|^2 + |Im(q_{ij})|^2)} \ge C\sqrt{\sum_{1\le i,\, j\le n} |q_{ij}|^2}$$

which leads to the desired result. □

Again, we use our generic algorithm presented in Section 8.2. In this case, we specify the function $f(\cdot)$ as follows:

$$f(t) = \begin{cases} \frac{t}{T} & \text{if } |t| \le T \\ \frac{t}{|t|} & \text{if } |t| > T \end{cases} \tag{8.23}$$

where T is a parameter which will be fixed later. If we let $z_j = f(v_j \cdot r)$, then the solution $z = (z_1, \ldots, z_n)$ obtained by this rounding may not be feasible, as the point may not have unit modulus. However, we know that $|z_j| \le 1$. Thus, we can further round the solution as follows:

$$\hat{z} = \begin{cases} z/|z| & \text{with probability } (1 + |z|)/2 \\ -\bar{z}/|z| & \text{with probability } (1 - |z|)/2 \end{cases}$$

The following lemma is a direct consequence of the second randomized rounding.

Lemma 8.4

For $i \ne j$, we have $\mathbb{E}[\hat{z}_i\overline{\hat{z}_j}] = \mathbb{E}[z_i\overline{z_j}]$.

Proof

By definition, conditioning on z_i, z_j, we have

$$\begin{aligned} \mathbb{E}[\hat{z}_i\overline{\hat{z}_j} \mid z_i, z_j] &= \Pr\{\hat{z}_i = z_i/|z_i|,\ \hat{z}_j = z_j/|z_j|\}\frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} \\ &\quad + \Pr\{\hat{z}_i = z_i/|z_i|,\ \hat{z}_j = -z_j/|z_j|\} - \frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} \\ &\quad + \Pr\{\hat{z}_i = -z_i/|z_i|,\ \hat{z}_j = z_j/|z_j|\} - \frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} \\ &\quad + \Pr\{\hat{z}_i = -z_i/|z_i|,\ \hat{z}_j = -z_j/|z_j|\}\frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} \\ &= \frac{1}{2}(1 + |z_i|\cdot|z_j|)\frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} - \frac{1}{2}(1 - |z_i|\cdot|z_j|)\frac{z_i\overline{z_j}}{|z_i|\cdot|\overline{z_j}|} \\ &= z_i\overline{z_j} \end{aligned}$$

The desired result then follows from the tower property of conditional expectation. □

This shows that the expected value of the solution on the circle equals that of the "fractional" solution obtained by applying $f(\cdot)$ to the SDP solution. Therefore, we could still restrict ourselves to the rounding function $f(\cdot)$.

Now, define

$$g(T) = \frac{1}{T} - \frac{1}{T}e^{-T^2} + \sqrt{\pi}(1 - \Phi(\sqrt{2}T))$$

where $\Phi(\cdot)$ is the probability distribution function of $\mathcal{N}(0, 1)$.

Lemma 8.5

For any pair of vectors $b, c \in C^n$ and $r \sim \mathcal{N}_C(0, I_n)$, we have

$$\mathbb{E}[(b \cdot r)\overline{f(c \cdot r)}] = g(T)(b \cdot c)$$

Proof

Again, without loss of generality, we assume that $c = (1, 0, \ldots, 0)$ and $b = (b_1, b_2, 0, \ldots, 0)$. Let $\mathbf{1}_A$ be the indicator function of the set A, i.e., $\mathbf{1}_A(\omega) = 1$ if $\omega \in A$ and $\mathbf{1}_A(\omega) = 0$ otherwise. Then, we have

$$\begin{aligned}
\mathbb{E}[(b \cdot r)\overline{f(c \cdot r)}] &= \mathbb{E}\left[(b_1\bar{r}_1 + b_2\bar{r}_2)\frac{r_1}{T} \cdot \mathbf{1}_{\{|r_1| \le T\}}\right] + \mathbb{E}\left[(b_1\bar{r}_1 + b_2\bar{r}_2)\frac{r_1}{|r_1|} \cdot \mathbf{1}_{\{|r_1| > T\}}\right] \\
&= \frac{1}{T}\mathbb{E}\left[b_1|r_1|^2 \cdot \mathbf{1}_{\{|r_1| \le T\}}\right] + \mathbb{E}\left[b_1|r_1| \cdot \mathbf{1}_{\{|r_1| > T\}}\right] \\
&= \frac{b_1}{T} \cdot \frac{1}{\pi}\int_{x^2+y^2 \le T^2} (x^2 + y^2)\ \exp(-(x^2 + y^2))\, dx\, dy \\
&\quad + \frac{b_1}{\pi}\int_{x^2+y^2 > T^2} \sqrt{x^2 + y^2}\ \exp(-(x^2 + y^2))\, dx\, dy \\
&= \frac{b_1}{\pi T}\int_0^{2\pi}\int_0^T \rho^3 \exp(-\rho^2)\, d\rho\, d\theta + \frac{b_1}{\pi}\int_0^{2\pi}\int_T^\infty \rho^2 \exp(-\rho^2)\, d\rho\, d\theta \\
&= g(T)b_1
\end{aligned}$$

where the last equality follows from the facts

$$\int_0^T \rho^3 \exp(-\rho^2)\, d\rho = \frac{1}{2}\left(1 - (T^2 + 1)\exp(-T^2)\right)$$

and

$$\int_T^\infty \rho^2 \exp(-\rho^2)\, d\rho = \frac{1}{2}\left(T\exp(-T^2) + \sqrt{\pi}(1 - \Phi(\sqrt{2}T))\right)$$

This completes the proof. □

In a similar fashion, one can show the following:

Lemma 8.6

For any pair of vectors $b, c \in C^n$ and $r \sim \mathcal{N}_C(0, I_n)$, we have

$$\mathbb{E}[f(c \cdot r)\overline{f(c \cdot r)}] = \frac{1}{T^2} - \frac{1}{T^2}\exp(-T^2)$$

Now, by putting everything together, we obtain the following:

Theorem 8.2

If Q satisfies Assumption 8.1, then there exists a constant $C > 0$ such that

$$\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] \geq \frac{1}{3\ln(\beta)}\, w_{SDP}$$

where $\beta = \max\left\{5, \frac{\sum_{1\leq k,m\leq n}|q_{km}|}{C\sqrt{\sum_{1\leq k,m\leq n}|q_{km}|^2}}\right\}$

Proof

By Lemmas 8.1 and 8.5, we have

$$\mathbb{E}[\{(b\cdot r) - Tf(b\cdot r)\}\overline{\{(c\cdot r) - Tf(c\cdot r)\}}] = (1-2Tg(T))(b\cdot c) + T^2\mathbb{E}[f(b\cdot r)\overline{f(c\cdot r)}]$$

It follows that

$$\begin{aligned}\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] &= \sum_{k=1}^{n}\sum_{m=1}^{n}\frac{2Tg(T)-1}{T^2}q_{km}(v_k\cdot v_m)\\ &\quad + \frac{1}{T^2}\sum_{k=1}^{n}\sum_{m=1}^{n}q_{km}\mathbb{E}[\{(v_k\cdot r) - Tf(v_k\cdot r)\}\overline{\{(v_m\cdot r) - Tf(v_m\cdot r)\}}]\end{aligned}$$

Again, the quantity $\mathbb{E}[\{(b\cdot r) - Tf(b\cdot r)\}\overline{\{(c\cdot r) - Tf(c\cdot r)\}}]$ can be seen as an inner product of two vectors in a Hilbert space. Moreover, by letting $b = c$ and using Lemma 8.6, we know that the norm of an Euclidean unit vector in this Hilbert space is

$$2 - 2Tg(T) - \exp(-T^2) = \exp(-T^2) - 2T\sqrt{\pi}(1-\Phi(\sqrt{2}T))$$

It follows that

$$\begin{aligned}&\frac{1}{T^2}\sum_{k=1}^{n}\sum_{m=1}^{n}q_{km}\mathbb{E}[\{(v_k\cdot r) - Tf(v_k\cdot r)\}\overline{\{(v_m\cdot r) - Tf(v_m\cdot r)\}}]\\ &\quad\geq -\frac{\exp(-T^2) - 2T\sqrt{\pi}(1-\Phi(\sqrt{2}T))}{T^2}\sum_{k=1}^{n}\sum_{m=1}^{n}|q_{km}|\end{aligned}$$

In contrast, by Lemma 8.3, we have $w_{SDP} \geq C\sqrt{\sum_{1\leq k,m\leq n}|q_{km}|^2} > 0$ for some constant $C > 0$. It follows that

$$\begin{aligned}&\frac{1}{T^2}\sum_{k=1}^{n}\sum_{m=1}^{n}q_{km}\mathbb{E}[\{(v_k\cdot r) - Tf(v_k\cdot r)\}\overline{\{(v_m\cdot r) - Tf(v_m\cdot r)\}}]\\ &\quad\geq -\frac{\exp(-T^2) - 2T\sqrt{\pi}(1-\Phi(\sqrt{2}T))}{T^2}\,\frac{\sum_{1\leq k,m\leq n}|q_{km}|}{C\sqrt{\sum_{1\leq k,m\leq n}|q_{km}|^2}}\cdot w_{SDP}\\ &\quad\geq -\frac{\exp(-T^2) - 2T\sqrt{\pi}(1-\Phi(\sqrt{2}T))}{T^2}\beta\cdot w_{SDP}\end{aligned}$$

where $\beta = \max\left\{5, \frac{\sum_{1\leq k,m\leq n}|q_{km}|}{C\sqrt{\sum_{1\leq k,m\leq n}|q_{km}|^2}}\right\}$. This implies that

$$\begin{aligned}\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] &\geq \left(\frac{2Tg(T)-1}{T^2} - \frac{\exp(-T^2) - 2T\sqrt{\pi}(1-\Phi(\sqrt{2}T))}{T^2}n\right)w_{SDP}\\ &\geq \frac{1-(2+\beta)\exp(-T^2)}{T^2}\,w_{SDP}\end{aligned}$$

By letting $T = \sqrt{2\ln\beta}$, we have $\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] \geq \frac{1}{3\ln\beta} w_{SDP}$. □

Note that

$$\frac{\sum_{1\leq k,m\leq n}|q_{km}|}{\sqrt{\sum_{1\leq k,m\leq n}|q_{km}|^2}} \leq \frac{1}{n}$$

Therefore, we have

Corollary 8.3

If Q satisfies Assumption 8.1, then $\mathbb{E}\left[\hat{z}^H Q\hat{z}\right] \geq O(\frac{1}{\ln n})\ w_{SDP}$.

8.6 Discrete Problems Where *Q* Is Not Positive-Semidefinite

Let us now consider problem (8.11) where Q is an indefinite Hermitian matrix with diag$(Q) = 0$. Its approximability was left open in Ref. [14] and is recently resolved by Huang and Zhang [19]. It is interesting to note that the techniques of Huang and Zhang encompass well-known ideas in the literature. Specifically, their rounding is similar to a technique introduced in Ref. [20], and their analysis uses some of the ideas from Ref. [21]. To be precise, let Z^* be an optimal solution to problem (8.11). Then, let $r \sim \mathcal{N}_C(0, Z^*)$ be a Gaussian random vector, and for each $j = 1, 2, \ldots, n$, set

$$z'_j = \begin{cases} r_j/|r_j| & \text{if } |r_j| > T \\ r_j/T & \text{if } |r_j| \leq T \end{cases}$$

where $T > 0$ is a parameter to be chosen later. As earlier, each z'_j satisfies $|z'_j| \leq 1$. However, the solution $\{z'_1, \ldots, z'_n\}$ is not feasible to problem (8.11). Thus, we need to perform a second randomized rounding as follows:

$$\hat{z}_j = \omega^l \quad \text{with probability } (1 + \text{Re}(\omega^{-l}z'_j))/k$$

where $l = 0, 1, \ldots, k-1$ and $j = 1, 2, \ldots, n$. Observe that

$$\sum_{l=0}^{k-1}\frac{(1+\text{Re}(\omega^{-l}z'_j))}{k} = 1 + \frac{1}{k}\text{Re}\left[\left(\sum_{l=0}^{k-1}\omega^{-l}\right)z'_j\right] = 1$$

and hence, we indeed have a probability distribution. The following lemma is similar in spirit to Lemma 8.4 and is crucial to the analysis.

Lemma 8.7

For $j \neq l$ *and* $k \geq 3$, *we have* $\mathbb{E}\left[\hat{z}_j\overline{\hat{z}_l}\right] = \frac{1}{4}\mathbb{E}\left[z'_j\overline{z'_l}\right]$.

To analyze the quality of the solution $\{\hat{z}_1, \ldots, \hat{z}_n\}$, we need the following lemma (see also Ref. [21]):

Lemma 8.8

For $j \neq l$ *and* $T > 1$, *we have* $\mathbb{E}[|\Delta_{jl}|] < \exp(-T^2)(4 + 5/T)$, *where* $\Delta_{jl} = r_j\overline{r_l}/T^2 - z'_j\overline{z'_l}$.

Proof

We first divide C^2 into the following (possibly overlapping) regions:

$$A = \{(r_j, r_l) : |r_j| \leq T,\ |r_l| \leq T\}, \quad B = \{(r_j, r_l) : |r_l| > T\}, \quad C = \{(r_j, r_l) : |r_j| > T\}$$

By symmetry, we may assume that $\mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_C] \le \mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_B]$. Thus, we have

$$\mathbb{E}[|\Delta_{jl}|] \le \mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_A] + \mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_B] + \mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_C] \le \mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_A] + 2\mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_B]$$

By construction, we have $\mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_A] = 0$. Now, suppose that $\mathbb{E}[r_j\overline{r_l}] = Z^*_{jl} = \gamma e^{i\alpha}$. Since we have

$$\begin{pmatrix} r_j \\ r_l \end{pmatrix} \sim \mathcal{N}_C\left(0, \begin{pmatrix} 1 & \gamma e^{i\alpha} \\ \gamma e^{-i\alpha} & 1 \end{pmatrix}\right)$$

it follows that

$$r_j = \gamma e^{i\alpha}\eta + \sqrt{1-\gamma^2}\,\lambda, \quad r_l = \eta$$

where

$$\begin{pmatrix} \eta \\ \lambda \end{pmatrix} \sim \mathcal{N}_C(0, I_2).$$

Hence, we conclude that

$$P(|r_l| > T) = P(|\eta| > T) = \frac{1}{\pi}\int_T^\infty \int_0^{2\pi} re^{-r^2}\, d\theta\, dr = 2\int_T^\infty re^{-r^2}\, dr = e^{-T^2}$$

Now, note that $\mathbb{E}[|z'_j\overline{z'_l}|] \le \mathbb{E}[\mathbf{1}_B] = P(|\eta| > T) = e^{-T^2}$. Moreover, since $\gamma \le 1$, we have

$$\begin{aligned}
\mathbb{E}[|r_j\overline{r_l}|\cdot \mathbf{1}_B] &= \mathbb{E}\left[\left(\gamma e^{i\alpha}|\eta|^2 + \sqrt{1-\gamma^2}\,\lambda\bar{\eta}\right)\cdot \mathbf{1}_B\right] \\
&\le \mathbb{E}\left[\left(|\eta|^2 + |\eta|\cdot|\lambda|\right)\cdot \mathbf{1}_B\right] \\
&= \frac{1}{\pi}\int_T^\infty\int_0^{2\pi} r^3e^{-r^2}\, d\theta\, dr + \left(\frac{1}{\pi}\int_T^\infty\int_0^{2\pi} r^2\, d\theta\, dr\right)\left(\frac{1}{\pi}\int_0^\infty\int_0^{2\pi} r^2e^{-r^2}\, d\theta\, dr\right) \\
&= \left(T^2 + \frac{\sqrt{\pi}\,T}{2} + 1\right)e^{-T^2} + \frac{\pi}{2}\left(1 - \Phi(\sqrt{2}T)\right)
\end{aligned}$$

where $\Phi(\cdot)$ is the cumulative distribution function of the real-valued standard normal distribution. It then follows that

$$\mathbb{E}[|\Delta_{jl}|\cdot \mathbf{1}_B] \le \mathbb{E}\left[\frac{|r_j\overline{r_l}|}{T^2} + |z'_j\overline{z'_l}|\right] \le e^{-T^2}\left(\frac{1}{T^2} + \frac{\sqrt{\pi}}{2T} + 2\right) + \frac{\pi}{2T^2}(1 - \Phi(\sqrt{2}T))$$

whence

$$\mathbb{E}[|\Delta_{jl}|] \le e^{-T^2}\left(\frac{2}{T^2} + \frac{\sqrt{\pi}}{T} + 4\right) + \frac{\pi}{T^2}(1 - \Phi(\sqrt{2}T)) \tag{8.24}$$

Now, observe that

$$\frac{\pi}{T^2}(1 - \Phi(\sqrt{2}T)) = \frac{\sqrt{\pi}}{T^2}\int_T^\infty e^{-s^2}\, ds \le \frac{\sqrt{\pi}}{T^2}\int_T^\infty se^{-s^2}\, ds = \frac{\sqrt{\pi}}{2T^2}e^{-T^2}$$

and hence it follows from (8.24) that

$$\mathbb{E}[|\Delta_{jl}|] \le e^{-T^2}\left(\frac{\sqrt{\pi}+4}{2T^2} + \frac{\sqrt{\pi}}{T} + 4\right) < e^{-T^2}\left(4 + \frac{5}{T}\right)$$

as desired. □

Now, by using Lemmas 8.7 and 8.8, and the techniques similar to that in Ref. [21], we are led to the following result:

Theorem 8.3

Suppose that $n \geq 3$, *and set* $T = \sqrt{9 \ln n}$. *Then, we have* $\mathbb{E}[z^H Qz] \geq O\left(\frac{1}{\ln n}\right) w_{SDP}$.

8.7 Summary

We presented a generic algorithm and a unified treatment of the two seemingly very different quadratic optimization problems in complex Hermitian form. Since these problems are NP-hard, we settled for approximation algorithms. We used their natural SDP relaxations, and to derive approximation guarantees we used variants of the Rietz identity [11].

Polynomial-Time Approximation Schemes

9.1 Introduction

Let Π be an NP-hard optimization problem, and let A be an approximation algorithm for Π. For an instance I of Π, let $A(I)$ denote the objective value when running A on I, and let $OPT(I)$ denote the optimal objective value. The approximation ratio of A for the instance I is $R_A(I) = A(I)/OPT(I)$, thus, when Π is minimization (maximization) problem $R_A(I) \geq 1$ ($R_A(I) \leq 1$).

A polynomial-time approximation scheme (PTAS) is an algorithm that takes as input an additional parameter, $\varepsilon > 0$, which determines the desired approximation ratio. As ε approaches 0, the approximation ratio gets arbitrarily close to 1. The time complexity of the scheme is polynomial in the input size, but may be exponential in $1/\varepsilon$. This gives a clear trade-off between running time and quality of approximation. Formally,

Definition 9.1

An approximation scheme *for an optimization problem* Π *is an algorithm* A *which takes as input an instance* I *of* Π *and an error bound* ε*, runs in time polynomial in* $|I|$*, and has approximation ratio* $R_A(I, \varepsilon) \leq (1+\varepsilon)$*. In fact, such an algorithm* A *is a family of algorithms* A_ε *such that for any instance* I*,* $R_{A_\varepsilon}(I) \leq (1+\varepsilon)$.

The approximation algorithm A may be deterministic or randomized. In the latter case, the result is a randomized approximation scheme.

Definition 9.2

A randomized approximation scheme *for an optimization problem* Π *is a family of algorithms* A_ε *which run in time polynomial in* $|I|$ *and have, for any instance* I*,* expected *approximation ratio* $EXP[R_{A_\varepsilon}(I)] \leq (1+\varepsilon)$.

In some approximation schemes, an additive constant k, whose value is independent of I and ε, is added to the approximation ratio. Asymptotically, this constant is negligible, thus, such a scheme is called an asymptotic PTAS.

Definition 9.3

An asymptotic approximation scheme *for an optimization problem* Π *is a family of algorithms* A_ε *that run in time polynomial in* $|I|$*, such that, for some constant k and for any instance* I, $A_\varepsilon(I) \leq (1+\varepsilon)OPT(I)+k$.

We refer the reader to Chapter 11 in this handbook for a detailed study of such schemes.

Some approximation algorithms provide a solution for a *relaxed instance* of the problem. For example, in packing problems, an algorithm may pack the items in bins whose sizes are slightly larger than the original. The objective value is achieved relative to the relaxed instance. This type of algorithm is called a *dual* approximation algorithm [1], or approximation with *resource augmentation* [2]. A *dual approximation scheme* is a family of algorithms A_ε that run in time polynomial in $|I|$, such that, for any instance I, $A(I) \leq (1+\varepsilon)OPT(I)$, and $A(I)$ is achieved for resources augmented by factor of $(1+\varepsilon)$.

Depending on the function $f(|I|, 1/\varepsilon)$, which gives the running time of the scheme, some schemes are classified as *quasi-polynomial* and others as *fully polynomial*. In particular, when the running time is $O(n^{polylog(n)})$ we get a quasi-PTAS (see, e.g., Refs. [3,4]); when the running time is polynomial in both $|I|$ and $1/\varepsilon$ we get a fully polynomial-time approximation scheme (FPTAS). Such schemes are studied in detail in Chapter 10.

There is wide literature on approximation schemes for NP-hard problems. Many of these works present PTASs for certain subclasses of instances of problems, which are in general extremely hard to solve. While some of the proposed schemes may have running times which render them inefficient in practice, these works essentially help identify the class of problems that admit PTAS. There have been some studies also toward characterizing this class of problems (see, e.g., Refs. [5,6] and Chapter 17 of this book). We focus here on the techniques that have been repeatedly used in developing PTASs.

We refer the reader also to the comprehensive survey on Approximation Algorithms by Motwani [7], a tutorial by Schuurman and Woeginger [8], and the survey on scheduling by Karger et al. [9], from which we borrowed some of the examples in this chapter.

9.2 Partial Enumeration

9.2.1 Extending Partial Small-Size Solutions

There are two main techniques based on extending partial small-size solutions. The first technique exploits our ability to solve the problem *optimally* on a constant-size subset of the instance. Thus, initially, such a constant-size subset is selected. This subset contains the most "significant" elements in the instance. We identify elements as *significant* depending on the problem at hand. The problem is solved optimally for this subset. This can be done by exhaustive search, since there is only a constant number of elements to consider. Next, this optimal partial solution is extended into a complete one, using some heuristic which has a bounded approximation ratio.

In the second technique, none of the elements is initially identified as "significant"; instead, *all* partial solutions of constant size are considered, and each is extended to a complete solution using some heuristic. The best extension is selected to be the output of the scheme.

The time-complexity analysis of such PTASs is based on the fact that the number of possible subsets, or solutions that are considered, is exponential in the (constant) size of these subsets. The step in which the constant-size partial solution is extended is usually based on some greedy rule that may require sorting, and is polynomial. The parameter ε specifying the required approximation ratio of $(1+\varepsilon)$ determines the size k of the partial solution to which an exponential exhaustive search is applied. This implies that the running time of such schemes is exponential in $1/\varepsilon$.

9.2.1.1 Extending an Optimal Solution for a Single Subset

We present the first technique in the context of a classical scheduling problem, namely, the problem of finding the *minimum makespan* (MM) (or, overall completion time) of a schedule of n jobs on m identical machines. The main idea in the PTAS of Graham [10] is to first optimally schedule the k longest jobs and then schedule, using some heuristic, the remaining jobs. Formally, the input for the MM problem consists of n jobs and m identical machines. The goal is to schedule the jobs nonpreemptively on the machines in a way that minimizes the maximum completion time of any job in the schedule.

Denote by $p_1, \dots, p_n$ the processing times of the jobs. Assume that $n > m$, and that the processing times are sorted in nonincreasing order, that is, for all $i < j$, $p_i \geq p_j$. A well-known heuristic for the makespan problem is the *LPT rule*, which selects the longest unscheduled job in the sorted list and assigns it to a processor which currently has the minimum load. The PTAS combines an optimal schedule of the longest k jobs with the longest processing time (LPT) rule, applied to the remaining jobs.

Formally, for any $k \in [0, n]$, the algorithm A_k is defined as follows:

1. Schedule optimally, with no intended idles, the first k jobs.
2. Add the remaining jobs greedily using the LPT rule.

Theorem 9.1

Let $A_k(I)$ denote the makespan achieved by A_k on an instance I, and let $OPT(I)$ denote the minimum makespan of I, then

$$A_k(I) \leq OPT(I)\left(1 + \frac{1 - \frac{1}{m}}{1 + \lfloor k/m \rfloor}\right)$$

Proof

Let T denote the makespan of an optimal schedule of the first k jobs. Clearly, T is a lower bound for $OPT(I)$, thus, if the makespan is not increased in the second step, i.e., $A_k(I) = T$, then A_k is optimal for I. Otherwise, the makespan of the schedule is greater than T. Let j be the job to determine the makespan (the one which completes last). By the definition of LPT, this implies that all the machines were busy when job j started its execution (otherwise, job j could start earlier). Since the optimal schedule from step 1 has no intended idles, all the machines are busy during the time interval $(0; A_k(I) - p_j)$.

Let $P = \sum_{i=1}^{n} p_i$ be the total processing time of the n jobs. By the above, $P \geq m(A_k(I) - p_j) + p_j$. Also, since the jobs are sorted in nonincreasing order of processing times, we have that $p_j \leq p_{k+1}$, and therefore, $P \geq mA_k(I) - (m-1)p_{k+1}$. A lower bound for the optimal solution is the makespan of a schedule in which the load on the m machines is perfectly balanced; thus, $OPT(I) \geq P/m$, which implies that $A_k(I) \leq OPT(I) + (1 - \frac{1}{m})p_{k+1}$.

To bound $A_k(I)$ in terms of $OPT(I)$, we need to bound p_{k+1} in terms of $OPT(I)$. To obtain such a bound, consider the $k+1$ longest jobs. In an optimal schedule, some machine is assigned at least $\lceil (k+1)/m \rceil \geq 1 + \lfloor k/m \rfloor$ of these jobs. Since each of these jobs has processing time at least p_{k+1}, we conclude that $OPT(I) \geq (1 + \lfloor k/m \rfloor)p_{k+1}$, which implies that $p_{k+1} \leq OPT(I)/(1 + \lfloor k/m \rfloor)$. It follows that

$$A_k(I) \leq OPT(I)\left(1 + \frac{1 - \frac{1}{m}}{1 + \lfloor k/m \rfloor}\right) \qquad \square$$

To observe that the above family of algorithms is a PTAS, we relate the value of k to $(1+\varepsilon)$, the required approximation ratio. Given $\varepsilon > 0$, let $k = \lceil \frac{1-\varepsilon}{\varepsilon} m \rceil$. It is easy to verify that the corresponding algorithm A_k achieves approximation ratio at most $(1+\varepsilon)$. Thus, we conclude that for a fixed m, there is a PTAS for the MM problem.

Note that for any fixed k, an optimal schedule of the first k jobs can be found in $O(m^k)$ steps. Applying the LPT rule takes additional $O(n \log n)$ steps. For A_ε, we get that the running time of the scheme is $O(m^{m/\varepsilon})$, i.e., exponential in m (that is assumed to be constant) and $1/\varepsilon$. This demonstrates the basic property of approximation schemes: a clear trade-off between running time and the quality of approximation.

9.2.1.2 Extend All Possible Solutions for Small Subsets

The second technique, of considering all possible subsets, is illustrated in an early PTAS of Sahni for the *knapsack problem* [11]. An instance of the knapsack problem consists of n items, each having a specified size and a profit, and a single knapsack having size B. Denote by $s_i \geq 0$, $p_i \geq 0$ the size and profit associated with item i. The goal is to find a subset of the items such that the total size of the subset does not exceed the knapsack capacity, and the total profit associated with the items is maximized.

The PTAS in Ref. [11] is based on considering all $O(kn^k)$ possible subsets of size at most k, where k is some fixed constant. Each of these subsets is extended to a larger feasible subset by adding more items to the knapsack, using some greedy rule. The best extension among these $O(kn^k)$ candidates is selected to be the output of the scheme. Formally, for any $k \in [0, n]$, the algorithm A_k is defined as follows:

1. (Preprocessing) Sort the items in nonincreasing order of their profit densities, p_i/s_i.
2. For each feasible subset of at most k items.
   (a) Pack the subset in the knapsack.
   (b) Add to the knapsack items in the sorted list one by one, while there is enough available capacity.
3. Select among the packings generated in Step 2, one which maximizes the profit.

Theorem 9.2

Let $P(A_k)$ denote the profit achieved by A_k, and let $P(OPT)$ denote the optimal profit, then

$$P(OPT) \leq P(A_k)\left(1 + \frac{1}{k}\right)$$

Proof

Let OPT be any optimal solution. If $|OPT| \leq k$ we are done, since the subset OPT will be considered in some iteration of Step 2. Otherwise, let $H = \{a_1, a_2, \ldots, a_k\}$ be the set of k most profitable items in OPT. There exists an iteration of A_k in which H is considered. We show that the profit gained by A_k in this iteration yields the statement of the theorem. Consider the list $L_1 = OPT \backslash H = \{a_{k+1}, \ldots, a_x\}$ of the remaining items of OPT, in the order they appear in the sorted list. Recall that, at some point, A_k will try H as the initial set of k packed items. The algorithm will then add greedily items, as long as the capacity constraint allows. If all the items are packed, A_k is clearly optimal; otherwise, at some point there is not enough space for the next item. Let m be the index of the first item in L_1 which is not packed in the knapsack by A_k, i.e., the items $a_{k+1}, \ldots, a_{m-1}$ are packed. The item a_m is not packed because B_e, the remaining empty space at this point, is smaller than s_m. The greedy algorithm packed into the knapsack only items with profit density at least p_m/s_m. At the time that a_m is dropped, the knapsack contains the items from H, the items $a_{k+1}, \ldots, a_{m-1}$ and some items which are not in OPT.

Let G denote the items packed in the knapsack so far by the greedy stage of A_k. All of these items have profit density at least p_m/s_m. In particular, the items in $G \backslash OPT$ that have total size $\Delta = B - (B_e + \sum_{i=1}^{m-1} s_i)$ all have profit density at least p_m/s_m. Thus, the total profit of the items in G is $P(G) \geq \sum_{i=k+1}^{m-1} p_i + \Delta \frac{p_m}{s_m}$. We conclude that the total profit of the items in OPT is

$$\begin{aligned}
P(OPT) &= \sum_{i=1}^{k} p_i + \sum_{i=k+1}^{m-1} p_i + \sum_{i=m}^{|OPT|} p_i \\
&\leq P(H) + \left(P(G) - \Delta \frac{p_m}{s_m}\right) + \left(B - \sum_{i=1}^{m-1} s_i\right)\frac{p_m}{s_m} \\
&= P(H) + P(G) + B_e \frac{p_m}{s_m} < P(H \cup G) + p_m
\end{aligned}$$

Since A_k packs at least $H \cup G$, we get that $P(A_k) \geq P(H) + P(G)$, which implies that $P(OPT) - P(A_k) < p_m$. Given that there are at least k items with a profit at least as large as a_m (those selected to H), we conclude that $p_m \leq P(OPT)/(k+1)$. This gives the approximation ratio. □

Assuming a single preprocessing step, in which the items are sorted by their profit densities, each subset is extended to a maximal packing in time $O(n)$. Since there are $O(kn^k)$ possible subsets to consider, the total running time of the scheme is $O(kn^{k+1})$.

To obtain a PTAS for the knapsack problem, let A_ε be the algorithm A_k with $k = \lceil 1/\varepsilon \rceil$. By the above, the approximation ratio is at most $1 + \varepsilon$, and the running time of A_ε is $O(\frac{1}{\varepsilon} n^{1+\frac{1}{\varepsilon}})$.

The technique of choosing the best among a small number of partial packings was applied also to variants of multidimensional packing. A detailed example is given in Section 9.3.2.

9.2.2 Applying Enumeration to a Compacted Instance

In this section we present the technique of applying exhaustive enumeration to a modified instance, in which we have a more compact representation of the input. Approximation schemes that are based on this approach consist of three steps:

1. The instance I is modified to a simpler instance, I'. The parameter ε determines how rough I' is compared with I. The smaller ε, the more refined is I'.
2. The problem is solved optimally on I'.
3. An approximate solution for I is induced from the optimal solution for I'.

The challenge is to modify I in the first step into an instance I' that is simple enough to be solved in polynomial time, yet not too different from the original I, so that we can use an exact solution for I' to derive an approximate solution for I.

The use of this technique usually involves partitioning the input into *significant* and *nonsignificant* elements. The partition depends on the problem at hand. For example, it is natural to distinguish between *long* and *short* jobs in scheduling problems, and between *big* and *small*, or *high-profit* and *low-profit* elements, in packing problems. For a given instance, the distinction between the two types of elements usually depends on the input parameters (including ε), and on the optimal solution value.

In some cases, the transformation from I to I' involves only grouping the nonsignificant elements. Each group of such elements thus forms a single significant element in I'. As a result, the instance I' consists of a small number of significant elements. More details and an example for this type of transformation are given in Section 9.2.2.1.

In other cases, all the elements, or only the more significant ones, are transformed into a set of elements with a small number of distinct values. This approach is described and demonstrated in Section 9.2.2.2.

9.2.2.1 Grouping Subsets of Elements

We illustrate the technique with the PTAS of Sahni [12] for the MM problem on two identical machines. The input consists of n jobs with processing times $p_1, \ldots, p_n$. The goal is to schedule the jobs on two identical parallel machines in a way that minimizes the latest completion time. In other words, we seek a schedule which balances the load on the two machines as much as possible.

Let $P = \sum_{j=1}^{n} p_j$ denote the total processing time of all jobs, and let p_{max} denote the longest processing time of a job. Let $C = \max(P/2,\ p_{max})$. Note that C is a lower bound on the MM (i.e., $OPT \geq C$), since $P/2$ is the schedule length if the load is perfectly balanced between the two machines, and since some machine must process the longest job.

The first step of the scheme is to modify the instance I into a simplified instance I'. This modification depends on the value of C and on the parameter ε. Given I, ε, partition the jobs into small jobs—of length at most εC, and big jobs—of length greater than εC. Let P_S denote the total length of small jobs. The modified instance I' consists of the big jobs in I together with $\lfloor P_S/(\varepsilon C) \rfloor$ jobs of length εC.

Next, we need to solve optimally the MM problem for the instance I'. Note that all jobs in I' have length at least εC and their total size is at most P, the total processing time of the jobs in the original instance, since the small jobs in I are replaced in I' by jobs of length εC with total length at most P_S. Therefore, the number of jobs in I' is at most *the constant* $P/\varepsilon C \leq 2/\varepsilon$. An optimal schedule of a constant number of jobs can be found by exhaustive search over all $O(2^{2/\varepsilon})$ possible schedules. This constant number is independent of n, but grows exponentially with ε, as we expect from our PTAS.

Finally, we need to transform the optimal schedule of I' into a feasible schedule of I. Note that, for the makespan objective, we are only concerned about the partition of the jobs between the machines, while the order in which the jobs are scheduled on each machine can be arbitrary. Denote by $OPT(I')$ the length of the optimal schedule for I'. To obtain a schedule of I, each of the big jobs is scheduled on the same machine as in the optimal schedule for I'. The small jobs are scheduled greedily in an arbitrary order on the first machine until, for the first time, the total load on the first machine is at least $OPT(I')$. The remaining small jobs are scheduled on the second machine. Clearly, the overflow on the first machine is at most εC (maximal length of a small job). Also, since the total number of (εC)-jobs was defined to be $\lfloor P_S/(\varepsilon C)\rfloor$, the overflow on the second machine is also bounded by εC. Therefore, the resulting makespan in the schedule of I is at most $OPT(I') + \varepsilon C$.

To complete the analysis we need to relate $OPT(I')$ to $OPT(I)$.

Claim 9.1

$OPT(I') \leq (1+\varepsilon)OPT(I)$

Proof

Given a schedule of I, in particular an optimal one, a schedule for I' can be derived by replacing—on each machine separately—the small jobs with jobs of size εC, with at least the same total size. Recall that the number of (εC)-jobs in I' is $\lfloor P_S/(\varepsilon C)\rfloor$. Regardless of the partition of the small jobs in I between the two machines, the result of this replacement is a feasible schedule of I' whose makespan is at most $OPT(I) + \varepsilon C$. Since $OPT(I) \geq C$, the statement of the claim holds. □

Back to our scheme, we showed that the optimal schedule of I' is transformed into a feasible schedule of I whose makespan is at most $OPT(I') + \varepsilon C$. By Claim 9.1, this value is at most $(1+\varepsilon)OPT(I) + \varepsilon C \leq (1+2\varepsilon)OPT(I)$. By selecting $\varepsilon' = \varepsilon/2$, and running the scheme with ε', we get the desired ratio of $(1+\varepsilon)$.

The above scheme can be extended to any constant number of machines. For *arbitrary* number of machines, a more complex PTAS exists: the scheme of Ref. [1], which requires reducing the number of distinct values in the input, is given in the next section.

9.2.2.2 Reducing the Number of Distinct Values in the Input

Any optimization problem can be solved optimally in polynomial, or even constant, time if the input size is some constant. For many optimization problems, an efficient algorithm exists if the input size is arbitrary, but the number of *distinct values* in the input is some constant. Alternatively, the problem can be solved by a pseudopolynomial-time algorithm (e.g., by dynamic programming), whose running time depends on the instance parameters, and is therefore polynomial only if the parameter values are polynomial in the problem size.

The idea behind the technique that we describe below is to transform the elements (or sometimes, only the significant elements) in the instance I into an instance I' in which the number of distinct values is fixed, or to scale the values according to the input size. The problem is then solved on I', and the solution for I' is transformed into a solution for the original instance. The nonsignificant elements, which are sometimes omitted from I', are added later to the solution, using some heuristic. The parameter ε determines the (constant) number of distinct values contained in I': the smaller the ε, the larger the number of distinct values. The following are the two main approaches for determining the values in I'.

1. *Rounding*. The values in I' form an arithmetic series in which the difference between elements is a function of ε. For example, multiples of $\varepsilon^2 T$, for some value T. In this approach, the gap between any two values bounds the difference between the original value of an element in I and the value of the corresponding element in I'. Note that the number of elements whose values are rounded to a single value in I' can be arbitrary.

2. *Shifting.* The values in I' are a subset of the values in I, selected such that the distribution on the number of values in I that are shifted to a single value in I' is uniform. However, in contrast to the rounding approach, there is no bound on the difference between the value of an element in I and its value in I'. For example, partition the elements into $\lceil 1/\varepsilon^2 \rceil$ groups, each having at most $\lfloor n/\varepsilon^2 \rfloor$ elements, and fix the values in each group to be (say) the minimal value of any element in the group.

In both approaches, the approximation ratio is guaranteed to be $(1+\varepsilon)$ if I' is close enough to I. Formally, an optimal solution for I' induces a solution for I whose value is greater/smaller by a factor of at most $(1+\varepsilon)$. Another factor of $(1+\varepsilon)$ may be added to the approximation ratio due to the nonsignificant items—in case they are handled separately.

We demonstrate this technique with the classic PTAS of Hochbaum and Shmoys [1] for the MM problem on parallel machines. The input for the problem is a set of n jobs having processing times $p_1, \ldots, p_n$, and m identical machines; the goal is to schedule the jobs on the machines in a way that minimizes the latest completion time of any job. The number of machines, m, can be arbitrarily large (otherwise, a simpler PTAS exists; see Section 9.2.2.1).

First, note that the MM problem is closely related to the *bin packing* (BP) problem. The input for BP is a collection of items whose sizes are in (0, 1). The goal is to pack all items using a minimal number of bins. Formally, let $I = \{p_1, \ldots, p_n\}$ be the sizes in a set of n items, where $0 \le p_j \le 1$. The goal is to find a collection of subsets $U = \{B_1, B_2, \ldots, B_k\}$ which forms a disjoint partition of I, such that for all i, $1 \le i \le k$, $\sum_{j \in B_i} p_j \le 1$, and the number of bins, k, is minimized.

The exact solutions of MM and BP relate in the following way. It is possible to schedule all the jobs in an MM instance on m machines with makespan C_{max} if and only if it is possible to pack all the items in a BP instance, where the size of item j is p_j/C_{max}, in m bins. The relation between the optimal solutions does not remain valid for approximations. In particular, BP admits an asymptotic FPTAS (see Chapter 11), while MM does not. However, this relation can be used to develop a PTAS for MM.

Let $OPT_{BP}(I)$ be the number of bins in an optimal solution of BP, and let $OPT_{MM}(I) = C_{max}$ be an optimal solution for MM. Denote by $\frac{I}{d}$ the BP input in which all the values are divided by d. We already argued that

$$OPT_{BP}\left(\frac{I}{d}\right) \le m \;\Leftrightarrow\; OPT_{MM}(I, m) \le d$$

We define a *dual* approximation scheme for BP. For an input I, we seek a solution with at most OPT_{BP} bins, where each bin is filled to capacity at most $1+\varepsilon$. In other words, we relax the bin capacity constraint by a factor of $1+\varepsilon$. Let $dual_\varepsilon(I)$ be such an algorithm, and let $DUAL_\varepsilon(I)$ be the number of bins in the corresponding packing.

Theorem 9.3

If there exists a dual approximation algorithm for BP, then there is a PTAS for the MM problem.

Proof

The PTAS performs a binary search to find OPT_{MM}. To bound the range in which the optimal makespan is searched, two lower bounds and one upper bound for this value are used. The lower bounds are the length of the longest job and the load on each machine when the total load is perfectly balanced. That is, let $SIZE(I, m) = max\{\frac{1}{m}\sum p_i, p_{max}\}$, then $OPT_{MM} \ge SIZE(I, m)$. The upper bound uses the fact that the simple *list scheduling* algorithm attains a 2-ratio to $SIZE(I, m)$ [10], therefore $OPT_{MM} \le 2SIZE(I, m)$.

Now it is possible to perform a binary search to find OPT_{MM}. Instead of checking whether $OPT_{MM} < d$, the algorithm checks whether $DUAL_\varepsilon(\frac{I}{d}) < m$.

```
$upper = 2SIZE(I, m)$
$lower = SIZE(I, m)$
repeat until $lower = upper$
    $d = (lower + upper)/2$
    call $dual_\varepsilon(\frac{I}{d})$
    if $DUAL_\varepsilon(\frac{I}{d}) > m$
        $lower \leftarrow d$
    else
        $upper \leftarrow d$
$d^\star \leftarrow upper$
return $dual_\varepsilon(\frac{I}{d^\star})$
```

Initially, $OPT_{MM}(I, m) \leq upper \Rightarrow OPT_{BP}(\frac{I}{upper}) \leq m$. Since $dual_\varepsilon$ is a relaxation of BP, $DUAL_\varepsilon(\frac{I}{upper}) \leq OPT_{BP}(\frac{I}{upper})$. This implies that $DUAL_\varepsilon(\frac{I}{upper}) \leq m$. By the update rule, the above remains true during the execution of the loop. However,

$$DUAL_\varepsilon\left(\frac{I}{upper}\right) \leq m \Rightarrow OPT_{MM}(I, m) \leq (1+\varepsilon)upper$$

and thus $(1+\varepsilon)upper$ remains an upper bound on $OPT_{MM}(I, m)$ during the search. Similarly, before the loop $OPT_{MM}(I, m) \geq lower$, which remains true since $DUAL_\varepsilon(\frac{I}{lower}) \geq m$, is an invariant of the loop, and

$$OPT_{BP}\left(\frac{I}{lower}\right) \geq DUAL_\varepsilon\left(\frac{I}{lower}\right) \geq m \Rightarrow OPT_{MM}(I, m) \geq lower$$

Thus, the solution value is bounded above by

$$(1+\varepsilon)\cdot d^\star = (1+\varepsilon)\cdot upper = (1+\varepsilon)\cdot lower \leq (1+\varepsilon)OPT_{MM}(I, m)$$

In practice, assume that we stop the binary search after k iterations. At this time, it is guaranteed that $upper - lower \leq 2^{-k}SIZE(I, m) \leq 2^{-k}OPT_{MM}(I, m)$, and the value of the solution is bounded above by $(1+\varepsilon)\cdot d^\star = (1+\varepsilon)\cdot upper \leq (1+\varepsilon)\cdot(lower + 2^{-k}OPT_{MM}(I, m)) \leq (1+\varepsilon)(1+2^{-k})OPT_{MM}(I, m)$.

By choosing $k = O(\log\frac{1}{\epsilon})$, and taking in the scheme $\varepsilon' = \varepsilon/3$, we obtain a $(1+\varepsilon)$-approximation. □

We now describe the $dual_\varepsilon$ approximation scheme for BP. This scheme uses the rounding and grouping technique.

Theorem 9.4

There exists an $O\left(n^{\lceil\frac{1}{\varepsilon^2}\rceil}\right)$-time dual approximation scheme for BP.

Proof

Recall that, for a given $\varepsilon > 0$, the dual approximation scheme needs to find a packing of all items using at most OPT_{BP} bins, such that the total size of the items packed in each bin is at most $1+\varepsilon$. The basic idea is to omit first the "small" items and then round the sizes of the "big" items; this yields an instance in which the number of distinct item sizes is fixed. We can now solve the problem exactly using dynamic programming, and the solution induces a solution for the original instance, where each bin is filled up to capacity $1+\varepsilon$.

The first observation is that small items, whose sizes are less than ε, can be initially omitted. The problem will be solved for big items only and the small items will be added later on greedily, in the following manner: if there is a bin filled with items of total size less than 1, small items are added to it; otherwise, a new bin is opened. If no new bin is opened, then, clearly, no more than the optimum number of bins is used (as the dual PTAS uses the minimal number of bins for the big items). If new bins were added, then all original bins are filled to capacity at least 1, and all the new bins (except maybe the last one) are also filled to capacity at least 1. This is optimal since $OPT(I) \geq \lceil\sum p_i\rceil \geq DUAL_\varepsilon(I)$. We conclude that, without loss of generality, all items are of size $\varepsilon \le p_i \le 1$. Divide the range $[\varepsilon, 1]$ into intervals of size ε^2. This gives $S = \lceil \frac{1}{\varepsilon^2} \rceil$ intervals. Denote by l_i the endpoints of the intervals and let b_i be the number of elements whose sizes are in the interval $(l_i, l_{i+1}]$.

We now examine a packed bin. Since the minimal item size is ε, the bin can contain at most $\lfloor \frac{1}{\epsilon} \rfloor$ items. Denote by X_i the number of items in the bin whose sizes are in the interval $(l_i, l_{i+1}]$. X_i is in the range $[0, \lfloor \frac{1}{\epsilon} \rfloor)$. Let the vector $(X_1, \dots, X_S)$ denote the *configuration* of the bin. The number of feasible configurations is bounded above by $\lfloor \frac{1}{\epsilon} \rfloor^S$. A configuration is *feasible* if and only if $\sum_{i=1}^{S} X_i l_i \le 1$.

For any bin B whose packing forms a feasible configuration, the total size of the items in the bin is bounded by

$$\sum_{j \in B} p_j \le \sum_{j \in B} X_j l_{j+1} \le \sum_{j \in B} X_j (l_j + \varepsilon^2) \le 1 + \varepsilon^2 \sum_{j \in B} X_j \le 1 + \varepsilon^2 \cdot \frac{1}{\epsilon} \le 1 + \varepsilon$$

Therefore, it is sufficient to solve the instance with all item sizes rounded down to sizes in $\{l_1, \dots, l_S\}$.

Finally, we describe a dynamic programming algorithm which solves the BP problem exactly when the number of distinct item sizes is fixed. Let $BINS(b_1, b_2, \dots, b_S)$ be the minimal number of bins required to pack b_1 items of size l_1, b_2 items of size l_2, …, and b_S items of size l_S. Let $\mathcal{C}$ denote the set of all feasible configurations. Observe that, by a standard dynamic programming recursion,

$$BINS(b_1, b_2, \dots, b_S) = 1 + min_{\mathcal{C}} BINS(b_1 - X_1, b_2 - X_2, \dots, b_S - X_S)$$

We minimize over all possible vectors $(X_1, X_2, \dots, X_s)$ that correspond to a feasible packing of the "first" bin (counted by the constant 1), and the best way to pack the remaining items (this is the recursive call). Thus, the dynamic programming procedure builds a table of size n^S, where the calculation of each entry requires $O(\lfloor \frac{1}{\epsilon} \rfloor^S)$.

This yields a running time of

$$O\left(n^S \cdot \lfloor \frac{1}{\epsilon} \rfloor^S\right) = O\left(\left(\frac{n}{\varepsilon}\right)^{\lceil \frac{1}{\varepsilon^2} \rceil}\right) = O\left(n^{\lceil \frac{1}{\varepsilon^2} \rceil}\right)$$

□

The technique of applying enumeration to a compacted instance through grouping/rounding has been extensively used in PTASs for scheduling problems (see, e.g., Refs. [13–15]). A common approach for compacting the instance is to reduce the input parameters to *poly bounded*, i.e., parameters whose values can be bounded as function of the input size. This approach is used, e.g., in the PTAS of Chekuri and Khanna for preemptive weighted flow time [4] (See the survey paper [9]).

9.2.3 More on Grouping and Shifting

In the following we outline two extensions of the techniques described in this section.

Randomized Grouping

In some cases, we need to define a partition of the input elements to groups $(I_1, \dots, I_k)$, using for each element x a parameter of the problem, $q(x)$, such that the elements in two groups I_j and I_{j+1} differ in their $q(x)$ value by roughly a factor of α, for some $\alpha > 1$. When such partition is infeasible, we can use randomization to achieve an *expected* separation between groups. For a parameter $\alpha > 1$, the following randomized geometric grouping technique yields an expected separation that is logarithmic in α. This technique extends the deterministic geometric rounding technique described in Section 9.2.2.2. Initially, pick a number $r \in [1, \alpha]$ at random, by a probability distribution having the density function $f(y) = 1/y \ln \alpha$. An element x with the value $q(x)$ belongs to the group I_j if $q(x) \in [r\alpha^j, r\alpha^{j+1}]$. Thus, the index of the group to which x belongs, denoted by $g(x)$, is a random variable which can take two possible values: $\lfloor \log_\alpha q(x) \rfloor$ or $\lfloor \log_\alpha q(x) \rfloor + 1$. It can be shown that for a fixed α, the number of distinct partitions induced by the random choices of r is at most the number of elements in the input. This enables to easily derandomize algorithms that use randomized geometric grouping. The technique was applied, e.g., by Chekuri and Khanna [4] in a PTAS for preemptive weighted flow time.

Oblivious Shifting

While applying the standard shifting technique (as described in Section 9.2.2.2) requires knowing the initial input parameters, it is possible to apply shifting also when not all values are known a-priori. In *oblivious shifting*, the input size is initially known, and the scheme starts by defining the number of values in the resulting instance, but the actual shifted values are revealed at a later stage, by optimizing on these values, considering the constraints of the problem. The technique can be used for defining a "good" compacted instance from a partial solution for the problem, which can then enable to obtain a complete solution for the problem efficiently.

For example, a variant of the BP problem, in which items may be *fragmented*, is solved in Ref. [16] in two steps. Given the input, we need to determine the set of items that will be fragmented, as well as the fragment sizes in a feasible approximate solution. Since the possible number of fragment sizes is large, a compact vector of fragments is generated, which contains a bounded number of *unknown* shifted fragment sizes. The actual sizes of the shifted fragments are determined by solving a linear program (LP) which attempts to find a feasible packing of these fragments. A detailed description is given in Ref. [16].

9.3 Rounding Linear Programs

In this section we discuss approximations obtained using linear programming relaxation of the integer program formulation of a given optimization problem. We refer the reader to Chapters 6 and 7 of this handbook for further background on linear programming and rounding linear programs. Most generally, the technique is based on solving a linear programming relaxation of the problem, for which an exact or approximate solution can be obtained efficiently. This solution is then rounded, thus yielding an approximate integral solution. The (fractional) solution obtained for the LP needs to have some nice properties that would allow rounding to be not too harmful, in terms of ε, the accuracy parameter of the scheme. One such property of an LP, which is commonly used, is the existence of a small *basic solution*. We illustrate below the usage of this property, with examples from *vector scheduling (VS)* and covering integer programs. An LP has a *small* basic solution, if there exists an optimal solution in which the number of nonzero variables is small as a function of the input size and ε. For such a solution, the error incurred by rounding can be bounded, such that the resulting integral solution is within factor of $1 + \varepsilon$ from the optimal. A natural example is the class of LPs in which either the number of variables or the number of constraints is some fixed constant. For such programs, there exists a basic solution in which the number of nonzero variables is fixed; however, depending on the problem, and in particular, on the value of an optimal solution for the LP, a basic solution can be "small," even if the number of nonzero variables is relatively large, for example, $\Omega(\varepsilon n)$, where n is the number of variables.

LP rounding can be combined with the techniques described in Section 9.2. In Section 9.3.1 we show the usage of LP rounding for a given subset of input elements satisfying certain properties. In Section 9.3.2 we show how LP rounding can be combined with the selection of *all* possible (small) subsets.

9.3.1 Solving LP for a Subset of Elements

As mentioned earlier, in many problems, an approximation scheme can be obtained by partitioning a set of input elements to subsets, and solving the problem for each subset separately. For some subsets, a good solution can be obtained by rounding an LP relaxation of the problem.

In certain assignment problems, we can find an almost integral basic solution for an LP, for part of the input, since the relation between the number of variables and nontrivial constraints in the linear programming relaxation, combined with the assignment requirement of the problem, imply that only few variables can get fractional values. This essential property is used, e.g., in the PTAS of Chekuri and Khanna for the *VS* problem [17]. The VS problem is to schedule d-dimensional jobs on m identical machines, such that the maximum load over all dimensions and over all machines is minimized. Formally, an instance I of VS consists of n jobs, $J_1, \ldots, J_n$, where J_j is associated with a rational d-dimensional vector $(p_j^1, \ldots, p_j^d)$, and m machines. We need to assign the jobs to the machines, i.e., schedule a subset of the jobs, A_i, on machine i, $1 \le i \le m$, such that $\max_{1 \le i \le m} \max_{1 \le h \le d} \sum_{J_j \in A_i} p_j^h$ is minimized.

Note that in the special case where $d = 1$, we get the minimum makespan problem (see Section 9.2.2.2). The PTAS in Ref. [17] for the VS problem, where d is fixed, applies a nontrivial generalization of the PTAS of Hochbaum and Shmoys for the case $d = 1$ [1]. The scheme is based on a primal-dual approach, in which the primal problem is VS and the dual problem is vector packing. Thus, the machines are viewed as d-dimensional bins, and the schedule length as bin capacity (or height). W.l.o.g., we may assume that the optimal schedule has the value 1. Given an $\varepsilon > 0$ and a correct guess of the optimal value, we describe below an algorithm A_ε that returns a schedule of height at most $1+\varepsilon$. Arriving at the correct guess involves a binary search for the optimal value (which can be done in polynomial time; see below).

Let $\delta = \varepsilon/d$ be a parameter. The scheme starts with a preprocessing step, which enables to bound the ratio of the largest coordinate to the smallest nonzero coordinate in any input vector. Specifically, let $\| J_j \|_\infty = \max_{1 \le h \le d} p_j^h$ be the ℓ_∞ norm of J_j, $1 \le j \le n$, then, for any J_j, and any $1 \le h \le d$, if $p_j^h \le \delta \cdot \| J_j \|_\infty$, we set $p_j^h = 0$. As shown in Ref. [17], any valid schedule for the resulting modified instance, I', yields a valid solution for the original instance, I, whose height is at most $(1+\varepsilon)$ times that of I'.

We consider from now on only transformed instances. The scheme proceeds by partitioning the jobs to the sets L (*large*) and S (*small*). The set L consists of all vectors whose ℓ_∞ norm is greater than δ, and S contains the remaining vectors. The algorithm A_ε packs first the large jobs and then the small jobs. Note that while in the case of $d = 1$ these packings are done independently, for $d \ge 2$, we need to consider the interaction between these two sets. Similar to the scheme of Hochbaum and Shmoys [1], a valid schedule is found for the jobs by guessing a configuration. In particular, let the d-tuple $(a_1, \ldots, a_d)$ $0 \le a_h \le \lceil 1/\varepsilon \rceil$, $1 \le h \le d$, denote a *capacity configuration*, that is, the way some bin is filled. Since $d \ge 2$ is a constant, the possible number of capacity configurations, given by $W = (1 + \lceil 1/\varepsilon \rceil)^d$, is also a constant. Then, by numbering the capacity configurations, we describe by a W-tuple $M = (m_1, \ldots, m_W)$ the number of bins having capacity configuration w, where $1 \le w \le W$. The possible number of *bin configurations* is then $O(m^W)$. This allows to guess a bin configuration which yields the desired $(1 + \varepsilon)$-approximate solution in polynomial time.

We say that a packing of vectors in a bin *respects* a capacity configuration $(a_1, \ldots, a_d)$ if the height of the packing is smaller than εa_h for any $1 \le h \le d$. Given a capacity configuration $(a_1, \ldots, a_d)$, we define the *empty capacity configuration* to be the d-tuple $(\bar{a}_1, \ldots, \bar{a}_d)$, where $\bar{a}_h = \lceil 1/\varepsilon \rceil + 1 - a_h$, for $1 \le h \le d$. For a given bin configuration, M, we denote by $\bar{M}$ the bin configuration obtained by taking for each of the bins in M the corresponding empty capacity configuration.

The scheme performs the following two steps for each possible bin configuration, M: (i) decides whether vectors in L can be packed respecting M, and (ii) decides whether vectors in S can be packed respecting $\bar{M}$. Given that we have guessed the correct bin configuration M, both steps will succeed, and we get a packing of height at most $1 + \varepsilon$.

We now describe how the scheme packs the large and the small vectors. The vectors in L are packed using rounding and dynamic programming. In particular, since by definition, any entry in a vector in L has the value δ^2 or greater, we use geometric rounding, that is, for each vector J_j, and any entry p_j^h, $1 \le h \le d$, p_j^h is rounded down to the nearest value of the form $\delta^2(1 + \varepsilon)^t$, for $0 \le t \le \lceil \frac{2}{\varepsilon} \log 1/\delta \rceil$. Denote the resulting set of vectors L', and the modified instance I'. The vectors in L' can be partitioned into

$$q = \left(1 + \lceil \frac{2}{\varepsilon} \log 1/\delta \rceil\right)^d \tag{9.1}$$

classes. The proofs of the next lemmas are given in Ref. [17].

Lemma 9.1

Given a solution for I', replacing each vector in L' by the corresponding vector in L results in a valid solution for I whose height is at most $1 + \varepsilon$ times that of I'.

Lemma 9.2

Given a correct guess of a bin configuration M, there exists an algorithm which finds a packing of the vectors in L' that respects M, and whose running time is $O((d/\delta)^q mn^q)$, where q is given in Eq. (9.1).

The small vectors are packed using a linear programming relaxation and careful rounding. Renumber the vectors in S by $1, \ldots, |S|$. Let $x_{ji} \in \{0, 1\}$ be an indicator variable for the assignment of the vector J_j to machine i, $1 \leq j \leq n$, $1 \leq i \leq m$. In the LP relaxation $x_{ji} \geq 0$. We solve the following LP.

$$(LP) \qquad \sum_{J_j \in S} p_j^h x_{ji} \leq b_i^h, \qquad 1 \leq i \leq m, \quad 1 \leq h \leq d \tag{9.2}$$

$$\textstyle\sum_{i=1}^m x_{ji} = 1, \qquad 1 \leq j \leq |S| \tag{9.3}$$

$$x_{ji} \geq 0, \qquad 1 \leq j \leq n, \quad 1 \leq i \leq m \tag{9.4}$$

The constraints (9.2) guarantee that the packing does not exceed a given height bound in any dimension (i.e., the available height after packing the large vectors). The constraints (9.3) reflect the requirement that each vector is assigned to one machine. A key property of the LP, which enables to obtain an integral solution that is close to the fractional, is given in the next result.

Lemma 9.3

In any basic feasible solution for LP, at most $d \cdot m$ vectors are assigned (fractionally) to more than one machine.

Proof

Recall that the number of nonzero variables, in any *basic* solution for an LP, is bounded by the number of tight constraints in some optimal solution (since nontight constraints can be omitted). Since the number of nontrivial constraints (i.e., constraints other than $x_{ji} \geq 0$) is $(|S| + d \cdot m)$, it follows that the number of strictly positive variables in any basic solution is at most $(|S| + d \cdot m)$. Since each vector is assigned to at least one machine, the number of vectors which are fractionally assigned to more than one machine is at most $d \cdot m$. □

The above type of argument was first made and exploited by Potts [18] in the context of parallel machine scheduling. It was later applied to other problems, such as job shop scheduling (see, e.g., Ref. [19]).

Thus, we solve the above program and obtain a basic solution. Denote by S' the set of vectors which are assigned fractionally to two machines or more. Since $|S'| \leq d \cdot m$, we can partition the set S' to subsets of size at most d each, and schedule the ith set to the ith machine. Since $\| J_j \|_\infty \leq \delta = \varepsilon/d$, for all $J_j \in S'$, the total height of the machines is violated at most by ε in any dimension. We can therefore summarize in the following theorem.

Theorem 9.5

For any $\varepsilon > 0$, there is a $(1 + \varepsilon)$-approximation algorithm for VS whose running time is $(nd/\varepsilon)^{O(f)}$, where $f = O((\frac{\ln(d/\varepsilon)}{\varepsilon})^d)$.

Proof

By the above discussion, given the correct guess of the optimal value, the scheme yields a schedule of value (height) at most $1 + O(\varepsilon)$ the optimal. We need to find a packing of the vectors in L and S, for each bin configuration M. The running time for a single configuration is dominated by the packing of L, and since the number of configurations is $m^W = O(n^{O(1/\varepsilon^d)})$, we get the running time from Lemma 9.2. The value of an optimal schedule can be guessed, within factor $1 + \varepsilon$, by obtaining first a $(d + 1)$-approximate solution. This can be done by applying an approximation algorithm for resource constrained scheduling due to Ref. [20]. □

9.3.2 LP Rounding Combined with Enumeration

As described in Section 9.2.1, a common technique for obtaining a PTAS is to extend all possible solutions for small subsets of elements. This technique can be combined with LP rounding as follows. Repeatedly select a small subset of input elements, $S_g \subseteq I$, to be the basis for an approximate solution; solve an LP for the remaining elements, $I \setminus S_g$. Select the subset S_g which gives the best solution. We exemplify the usage of the technique to obtain a PTAS for *covering integer programs with multiplicity constraints (CIP)*. In this core problem, we must fill up an R-dimensional bin by selecting (with bounded number of repetitions) from a set of n R-dimensional items, such that the overall cost is minimized. Formally, let $A = \{a_{ji}\}$ denote the sizes of the items in the R dimensions, $1 \le j \le R$, $1 \le i \le n$; the cost of item i is $c_i \ge 0$. Let x_i denote the number of copies selected from item i, $1 \le i \le n$. We seek an n-vector $\mathbf{x}$ of nonnegative integers, which minimizes $c^T\mathbf{x}$, subject to the R constraints given by $A\mathbf{x} \ge b$, where $b_j \ge 0$ is the size of the bin in dimension j. In addition, we have multiplicity constraints for the vector $\mathbf{x}$, given by $\mathbf{x} \le d$, where $d \in \{1, 2, \ldots\}^n$.

Covering integer programs form a large subclass of integer programs encompassing such NP-hard problems as minimum knapsack and set cover. This implies the hardness of CIP in fixed dimension (i.e., where R is a fixed constant). For general instances, the hardness of approximation results for set cover carry over to CIP. Comprehensive surveys of known results for CIP and CIP_∞, where the multiplicity constraints are omitted, are given in Refs. [21,22] (see also in Ref. [23]).

We describe below a PTAS for CIP in fixed dimension. The scheme presented in Ref. [21] builds on the classic LP-based scheme due to Frieze and Clarke for the R-dimensional knapsack problem [24]. Consider an instance of CIP in fixed dimension, R. We want to minimize $\sum_{i=1}^{n} c_i x_i$ subject to the constraints $\sum_{i=1}^{n} a_{ij} x_i \ge b_j$ for $j = 1, \ldots, R$, and $x_i \in \{0, 1, \ldots d_i\}$ for $i = 1, \ldots, n$.

Assume that we know the optimal cost, C, for the CIP instance. The scheme of Ref. [21] uses a reduction to the binary *minimum R-dimensional multiple choice knapsack (R-MMCK)* problem. For some $R \ge 1$, an instance of binary R-MMCK consists of a single R-dimensional knapsack, of size b_j in the jth dimension, and m sets of items. Each item has an R-dimensional size and is associated with a cost. The goal is to pack a subset of items, by selecting at most one item from each set, such that the total size of the packed items in dimension j is at least b_j, $1 \le j \le R$, and the overall cost is minimized.

Given the value of C, the parameter ε, and a CIP instance with bounded multiplicity, the scheme constructs an R-MMCK instance in which the knapsack capacities in the R dimensions are b_j, $1 \le j \le R$. Also, there are n sets of items denoted by A^i, $1 \le i \le n$. Let $\hat{K}^i$ be the integer value satisfying $d_i c_i \in [\hat{K}^i \varepsilon C/n, (\hat{K}^i + 1)\varepsilon C/n)$, then the number of items in A^i is $K^i = \min(\hat{K}^i, \lfloor n/\varepsilon \rfloor)$. The set A^i represents all possible values which x_i can take in the solution for CIP. In particular, the kth item in A^i, denoted (i, k), represents the assignment of a value in $[0, d_i]$ to x_i, such that $c(i, k)$, the total cost incurred by item i is in $[k\varepsilon C/n, (k + 1)\varepsilon C/n)$. This total cost is rounded down to the nearest integral multiple of $\varepsilon C/n$; thus, $c(i, k) = k\varepsilon C/n$. The size of the item (i, k) in dimension j, $1 \le j \le R$, is given by $s_j(i, k) = a_{ij}$.

Given an instance of R-MMCK, guess a partial solution, given by a small size set, S; these items have the maximal costs in some optimal solution. The size of S is a fixed constant, namely, $|S| = h = \lfloor \frac{2R(1+\varepsilon)}{\varepsilon} \rfloor$. The set S will be extended to an *approximate* solution, by solving an LP for the remaining items. The value of h is chosen such that the resulting solution is guaranteed to be within $1 + \varepsilon$ from the optimal, as computed below. Let $E(S)$ be the subset of items with costs that are larger than the minimal cost of any item in S, that is, $E(S) = \{(i, k) \notin S \mid c(i, k) > c_{min}(S)\}$, where $c_{min}(S) = \min_{(i,k)\in S} c(i, k)$. Select all the items $(i, k) \in S$, and eliminate from the instance all the items $(i, k) \in E(S)$ and the sets A^i from which an item has been selected. In the next step we find an optimal *basic solution* for the following LP, in which $x_{i,k}$ is an indicator variable for the selection of the item (i, k).

$$
\begin{aligned}
(LP(S)) \quad & \text{minimize} && \sum_{i=1}^{n}\sum_{k=1}^{K^i} x_{i,k} \cdot c(i, k) \\
& \text{subject to} && \sum_{k=1}^{K^i} x_{i,k} \le 1, \quad \text{for } i = 1, \ldots, n, \\
& && \sum_{i=1}^{n}\sum_{k=1}^{K^i} s_j(i, k) x_{i,k} \ge b_j \quad \text{for } j = 1, \ldots, R \\
& && 0 \le x_{i,k} \le 1 \quad \text{for } (i, k) \notin S \cup E(S) \\
& && x_{i,k} = 1 \quad \text{for } (i, k) \in S \\
& && x_{i,k} = 0 \quad \text{for } (i, k) \in E(S)
\end{aligned}
$$

Given an optimal fractional solution for the above program, we get an integral solution as follows. For any i, $1 \leq i \leq n$, let $k_{max} = k_{max}(i)$ be the maximal value of $1 \leq k \leq K^i$ such that $x_{i,k} > 0$, then we set $x_{i,k_{max}} = 1$ and, for any other item in A^i, $x_{i,k} = 0$. Finally, we return to the CIP instance and assign to x_i the maximum value for which the total (rounded down) cost for item i is $c(i, k_{max})$.

The next three lemmas show that the scheme yields a $(1 + \varepsilon)$-approximation to the optimal cost, and that the resulting integral solution is feasible.

Lemma 9.4

If there exists an optimal (integral) solution for CIP with cost C, then the integral solution obtained from the rounding for R-MMCK has the cost $\hat{z} \leq (1 + \varepsilon)C$.

Proof

Let $\mathbf{x}^*$ be an optimal (fractional) solution for the linear program LP(S), and let S^* be the corresponding subset of items, that is, $S^* = \{(i, k)|\ x^*_{i,k} = 1\}$. If $|S^*| < h$ then we are done: in some iteration, the scheme will try S^*; otherwise, let $S^* = \{(i_1, k_1), \ldots, (i_g, k_g)\}$, such that $c(i_1, k_1) \geq \cdots \geq c(i_g, k_g)$, for some $g > h$. Let $S^*_h = \{(i_1, k_1), \ldots, (i_h, k_h)\}$, and $\sigma = \sum_{t=1}^{h} c(i_t, k_t)$. Then, for any item $(i, k) \notin (S^*_h \cup E(S^*_h))$, we have $c(i, k) \leq \sigma/h$. Let z^*, $\hat{z}$ denote the optimal (integral) solution and the solution output by the scheme for the R-MMCK instance, respectively. Denote by $\mathbf{x}^B(S^*_h)$, $\mathbf{x}^I(S^*_h)$ the basic and integral solutions of LP(S) as computed by the scheme, for the initial guess S^*_h.

By the above rounding method, for any $1 \leq i \leq n$, the cost of the item selected from A^i is $c(i, k_{max})$. Let F denote the set of items for which the basic variable was a fraction, that is, $F = \{(i, k)|\ x^B_{i,k}(S^*_h) < 1\}$, and let $\delta = \sum_{(i,k)\in F} c(i, k)$.

Then, we get that

$$z^* \geq \sum_{i=1}^{n} \sum_{k=1}^{K^i} c(i, k) x^B_{i,k}(S^*_h)$$

$$\geq \sum_{i=1}^{n} \sum_{k=1}^{K^i} c(i, k) x^I_{i,k}(S^*_h) - \delta$$

Recall that in any *basic* solution for an LP, the number of nonzero variables is bounded by the number of tight constraints in some optimal solution. Assume that in the optimal (fractional) solution of $LP(S^*_h)$ there are L tight constraints, where $0 \leq L \leq n + R$. Then in the basic solution $\mathbf{x}^B(S^*_h)$, at most L variables can be strictly positive. Thus, at least $L - 2R$ variables get an integral value (i.e., "1"), and $|F| \leq 2R$. Note that for any $(i, k) \in F$, $c(i, k) \leq \sigma/h$, since $F \cap (S^*_h \cup E(S^*_h)) = \emptyset$. Hence, we get that $z^* \geq \hat{z} + \frac{2R\sigma}{h} \geq \hat{z} + \frac{2R\hat{z}}{h} \geq \frac{\hat{z}}{1+\varepsilon}$. □

The next two lemmas follow from the rounding method used by the scheme.

Lemma 9.5

The scheme yields a feasible solution for the CIP instance.

Lemma 9.6

The cost of the integral solution for the CIP instance is at most $\hat{z} + \varepsilon C$.

Note that C can be guessed in polynomial time within factor $(1 + \varepsilon)$, using binary search over the range $(0, \sum_{i=1}^{n} d_i c_i)$. Thus, combining the above lemmas we get:

Theorem 9.6

There is a PTAS for CIP in fixed dimension.

Consider now the special case where the multiplicity constraints are omitted; that is, each variable x_i can get any nonnegative (integral) value. For this special case, we can use a linear programming formulation in which the number of constraints is R, which is fixed. A PTAS for this problem can be derived from the scheme of Chandra et al. [25] for integer multidimensional knapsack. Drawing from recent results for CIPs, we describe below the PTAS in Ref. [21], which improves the running time in Ref. [25] by using a fast approximation scheme for solving the LP.

A Scheme for CIP$_\infty$

The scheme, called below *multidimensional cover with parameter* ε (MDC_ε), proceeds in the following steps:

(i) For a given $\varepsilon \in (0, 1)$, let $\delta = \lceil R \cdot ((1/\varepsilon) - 1)\rceil$.

(ii) Renumber the items by $1, \ldots, n$, such that $c_1 \geq c_2 \geq \cdots \geq c_n$.

(iii) Denote by Ω the set of integer vectors $\mathbf{x} = (x_1, \ldots, x_n)$ satisfying $x_i \geq 0$, and $\sum_{i=1}^n x_i \leq \delta$. For any vector $\mathbf{x} \in \Omega$: Let $d \geq 1$ be the maximal integer i for which $x_i \neq 0$. Find a $(1 + \varepsilon)$-approximation to the optimal (fractional) solution of the following LP.

$$
\begin{aligned}
(LP') \quad & \text{minimize} && \sum_{i=d+1}^{n} c_i z_i \\
& \text{subject to} && \sum_{i=d+1}^{n} a_{ij} z_i \geq b_j - \sum_{i=1}^{n} a_{ij} x_i \ \text{ for } j = 1, \ldots, R \qquad (9.5)\\
& && z_i \geq 0 \ \text{ for } i = d+1, \ldots, n
\end{aligned}
$$

The constraints (9.5) reflect the fact that we need to fill in each dimension j at least the capacity $b_j - \sum_{i=1}^n a_{ij} x_i$, once we obtained the vector $\mathbf{x}$.

Let $\hat{z}_i$, $d + 1 \leq i \leq n$, be a $(1 + \varepsilon)$-approximate solution for LP'. We take $\lceil \hat{z}_i \rceil$ as the integral solution. Denote by $C_{MDC}(\mathbf{x}) = \sum_{i=d+1}^n c_i \lceil \hat{z}_i \rceil$, the value obtained from the rounded solution, and let $c(\mathbf{x}) = \sum_{i=1}^n c_i x_i$.

(iv) Select the vector $\mathbf{x}^*$ for which $C_{MDC_\varepsilon}(\mathbf{x}^*) = \min_{\mathbf{x}}(c(\mathbf{x}) + C_{MDC}(\mathbf{x}))$.

We now show that MDC_ε is a PTAS for CIP_∞. Let C_o be the cost of an optimal integral solution for the CIP_∞ instance.

Theorem 9.7

MDC_ε is a PTAS for CIP_∞ which satisfies the following. (i) If $C_o \neq 0, \infty$ then $C_{MDC_\varepsilon}/C_o < 1 + \varepsilon$. (ii) The running time of algorithm MDC_ε is $O(n^{\lceil R/\varepsilon \rceil} \cdot \frac{1}{\varepsilon^2} \log C)$, where $C = \max_{1 \leq i \leq n} c_i$ is the maximal cost of any item, and its space complexity is $O(n)$.

To prove the theorem, we need the next lemma.

Lemma 9.7

For any $\varepsilon > 0$, a $(1+\varepsilon)$-approximation to the optimal solution for LP' can be found in $O(1/\varepsilon^2 R \log(C \cdot R))$ steps.

Proof

For a system of inequalities as given in LP', there is a solution in which at most R variables get nonzero values. This follows from the fact that the number of nontrivial constraints is R. Hence, it suffices to solve LP' for the $\binom{n-d}{R}$ possible subsets of R variables, out of $(z_{d+1}, \ldots, z_n)$. This can be done in polynomial time since R is fixed. Now, for each subset of R variables, we have an instance of the *fractional covering problem*, for which we can use a fast approximation scheme (see, e.g., in Ref. [26]) to obtain a $(1 + \varepsilon)$-approximate solution. □

Proof of Theorem 9.7

For showing (i), assume that the optimal (integral) solution for the CIP_∞ instance is obtained by the vector $\mathbf{y} = (y_1, \ldots, y_n)$. If $\sum_{i=1}^n y_i \leq \delta$ then $C_{MDC_\varepsilon} = C_o$, since in this case $\mathbf{y}$ is a valid solution, and $\mathbf{y} \in \Omega$, therefore, in some iteration MDC_ε will examine $\mathbf{y}$. Suppose that $\sum_{i=1}^n y_i > \delta$, then we define the vector $\mathbf{x} = (y_1, \dots, y_{d-1}, x_d, 0, \dots, 0)$, such that $y_1 + \cdots + y_{d-1} + x_d = \delta$. (Note that $x_d \neq 0$.) Let $\tilde{C}_o(\mathbf{x}) = \sum_{i=d+1}^{n} c_i \hat{z}_i$ be the approximate fractional solution for LP'. We have that $\mathbf{x} \in \Omega$, therefore,

$$C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x}) \leq Rc_d \tag{9.6}$$

Let $C_o(\mathbf{x})$ be the optimal fractional solution for LP' with the vector $\mathbf{x}$. Note that C_o, the optimal (integral) solution for CIP_∞, satisfies

$$C_o > c(\mathbf{x}) + C_o(\mathbf{x}) \tag{9.7}$$

since $C_o(\mathbf{x})$ is a lower bound for the cost incurred by the integral values $y_{d+1}, \dots, y_n$. In addition,

$$c(\mathbf{x}) + C_{MDC}(\mathbf{x}) \geq C_{MDC_\varepsilon} \tag{9.8}$$

Hence, we get that

$$\begin{aligned}
\frac{C_o}{C_{MDC_\varepsilon}} &\geq \frac{c(\mathbf{x}) + C_o(\mathbf{x})}{c(\mathbf{x}) + C_{MDC}(\mathbf{x})} > 1 - \frac{C_{MDC}(\mathbf{x}) - C_o(\mathbf{x})}{c(\mathbf{x}) + C_{MDC}(\mathbf{x}) - C_o(\mathbf{x})} \\
&\geq 1 - \frac{C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})(1-\varepsilon)}{c(\mathbf{x}) + C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})} \\
&\geq (1-\varepsilon)\left(1 - \frac{C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})}{c(\mathbf{x}) + C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})}\right) \\
&\geq (1-\varepsilon)\left(1 - \frac{C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})}{\delta c_d + C_{MDC}(\mathbf{x}) - \tilde{C}_o(\mathbf{x})}\right)
\end{aligned}$$

The first inequality follows from Eq. (9.7) and Eq. (9.8), and the third inequality follows from the fact that $\tilde{C}_o(\mathbf{x})(1-\varepsilon) \leq C_o(\mathbf{x}) \leq \tilde{C}_o(\mathbf{x})$. The last inequality follows from the fact that $c(\mathbf{x}) \geq \delta c_d$.

Using Eq. (9.6), we get that $\frac{C_o}{C_{MDC_\varepsilon}} \geq (1-\varepsilon)1 - Rc_d/(\delta c_d + Rc_d) \geq (1-\varepsilon)^2$. Taking in the scheme $\tilde{\varepsilon} = \varepsilon/2$, we get the statement in (i).

Next, we show (ii). Note that $|\Omega| = O(n^\delta)$ since the number of possible choices of n nonnegative integers, whose sum is at most δ is bounded by $\binom{n+\delta}{\delta}$. Now, given a vector $\mathbf{x} \in \Omega$, we can compute $C_{MDC}(\mathbf{x})$ in $O(n^R)$ steps since at most R variables out of $z_{d+1}, \dots, z_n$ can have nonzero values. Multiplying by the complexity of the FPTAS for fractional covering, as given in Lemma 9.7, we get the statement of the theorem. □

Enumeration is combined with LP rounding also in the PTAS of Caprara et al. [27] for the *knapsack problem with cardinalities constraints*, and in a PTAS for the *multiple knapsack* problem due to Chekuri and Khanna [28], among others. The scheme in Ref. [27] is based on the scheme of Frieze and Clarke [24], with the running time improved by factor of n, the number of items. The scheme in Ref. [24] is also the basis for PTASs for other variants of the knapsack problem. (A comprehensive survey is given in Ref. [29]; see also Ref. [30].)

9.4 Approximation Schemes for Geometric Problems

In this section we present approximation techniques that are specialized for geometric optimization problems. For a complete description of these techniques we refer the reader to the survey by Arora [31], Chapter 11 in Ref. [32], and Chapter 8 and Section 9.3.3 in Ref. [33]. A typical input for a geometric problem is a set of elements in the space (such as points in the plane); the goal is to connect or pack these elements in a way that minimizes the resources used (e.g., total length of connecting lines, total number of covering objects).

9.4.1 Randomized Dissection

We present below the techniques used in the PTAS of Arora [34] for the Euclidean Traveling Salesman Problem (TSP). In the classical TSP, given are nonnegative edge weights for the complete graph K_n, and the goal is to find a tour of minimum cost, where a tour refers to a cycle of length n. In other words, the goal is to find an ordering of the nodes such that the total cost of the edges along the path visiting all nodes according to this ordering is minimal. In general, TSP is NP-hard in the strong sense, and it cannot be approximated within any multiplicative factor $c > 1$, unless P = NP. The PTAS of Arora considers the relaxed problem of *Euclidean* TSP. The input is a set of n points in $\Re^d$, and the edge weights are the Euclidean (ℓ_2) distances between them.

The idea of the PTAS is to dissect the plane into squares, and to look (using dynamic programming) for a tour that crosses the resulting grid lines only at specific points, denoted *portals*. The parameter ε of the PTAS determines the depth of the recursive dissection as well as the density of the portals. A smaller ε results in more portals and a finer dissection, which lead to a less restricted tour and a larger dynamic programming instance. Randomization is used to determine an initial shift of the grid lines.

A dissection of a square is a recursive partitioning into squares. It can be viewed as a tree of squares whose root is the square we started with. Each square in the tree is partitioned into four equal squares, which are its children. The leaves are squares of a small sidelength—determined by the parameter ε of the PTAS.

The location of the grid lines is determined *randomly* as follows. Given a set of n points in $\Re^2$, enclose the points in a minimum bounding square. Let ℓ be the side of this square. Let $p \in \Re^2$ be the lower left endpoint of the bounding box. Enclose the bounding box inside a larger square, denoted the *enclosing box* of sidelength $L = 2\ell$, and position the enclosing box such that p has distance a from the left edge and b from the lower edge, where $a, b \leq \ell$ are chosen randomly. The randomized dissection is the dissection of this enclosing box. Note that the randomness is used only to determine the placement of the enclosing box (and its accompanying dissection).

We now describe the PTAS in Ref. [34] for the Euclidean TSP, which uses the above randomized dissection. Formally, for every $\varepsilon > 0$, this PTAS finds a $(1 + \varepsilon)$-approximation to Euclidean TSP.

First, perform randomized dissection to the bounding box of the n points. Recall that L is the side of the enclosing box. The recursive procedure of subdividing the squares stops when the sidelengths of the squares becomes less than $L\varepsilon/8n$, or when each square at the last level contains at most one point. We may assume (by scaling) that L is a power of 2 and that the sides of squares at the last level are unit length. Thus, at most $\log L$ iterations are required, and $L \leq 8n/\varepsilon$. When there is more than one point in a unit square, consolidate them into one new "bigger" point. Any tour for the resulting set of points can be augmented to a tour for the original set of points with an increase in length bounded by $\sqrt{2}nL\varepsilon/8n$, which is negligible, since $L \leq OPT/2$. Henceforth, we shall assume that there is at most one point per unit square.

The *level* of a square in the dissection is its depth in the recursive dissection tree; the root square has level 0. We also assign a level from 0 to $\log(L - 1)$ to each horizontal and vertical grid line that participates in the dissection. The horizontal (resp., vertical) line that divides the enclosing box into two has level 0. Similarly, the 2^i horizontal and 2^i vertical lines that divide the level i squares into level $i + 1$ squares have level i. The following property of a randomized dissection is used: Any fixed vertical grid line that intersects the bounding box of the instance has probability $\frac{2^i}{\ell} = \frac{2^{i+1}}{L}$ to be a line at level i.

Next, the location of the portals is determined. Let $m = \frac{1}{\varepsilon} \log L$. The parameter m is the *portal parameter* that determines the density of the points the path can pass through. A level i line has $2^{i+1}m$ equally spaced portals. In addition, we also refer to the corners of each square as a portal. Since a level i line has 2^{i+1} level $i + 1$ squares touching it, it follows that each side of the square has at most $m + 2$ portals (m regular portals plus the 2 corners), and a total of at most $4m + 4$ portals on its boundary. A *portal-respecting tour* is one that, whenever it crosses a grid line, does so at a portal.

Finally, dynamic programming is used to find the optimum portal-respecting tour in time $2^{O(m)} L \log L$. Since $m = O(\log n/\varepsilon)$, we get a total running time of $n^{O(1/\varepsilon)}$. The dynamic programming as well as the complete analysis of bounding the PTAS error and the time complexity are given in Ref. [31].

Note that since the PTAS uses randomization, the error of the PTAS is a random variable. Formally, let OPT denote the cost of the optimum salesman tour and $OPT_{a,b,m}$ denote the cost of the best portal-respecting tour when the portal parameter is m and the random shifts are a, b.

Theorem 9.8

The expectation (over the choices of a, b) of $OPT_{a,b,m} - OPT$ is at most $2 \log L/mOPT$, where L is the sidelength of the enclosing box.

As mentioned in the survey of Arora [31], this method of dissection can be used to develop PTASs for other geometric optimization problems such as minimum Steiner tree, facility location with capacities and demands, and Euclidean min-cost k-connected subgraph.

Another class of geometric optimization problem is the class of *clustering* problems, such as metric max-cut and k-median. In recent research on clustering problems, a core idea in the design of approximation schemes is to use random sampling of data points from a biased distribution, which depends on the pairwise distances. This technique is used, e.g., in the PTAS of Fernandez de la Vega and Kenyon for metric max-cut [35], and in the work of Indyk on metric 2-clustering [36]. For more details on the technique and its applications, we refer the reader to Ref. [37].

9.4.2 Shifted Plane Partitions

The *shifting* technique that is applied to geometric problems is based on selecting the best solution over a (polynomial size) set of feasible solutions. Each candidate feasible solution is obtained using a divide-and-conquer approach, in which the plane is partitioned into disjoint areas (strips). The technique can be applied to geometric problems such as square packing or covering with disks, which arise in Very Large Scale Integration (VLSI) design, image processing, and many other important areas. A common goal in these problems is to cover or pack elements (e.g., points in the plane) into a minimal number of objects (e.g., squares of given size).

Recall that each candidate solution is obtained by using divide-and-conquer approach, in which the plane is partitioned into strips. A solution for the original problem is formed by taking the union of the solutions for these strips. Consecutive solutions refer to consecutive partitions of the plane into strips, which differ from each other by *shifting the partitioning bars*, using the shifting parameter. The smaller the shifting parameter, the larger the number of candidate solutions to be considered, and the better resulting approximation.

We illustrate the shifting technique for the problem of covering n points in the two-dimensional plane. The complete analysis is given in Refs. [33,38]. Assume that the n points are enclosed in an area I. The goal is to cover these points with a minimal number of disks of diameter D. Denote by ℓ the shifting parameter. The area I is divided into vertical strips of width D. Each set of ℓ consecutive strips are grouped together to form strips of width ℓD. Note that there are ℓ different ways to determine this grouping—and they can derive from each other by shifting the partitioning bars to the right over distance D. Denote the ℓ distinct partitions obtained this way by $S_1, S_2, \ldots, S_\ell$.

Let A be an algorithm to solve the covering problem on strips of width at most ℓD. The algorithm A can be used to generate a solution for a given partition S_j. We apply A to each strip in S_j and then union the sets of disks used. The *shift algorithm*, s_A, defined for a given A, uses A to solve the problem for the ℓ possible partitions and selects the solution that requires minimum number of disks.

The following lemma gives the performance ratio of s_A (denoted r_{s_A}) as function of ℓ and the performance ratio of A (denoted r_A).

Lemma 9.8

$$r_{s_A} \leq r_A \left(1 + \frac{1}{\ell}\right)$$

The algorithm A may itself be derived from an application of the shifting technique. In our example, to solve the covering problem on a strip of width ℓD, the strip is cut into squares of size $\ell D \times \ell D$, for which an optimal solution can be found by exhaustive search.

We note that the above shifting technique can be used to derive PTASs for several other problems, including minimum vertex cover and maximum independent set in planar graphs [39]. The idea is that a planar graph can be decomposed into components of bounded outer-planarity. The solution for each component can be found using dynamic programming. The shifting idea is to remove one "layer" from the graph in each iteration. This removal guarantees that the number of cross-cluster edges is small, so by considering the union of the local cluster solutions one can get a good approximation for the original problem.

9.5 Concluding Remarks

There are many other interesting applications of the techniques described in this chapter. We mention a few of them. Golubchik et al. [49] apply enumeration to a *structured* instance in solving the problem of data placement on disks (see also Ref. [40]). The technique of extending solutions for small subsets is applied by Khuller et al. [41] to the problem of broadcasting in heterogeneous networks. Kenyon et al. [42] used a nontrivial combination of grouping with periodic scheduling to obtain a PTAS for data broadcast.

As mentioned in Section 9.4, some techniques are specialized for certain types of problems. For graph problems, some PTASs exploit the density of the input graph (see, e.g., Ref. [43]). There are PTASs which build on the properties of *planar graphs* (see, e.g., Refs. [44,45]).

Finally, we have mentioned in Sections 9.2.3 and 9.4 some techniques used in *randomized* approximation schemes. A detailed exposition of randomized approximation schemes for counting problems is given in Chapter 11 in Ref. [46] (see also Chapter 12 of this handbook). Benczúr and Karger presented in Ref. [47] randomized approximation schemes for cuts and flows in capacitated graphs. Efraimidis and Spirakis used in Ref. [48] the technique of *filtered randomized rounding* in developing randomized approximation schemes for scheduling unrelated parallel machines.

Rounding, Interval Partitioning, and Separation

Sartaj Sahni
University of Florida

10.1 Introduction

This chapter reviews three general methods—rounding, interval partitioning, and separation—proposed by Sahni [1] to transform pseudopolynomial-time algorithms into fully polynomial-time approximation schemes. The three methods, which generally apply to dynamic-programming and enumeration-type pseudopolynomial-time algorithms, are illustrated using the 0/1-knapsack and multiconstrained shortest paths problems. Both of these problems are known to be NP-hard and both are solvable in pseudopolynomial time using either dynamic programming or enumeration.

10.2 Rounding

The rounding method of Ref. [1] is also known by the names digit truncation and scaling. The key idea in the rounding method is to reduce the magnitude of some or all of the numbers in an instance so that the pseudopolynomial-time algorithm actually runs in polynomial time on the reduced instance. The amount by which each number is reduced is such that the optimal solution for the reduced instance is an ϵ-approximate solution for the original instance.

Rounding up, rounding down, and random rounding are three possible strategies to construct the reduced instance. In each, we employ a rounding factor $\delta(n, \epsilon)$, where n is a measure of the problem size. For convenience, we abbreviate $\delta(n, \epsilon)$ as δ. When rounding up, each number α (for convenience, we assume that all numbers in all instances are positive) that is to be rounded is replaced by $\lceil \alpha/\delta \rceil$ and when rounding down, α is replaced by $\lfloor \alpha/\delta \rfloor$. In random rounding, we round up with probability equal to the fractional part of α/δ and round down with probability equal to 1—the fractional part of α/δ. So, for example, if $\alpha = 7$ and $\delta = 4$, α is replaced by (or reduced to) 2 when rounding up and by 1 when rounding down. In random rounding, α is replaced by 2 with probability 0.75 and by 1 with probability 0.25. Random rounding is typically implemented using a uniform random number generator that generates real numbers in the range [0, 1). The decision on whether to round up or down is made by generating a random number. If the generated number is $\leq$ the fractional part of α/δ, we round up; otherwise, we round down.[1]

As an example of the application of rounding, consider the 0/1-knapsack problem, which is known to be NP-hard [3]. In the 0/1-knapsack problem, we wish to pack a knapsack (bag or sack) with a capacity of c. From a list of n items/objects, we must select the items that are to be packed into the knapsack. Each item i has a weight w_i and a profit p_i. We assume that all weights and profits are positive integers. In a feasible knapsack packing, the sum of the weights of the packed objects does not exceed the knapsack capacity c, which also is assumed to be a positive integer. Since an item with weight more than c cannot be in any feasible packing, we may assume that $w_i \leq c$ for all i. An optimal packing is a feasible packing with maximum profit. The problem formulation is

$$\text{maximize} \quad \sum_{i=1}^{n} p_i x_i$$

subject to the constraints

$$\sum_{i=1}^{n} w_i x_i \leq c \text{ and } x_i \in \{0, 1\}, \quad 1 \leq i \leq n$$

In this formulation we are to find the values of x_i. When $x_i = 1$, it means that object i is packed into the knapsack, and $x_i = 0$ means that object i is not packed.

For the instance $n = 5$, $(p_1, \ldots, p_5) = (w_1, \ldots, w_5) = \{1, 2, 4, 8, 16\}$ and $c = 27$, the optimal solution is $X = (x_1, x_2, \ldots, x_5) = (1, 1, 0, 1, 1)$, which corresponds to packing items 1, 2, 4, and 5 into the knapsack. This solution uses all of the knapsack capacity and yields a profit of 27. With each feasible packing, we associate a profit and weight pair (P, W), where P is the sum of the profits of the items in the packing and $W \leq c$ the sum of their weights. For example, a packing that generates a profit of 15 and uses 20 units of capacity is represented by the pair (15, 20). P is the profit or value of the packing (P, W) and W its weight.

Several of the standard algorithm design methods of Ref. [3]—for example backtracking, branch and bound, dynamic programming, and divide and conquer—may be applied to the knapsack problem. Backtracking and branch and bound result in algorithms whose complexity is $O(2^n)$ and dynamic programming results in a pseudopolynomial-time algorithm whose complexity is $O(\min\{2^n, n\tilde{F}, nc\})$, where $\tilde{F}$ is the value of the optimal solution [4]. A pseudopolynomial-time algorithm with this same complexity also may be arrived at using an enumerative approach. By coupling a divide and conquer step to this enumerative algorithm, we obtain a pseudopolynomial-time algorithm whose complexity is $O(\min\{2^{n/2}, n\tilde{F}, nc\})$ [4].

Let $(P1, W1)$ and $(P2, W2)$ represent two different feasible packings of items selected from the first i items. Tuple $(P1, W1)$ *dominates* $(P2, W2)$ iff either $P1 \geq P2$ and $W1 < W2$ or $P1 > P2$ and $W1 = W2$. The enumerative algorithm for the 0/1-knapsack problem constructs a list of (or enumerates) the profit and weight pairs that correspond to all possible nondominated feasible packings. This list is constructed incrementally. Let S_i be the list of nondominated profit and weight pairs for all possible feasible packings chosen from the first i items. We start with the list $S_0 = \{(0, 0)\}$, and construct $S_1, S_2, \ldots, S_n$ in this order. Note that each S_i, $i > 0$, may be constructed from S_{i-1} using the equality

$$S_i = S_{i-1} \oplus \{(a + p_i, b + w_i) | (a, b) \in S_{i-1} \text{ and } b + w_i \leq c\} \tag{10.1}$$

where $\oplus$ denotes a union in which dominated pairs are eliminated. Eq. (10.1) simply states that the nondominated pairs obtainable from the first i items are a subset of those obtainable from the first $i - 1$

[1] There is a similar sounding, but quite different, method for approximation algorithms—randomized rounding —due to Raghavan and Thompson [2]. In randomized rounding, we start with an integer linear program formulation; relax the integer constraints to real number constraints; solve the resulting linear program; transform the noninteger values in the obtained solution to the linear program to integers using the random rounding strategy stated above.

items (these have $x_i = 0$) plus those obtainable from feasible packings of the first i items that necessarily include w_i (i.e., $x_i = 1$). The subset is identified by eliminating dominated pairs. Trying Eq. (10.1) out in the above $n = 5$ instance, we get (since $P = W$ for every pair (P, W) in this example, we represent each pair by a single number)

$$\begin{aligned}
S_0 &= \{0\}\\
S_1 &= \{0\} \oplus \{1\} = \{0, 1\}\\
S_2 &= \{0, 1\} \oplus \{2, 3\} = \{0, 1, 2, 3\}\\
S_3 &= \{0, 1, 2, 3\} \oplus \{4, 5, 6, 7\} = \{0, 1, 2, 3, 4, 5, 6, 7\}\\
S_4 &= \{0, \ldots, 7\} \oplus \{8, \ldots, 15\} = \{0, \ldots, 15\}\\
S_5 &= \{0, \ldots, 15\} \oplus \{16, \ldots, 27\} = \{0, \ldots, 27\}
\end{aligned}$$

For the case $n = 4$, $(p_1, \ldots, p_4) = (w_1, \ldots, w_4) = \{1, 1, 8, 8\}$, and $c = 17$, we get

$$\begin{aligned}
S_0 &= \{0\}\\
S_1 &= \{0\} \oplus \{1\} = \{0, 1\}\\
S_2 &= \{0, 1\} \oplus \{1, 2\} = \{0, 1, 2\}\\
S_3 &= \{0, 1, 2\} \oplus \{8, 9, 10\} = \{0, 1, 2, 8, 9, 10\}\\
S_4 &= \{0, 1, 2, 8, 9, 10\} \oplus \{8, 9, 10, 16, 17\} = \{0, 1, 2, 8, 9, 10, 16, 17\}
\end{aligned}$$

The solution to the knapsack instance may be determined from the S_is using the procedure of Figure 10.1.

For our $n = 5$ instance with $c = 27$, (P, W) is determined to be $(27, 27)$ in Step 1. In Step 2, x_5 is set to 1 as $(27, 27) \notin S_4$ and P and W are updated to 11. Then x_4 is set to 1 as $(11, 11) \notin S_3$ and P and W are updated to 3. Next, x_3 is set to 0 as $3 \in S_2$. x_2 and x_1 are set to 1 in the remaining two iterations of the **for** loop.

The S_is may be implemented as sorted linear lists (note that the dominance rule ensures that if S_i is in ascending order of P, S_i is also in ascending order of W; also, no two pairs of S_i may have the same P or the same W value). The set S_i may be computed from S_{i-1} in $O(|S_{i-1}|)$ time using Eq. (10.1). The time to compute all S_is is, therefore, $\sum_{1 \le i \le n} |S_{i-1}|$. (Note that in S_n we need to only compute the pair with maximum profit. When the S_is are in ascending order of profit, this maximum pair may be determined easily.) From Eq. (10.1) it follows that $|S_i| \le 2^i$ (this also follows from the observation that there are 2^i different subsets of i items). Also, since the w_is and p_is are positive integers and S_i has only nondominated pairs, $|S_i| \le \min\{\tilde{F}, c\} + 1$. Hence, the time needed to generate the S_is is $O(\min\{2^n, n\tilde{F}, nc\})$. If the sorted linear lists are array lists, each S_i may be searched for (P, W) in $O(\log |S_i|)$ time. In this case the complexity of the procedure to determine the x_is from the S_is is $O(n * \min\{n, \log\ \tilde{F}, \log\ c\})$. This may be reduced to $O(n)$ by retaining with each $(P, W) \in S_i$ a pointer to the pair (P, W) or $(P - p_i, W - w_i)$ that is in S_{i-1} (note that at least one of these pairs must be in S_{i-1}). These pointers are added to the members

```
Step 1: [Determine solution value]
    Determine the pair $(P, W) \in S_n$ with maximum profit value. The value of an optimal packing is $P$.

Step 2: [Determine $x_i$s]
    for $(i = n; i > 0; i - -)$
        if $((P, W) \notin S_{i-1})$ { $x_i = 1$; $P- = p_i$; $W- = w_i$; }
        else $x_i = 0$;
```

FIGURE 10.1 Procedure to determine x_is from the S_is.

of S_i at the time S_i is constructed using Eq. (10.1). The inclusion of these pointers does not change the asymptotic complexity of the procedure to compute the S_is.

The enumerative pseudopolynomial-time algorithm just described for the knapsack problem may be transformed into a fully polynomial-time approximation scheme by suitably rounding down the p_is. Suppose we round using the rounding factor δ to obtain the reduced instance with $p'_i = \lfloor p_i/\delta \rfloor$ and $w'_i = w_i$, $1 \leq i \leq n$, and $c' = c$. The time to solve the reduced instance is $O(n\tilde{F}')$, where $\tilde{F}'$ is the value of the optimal solution to the reduced problem (we assume the reduction is sufficient so that $n\tilde{F}' < \min\{2^n, nc'\}$). Notice that the original and reduced instances have the same feasible packings; only the profit associated with each feasible packing is different. A feasible packing has a smaller profit in the reduced instance than in the original instance.

Consider any feasible packing $(x_1, \ldots, x_n)$. Since $p'_i * \delta \leq p_i < (p'_i + 1) * \delta$,

$$\delta * \sum_i p'_i x_i \leq \sum_i p_i x_i < \delta * \sum_i (p'_i + 1)x_i \tag{10.2}$$

So,

$$\delta \tilde{F}' \leq \tilde{F} < \delta(\tilde{F}' + n) \tag{10.3}$$

Suppose we use the just described rounding strategy on our $n = 4$ example with $(p_1, \ldots, p_4) = (w_1, \ldots, w_4) = (1, 1, 8, 8)$, $c = 17$ and $\delta = 3$. We obtain $(p'_1, \ldots, p'_4) = (0, 0, 2, 2)$, $(w'_1, \ldots, w'_4) = (1, 1, 8, 8)$ and $c' = 17$. One of the optimal solutions for the reduced instance has $(x_1, x_2, x_3, x_4) = (0, 0, 1, 1)$ and the value of this solution is $p'_3 + p'_4 = 4$. In the original instance, the solution (0, 0, 1, 1) has value 16. Note that many different knapsack instances round to the same reduced instance. For example, $(p_1, \ldots, p_4) = (2, 1, 6, 7)$, $(w_1, \ldots, w_4) = (1, 1, 8, 8)$ and $c = 17$ (using $\delta = 3$). The value of the solution (0, 0, 1, 1), for this original instance, is 13. From Eq. (10.2), regardless of the original instance, the value of (0, 0, 1, 1) must be at least $\delta * \sum p'_i x_i = 12$ and cannot equal or exceed $\delta * \sum (p'_i + 1)x_i = 18$.

To ensure that every optimal solution to the reduced instance also defines an ϵ-approximate solution for the original instance, we must select δ carefully. Let $\hat{F}$ be the value, in the original instance, of the optimal solution for the reduced instance. From Eq. (10.2) and Eq. (10.3), we obtain

$$\hat{F} \geq \delta \tilde{F}' > \tilde{F} - n\delta$$

So, $(\tilde{F} - \hat{F}) < n\delta$ and $(\tilde{F} - \hat{F})/\tilde{F} < n\delta/\tilde{F}$. To gurantee that the optimal solution for the reduced instance is an ϵ-approximate solution for the original instance, we require $n\delta/\tilde{F} \leq \epsilon$ or $\delta \leq \epsilon\tilde{F}/n$. Since the reduced instance has smaller p'_i values and hence smaller complexity when δ is larger, we would like to use

$$\delta = \epsilon\tilde{F}/n$$

With this choice of δ, $\tilde{F}' \leq \tilde{F}/\delta = n/\epsilon$ (Eq. [10.3]). So, $|S_i| \leq n/\epsilon + 1$ and the complexity of the enumerative algorithm becomes $O(n^2/\epsilon)$. In other words, the enumerative algorithm becomes a fully polynomial-time approximation scheme for the 0/1-knapsack problem! Unfortunately, this choice of δ is problematic as we cannot easily compute $\tilde{F}$. Since any $\delta \leq \epsilon\tilde{F}/n$ guarantees ϵ-approximate solutions, we may use

$$\delta = \epsilon LB/n$$

where $LB \leq \tilde{F}$ is a lower bound on the value of the optimal solution. Let $Pmax = \max_i\{p_i\}$ be the maximum profit value. Since $w_i \leq c$ for all i (by assumption), $Pmax \leq \tilde{F}$, and $LB = Pmax$ is a lower bound on $\tilde{F}$. So, using $\delta = \epsilon Pmax/n$ guarantees ϵ-approximate solutions. Since $\tilde{F} \leq nPmax$, $\tilde{F}' \leq nPmax/\delta = n^2/\epsilon$ and the complexity of the enumerative algorithm becomes $O(n^3/\epsilon)$.

An alternative way to determine a lower bound for $\tilde{F}$ is to sort the knapsack items into nondecreasing order of profit denisty p_i/w_i and pack the items into the knapsack in density order upto and including the first item that causes the knapsack to be either filled or overfilled. Note that if there is no such first item, all items can be packed into the knapsack and this packing represents the optimal solution. Also note that if the stated packing strategy fills the knapsack completely, it represents an optimal packing. So, assume that the capacity is exceeded. Let $\bar{F}$ be the value of this packing that overfills the knapsack. In Ref. [5], it is shown that $\bar{F}/2 \leq \tilde{F} \leq \bar{F}$. So, using $\delta = \epsilon\bar{F}/(2n)$ as the rounding factor, guarantees ϵ-approximate solutions. Since $\tilde{F} \leq \bar{F}$, $\tilde{F}' \leq \bar{F}/\delta$ and, for the reduced instance, $|S_i| \leq \bar{F}/\delta + 1 = 2n/\epsilon + 1$. For the reduced instance, the complexity of the enumerative algorithm is, therefore, $O(n^2/\epsilon)$ and we get a fully polynomial-time ϵ-approximation scheme of this complexity.

10.3 Interval Partitioning

Unlike rounding, which reduces an instance to one that is easier to solve using a known pseudopolynomial-time algorithm, in interval partitioning we work with the nonreduced (original) instance. In interval partitioning, we partition the solution space into buckets or intervals and for each interval, we retain only one of the (feasible) solutions (or partial solutions) that fall into it.

For the 0/1-knapsack problem, for example, each pair $(P, W) \in S_i, i \leq n$, represents a feasible solution. We may partition the solution space based on the profit value of the pair (P, W). If we partition using an interval size of δ, then the intervals are $[0, \delta)$, $[\delta, 2\delta)$, $[2\delta, 3\delta)$, and so on. When two or more solutions fall into the same interval, all but one of them is eliminated. Specifically, we eliminate all but the one with least weight. Let S_i' be the list of (P, W) pairs for all possible feasible packings chosen from the first i items subject to the interval partitioning constraint that S_i' has at most 1 (P, W) pair in each interval. We begin with $S_0' = \{(0, 0)\}$ and compute S_i' from S_{i-1}' using the equation

$$S_i' = S_{i-1}' \odot \{(a + p_i, b + w_i) | (a, b) \in S_{i-1}' \text{ and } b + w_i \leq c\} \tag{10.4}$$

where $\odot$ denotes a union in which only the least weight pair from each interval is retained. The maximum profit pair in S_n' is used as the approximate optimal solution. The x_is for this pair are obtained using the procedure of Figure 10.1 with S_i replaced by S_i'.

Consider the 0/1-knapsack instance $n = 5, (p_1, \ldots, p_5) = (w_1, \ldots, w_5) = \{1, 2, 4, 8, 16\}$, and $c = 27$, which was first considered in Section 10.2. Suppose we work with an interval size $\delta = 2$. The intervals are $[0, 2)$, $[2, 4)$, $[4, 6)$, and so on. The S_i's are

$$\begin{aligned}
S_0' &= \{0\}\\
S_1' &= \{0\} \odot \{1\} = \{0\}\\
S_2' &= \{0\} \odot \{2\} = \{0, 2\}\\
S_3' &= \{0, 2\} \odot \{4, 6\} = \{0, 2, 4, 6\}\\
S_4' &= \{0, 2, 4, 6\} \odot \{8, 10, 12, 14\} = \{0, 2, 4, 6, 8, 10, 12, 14\}\\
S_5' &= \{0, 2, 4, \ldots, 14\} \odot \{16, 18, 20, \ldots, 26\} = \{0, 2, 4, \ldots, 26\}
\end{aligned}$$

The maximum profit pair in S_4 is $(26, 26)$. For this instance, therefore, the best solution found using interval partitioning with $\delta = 2$ has a profit 1 less than that of the optimal.

Consider the instance $n = 6$, $(p_1, \ldots, p_6) = (w_1, \ldots, w_6) = (1, 2, 5, 6, 8, 9)$, and $c = 27$. Suppose we use $\delta = 3$. The intervals are $[0, 3)$, $[3, 6)$, $[6, 9)$, and so on. The S_i's are

$$\begin{aligned}
S_0' &= \{0\}\\
S_1' &= \{0\} \odot \{1\} = \{0\}\\
S_2' &= \{0\} \odot \{2\} = \{0\}\\
S_3' &= \{0\} \odot \{5\} = \{0, 5\}\\
S_4' &= \{0, 5\} \odot \{6, 11\} = \{0, 5, 6, 11\}\\
S_5' &= \{0, 5, 6, 11\} \odot \{8, 13, 14, 19\} = \{0, 5, 6, 11, 13, 19\}\\
S_6' &= \{0, 5, 6, 11, 13, 19\} \odot \{9, 14, 15, 20, 22\} = \{0, 5, 6, 9, 13, 15, 19, 22\}
\end{aligned}$$

The profit of the best solution found for this instance is 22; the profit for the optimal solution is 27. Note that if c were 28 instead of 27,

$$S'_6 = \{0, 5, 6, 11, 13, 19\} \odot \{9, 14, 15, 20, 22, 28\} = \{0, 5, 6, 9, 13, 15, 19, 22, 28\}$$

and we would have found the optimal solution.

Let $\check{F}$ be the value of the solution found by interval partitioning. It is easy to see that $\tilde{F} < \check{F} + n\delta$. So, $(\tilde{F} - \check{F})/\tilde{F} < n\delta/\tilde{F}$. To guarantee that the solution found using interval partitioning is an ϵ-approximate solution, we require $n\delta/\tilde{F} \le \epsilon$. For this, we must choose δ so that $\delta \le \epsilon\tilde{F}/n$. Since $\tilde{F}$ is hard to compute, we opt to select δ as in Section 10.2. Both the choices $\delta = \epsilon Pmax/n$ and $\delta = \epsilon\bar{F}/(2n)$ guarantee that the solution generated using interval partitioning is ϵ-approximate. When $\delta = \epsilon Pmax/n$, the number of intervals is $\tilde{F}/\delta + 1 \le nPmax/\delta + 1 = n^2/\epsilon + 1$ and the complexity of the (modified) enumerative algorithm is $O(n^3/\epsilon)$. When $\delta = \epsilon\bar{F}/(2n)$, the number of intervals is $\tilde{F}/\delta + 1 \le \bar{F}/\delta + 1 = 2n/\epsilon + 1$ and the complexity is $O(n^2/\epsilon)$.

10.4 Separation

An examination of our $n = 6$ example of Section 10.3 reveals that interval partitioning misses some opportunities to reduce the size of an S'_i while yet preserving the relationship $\tilde{F} \le \hat{F} + n\delta$, which is necessary to ensure an ϵ-approximate solution. For example, in S'_4 we have two solutions, one with value 5 and the other with value 6. Although these are within δ of each other, they fall into two different intervals and so neither is eliminated. In the separation method, we ensure that the value of retained solutions differs by more than δ.

For the 0/1-knapsack problem, let S''_i be the list of (P, W) pairs for all possible feasible packings chosen from the first i items subject to the separation constraint that no two pairs of S''_i have value within δ of each other. We begin with $S''_0 = \{(0, 0)\}$ and compute S''_i from S''_{i-1} using the equation

$$S''_i = S''_{i-1} \otimes \{(a + p_i, b + w_i) | (a, b) \in S''_{i-1} \quad \text{and} \quad b + w_i \le c\} \tag{10.5}$$

where $\otimes$ denotes a union that implements the separation constraint. More precisely, suppose that

$$T = S''_{i-1} \oplus \{(a + p_i, b + w_i) | (a, b) \in S''_{i-1} \quad \text{and} \quad b + w_i \le c\}$$

Let (P_i, W_i), $1 \le i \le |T|$ be the pairs in T in ascending order of profit (and hence of weight). The set S''_i is obtained from T using the code of Figure 10.2.

The maximum profit pair in S''_n is used as the approximate optimal solution.

Consider the $n = 6$ example of Section 10.3. $S''_i = S'_i$, $0 \le i \le 3$. The remaining S''_i's are

$$\begin{aligned}
S''_0 &= \{0\} \\
S''_1 &= \{0\} \otimes \{1\} = \{0\} \\
S''_2 &= \{0\} \otimes \{2\} = \{0\} \\
S''_3 &= \{0\} \otimes \{5\} = \{0, 5\} \\
S''_4 &= \{0, 5\} \otimes \{6, 11\} = \{0, 5, 11\} \\
S''_5 &= \{0, 5, 11\} \otimes \{8, 13, 19\} = \{0, 5, 11, 19\} \\
S''_6 &= \{0, 5, 11, 19\} \otimes \{9, 14, 20\} = \{0, 5, 9, 14, 19\}
\end{aligned}$$

```
$S''_i = \{(P_1, W_1)\}$;
$P_{prev} = P_1$;
for (int $i = 1$; $i <= |T|$; $i++$)
    if ($P_i > P_{prev} + \delta$) {$S''_i = S''_i \cup \{(P_i, W_i)\}$; $P_{prev} = P_i$;}
```

FIGURE 10.2 Computing S''_i from T.

The profit of the best solution found for this instance is 19; the profit for the optimal solution is 27. We could have produced a slightly better solution by noting that we can replace the computation of S''_n by a step in which we determine the maximum profit pair in

$$S''_{n-1} \oplus \{(a + p_i, b + w_i) | (a, b) \in S''_{n-1} \quad \text{and} \quad b + w_i \le c\}$$

For our example, this pair has value 20.

Let $\check{F}$ be the value of the solution found by the separation method. It is easy to see that $\tilde{F} \le \check{F} + n\delta$. So, $\delta \le \epsilon \tilde{F}/n$ ensures that an ϵ-approximate solution is found. As was the case in Section 10.3, for the knapsack problem, the choices $\delta = \epsilon Pmax/n$ and $\epsilon \bar{F}/(2n)$ guarantee that the solution generated using separation is ϵ-approximate. When $\delta = \epsilon Pmax/n$, the complexity of the (modified) enumerative algorithm is $O(n^3/\epsilon)$ and when $\delta = \epsilon \bar{F}/(2n)$, the complexity is $O(n^2/\epsilon)$.

Intuitively, we may expect that using the same δ value, $|S''_i| \le |S'_i|$ for all i. Although this relationship holds for the $n = 6$ example considered above, the relationship does not always hold. For example, consider the knapsack instance $n = 5$, $(p_1, \ldots, p_5) = (w_1, \ldots, w_5) = (30, 10, 51, 51, 51)$, $c = 186$, and $\delta = 20$. Using interval partitioning, we get

$$\begin{aligned}
S'_0 &= \{0\} \\
S'_1 &= \{0\} \odot \{30\} = \{0, 30\} \\
S'_2 &= \{0, 30\} \odot \{10, 40\} = \{0, 30, 40\} \\
S'_3 &= \{0, 30, 40\} \odot \{51, 81, 91\} = \{0, 30, 40, 81\} \\
S'_4 &= \{0, 30, 40, 81\} \odot \{51, 81, 91, 132\} = \{0, 30, 40, 81, 132\} \\
S'_5 &= \{0, 30, 40, 81, 132\} \odot \{51, 81, 91, 132, 183\} = \{0, 30, 40, 81, 132, 183\}
\end{aligned}$$

and using separation, we get

$$\begin{aligned}
S''_0 &= \{0\} \\
S''_1 &= \{0\} \otimes \{30\} = \{0, 30\} \\
S''_2 &= \{0, 30\} \otimes \{10, 40\} = \{0, 30\} \\
S''_3 &= \{0, 30\} \otimes \{51, 81\} = \{0, 30, 51, 81\} \\
S''_4 &= \{0, 30, 51, 81\} \otimes \{51, 81, 102, 132\} = \{0, 30, 51, 81, 102, 132\} \\
S''_5 &= \{0, 30, 51, 81, 102, 132\} \otimes \{51, 81, 102, 132, 153, 183\} = \{0, 30, 51, 81, 102, 132, 153, 183\}
\end{aligned}$$

10.5 0/1-Knapsack Problem Revisited

In Sections 10.2–10.4, we saw how to apply the generic rounding, interval partitioning, and separation methods to the 0/1-knapsack problem and obtain an ϵ-approximate fully polynomial-time approximation scheme for this problem. The complexity of the approximation scheme is either $O(n^3/\epsilon)$ or $O(n^2/\epsilon)$, depending on the choice of δ. By tailoring the approximation method to the application, we can, at times, reduce the complexity of the approximation scheme. Ibarra and Kim [5], for example, combine rounding and interval partitioning to arrive at an $O(n \log n - (\log \epsilon)/\epsilon^4)$ ϵ-approximate fully polynomial-time approximation scheme for the 0/1-knapsack problem. Figure 10.3 gives their algorithm. The correctness proof and complexity analysis can be found in Ref. [5].

10.6 Multiconstrained Shortest Paths

10.6.1 Notation

Assume that a communication network is represented by a weighted directed graph $G = (V, E)$, where V is the set of network vertices or nodes and E the set of network links or edges. We use n and e, respectively,

```
Step 1: [Determine $\delta$]
    Sort the $n$ items into nondecreasing order of profit density $p_i/w_i$.
    Let $\bar{F}$ be as in Section ??.
    Let $\delta = \epsilon^2\bar{F}/9$.
Step 2: [Partition Items]
    Let small be the items with $p_i \leq \epsilon\bar{F}/3$.
    Let big be the remaining items.
Step 3: [Rounding]
    Let big' be obtained from big by rounding down the profits using the rounding factor $\delta$.
    For each rounded-down profit $p$, retain up to $9/(\epsilon^2 p)$ items of least weight.
    Let big'' be the resulting item set.
    Let $m$ be the number of items in big''.
Step 4: [Interval Partitioning]
    Use interval partitioning on big'' and determine $S'_m$.
Step 5: [Augmentation]
    Augment each $(P, W) \in S'_m$ by adding in items from small in order of nondecreasing density so as not
    to exceed the capacity of the knapsack.
    Select the augmentation that yields maximum profit as the approximate solution.
```

FIGURE 10.3 Fully polynomial-time ϵ-approximation scheme of Ref. [5].

to denote the number of nodes and links in the network, that is, $n = |V|$ and $e = |E|$. We assume that each link (u, v) of the network has $k > 1$ nonnegative weights $w_i(u, v)$, $1 \leq i \leq k$. These weights, for example, may represent link cost, delay, and delay-jitter. The notation $w(u, v)$ is used to denote the vector $(w_1(u, v), \ldots, w_k(u, v))$, which gives the k weights associated with the edge (u, v). Let p be a path in the network. We use $w_i(p)$ to denote the sum of the w_is of the edges on the path p.

$$w_i(p) = \sum_{(u,v) \in p} w_i(u, v)$$

By definition, $w(p) = (w_1(p), \ldots, w_k(p))$.

In the *multiconstrained path* (*k-MCP*) problem, we are to find a path p from a specified source vertex s to a specified destination vertex d such that

$$w_i(p) \leq c_i, \quad 1 \leq i \leq k \tag{10.6}$$

The c_is are specified QoS (quality of service) constraints. Note that Eq. (10.6) is equivalent to $w(p) \leq c$, where $c = (c_1, \ldots, c_k)$. A *feasible path* is any path that satisfies Eq. (10.6).

The *restricted shortest path* (*k-RSP*) problem is a related optimization problem in which we are to find a path p from s to d that minimizes $w_1(p)$ subject to

$$w_i(p) \leq c_i, \quad 2 \leq i \leq k$$

An algorithm is an ϵ-*approximation algorithm* (or simply, an *approximation algorithm*) for *k-MCP* iff the algorithm generates a source to destination path p that satisfies Eq. (10.6) whenever the network has a source to destination path p' that satisfies

$$w_i(p) \leq \epsilon * c_i, \quad 1 \leq i \leq k \tag{10.7}$$

where ϵ is a constant between 0 and 1.

Both the *k-MCP* and *k-RSP* problems for $k > 1$ are known to be NP-hard [6] and several pseudopolynomial-time algorithms, heuristics, and approximation algorithms have been proposed [7–9.] Jaffe [10] has proposed a polynomial-time approximation algorithm for 2-*MCP*. This algorithm, which uses a shortest path algorithm such as Dijkstra's [11], replaces the two weights on each edge by a linear combination of these two weights. The algorithm is expected to perform well when the two weights are positively correlated. Chen and Nahrstedt [12] use rounding to arrive at a polynomial-time approximation algorithm for *k-MCP*. Korkmaz and Krunz [13] propose a randomized heuristic that employs two phases. In the first phase a shortest path from each vertex of V to the destination vertex d is computed for each of the k weights as well as for a linear combination of all k weights. The second phase performs a randomized breadth-first search for a solution to the *k-MCP* problem. Yuan [14] has proposed two heuristics for *k-MCP*—limited granularity and limited path. By properly selecting the parameters for the limited granularity heuristic (LGH), this heuristic becomes an ϵ-approximation algorithm for *k-MCP*.

The papers [15–19] use rounding (up, down, and random) and interval partitioning to arrive at fully polynomial-time approximation schemes for *k-RSP*. Song and Sahni [20] use rounding (up), interval partitioning, and separation to develop fully polynomial-time approximation schemes for *k-MCP*. We focus on the work of Ref. [20] and this section is derived from Ref. [20].

10.6.2 Extended Bellman–Ford Algorithm

This is an extension of the well-known dynamic programming algorithm due to Bellman and Ford that is used to find shortest paths in weighted graphs [11]. The original Bellman–Ford algorithm was proposed for graphs in which each edge has a single weight. The extension allows for multiple weights (e.g., cost, delay, and delay-jitter).

Let u and v be two vertices in an instance of *k-MCP*. Let p and q be two different u to v paths. Path p is *dominated* by path q iff $w(q) \leq w(p)$ (i.e., $w_i(q) \leq w_i(p)$, $1 \leq i \leq k$).

In its pure form, the Bellman–Ford algorithm works in $n - 1$ (n is the number of vertices in the graph) rounds numbered 1 through $n - 1$. In round 1, the algorithm implicitly enumerates one-edge paths from the source vertex; then, in round 2, those with two edges are enumerated; and so on until finally paths with $n - 1$ edges are enumerated. Since no simple path has more than $n - 1$ edges, by the end of round $n - 1$, all simple paths have been (implicitly) enumerated. The enumeration of paths that have $i + 1$ edges is accomplished by considering all one-edge extensions of the enumerated i-edge paths. During the implicit enumeration, suboptimal paths (i.e., paths that are dominated by others) are eliminated. Suppose we have two paths p and q to vertex u and that p is dominated by q. If path p can be extended to a path that satisfies Eq. (10.6), then so also can q. Hence there is no need to retain p for further enumeration by path extension. Actual implementations rarely follow the pure Bellman–Ford paradigm and enumerate some paths of length more than $i + 1$ in round i.

Figure 10.4 gives the version of the Extended Bellman–Ford algorithm employed by Ref. [20]. This version is very similar to the version used by Yuan and others [14,21]. *PATH*(u) is a set of paths from the source s to vertex u. *PATH*(u) never contains two paths p and q for which $w(p) \leq w(q)$. Lines 12–14 initialize *PATH*(u) for all vertices u. The **for** loop of lines 16–20 attempts to implement the pure form of the Extended Bellman–Ford algorithm and performs the required $n - 1$ rounds (there is a provision to terminate in fewer rounds in case the previous round added a path to no *PATH*(u)). The method $Relax(u, v)$ extends the new[2] paths in *PATH*(u) by appending the edge (u, v). Feasible extended paths (i.e., those that satisfy the k constraints of Eq. [10.6]) are examined further. If v is the destination, the algorithm terminates as we have found a feasible source to destination path. Let the extended path $p||(u, v)$ be r. The inner **for** loop (lines 4–8) removes from *PATH*(v) all paths that are dominated by r (lines 7 and 8). This loop also verifies that r is not dominated by a path in *PATH*(v) (lines 5 and 6). Notice that if r is dominated by or equal to a path in *PATH*(v), r cannot dominate a path in *PATH*(v). Finally, in lines 9 and 10, r is added to *PATH*(v) only if it is not dominated by or equal to any path in *PATH*(v).

[2] A path is new iff it has not been the subject of a similar extension attempt on a previous round.

```
Relax($u$, $v$)
1.  for each new $p \in PATH(u)$ such that $w(p) + w(u, v) \leq c$ do
2.      if ($v = d$) return TRUE;
3.      Flag = TRUE;
4.      for each $q \in PATH(v)$ do
5.          if ($w(q) \leq w(p) + w(u, v)$)
6.              Flag = FALSE; Break; // exit inner for loop
7.          if ($(w(p) + w(u, v)) \leq w(q)$)
8.              remove $q$ from $PATH(v)$;
9.      if ($Flag == TRUE$)
10.         insert $p||(u, v)$ into $PATH(v)$; Change = TRUE;
11. return FALSE;

Extended Bellman–Ford($G$, $c$, $s$, $d$)
12. for $i = 0$ to $n - 1$ do
13.     $PATH(i) = NULL$;
14. $PATH(s) = \{s\}$;
15. Result = FALSE;
16. for $round = 1$ to $n - 1$ do
17.     Change = FALSE;
18.     for each edge $(u, v) \in E$ do
19.         if (Relax(u, v)) return "YES";
20.     if (Change == FALSE) return "NO";
21. return "NO";
```

FIGURE 10.4 Extended Bellman–Ford algorithm for *k-MCP*.

To see that the algorithm of Figure 10.4 is not a faithful implementation of the pure form of the Bellman–Ford algorithm, consider any iteration of the **for** loop of lines 16–20 (i.e., consider one round) and suppose that edge (u, v) is considered before edge (v, w) in the **for** loop of lines 13–14. Following the consideration of (u, v), *PATH*(v) possibly contains paths with *round* edges. So, when (v, w) is considered, *Relax* extends the paths in *PATH*(v) by a single edge (v, w) thereby permitting a path of length *round* $+ 1$ to be included in *PATH*(w). This lack of faithfulness in implementation of the pure Bellman–Ford algorithm does not affect the correctness of the algorithm and, in fact, agrees with the traditional implementation of the Bellman–Ford algorithm for the case when each edge has a single weight (i.e., $k = 1$) [11].

Another implementation point worth mentioning is that although we have defined *PATH*(u) to be a set of paths from the source to vertex u, it is more efficient to implement *PATH*(u) to be the set of weights (or more accurately, weight vectors $w(\,)$) of these paths. This, in fact, is how the algorithm is implemented in Ref. [14].

10.6.3 Rounding

Let $\delta_i = c_i * (1 - \epsilon)/n$, $2 \leq i \leq k$. Suppose we replace each $w_i(u, v)$ with the weight

$$w'_i(u, v) = \lceil \frac{w_i(u, v)}{\delta_i} \rceil * \delta_i$$

Let p be a path such that it satisfies Eq. (10.7). Then,

$$w'_i(p) < w_i(p) + n\delta_i \leq \epsilon c_i + (1 - \epsilon)c_i = c_i$$

So, algorithm *Extended Bellman–Ford* of Figure 10.4 when run with the edge weights $w_i(u, v)$ replaced by the weights $w'_i(u, v)$, $2 \leq i \leq k$ will find a feasible path (either p or some other feasible path). In an implementation of the rounding method, we actually replace each $w_i(u, v)$, $2 \leq i \leq k$ by

$$w_i''(u, v) = \lceil \frac{w_i(u, v)}{\delta_i} \rceil$$

and each c_i by $\lfloor c_i/\delta_i \rfloor$, $2 \leq i \leq k$. From the computation stand point, using the w_i's is equivalent to using the w_i''s.

Let $S = (n/(1 - \epsilon))^{k-1}$. In the w_i''s formulation, it is easy to see that $|PATH(u)| \leq S$. Hence the complexity of *Extended Bellman–Ford* when the w_i'' (equivalently, w_i') weights are used is $O(neS^2)$ and we have a fully polynomial-time approximation scheme for *k-MCP*. For the case $k = 2$, the complexity is $O(neS)$ if we employ the merge strategy of Horowitz and Sahni [4] to implement *Relax* (i.e., maintain *PATH*(u) in ascending order of w_1; extend the new paths in one step; then merge these extensions with *PATH*(v) in another step).

10.6.4 Interval Partitioning and Separation

In interval partitioning, we partition the space of $[w_2(p), w_3(p), \ldots, w_k(p)]$ values into buckets of size $[\delta_2, \delta_3, \ldots, \delta_k]$. *PATH*$(u)$ is maintained so as to have at most one path in each bucket. When a *Relax* step attempts to put a second path into a bucket, only the path with the smaller w_1 value is retained. When the δ_is are chosen as in Section 10.6.3, we get a fully polynomial-time approximation scheme. By choosing larger values for the δ_is, we lose the guarantee of an ϵ-approximate solution but we reduce the run time. We use the term *interval partitioning heuristic* (IPH) to refer to the interval partitioning algorithm in which the δ_is are chosen arbitrarily.

Figure 10.5 gives the relax method used by IPH. The driver *Extended Bellman–Ford* is unchanged. By choosing the number of buckets (equivalently, the bucket size) as in Section 10.6.3, we get a fully polynomial-time ϵ-approximation scheme. The proof of this claim is quite similar to that of the proof provided in Section 10.6.3.

Theorem 10.1

IPH is an ϵ-approximation algorithm for k-MCP when the bucket size is chosen as in Section 10.6.3.

In the separation method, *PATH*(u) is such that no two paths of *PATH*(v) are within $\delta_i/2$ of their w_i values for $2 \leq i \leq k$. So, if we attempt to add to *PATH*(v) a path q such that $w_i(p)+\delta_i/2 \leq w_i(q) \leq w_i(p)+\delta_i/2$, $2 \leq i \leq k$, where $p \in PATH(v)$, then only the path with the smaller w_1 value is retained.

Since separation comes with greater implementation overheads than associated with interval partitioning [20] focuses on the interval partitioning method for k-MCP.

```
RelaxIPH($u$, $v$)
for each new $p \in PATH(u)$ such that $w(p) + w(u, v) \leq c$ do
    if ($v = d$) return TRUE;
    Let $r = p||(u, v)$;
    Let $q \in PATH\,(v)$ such that $r$ and $q$ fall in the same bucket;
    if (there is no such $q$)
        Add $r$ to $PATH\,(v)$; Change = TRUE;
    else if ($w_1(r) < w_1(q)$)
        Replace $q$ by $r$ in $PATH(v)$; Change = TRUE;
return FALSE;
```

FIGURE 10.5 Relax method for IPH.

10.6.5 The Heuristics of Yuan [14]

The LGH of Yuan [14] combines the interval partitioning and rounding methods. *PATH*(v) is represented as a $(k-1)$-dimensional array with each array position representing a bucket of size $[s_2, s_3, \ldots, s_k]$. As in the pure form of interval partitioning, each bucket can have at most one path. However, unlike interval partitioning, the exact w_i values of the retained path are not stored. Instead, the w_i values, $2 \leq i \leq k$ are rounded up to the maximum possible for the bucket; the smallest w_1 value of the paths that fall into a bucket is stored in the bucket. Note that because of the rounding of the w_i values, $2 \leq i \leq k$, we do not store these values along with the path; they may be computed as needed from the bucket indexes.

We may regard the LGH as one with delayed rounding; the rounding done at the outset when the traditional rounding method is used, is delayed to the time a path is actually constructed. By incorporating buckets, we eliminate the need to store the w_i, $2 \leq i \leq k$, values stored explictly with each path when either the rounding or interval partitioning methods are used. Although there is a reduction in space (by a factor of k) on a per path basis, the array of buckets used to implement each *PATH*(u) needs $\prod_{2\leq i\leq k} c_i/s_i$ space, whereas when the w_is are explicitly stored, the space requirements can be reduced to $O(k *$ total number of paths stored). The time complexity of LGH is $O(ne\prod_{2\leq i\leq k} c_i/s_i)$.

Note that when $s_i = \delta_i$, $2 \leq i \leq k$, the LGH becomes an ϵ-approximation algorithm.

The limited path heuristic (LPH) of Yuan [14] limits the size of *PATH*(v) to be X, where X is a specified parameter. It differs from *Extended Bellman–Ford* (Figure 10.4) only in that line 9 is changed to **if** (*Flag* == *True* && |*PATH*$(v)| < X$). With this modification, the complexity of *Extended Bellman–Ford* becomes $O(neX^2)$. The success of LPH hinges on the expectation that the first X nondominated paths, to vertex v, found by *Extended Bellman–Ford* are more likely to lead to a feasible path to the destination than subsequent paths to v. In a pure implementation of the Bellman–Ford method (which Figure 10.4 is not), this expectation may be justified with the expectation that paths to nondestination vertices with a smaller number of edges (these are found first in a pure Bellman–Ford algorithm) are more likely to lead to a feasible path to the destination than those with a larger number of edges.

10.6.6 Generalized Limited Path Heuristic

LPH limits the number of paths in *PATH*(u) to be at most X. In generalized limited path heuristic (GLPH), the constraint on the number of paths is

$$\sum_{u\in V, u\neq s} |PATH(u)| \leq (n-1) * X$$

While both LPH and GLPH place the same limit on the total number of paths retained (i.e., $(n-1)*X$), LPH accomplishes this by explicitly restricting the number of paths in each *PATH*(u), $u \neq s$ to be no more than X.

To ensure a performance at least as good as that of LPH, GLPH ensures that each *PATH*(u) maintains a superset of the *PATH*(u) maintained by LPH. So, GLPH permits the size of a *PATH*(u) to exceed X so long as the sum of the sizes is no more than $(n-1) * X$. When the sum of the sizes equals $(n-1) * X$, we continue to add paths to those *PATH*(u)s that have fewer than X paths. However, each such addition is accompanied by the removal of a path that would not be in any *PATH*(v) of LPH.

10.6.7 Hybrid Interval Partitioning Heuristics (HIPHs)

Although IPH becomes an ϵ-approximation algorithm when the bucket size is chosen appropriately, LPH is expected to perform well on many real-world networks because we expect paths with a small number of edges to be more likely to lead to feasible source–destination paths than those with a large number of edges. In this section we describe four hybrid heuristics: HIPH1, HIPH2, HIPH3, and HIPH4.

HIPH1 and HIPH2 combine IPH and LPH into a unified heuristic that has the merits of both. HIPH1 maintains two sets of paths for each vertex $u \in V$. The first set *PATH*(u) is limited to have at most X

```
RelaxHIPH1$(u, v)$
for each new $p \in PATH(u)$ such that $w(p) + w(u, v) \leq c$ do
    if $(v = d)$ return TRUE;
    Flag = TRUE;

```

FIGURE 10.6 Relax method for HIPH1.

paths. This set is a faithful replica of *PATH*(u) as maintained by LPH. The second set, *ipPATH*(u), uses interval partitioning to store additional paths found to vertex u. For the source vertex s, *PATH*$(s) = \{s\}$ and *ipPATH*(s)= $\emptyset$. Figure 10.6 gives the new relax method employed by HIPH1. It is easy to see that if on entry to *RelaxHIPH1*, *PATH*(u) as maintained by HIPH1 is the same as that maintained by the relax method of LPH, then on exit, *PATH*(v) is the same for both HIPH1 and LPH. Since both heuristics start with the same *PATH*(u) for all u, both maintain the same *PATH*(u) sets throughout. Hence HIPH1 produces a feasible solution whenever LPH does. Furthermore, because HIPH1 maintains additional paths in *ipPATH*( ), it has the potential to find feasible source-to-destination paths even when LPH fails to do so. It is easy also to see that when bucket size is selected as in Section 10.6.3, HIPH1 is an ϵ-approximation algorithm.

Theorem 10.2

HIPH1 is an ϵ-approximation algorithm for k-MCP when the bucket size for ipPATH( ) is chosen as in Section 10.6.3. Further, for any given X, HIPH1 finds a feasible source-to-destination path whenever LPH finds such a path.

HIPH2 is quite similar to HIPH1. In HIPH1 the extension $r = p||(u, v)$ of a path $p \in$ *ipPATH*(u) can be stored only in *ipPATH*(v). In HIPH2, however, this extension is stored in *PATH*(v) whenever $|PATH(v)| < X$. When $|PATH(v)| = X$, lines 4–8 of *RelaxIPH* are applied (using *ipPATH*(v) in place of *PATH*(v)) to determine the fate of r. With this change, *PATH*(u) as maintained by LPH may not be the same as that maintained by HIPH2. However, by choosing the bucket size for *ipPATH*(u) as in Section 10.6.3, HIPH2 becomes an ϵ-approximation algorithm.

Theorem 10.3

HIPH2 is an ϵ-approximation algorithm for k-MCP when the bucket size for ipPATH( ) is chosen as in Section 10.6.3.

HIPH3 and HIPH4 are the GLPH analogs of HIPH1 and HIPH2; that is they are based on GLPH rather than LPH.

Theorem 10.4

HIPH3 and HIPH4 are ϵ-approximation algorithms for k-MCP when the bucket size for ipPATH( ) is chosen as in Section 10.6.3.

FIGURE 10.7 Smallest X at which competitive ratio becomes 1.0 [20].

10.6.8 Performance Evaluation

The *existence ratio* (ER) and *competitive ratio* (CR) are defined, respectively, by Yuan [14] to be the number of routing requests satisfied by the extended Bellman–Ford algorithm divided by the total number of routing requests and the number of routing requests satisfied by a heuristic divided by the number satisfied by the extended Bellman–Ford algorithm. For example, if we make 500 routing requests, 100 of which are satisfiable, the ER is $100/500 = 0.2$. If LPH is able to find a feasible path for 80 of the 100 requests for which such a path exists, the CR of LPH is $80/100 = 0.8$.

Song and Sahni [20] report on an extensive simulation study involving mesh [14], power-law [22], and augmented directed chain (ADC) [20] networks. Figure 10.7 gives the smallest of the tested X values for which the CR becomes 1.0. For the case when $k = 2$, X is the bound placed on $|PATH(u)|$ and $|ipPATH(u)|$. In particular, for LGH, X is the number of positions in the one-dimensional array used to represent each *PATH(u)* and for IPH, X is the number of intervals for each *PATH(u)*. GLPH working on a network with n vertices is able to store at most $X*(n-1)$ paths, which is the maximum number of paths in all *PATH(u)* lists of LPH. For the hybrid heuristics HIPH1 and HIPH2, $|PATH(u)| \leq X$ and $|ipPATH(u)| \leq X$. For HIPH3 and HIPH4, $\sum |PATH(u)| \leq X*(n-1)$ and $|ipPATH(u)| \leq X$. Note that since every heuristic other than LGH stores both w_1 and w_2 for each path while LGH stores only w_1, the worst-case space requirements of LGH for any X are one-half for LPH and GLPH and one-fourth for HIPH1 through HIPH4. In Figure 10.7, X values labeled with an "$*$" indicate that the CR becomes almost 1.0, more precisely, larger than 0.99. So, for example, the entry $8*/16$ for GLPH, HIPH3, and HIPH4 working on 16 × 16 unbiased meshes means that these heuristics achieved a CR very close to 1.0 when $X = 8$ and a CR of 1.0 when $X = 16$. The "$-$" in the entry for 16 × 16 unbiased meshes for LGH means that the CR ratio for LGH did not become close to 1.0 for any of the tested X values.

10.6.9 Summary

All of the studied *k-MCP* heuristics, with the exception of GLPH, become ϵ-approximation schemes when the bucket size is chosen as in Section 10.6.3. Although GLPH has the same bound on total memory as does the limited path heuristic LPH of Ref. [14], GLPH provides better CR; in fact, GLPH finds a feasible path whenever LPH does and is able to find feasible solutions for several instances on which LPH fails to do so. The IPH heuristic achieves significantly better CRs than are achieved by the LGH of Ref. [14]. LPH and GLPH do well on graphs in which there is at least one feasible path that has a small number of edges. On ADCs that do not have such feasible paths, LPH and GLPH provide miserable performance [20]. The hybrid heuristics HIPH1 through HIPH4 combine the merits of IPH (ϵ-approximation when bucket size is chosen properly) and LPH and GLPH (guaranteed success when the graph has a feasible path with few edges). Of the four hybrid heuristics, HIPH4 performed best in the experiments of Ref. [20].

11.1 Introduction

We illustrate the concept of asymptotic (fully) polynomial-time approximation schemes (APTAS, AFPTAS) via a study of the bin packing problem. We discuss in detail an APTAS due to Fernandez de la Vega and Lueker [1] and an AFPTAS due to Karmakar and Karp [2]. Many of the algorithmic and analytical techniques described in this chapter can be applied elsewhere in the development and study of other polynomial-time approximation schemes. We conclude with a brief survey of other bin packing-related results and other examples of APTAS and AFPTAS.

We first introduce the classic bin packing problem, which is $\mathcal{NP}$-complete. Informally, we are given a collection of items of sizes between 0 and 1. We are required to pack them into bins of unit size so as to minimize the number of bins used. Thus, we have the following minimization problem.

BIN PACKING **(BP):**

- [**Instances**] $I = \{s_1, s_2, \ldots, s_n\}$, such that $\forall i,\ s_i \in [0, 1]$.
- [**Solutions**] A collection of subsets $\sigma = \{B_1, B_2, \ldots, B_k\}$ which is a disjoint partition of I, such that $\forall i,\ B_i \subset I$ and $\sum_{j \in B_i} s_j \leq 1$.
- [**Value**] The value of a solution is the number of bins used, or $f(\sigma) = |\sigma| = k$.

BIN PACKING is a perfect illustration of why sometimes the absolute performance ratio is not the best possible definition of the performance guarantee for an approximation algorithm. Recall that the absolute performance ratio, a.k.a. the approximation ratio, of an algorithm A for a minimization problem is defined as

$$R_A = \inf\left\{ r \mid R_A(I) = \frac{A(I)}{OPT(I)} < r, \forall I \right\}$$

where $A(I)$ and $OPT(I)$ denote the value of algorithm A's solution and the optimal solution for instance I, respectively.[1] Note that the problem of deciding if an instance of BIN PACKING has a solution with two bins is $\mathcal{NP}$-complete—this is exactly the PARTITION problem [3]. This implies that no algorithm can guarantee an approximation ratio better than 3/2 for BIN PACKING. Consequently, no approximation schemes, PTAS or FPTAS [4], exist for BIN PACKING.

The hardness of 3/2 comes from the fact that we cannot decide between two or three bins, a difference of one bin only. It is the small value of the optimum solution that makes the approximation ratio appear to be large; the approximation ratio is misleading, since on larger instances the ratio could still be bounded by a small constant. Therefore, we introduce the asymptotic performance ratio:

Definition 11.1

The asymptotic performance ratio, R_A^∞, *of an approximation algorithm A for an optimization problem is*

$$R_A^\infty = \inf\{r \mid \exists N_0,\ R_A(I) \le r \ \text{ for all } I \text{ with } OPT(I) \ge N_0\}$$

For BIN PACKING, the 3/2-hardness result does not preclude the existence of *asymptotic* approximation schemes, which give an approximation factor that approaches 1 in the limit:

Definition 11.2

An Asymptotic PTAS (APTAS) *is a family of algorithms* $\{A_\epsilon \mid \epsilon > 0\}$ *such that each* A_ϵ *runs in time polynomial in the length of the input and* $R_{A_\epsilon}^\infty \le 1 + \epsilon$.

Definition 11.3

An Asymptotic FPTAS (AFPTAS) *is a family of algorithms* $\{A_\epsilon \mid \epsilon > 0\}$ *such that each* A_ϵ *runs in time polynomial in the length of the input and* $1/\epsilon$, *while* $R_{A_\epsilon}^\infty \le 1 + \epsilon$.

In this chapter we present two algorithms, an APTAS and an AFPTAS, due to Fernandez de la Vega and Lueker [1] and Karmakar and Karp [2], respectively, for BIN PACKING. The algorithmic and analytic tools demonstrated here are widely applicable to the study and development of approximation schemes. Some of the techniques, such as interval partitioning, have been applied to similar problems such as Multiprocessor Scheduling, Knapsack [3] and various packing-related problems and their generalizations. Other techniques are more general and apply in a broader range of problem settings; for instance, linear programming is a very powerful tool and has been used with enormous success throughout operations research, management science, and theoretical computer science.

The rest of this chapter is organized as follows: Section 11.2 presents a summary of the techniques used in the two algorithms; Section 11.3 presents the APTAS, Section 11.4 presents the AFPTAS, and finally, Section 11.5 summarizes some other results related to BIN PACKING, and lists some other examples of APTAS and AFPTAS.

11.2 Summary of Algorithms and Techniques

The first result we present is due to Fernandez de la Vega and Lueker [1], who provided an APTAS for BIN PACKING that runs in *linear time* and has $A_\epsilon(I) \le (1+\epsilon) \cdot OPT(I) + 1$. To be more specific, the running time is linear in the size of the input instance I but is severely exponential in ϵ. Note that the reason this scheme is an APTAS, and not a PTAS, is the additive error term of 1 in the approximation bound. The basic techniques used in this result may be summarized as follows:

[1] $R_A(I)$, the absolute performance ratio of algorithm A on an input instance I, is defined as $OPT(I)/A(I)$ for maximization problems. Such a definition ensures that $R_A(I) \ge 1$ always.

- Separate handling of “small” items.
- Discretization via interval partitioning or linear grouping.
- Rounding of “fractional” solutions.

We then present the modification of this result due to Karmakar and Karp [2], which leads to an AFPTAS for BIN PACKING. They give an approximation scheme with a performance guarantee similar to the one described above, with running time improved to $O(\frac{n \log n}{\epsilon^8})$.

We now derive the results described above. Our presentation combines the methods of Fernandez de la Vega and Lueker with those of Karmakar and Karp, as the two techniques share many of the same basic tools. The general approach used in both techniques is as follows: We first define a restricted version of the problem in which all items are of at least some minimum size, and the item sizes can only take on a few distinct values. This new version of BIN PACKING turns out to be reasonably easy to solve. Then we provide a two-step reduction from the original problem instance to a restricted problem instance. The first step is to pull out the “small” items; it is shown that given any packing of the remaining items, the small items can be added back in without a significant increase in the number of bins used. The second step is to divide the item sizes into m intervals, and replace all items in the same interval by items of the same size. It turns out that this “linear grouping” affects the value of the optimal solution only marginally. In the next two sections, we consider each of these ingredients in turn and finally show how they can be combined to produce an APTAS and then an AFPTAS.

11.3 Asymptotic Polynomial-Time Approximation Scheme

Definition 11.4

For any instance $I = \{s_1, \ldots, s_n\}$, let $SIZE(I) = \sum_{i=1}^{n} s_i$ denote the total size of the n items.

Recall that $OPT(I)$ denotes the value of the optimal solution, i.e., the minimum number of unit size bins needed to pack the items. We now give two inequalities relating these quantities.

Lemma 11.1

$SIZE(I) \leq OPT(I) \leq |I| = n.$

Proof

In the optimal solution, at best each bin is filled to its maximum capacity, i.e., 1. Thus, the total number of bins needed is at least $SIZE(I)/1$, proving $SIZE(I) \leq OPT(I)$. Since each item is of size between 0 and 1, putting each item in a separate bin is clearly a feasible (if not optimal) solution, proving $OPT(I) \leq |I| = n$. □

Lemma 11.2

$OPT(I) \leq 2 \cdot SIZE(I) + 1.$

Proof

Prove by contradiction. Suppose this is not the case, i.e., there exists an instance I, where $OPT(I) > 2 \cdot SIZE(I) + 1$. Then in the optimal solution, there must exist at least two bins that are at least half empty. Otherwise, we have at least $OPT(I) - 1$ number of bins that are at least half full, i.e., $(OPT(I) - 1)/2 \leq SIZE(I)$, which contradicts our initial assumption. Now the fact that we have two bins at least half empty contradicts the assumption that we have an optimal solution. We could have easily combined the two bins into one, and reduce the number of bins used by 1. Thus, our initial assumption must be false, proving the lemma. □

We will represent an instance I as an *ordered* list of items $I = s_1 s_2 \ldots s_n$ such that $1 \geq s_1 \geq s_2 \geq \cdots \geq s_n > 0$.

Definition 11.5

Let $I_1 = x_1 x_2 \dots x_n$ and $I_2 = y_1 y_2 \dots y_n$ be two instances of equal cardinality. The instance I_1 is said to **dominate** *the instance I_2, or $I_1 \geq I_2$, if it is the case that $x_i \geq y_i$, for all i.*

The following lemma follows from the fact that any feasible packing of I_1 gives a feasible packing of I_2, using the same number of bins.

Lemma 11.3

Let I_1 and I_2 be two instances of equal cardinality such that $I_1 \geq I_2$. Then, $SIZE(I_1) \geq SIZE(I_2)$ and $OPT(I_1) \geq OPT(I_2)$.

We define a restricted version of BIN PACKING as follows. Suppose that the item sizes in I take on only m distinct values. Now the instance I can be represented as a multiset of items which are drawn from these m types of items.

Definition 11.6

Suppose that we are given m distinct item sizes $V = \{v_1, \dots, v_m\}$, such that $1 \geq v_1 > v_2 > \cdots > v_m > 0$, and an instance I of items whose sizes are drawn only from V. Then, we can represent I as multiset $M_I = \{n_1 : v_1, n_2 : v_2, \dots, n_m : v_m\}$, where n_i is a nonnegative integer denoting the number of items in I of size v_i.

It follows that $|M_I| = \sum_{i=1}^{m} n_i = n$, $SIZE(M_I) = \sum_{i=1}^{m} n_i v_i = SIZE(I)$ and $OPT(M_I) = OPT(I)$. We now define RBP, the restricted version of BIN PACKING.

Definition 11.7

For all $0 < \delta < 1$ and positive integers m, the problem $RBP[\delta, m]$ is defined as BIN PACKING *restricted to instances where the item sizes take on at most m distinct values and the size of each item is at least δ.*

Next we show how to approximately solve *RBP* via a linear programming formulation.

11.3.1 Restricted Bin Packing

Assume that δ and m are fixed independently of the input size n. The input instance for $RBP[\delta, m]$ is a multiset $M = \{n_1 : v_1, n_2 : v_2, \dots, n_m : v_m\}$, such that $1 \geq v_1 > v_2 > \cdots > v_m \geq \delta$. Let $n = |M| = \sum_{i=1}^{n} n_i$. In the following discussion, we will assume that the underlying set V for M is fixed. Note that, given M, it is trivial to determine V and verify that M is a valid instance of $RBP[\delta, m]$.

Consider a packing of some subset of the items in M into a unit size bin. We can denote this packing by a multiset $\{b_1 : v_1, b_2 : v_2, \dots, b_m : v_m\}$, such that b_i is the number of items of size v_i that are packed into the bin. More concisely, having fixed V, we can denote the packing by the m-vector $B = (b_1, \dots, b_m)$ of nonnegative integers. We will say that two bins packed with items from M are of the same *type* if the corresponding packing vectors are identical:

Definition 11.8

A bin type *T is an m-vector $(T_1, \dots, T_m)$ of nonnegative integers such that $\sum_{i=1}^{m} T_i v_i \leq 1$.*

Having fixed the set V, the collection of possible bin types is fully determined and is finite, because each T_i in T must take on an integer value from 0 to $\lfloor 1/v_i \rfloor$. Let $T^1, \dots, T^q$ denote the set of all legal bin types with respect to V. Here q, the number of distinct types, is a function of δ and m. We bound the value of q in the following lemma:

Lemma 11.4

Let $k = \lfloor \frac{1}{\delta} \rfloor$. Then

$$q(\delta, m) \leq \binom{m+k}{k}$$

Proof

Each type vector $T^t = (T_1^t, \ldots, T_m^t)$ has the property that, for all i, $T_i^t \geq 0$ and $\sum_{i=1}^{m} T_i^t v_i \leq 1$. It follows that $\sum_{i=1}^{m} T_i^t \leq k$, since we have a lower bound of δ on the values v_i in V. Thus, each type vector corresponds to a way of choosing m nonnegative integers whose sum is at most k. This is the same as choosing $m + 1$ nonnegative integers whose sum is exactly k. The number of such choices is an upper bound on the value of q. A standard counting argument now gives the desired bound. □

Consider an arbitrary feasible solution x to an instance M of $RBP[\delta, m]$. Each packed bin in this solution can be classified as belonging to one of the $q(\delta, m)$ possible types of packed bins. The solution x can therefore be specified completely by a vector giving the number of bins of each of the q types.

Definition 11.9

A feasible solution x to an instance M of $RBP[\delta, m]$ is a q-vector of nonnegative integers, say $x = (x_1, \ldots, x_q)$, where x_t denotes the number of bins of type T^t used in x.

Note that not all q-vectors correspond to a feasible solution. A feasible solution must guarantee, for each i, that exactly n_i items of size v_i are packed in the various copies of the bin types. The feasibility condition can be phrased as a series of linear equations as follows:

$$\forall i \in \{1, \ldots, m\}, \quad \sum_{t=1}^{q} x_t T_i^t = n_i$$

Let the matrix A be a $q \times m$ matrix whose tth row is the type vector T^t, and $\vec{n} = (n_1, \ldots, n_m)$ denote the multiplicities of the various item sizes in the input instance M. Then the above set of equations can be concisely expressed as $\vec{x}.A = \vec{n}$. The number of bins used in the solution x is simply $\vec{x} \cdot \vec{1} = \sum_{t=1}^{q} x_t$, where $\vec{1}$ denotes all-ones vector. In fact, we have proved the following lemma.

Lemma 11.5

The optimal solution to an instance M of $RBP[\delta, m]$ is exactly the solution to the following integer linear program ILP(M)

$$\begin{aligned} \text{minimize} \quad & \vec{x} \cdot \vec{1} \\ \text{subject to} \quad & \\ & \vec{x} \geq 0 \\ & \vec{x} \cdot A \geq \vec{n} \end{aligned}$$

We have replaced the equations by inequalities, but, since a packing of a superset of M can always be converted into a packing of M using the same number of bins, the validity of the lemma is unaffected. It is also worth noting that the matrix A is determined completely by the underlying set V; the vector $\vec{n}$, however, is not determined *a priori* but depends on the instance M.

How easy is it to obtain this integer program? Note that the number of constraints in ILP(M) is exponentially large in terms of δ and m. However, we are going to assume that both δ and m are constants which are fixed independently of the length of the input, which is n. Thus, ILP(M) can be obtained in time linear in n, given any instance M of cardinality n.

How about solving ILP? Recall that the integer programming problem is $\mathcal{NP}$-complete in general [3]. However, there is an algorithm due to Lenstra [5–7] that solves any integer linear program in time linear in the number of constraints, provided the number of variables is fixed. This is exactly the situation in ILP: the number of variables q is fixed independent of n, as is the number of constraints, which is $q + m$. Thus, we can solve ILP exactly in time independent of n. (A more efficient algorithm for approximately solving ILP will be described in a later section.) The following theorem results. Here $f(\delta, m)$ is some constant which depends only on δ and m.

Theorem 11.1

Any instance of RBP$[\delta, m]$ can be solved in time $O(n + f(\delta, m))$.

11.3.2 Eliminating Small Items

We now present the second ingredient of the APTAS devised by Fernandez de la Vega and Lueker: the separate handling of small items. It is shown that if we have a packing of all items except those whose sizes are bounded from above by δ, then it is possible to add the small items back in without much increase in the number of bins. This fact is summarized in the following lemma; the rest of this subsection is devoted to the proof of this lemma.

Lemma 11.6

Fix some constant $\delta \in (0, \frac{1}{2}]$. Let I be an instance of BIN PACKING *and suppose that all items of size greater than δ have been packed into β bins. Then it is possible to find in linear time a packing for I which uses at most* $\max\{\beta, (1+2\delta)\cdot OPT(I)+1\}$ *bins.*

Proof

The basic idea is to start with the packing of the "large" items and to use the greedy algorithm First Fit to pack the "small" items into the empty space in the β bins.

First Fit (*FF*) is a classic bin packing algorithm of historical importance, as we shall see later. The algorithm is as follows. We are given the set of items in an arbitrary order, and we start with zero bins. For each item in the list, we consider the existing bins (if any) in order and place the item in the first bin that can accommodate it. If no existing bin can accommodate it, we make a new bin after all the existing ones, and put the item in the new bin.

To use First Fit to add the small items into an existing packing of the large ones, we can start by numbering the β bins in an arbitrary fashion, and also ordering the small items arbitrarily. Then we run First Fit as usual using this ordering to decide where each small item will be placed. If at some point the small items do not fit into any of the currently available bins, a new bin is initiated.

In the best case, the small items can all be greedily packed into the β bins which were open initially. Clearly, the lemma is valid in that case. Suppose now that some new bins were required for the small items. We claim that at the end of the entire process, each of the bins used for packing I has at most δ empty space in it, with the possible exception of at most one bin. To see why this claim holds, note that at the moment when the first new bin was started, each of the original bins must have had at most δ free space. Next, observe that whenever another new bin was opened, no earlier bin could have had more than δ free space. Therefore, at every moment, at most one bin had more than δ free space.

Let $\beta' > \beta$ be the total number of bins used by *FF*. We are guaranteed that all the bins, except one, are at least $1-\delta$ full. This implies that *SIZE*$(I) \geq (1-\delta)(\beta'-1)$. But we know that *SIZE*$(I) \leq OPT(I)$, implying that

$$\beta' \leq \frac{1}{1-\delta} OPT(I) + 1 \leq (1+2\delta)\cdot OPT(I) + 1$$

and we have the desired result. □

11.3.3 Linear Grouping

The final ingredient needed for the APTAS is called interval partitioning or linear grouping. This is a technique for converting an instance I of BIN PACKING into an instance M of *RBP*$[\delta, m]$, for an appropriate choice of δ and m, without changing the value of the optimal solution too much. Let us assume for now that all the items in I are of size at least δ, for some choice of $\delta \in (0, \frac{1}{2}]$. All that remains is to show how to obtain an instance where the item sizes take on only m different values. First, let us fix some parameter k, a nonnegative integer to be specified later. We now show how to convert an instance of *RBP*$[\delta, n]$ into an instance of *RBP*$[\delta, m]$, for $m = \lfloor n/k \rfloor$.

Definition 11.10

Given an instance I of RBP$[\delta, n]$ and a parameter k, let $m = \lfloor n/k \rfloor$. Define the groups of items $G_i = s_{(i-1)k+1} \ldots s_{ik}$, for $i = 1, \ldots, m$, and let $G_{m+1} = s_{mk+1} \ldots s_n$.

Here, the group G_1 contains the k largest items in I, G_2 the next k largest items, and so on. The following fact is an easy consequence of these definitions.

Fact 11.1

$G_1 \geq G_2 \geq \cdots \geq G_m$.

From each group G_i we can obtain a new group of items H_i by increasing the size of each item in G_i to that of the largest item in that group. The following fact is also obvious.

Definition 11.11

Let $v_i = s_{(i-1)k+1}$ be the largest item in group G_i. Then the group H_i is a group of $|G_i|$ items, each of size v_i. In other words, $H_i = v_i v_i \ldots v_i$ and $|H_i| = |G_i|$.

Fact 11.2

$H_1 \geq G_1 \geq H_2 \geq G_2 \geq \cdots \geq H_m \geq G_m$ *and* $H_{m+1} \geq G_{m+1}$.

The entire point of these definitions is to obtain two instances of *RBP*$[\delta, m]$ such that their optimal solutions bracket the optimal solution for I. These instances are defined as follows.

Definition 11.12

Let the instance $I_{LO} = H_2 H_3 \ldots H_{m+1}$ and $I_{HI} = H_1 H_2 H_3 \ldots H_{m+1}$.

Note that I_{LO} is an instance of *RBP*$[\delta, m]$. Moreover, it is easy to see that $I \leq I_{HI}$. We now present some properties of these three instances.

Lemma 11.7

$$OPT(I_{LO}) \leq OPT(I) \leq OPT(I_{HI}) \leq OPT(I_{LO}) + k$$
$$SIZE(I_{LO}) \leq SIZE(I) \leq SIZE(I_{HI}) \leq SIZE(I_{LO}) + k$$

Proof

First, observe that

$$I_{LO} = H_2 H_3 \ldots H_m H_{m+1} \leq G_1 G_2 \ldots G_{m-1} X$$

where X is any set of $|H_{m+1}|$ items from G_m. The right-hand side of this inequality is a subset of I, and so, from Lemma 11.3, $OPT(I_{LO}) \leq OPT(I)$ and $SIZE(I_{LO}) \leq SIZE(I)$. Similarly, since $I \leq I_{HI}$, $OPT(I) \leq OPT(I_{HI})$ and $SIZE(I) \leq SIZE(I_{HI})$.

Now observe that $I_{HI} = H_1 I_{LO}$. Given any packing of I_{LO}, we can obtain a packing of I_{HI} which uses at most k extra bins. (Just pack each item in H_1 in a separate bin.) This implies that $OPT(I_{HI}) \leq OPT(I_{LO}) + k$ and $SIZE(I_{HI}) = SIZE(I_{LO}) + SIZE(H_1) \leq SIZE(I_{LO}) + k$. □

It is worth noting that the result presented in this lemma is constructive. It is possible in $O(n \log n)$ time to construct the instances I_{LO} and I_{HI}, and given an optimal packing of I_{LO} it is possible to construct a packing of I that meets the guarantee of the above lemma. To construct I_{LO} and I_{HI}, it is necessary only to sort the items and perform the linear grouping. (Actually, one ingredient is still unspecified, namely the value of k; this will be given in the next section.) Given a packing of I_{LO}, we can assign all elements in $I \backslash G_1$ to bins according to the assignments of the corresponding members of I_{LO}; finally, each member of G_1 can get its own bin.

11.3.4 APTAS for Bin Packing

We now put together all these ingredients and obtain the APTAS. The algorithm A_ϵ, for any $\epsilon \in (0, 1]$, takes as input an instance I of BIN PACKING consisting of n items.

Algorithm A_ϵ:
Input: Instance I consisting of n item sizes $\{s_1, \ldots, s_n\}$.
Output: A packing into unit-sized bins.

1. $\delta \leftarrow \frac{\epsilon}{2}$
2. Set aside all items of size smaller than δ, obtaining an instance J of $RBP[\delta, n']$ with $n' = |J|$.
3. $k \leftarrow \lceil \frac{\epsilon^2}{2} n' \rceil$
4. Perform linear grouping on J with parameter k. Let J_{LO} be the resulting instance of $RBP[\delta, m]$ and $J_{HI} = H_1 \cup J_{LO}$, with $|H_1| = k$ and $m = \lfloor \frac{n'}{k} \rfloor$.
5. Pack J_{LO} optimally using Lenstra's algorithm on $ILP(J_{LO})$.
6. Pack the k items in H_1 into at most k bins.
7. Obtain a packing of J using the same number of bins as in steps 5 and 6, by replacing each item in J_{HI} by the corresponding (smaller) item in J.
8. Using FF, pack all the small items set aside in step 2, using new bins only if necessary.

How many bins does A_ϵ use in the worst case? Observe that we have packed the items in J_{HI}, hence the items in J, into at most $OPT(J_{LO}) + k$ bins. Consider now the value of k in terms of the optimal solution. Since all items have size at least $\epsilon/2$ in J, it must be the case that $SIZE(J) \geq \epsilon n'/2$. This implies that

$$k \leq \frac{\epsilon^2 n'}{2} + 1 \leq \epsilon \cdot SIZE(J) + 1 \leq \epsilon \cdot OPT(J) + 1$$

Using Lemma 11.7, we obtain that J is packed into a number of bins not exceeding

$$OPT(J_{LO}) + k \leq OPT(J) + \epsilon \cdot OPT(J) + 1 \leq (1 + \epsilon) \cdot OPT(J) + 1$$

Finally, Lemma 11.6 implies that, while packing the small items at the last step, we use a number of bins not exceeding

$$\max\{(1 + \epsilon) \cdot OPT(J) + 1,\ (1 + \epsilon) \cdot OPT(I) + 1\} \leq (1 + \epsilon) \cdot OPT(I) + 1$$

since $OPT(J) \leq OPT(I)$. We have obtained the following theorem.

Theorem 11.2

The algorithm A_ϵ finds a packing of I into at most $(1 + \epsilon) \cdot OPT(I) + 1$ bins in time $c(\epsilon) n \log n$, where $c(\epsilon)$ is a constant depending only on ϵ.

For the running time, note that the only really expensive step in the algorithm is the one where we solve ILP using Lenstra's algorithm. As we observed earlier, this requires time linear in n, although it may be severely exponential in δ and m, which are functions of ϵ.

11.4 Asymptotic Fully Polynomial-Time Approximation Scheme

Our next goal is to convert the preceding APTAS into an AFPTAS. The reason that the above scheme is not fully polynomial is the use of the algorithm for integer linear programming, which requires time exponential in $1/\epsilon$. We now describe a technique for getting rid of this step via the construction of a "fractional" solution to the restricted bin packing problem, and a "rounding" of this to a feasible solution which is not very far from optimal. This is based on the ideas due to Karmakar and Karp.

11.4.1 Fractional Bin Packing and Rounding

Consider again the problem *RBP*$[\delta, m]$. By the preceding discussion, any instance I of this problem can be formulated as the integer linear program *ILP*(I).

$$\begin{array}{ll} \text{minimize} & \vec{x} \cdot \vec{1} \\ \text{subject to} & \\ & \vec{x} \geq 0 \\ & \vec{x} \cdot A = \vec{n} \end{array}$$

Note that we are stating the last constraint as we originally did: as an equality. Recall that A is a $q \times m$ matrix, $\vec{x}$ a q-vector, and $\vec{n}$ an m-vector. The bin types matrix A as well as $\vec{n}$ are determined by the instance I.

Consider now the linear programming relaxation of *ILP*(I). This system *LP*(I) is exactly the same as *ILP*(I), except that we now relax the requirement that $\vec{x}$ be an integer vector. Recall that *SIZE*(I) is the total size of the items in I, and that *OPT*(I) is the value of the optimal solution to *ILP*(I) as well as the smallest number of bins into which the items of I can be packed.

Definition 11.13

LIN(I) *is the value of the optimal solution to LP*(I)*, the linear programming relaxation of ILP*(I).

What does a noninteger solution to *LP*(I) mean? The value of x_i is a real number that denotes the number of bins of type T^i which are used in the optimal packing. One may interpret this as saying that items can be "broken up" into fractional parts, and these fractional parts can then be packed into fractional bins. This in general would give us a solution of value *SIZE*(I), but keep in mind that the constraints in *LP*(I) do not allow any arbitrary "fractionalization." The constraints require that in any fractional bin, the items packed therein must be the same fraction of the original items. Thus, this solution does capture some of the features of the original problem. We will refer to the solution of *LP*(I) as a *fractional bin packing.*

To analyze the relationship between the fractional and integral solutions to any instance we will have to use some basic facts from the theory of linear programming. The uninitiated reader is referred to any standard textbook for a more complete treatment; e.g., see the book by Papadimitriou and Steiglitz [8].

Consider the system of linear equations implicit in the constraint[2] $\vec{x}.A = \vec{n}$. Here we have m linear equations in q variables, where q is much larger than m. This is an underconstrained system of equations. Let us assume that $rank(A) = m$; it is easy to modify the following analysis when $rank(A) < m$. Assume, without loss of generality, that the first m rows of A form a basis, i.e., they are linearly independent. The following are standard observations from linear programming theory.

Definition 11.14

A basic feasible solution *to LP is a solution* $\vec{x}^*$ *such that only the entries corresponding to the basis of A are nonzero. In other words,* $x_i^* = 0$ *for all* $i > m$.

Fact 11.3

Every LP has an optimal *solution which is a basic feasible solution.*

We can now derive the following lemma which relates *LIN*(I) to both *SIZE*(I) and *OPT*(I).

Lemma 11.8

For all instances I of RBP$[\delta, m]$,

$$SIZE(I) \leq LIN(I) \leq OPT(I) \leq LIN(I) + \frac{m+1}{2}$$

[2] We will ignore the nonnegativity constraints for now as they do not bear upon the following discussion.

Proof

To prove the first inequality, we note that $SIZE(I) = \sum_{j=1}^{m} n_j v_j = \sum_{j=1}^{m} (\vec{x} \cdot A_j) v_j$, where we use A_j to mean the jth column of A. This sum is equal to $\sum_{i=1}^{q} x_i (\sum_{j=1}^{m} a_{ij} v_j)$. Note that for all $1 \leq i \leq q$, $\sum_{j=1}^{m} a_{ij} v_j \leq 1$ is the total size accounted for by the ith bin type and is therefore at most 1. It follows that $SIZE(I) \leq \sum_{i=1}^{q} x_i = LIN(I)$. The second inequality follows from the observation that an optimal solution to $ILP(I)$ is also a feasible solution to $LP(I)$.

To see the last inequality, fix I and let $\vec{y}$ be some basic optimal solution to $LP(I)$. Since $\vec{y}$ has at most m nonzero entries, it uses only m different types of bins. Rounding up the value of each component of $\vec{y}$ will increase the number of bins by at most m, and will yield a solution to ILP. The bound promised in the lemma is slightly stronger and may be observed as follows. Define the vectors $\vec{w}$ and $\vec{z}$ in the following way:

$$\forall i, \quad w_i = \lfloor y_i \rfloor$$
$$\forall i, \quad z_i = y_i - w_i$$

The vector $\vec{w}$ is the integer part of the solution and $\vec{z}$ the fractional part. Let J denote the instance of $RBP[\delta, m]$ that consists of the items not packed in the (integral) solution specified by $\vec{w}$. (Note that J is, indeed, a legal instance of $RBP[\delta, m]$, i.e., all items occur in integral quantities, because in $\vec{w}$, all bin types, and therefore all items, occur in integral quantities.) The vector $\vec{z}$ gives a fractional packing of the items in J, such that each of the m bin types is used a number of times which is a fraction less than 1.

Just as $SIZE(I) \leq LIN(I)$, a similar argument implies that

$$SIZE(J) \leq LIN(J)$$

By Lemma 11.2 we know that

$$OPT(J) \leq 2 \cdot SIZE(J) + 1$$

It is also obvious that $OPT(J) \leq \sum_{i=1}^{m} z_i \leq m$, since rounding each nonzero z_i up to 1 gives a feasible packing of J. Thus,

$$\begin{aligned} OPT(J) &\leq \min\{m,\ 2 \cdot SIZE(J) + 1\} \\ &\leq (m + 2 \cdot SIZE(J) + 1)/2 \\ &= SIZE(J) + \frac{m+1}{2} \end{aligned}$$

We will now bound $OPT(I)$ in terms of $LIN(I)$ and m.

$$\begin{aligned} OPT(I) &\leq OPT(I - J) + OPT(J) \\ &\leq \sum_{i=1}^{m} w_i + \left(SIZE(J) + \frac{m+1}{2} \right) \\ &\leq \sum_{i=1}^{m} w_i + LIN(J) + \frac{m+1}{2} \\ &\leq \sum_{i=1}^{m} w_i + \sum_{i=1}^{m} z_i + \frac{m+1}{2} \\ &= LIN(I) + \frac{m+1}{2} \end{aligned}$$

The first inequality follows from the fact that independent integer packings of $I - J$ and J can be combined to form an integer packing of I. The second and third follow from facts proved above, and the fact that $\vec{w}$ is a feasible solution to the $RBP[\delta, m]$ instance I. The fourth holds because $\vec{z}$ is a feasible fractional packing of J. Finally, the equality holds by the optimality of $\vec{y}$ as a solution to $LIN(I)$. □

It is not very hard to see that all of the above is constructive. More precisely, given the solution to $LP(I)$, we can construct in linear time a solution to I such that the bound from the above theorem is met: We take an optimal basic solution $\vec{y}$ and break it into $\vec{w}$ and $\vec{z}$ as described, and define J as above. We find an integral solution for J either by rounding up each nonzero entry to 1 or by using First Fit, whichever produces a better solution. We then put together the solution given by $\vec{w}$ and that found for J.

The only problem is that it is not obvious that we can solve the linear program in fully polynomial time, even though there exist polynomial-time algorithms for linear programming [9], unlike the general problem of integer programming. The reason is that the number of variables is still exponential in $1/\epsilon$. All we have achieved is that we no longer need to solve an integer program.

Karmakar and Karp show how to get around this problem by resorting to the ellipsoid method of Grötschel et al. [6,7,10]. In this method, it is possible to solve a linear program with an exponential number of constraints in time which is polynomial in the number of variables and the number sizes, given a *separation oracle*. A separation oracle takes any proposed solution vector $\vec{x}$ and either guarantees that it is a feasible solution, or provides any one constraint which is violated by it. Karmakar and Karp gave an efficient construction of a separation oracle for $LP(I)$. This would result in a polynomial-time algorithm for $LP(I)$ if it had a small number of variables, even if it has an exponential number of constraints. Since our situation is exactly the reverse, i.e., we have a small number of constraints and an exponential number of variables, we will consider the *dual linear program* for $LP(I)$, which has the desired features of a small number of variables. By Linear Program Duality, its optimal solution corresponds exactly to the optimal solution of $LP(I)$.

One important detail is that it is impossible to solve $LP(I)$ exactly in fully polynomial time. However, it can be solved within an additive error of 1 in fully polynomial time. Moreover, the implementation of the separation oracle is in itself an approximation algorithm. The idea behind this method is due to Gilmore and Gomory [11] who observed that, in the case of an infeasible proposed solution, a violated constraint can be computed via the solution of a knapsack problem. Since this problem is $\mathcal{NP}$-complete, one must resort to the use of an approximation scheme for KNAPSACK [3], and so the solution of the dual is not exact but a close approximation. Karmakar and Karp used this approximate solution to the dual to obtain an approximate lower bound on the optimal value of the original problem. Having devised the procedure for efficiently computing an approximate lower bound, they then construct an approximate solution.

This algorithm is rather formidable and the details are omitted as it is outside the scope of this discussion. The following theorem results.

Theorem 11.3

There is a fully polynomial-time algorithm A for solving an instance I of $RBP[\delta, m]$ such that $A(I) \leq LIN(I) + \frac{m+1}{2} + 1$.

11.4.2 AFPTAS for Bin Packing

We are now ready to present the AFPTAS for BIN PACKING. We will need the following variant of Lemma 11.7.

Lemma 11.9

Using the linear grouping scheme on an instance I of $RBP[\delta, n]$, we obtain an instance I_{LO} of $RBP[\delta, m]$ and a group H_1 such that, for $I_{HI} = H_1 I_{LO}$,

$$LIN(I_{LO}) \leq LIN(I) \leq LIN(I_{HI}) \leq LIN(I_{LO}) + k$$

Proof

The proof is almost identical to that of Lemma 11.7. Recall that $m = \lfloor n/k \rfloor$. Take the original instance I, and define $G_1, \ldots, G_{m+1}, H_1, \ldots, H_m, I_{LO}$, and I_{HI} as before. From Lemma 11.3 the first two inequalities follow. The third follows from the fact that, given a solution to I_{LO}, we can solve I_{HI} by putting all members of $I_{HI} \cup I_{LO}$ in the bins assigned by the given solution, and then putting each member of H_1 in a bin by itself. □

The basic idea behind the AFPTAS of Karmakar and Karp is very similar to that used in the APTAS. We first eliminate all the small items, and then apply linear grouping to the remaining items. The resulting instance of $RBP[\delta, m]$ is then formulated as an *ILP*, and the solution to the corresponding relaxation *LP* is computed using the ellipsoid method. The fractional solution is then rounded to an integer solution. The small items are then added into the resulting packing exactly as before.

Algorithm A_ϵ:
Input: Instance I consisting of n item sizes $\{s_1, \ldots, s_n\}$.
Output: A packing into unit-sized bins.

```
1. $\delta \leftarrow \frac{\epsilon}{2}$.
2. Set aside all items of size smaller than $\delta$, obtaining an instance $J$ of $RBP[\delta, n']$ with $n' = |J|$.
3. $k \leftarrow \lceil \frac{\epsilon^2 n'}{2} \rceil$
4. Perform linear grouping on $J$ with parameter $k$. Let $J_{LO}$ be the resulting instance of $RBP[\delta, m]$ and
   $J_{HI} = H_1 \cup J_{LO}$, with $|H_1| = k$ and $m = \lfloor \frac{n'}{k} \rfloor$.
5. Pack the $k$ items in $H_1$ into at most $k$ bins.
6. Pack $J_{LO}$ using the ellipsoid method and rounding the resulting fractional solution.
7. Obtain a packing of $J$ using the same number of bins as used for $J_{HI}$, by replacing each item in $J_{HI}$
   by the corresponding (smaller) item in $J$.
8. Using FF, pack all the small items set aside in step 2, using new bins only if necessary.
```

Theorem 11.4

The approximation scheme $\{A_\epsilon : \epsilon > 0\}$ is an AFPTAS for BIN PACKING *such that*

$$A_\epsilon(I) \leq (1+\epsilon) \cdot OPT(I) + \frac{1}{\epsilon^2} + 3$$

Proof
The running time is dominated by the time required to solve the linear program, and we are guaranteed that this is fully polynomial.

By Lemma 11.8, the number of bins used to pack the items in J_{LO} is at most

$$(LIN(J_{LO}) + 1) + \frac{m+1}{2} \leq OPT(I) + \frac{1}{\epsilon^2} + 2$$

given the preceding lemmas and the choice of m. The number of bins used to pack the items in H_1 is at most k, which in turn can be bounded as follows using the observation that $OPT(J) \geq SIZE(J) \geq \epsilon n'/2$:

$$k \leq \left\lceil \frac{n'\epsilon^2}{2} \right\rceil \leq \epsilon \cdot OPT(J) + 1 \leq \epsilon \cdot OPT(I) + 1$$

Thus, the total number of bins used to pack the items in J cannot exceed

$$(1+\epsilon) \cdot OPT(I) + \frac{1}{\epsilon^2} + 3$$

Lemma 11.6 guarantees that the small items can be added without an increase in the number of bins, and so the desired result follows. □

11.5 Related Results

We conclude the chapter by presenting a literature survey on topics related to BIN PACKING and asymptotic approximation schemes.

BIN PACKING is a classic problem in theoretical computer science; the algorithms proposed for this problem, and the analysis of these algorithms, employ a wide variety of techniques. In the foregoing discussion, we used the fact that the First Fit algorithm has an asymptotic worst-case performance ratio of 2, but this is not the best bound. Ullman [12] proved an asymptotic worst-case performance bound of 17/10 for this algorithm, and subsequent papers [13–15] reduced the additive constant term from 3 to 1 or less eventually. First Fit is not the only algorithm considered for BIN PACKING. Many other online algorithms, semionline algorithms, and offline algorithms have been proposed and their worst- and average-case behavior studied extensively. We refer the reader to survey articles by Coffman et al. [16–18], and Chapters 32–35 of this handbook for further details.

There are several commonly considered variants of the basic bin packing problem, all of which are $\mathcal{NP}$-complete. In most of these cases, it is reasonably easy to come up with bounded-ratio approximations. These variants can be classified under four main headings: packings in which the number of items per bin is bounded, packings in which certain items cannot be packed into the same bin, packings in which there are constraints (e.g., partial orders) on the way in which the items are packed, and dynamic packings in which items may be added and deleted. These variants are discussed in Chapters 33–35 of this handbook.

There are also some generalizations of the basic packing problem, many of which are covered in the three survey papers and chapters mentioned above. While some generalizations do not admit APTAS or AFPTAS, several approximation schemes have been found successful, generally based on the ideas described above. Here we focus on three generalizations that admit APTAS and AFPTAS: packings into variable-sized bins, multidimensional bin packing, and BIN COVERING, the dual of BIN PACKING.

Murgolo shows an approximation scheme for the case of variable-sized bins [19]. For multidimensional bin packing, APTAS have recently been found for packing d-dimensional[3] cubes into the minimum number of unit cubes by Bansal and Sviridenko [20], and Correa and Kenyon [21], independently. Interestingly, the problem of packing (two-dimensional) rectangles into squares does not admit APTAS or AFPTAS [20]. However, for a more restricted version, namely, a two-stage packing of the rectangles, Caprara et al. show an AFPTAS [22]. The dual problem of BIN PACKING is BIN COVERING, in which we want to maximize the total number of bins used, but must fill each bin to at least a certain capacity. Jansen and Solis-Oba show an AFPTAS for BIN COVERING [23].

BIN PACKING is not the only problem that admits APTAS and AFPTAS. Raghavan and Thompson give an APTAS for the 0–1 multicommodity flow problem [24]. Their approaches include probabilistic rounding of fractional linear-programming solutions. Cohen and Nakibli [25] show an APTAS for a somewhat related problem, the n-hub shortest path routing problem. The goal is to minimize the overloading of links in a directed network with pairwise source–sink flows, by setting an n-hub route for each source–sink pair. This APTAS also uses probabilistic rounding. Aingworth et al. [26] show an AFPTAS for pricing Asian options on the lattice, using discretization to reduce the number of possible option values.

There are other problems that admit *absolute* approximation algorithms, i.e., algorithms guaranteed to produce solutions whose costs are at most an additive constant away from the optimal. In contrast to APTAS and AFPTAS, whose approximation ratios approach a value arbitrarily *close* to 1 as the optimal cost grows, these algorithms have an asymptotic performance ratio *equal* to 1; that is, as the optimal cost grows, the approximation ratio of an absolute approximation algorithm approaches 1 itself. Examples of problems admitting absolute approximations include minimum-edge coloring [27] and minimum-degree spanning tree [28], where the approximate solution is guaranteed to exceed the optimal solution by at most 1. The techniques used in these algorithms, however, differ from the ones discussed in this chapter. A variation of Karmakar and Karp's ideas leads to a stronger result for BIN PACKING, which is the construction of an approximation algorithm A that is fully polynomial and has the performance guarantee $A(I) \leq OPT(I) + O(\log^2 OPT(I))$. One is tempted to believe that there also exists an absolute approximation algorithm for BIN PACKING, i.e., an algorithm that runs in polynomial time and guarantees that $A(I) \leq OPT(I) + O(1)$. The existence of such an algorithm is still an open question.

[3] Here d is assumed to be a fixed constant.

12.1 Introduction

Randomization (i.e., the use of random choice as an algorithmic step) is one of the most interesting tools in designing efficient algorithms. A remarkable property of randomized algorithms is their structural simplicity. In fact, in several cases, while the known deterministic algorithms are quite involved, the randomized ones are simpler and much easier to code.

This happens also in the case of approximation algorithms to NP-hard problems. In fact, it is exactly the area of efficient approximations where the value of randomization has been demonstrated via at least two very general techniques. The first of them is the notorious randomized rounding method, which provides an unexpected association between the optimal solutions of 0/1 integer linear programs (ILPs) and their linear programming (LP) relaxations. Randomized rounding is a way to return from the fractional optimal values of the LP relaxation (which can be efficiently computed) to a good integral solution, whose expected cost is the cost of the fractional solution! We demonstrate this method here via an example application to the optimization version of the NP-complete set cover problem, and we comment also on its use (as a random projection technique) in approximations via semidefinite programs.

The second technique is used in approximately counting the number of solutions to #P-complete problems. Most of this technique is built around the Markov chain Monte Carlo (MCMC) method. It essentially states that the time required for a Markov chain to mix (to approach its steady state) is an approximate estimator of the size of the state space of the chain (i.e., the number of the combinatorial objects that we wish to count). If the Markov chain is *rapidly mixing* (i.e., it converges in polynomial time), then we can also count the size of the state space approximately in polynomial time. We demonstrate this second approach here via an application to approximate counting of a special kind of colorings of the vertices of a graph.

The main drawback of the use of randomization in approximations is that it may only derive good results in expectation (or sometimes with high probability). This means that in certain inputs a randomized approximation technique may take a lot of time (if we want it not to fail) or may even fail. In certain cases, it is possible to convert a randomized approach to a deterministic one via a *derandomization* technique (for example, either by making the random choices dependent on each other and thus reduce the amount of randomness to the limit of allowing a deterministic brute-force search of the probability space, or by the use of *conditional probabilities*). We do not discuss derandomization here, since its application has been quite limited and since our purpose is to let the reader appreciate the simplicity and generality of the randomized methods.

12.2 Optimization and Randomized Rounding

12.2.1 Introduction

NP-hard optimization problems are not known to allow finding optimal solutions efficiently. Their combinatorial structure is elaborate and sometimes quite cryptic in the general sense.

Many NP-hard optimization problems can be coded as ILPs. In fact, in quite a lot of them, the values of the integer variables involved are only 0 and 1. We are then speaking of 0/1 Integer Linear Programming Problems (or 0/1 ILP). An example here is hard problems involving Boolean solutions.

Relaxing the integer constraints of the form "$x_i \in \{0, 1\}$" to the linear inequalities "$0 \leq x_i \leq 1$," converts a 0/1 ILP into an LP problem. Nowadays it is known that LP optimization problems can be solved in polynomial time (via the ellipsoid or interior point methods). This strong similarity between 0/1 ILP and LP allows us to design efficient approximation algorithms for the hard problem at hand.

A feasible solution to the LP-relaxation can be thought of as a *fractional solution* to the original problem. The set of feasible solutions of a system of linear inequalities is known to build a *polytope* (a convex, multidimensional object, a *polyhedron*, like a diamond). To search for an optimum with respect to a linear function in a polytope is not so hard, since it has been proved that the optimum is located in some vertex of the polytope. However, in the case of an NP-hard problem, we cannot expect the polyhedron defining the set of feasible solutions to have integer vertices. Thus, our task is to somehow transform the optimal solution of the LP relaxation into a near-optimal *integer* solution.

A basic technique for obtaining approximation algorithms using LP is what we call *LP rounding*: i.e., solve the (relaxed) linear program and then convert the fractional solutions obtained (e.g., $x_i = 2/3$) to an integral solution (e.g., here $x_i = 1$ seems more reasonable than $x_i = 0$) trying of course to make sure that the cost of the solution does not increase much in the process.

A natural idea for rounding an optimal fractional solution is to view the fractions as *probabilities*. Then we can "flip coins" with these probabilities as biases, and round accordingly. So, the case "$x_i = 2/3$," obtained via LP, now leads to an experiment where "$x_i = 1$ with probability 2/3 and 0 else." This idea is called *randomized rounding*. In the sequel, we present the method via an application to the set cover problem. This application is also demonstrated in the book of Vazirani [1]. We try to be more thorough here and provide details.

12.2.2 The Set Cover Problem

The set cover problem is one of the oldest known NP-complete problems (it generalizes the vertex cover problem).

Problem SET COVER

Given is a universal set U of n elements and also a collection of subsets of U, $S = \{S_1, S_2, \ldots, S_k\}$. Given is also a cost function $c : S \to Q^+$.

We seek to find a minimum cost subcollection of S that covers all the elements of U.

Note here that the cost of a subcollection of S, e.g., $F = \{S_{i_1}, \ldots, S_{i_\lambda}\}$ is $\sum_{j=1}^{\lambda} c(S_{i_j})$. Note also that any feasible answer to the problem requires covering all of U, i.e., if F is a feasible answer, then we demand that $\bigcup_{j=1}^{\lambda} S_{i_j} = U$. Define the *frequency* of an element of U to be the number of sets it is in.

Let us denote the frequency of the most frequent element by f. The various known approximation algorithms for set cover achieve one of the two approximation factors $O(\log n)$ or f. The special case with $f = 2$ is, basically, the vertex cover problem in graphs (see Ref. [2]).

12.2.3 The Set Cover as an Integer Program

To formulate the set cover problem as a problem in 0/1 ILP, let us assign a variable $x(S_i)$ for each set $S_i \in S$. This variable will have the value 1 iff the set S_i is selected to be in the set cover (and will have the value 0 else).

Clearly, for each element $\alpha \in U$ we want it to be covered, i.e., we want it to be in at least one of the picked sets. In other words, we want, for each $\alpha \in U$ that, at least one of the sets containing it is picked by our candidate algorithm. These considerations give the following ILP program.

Set Cover ILP

Minimize $\sum_{S_i \in S} c(S_i)x(S_i)$

subject to:

$\forall \alpha \in U \;\; \sum_{S_i : \alpha \in S_i} x(S_i) \geq 1$

and $x(S_i) \in \{0, 1\}$ for all $S_i \in S$.

The LP relaxation of this integer program can be obtained by replacing each "$x(S_i) \in \{0, 1\}$" with "$0 \leq x(S_i) \leq 1$." The reader can easily see that the upper bound on $x(S_i)$ is redundant here. So we get the following linear program:

Set Cover Relaxation

Minimize $\sum_{S_i \in S} c(S_i)x(S_i)$

subject to:

(1) $\forall \alpha \in U \;\; \sum_{S_i : \alpha \in S_i} x(S_i) \geq 1$

(2) $\forall S_i \in S \;\; x(S_i) \geq 0$

Note 1: A solution to the above LP is a "fractional" set cover.

Note 2: A fractional set cover may be *cheaper* than the optimal (integral) set cover! To see this, let $U = \{\alpha_1, \alpha_2, \alpha_3\}$ and $S = \{S_1, S_2, S_3\}$ with $S_1 = \{\alpha_1, \alpha_3\}$, $S_2 = \{\alpha_2, \alpha_3\}$ and $S_3 = \{\alpha_3, \alpha_1\}$, and let $c(S_i) = 1$, $i = 1, 2, 3$. Any integral cover must pick two sets, for a cost of 2. However, if we pick each set with $x(S_i) = 1/2$, we satisfy all the constraints and the cost of the fractional cover obtained is $3/2$.

Note 3: The LP dual (see, e.g., Ref. [3]) of the set cover relaxation is a "packing" LP: The dual tries to pack the "material" into elements, trying to maximize the total amount packed, but no set must be "overpacked" (i.e., the total amount of the material packed into the elements of the set should not exceed its cost). The duality of covering–packing is a basic remark and has given lots of approximation results.

12.2.4 A Randomized Rounding Approximation to Set Cover

Let $x(S_i) = p_i$, $i = 1, \ldots, k$ be an *optimal* solution to the set cover relaxation program. Such a solution can be found in polynomial time.

Now, for each $S_i \in S$, select S_i with probability p_i, *independently* of the other selections.

Note: We can do it via choosing (independently for each i) k values $\gamma_1, \ldots, \gamma_k$ randomly and uniformly from the interval $[0, 1]$. Then, for $i = 1$ to k, if $\gamma_i \in [0, p_i]$, we select S_i, otherwise we do not.

Let F be the collection of the selected sets via the experiment.

The expected cost of F is

$$E(cost(F)) = \sum_{S_i \in S} c(S_i) \cdot Prob\{S_i \text{ is selected}\}$$

that is,

$$E(cost(F)) = \sum_{S_i \in S} c(S_i)\, p_i$$

But $\{p_i,\ i = 1, \dots, k\}$ is the optimal solution to the set cover relaxation program, hence $\sum_{S_i \in S} c(S_i)\,p_i$ is the optimal (minimum) value. Let us denote it by OPT_R (optimal for the relaxation).

Now let us examine whether F is a cover. For an $\alpha \in U$, suppose that α occurs in λ sets of S. W.l.o.g., let the probabilities of these sets in the optimal solution of the relaxation be $p_1, \dots, p_\lambda$. Since all the constraints are satisfied by the optimal solution, we get

$$p_1 + \cdots + p_\lambda \geq 1 \tag{12.1}$$

But

$$Prob\{\alpha \text{ is covered by } F\} = 1 - \prod_{i=1}^{\lambda}(1 - p_i)$$

Because of Eq. (12.1), the above expression becomes minimum when $p_i = \cdots = p_\lambda = \frac{1}{\lambda}$, so

$$Prob\{\alpha \text{ is covered by } F\} \geq 1 - \left(1 - \frac{1}{\lambda}\right)^{\lambda} \geq 1 - \frac{1}{e}$$

where $e \simeq 2.73$ is the basis of the natural logarithms. The above analysis holds for any $\alpha \in U$.

We now repeat the part of the experiment where we pick the collection F, independently each time.

Let us pick the collections $F_1, F_2, \dots, F_t$. Let $\tilde{F} = \cup_{i=1}^{t} F_i$. So, for all $\alpha \in U$

$$Prob\{\alpha \text{ is not covered by } \tilde{F}\} \leq \left(\frac{1}{e}\right)^{t}$$

By summing over all $\alpha \in U$ we have

$$Prob\{\tilde{F} \text{ is not a cover}\} \leq n\left(\frac{1}{e}\right)^{t} \tag{12.2}$$

By selecting now $t = \log \xi n$ (with $\xi \geq 4$, a constant) we eventually get

$$Prob\{\tilde{F} \text{ is not a cover}\} \leq n\frac{1}{4n} = \frac{1}{4} \tag{12.3}$$

Having established that $\tilde{F}$ is a cover with constant probability let us see its cost. Clearly,

$$E(c(\tilde{F})) \leq OPT_R \cdot \log \xi n$$

Thus, by the Markov inequality ($Prob\{X \geq mE[X]\} \leq 1/m$, for $x \geq 0$) we get

$$Prob\{c(\tilde{F}) \geq 4OPT_R \cdot \log \xi n\} \leq \frac{1}{4} \tag{12.4}$$

Let A be the (undesirable) event: "$\tilde{F}$ is not a valid cover or $c(\tilde{F})$ is at least $4OPT_R \log \xi n$."

$$Prob(A) \leq \frac{1}{4} + \frac{1}{4} = \frac{1}{2} \tag{12.5}$$

Note that, given $\tilde{F}$, we can verify in polynomial time whether the negation of A holds. If it holds (this happens with probability $\geq 1/2$) then we have an $\tilde{F}$ which is (a) a valid set cover, (b) with cost at most $4 \log \xi n$ times above the OPT_R.

Let OPT be the optimal cost of the integer program. Clearly $OPT_R \leq OPT$ hence, when $\overline{A}$ holds, we have found a valid cover with an approximation ratio (w.r.t. the cost)

$$R = \frac{c(\tilde{F})}{OPT} \leq \frac{c(\tilde{F})}{OPT_R} \leq 4 \log \xi n$$

Now, if A happens to hold, then we repeat the entire algorithm. The expected number of repetitions needed to get a valid cover with $R = \Theta(\log n)$ is then at most 2.

We summarize all this in the following.

Theorem 12.1

The method of randomized rounding gives us in expected polynomial time a valid set cover with a cost approximation ratio $R = \Theta(\log n)$.

Note: The algorithm presented here never errs (since we repeat it if $\tilde{F}$ is not a valid cover of small cost). The penalty is time, but it is small since the number of repetitions follows a geometric distribution.

12.2.5 A Remark in the Analysis

In the analysis of the last section we established Eq. (12.2) namely

$$Prob\{\tilde{F} \text{ is not a cover}\} \leq n\left(\frac{1}{e}\right)^t$$

where t is the number of collections selected independently. By using $t = \xi \log n$ with $\xi \geq 2$ we get

$$Prob\{\tilde{F} \text{ is not a cover}\} \leq ne^{-2\log n} \leq \frac{1}{n}$$

with an expected cover cost of $E(c(\tilde{F})) \leq OPT_R \cdot \xi \log n$, i.e., $E(c(\tilde{F})) \leq OPT \cdot 2\log n$.

If we are satisfied with a good *expected* cost, we can stop here. We get a valid cover with probability at least $1 - \frac{1}{n}$ in one repetition and the expected cost is $\Theta(OPT \cdot \log n)$.

12.2.6 Literature Notes

For more information about set cover approximation via randomized rounding, see the excellent book by Vazirani, Chapter 14. For a more advanced randomized rounding method for set cover see Ref. [4]. A quite similar method can be applied to the MAX-SAT problem (see Ref. [1], Chapter 16 or Ref. [5], Chapter 7). Randomized rounding (actually the random projection method) has been also used together with semidefinite programming to give an efficient approximation to the MAX-CUT problem and its variations (see Ref. [1], Chapter 26) or the seminal work of Goemans and Williamson [6] who introduced the use of semidefinite programs in approximation algorithms.

12.3 Approximate Counting Using the Markov Chain Monte Carlo Method

The MCMC method is a development of the classic, well-known Monte Carlo method for approximately estimating measures and quantities whose exact computation is a difficult task. In fact, the Monte Carlo method expresses the quantity under evaluation (say x) as the expected value $x = E(X)$ of a random variable X, whose samples can be estimated efficiently. By taking the mean of a sufficiently large set of samples, an approximate estimation of the quantity of interest can be obtained.

Jerrum [7] illustrates the use of the Monte Carlo method by a simple example: the estimation of the area of the region of the unit square defined by a system of polynomial inequalities. To do this, points of the unit square are randomly uniformly sampled, i.e., a point is chosen uniformly at random (u.a.r.) and then it is tested whether it belongs to the region of interest (i.e., whether it satisfies or not all inequalities in the system). The probability that a randomly chosen point belongs to the area under investigation (i.e., the expectation of a random variable indicating whether the chosen point satisfies all inequalities in the system or not) is then an estimate of the area of the region of interest. By performing a sufficiently long sequence of such trials and taking their sample mean, an approximate estimation is obtained. More complex examples are the estimation of a size of a tree by sampling paths from its root to a leaf [8] and the estimation of the permanent of a 0,1 matrix [9].

It is, however, not always possible to get such samples of the random variable used. The Markov chain simulation can then be employed. The main idea of the MCMC method is to construct, for a random variable X, a Markov chain whose state space is (or includes) the range of X. The Markov chain constructed should be ergodic, i.e., it converges to a stationary distribution π, and this stationary distribution matches the probability distribution of the random variable X. The desired samples can then be (indirectly) obtained by simulating the Markov chain for sufficiently many steps T, from any fixed initial state, and by taking the final state reached. If T is large enough, the Markov chain gets very close to stationarity and, thus, the distribution of the samples obtained in this way is very close to the probability distribution of the random variable X; the obtained samples are thus close to perfect and the approximation error will be negligible.

The estimation of a sufficiently large time T is important for the efficiency of the simulation. In contrast to the classical theory of stochastic process that only studies the asymptotic convergence to the stationarity, the MCMC method investigates the nonasymptotic speed of convergence and thus the computational efficiency in practical applications of the simulation. The efficiency of an algorithm using the method depends on how small the number of simulation steps T is. In efficient algorithmic uses of the MCMC method with provable performance guarantees (not just heuristic applications), we require T to be small, i.e., very much smaller than the size of the state space of the simulated space. In other words, we want the Markov chain to get close to stationarity after a very short random walk on its state space. We call this time the "mixing time" of the chain and we say that an efficiently converging chain is "rapidly mixing."

Proving satisfactory upper bounds for the mixing time of the simulated Markov chain is in fact the most interesting (nontrivial) point in the application of the MCMC method. Several analytical tools have recently been devised, including the "canonical path" argument, the "conductance" argument, and the "coupling" method. We here choose to illustrate the application of the "coupling" method in a particular approximate counting problem, the problem of counting radiocolorings of a graph. For the other two methods, the reader can consult Refs. [7 and 10].

The approximate counting problem is a general computing task of estimating the number of elements in a combinatorial space. Several interesting counting problems turn out to be complete for the complexity class #P of counting problems, and thus efficient approximation techniques become essential. Furthermore, the problem of approximate counting is closely related to the problem of random sampling of combinatorial structures, i.e., generating the elements of a very large combinatorial space randomly according to some probability distribution. Combinatorial sampling problems have major computational applications, including (besides approximate counting) applications in statistical physics and in combinatorial optimization.

12.3.1 Radiocolorings of Graphs

An interesting variation of graph coloring is the k-coloring problem of graphs, defined as follows ($D(u, v)$ below denotes the distance of vertices u and v in a graph G).

Definition 12.1 k-Coloring Problem (Hale [11])

Given a graph $G(V, E)$ find a function $\phi : V \rightarrow \{1, \ldots, \infty\}$ such that $\forall\ u, v \in V, x \in \{0, 1, \ldots, k\}$: if $D(u, v) = k - x + 1$ then $|\phi_u - \phi_v| \geq x$. This function is called a k-coloring of G. Let $|\phi(V)| = \lambda$. Then λ is the number of colors *that ϕ actually uses (it is usually called* order *of G under ϕ). The number $\nu = max_{v\in V}\phi(v) - min_{u\in V}\phi(u) + 1$ is usually called the* span *of G under ϕ.*

The problem of k-coloring graphs is well motivated by practical considerations and algorithmic applications in modern networks. In fact, k-coloring is a discrete version of the frequency assignment problem (FAP) in wireless networks. Frequency assignment problem aims at assigning frequencies to transmitters exploiting frequency reuse while keeping signal interference to acceptable levels. The interference between transmitters are modeled by an interference graph $G(V, E)$, where $V(|V| = n)$ corresponds to the set of transmitters and E represents distance constraints (e.g., if two neighbor nodes in G get the same or close frequencies then this causes unacceptable levels of interference). In most real-life cases, the network topology formed has some special properties, e.g., G is a lattice network or a planar graph. The FAP is usually modeled by variations of the graph coloring problem. The set of colors represents the available frequencies. In addition, each color in a particular assignment gets an integer value which has to satisfy certain inequalities compared to the values of colors of nearby nodes in G (frequency-distance constraints). The FAP has been considered in Refs. [12–14]. *Planar* interference graphs have been studied in Refs. [15,16].

We have studied the case of k-coloring problem, where k = 2 called the radiocoloring problem (RCP).

Definition 12.2 RCP

Given a graph $G(V, E)$ find a function $\Phi : V \rightarrow N^*$ such that $|\Phi(u) - \Phi(v)| \geq 2$ if $D(u, v) = 1$ and $|\Phi(u) - \Phi(v)| \geq 1$ if $D(u, v) = 2$. The least possible number λ (order) needed to radiocolor G is denoted by $X_{order}(G)$. The least possible number $\nu = max_{v \in V}\Phi(v) - min_{u \in V}\Phi(u) + 1$ (span) needed for the radiocoloring of G is denoted as $X_{span}(G)$.

Real networks reserve bandwidth (range of frequencies) rather than distinct frequencies. In this case, an assignment seeks to use as small range of frequencies as possible. It is sometimes desirable to use as few distinct frequencies of a given bandwidth (span) as possible, since the unused frequencies are available for other use. Such optimization versions of the RCP are defined as follows.

Definition 12.3 Min Span RCP

The optimization version of the RCP that tries to minimize the span. The optimal span is called X_{span}.

Definition 12.4 Min Order RCP

The optimization version of the RCP that tries to minimize the order. The optimal order is called X_{order}.

Fotakis et al. [17] provide an $O(n\Delta)$ algorithm that *approximates* the minimum order of RCP, X_{order}, of a planar graph G *by a constant ratio which tends to 2* as the maximum degree Δ of G increases.

We study here the problem of *estimating the number of different radiocolorings* of a planar graph G. This is a #P-complete problem. We employ here standard techniques of rapidly mixing Markov chains and the *new method of coupling* for proving *rapid convergence* (see, e.g., Ref. [18]) and we present *a fully polynomial randomized approximation scheme (FPRAS)* for estimating the number of radiocolorings with λ colors for a planar graph G, when $\lambda \geq 4\Delta + 50$.

Results on radiocoloring other types (periodic, hierarchical) of graphs can be found in [19–21].

12.3.2 Outline of Our Approach

Let G be a *planar* graph of maximum degree $\Delta = \Delta(G)$ on vertex set $V = \{0, 1, \ldots, n-1\}$ and C be a set of λ colors. Let $\Phi : V \rightarrow C$ be a (proper) radiocoloring assignment of the vertices of G. Such a radiocoloring always exists if $\lambda \geq 2\Delta + 25$ and can be found by the $O(n\Delta)$ time algorithm provided in Ref. [17].

Consider the Markov chain (X_t) whose state space $R = R_\lambda(G)$ is the set of all radiocolorings of G with λ colors and whose transition probabilities from state (radiocoloring) X_t are modeled by

1. choosing a vertex $v \in V$ and a color $c \in C$ uniformly at random (u.a.r.),
2. recoloring vertex v with color c. If the resulting coloring X' is a *valid* radiocoloring assignment then let $X_{t+1} = X'$, else $X_{t+1} = X_t$.

The procedure above is similar to the "Glauber dynamics" of an antiferromagnetic Potts model at zero temperature, and was used in Ref. [18] to estimate the number of proper colorings of any low-degree graph with k colors.

The Markov chain (X_t), which we refer to in the sequel as $M(G, \lambda)$, is *ergodic* (as we show below), provided $\lambda \geq 2\Delta + 26$, in which case its stationary distribution is *uniform* over R. We show here that $M(G, \lambda)$ is *rapidly mixing*, i.e., converges, in time polynomial in n, to a close approximation of the stationary distribution, provided that $\lambda \geq 2(2\Delta + 25)$. This can be used to get an FPRAS for the number of radiocolorings of a planar graph G with λ colors, in the case where $\lambda \geq 4\Delta + 50$.

12.3.3 The Ergodicity of the Markov Chain $M(G, \lambda)$

For $t \in N$ let $P^t : R^2 \to [0, 1]$ denote the t-step transition probabilities of the Markov chain $M(G, \lambda)$ so that $P^t(x, y) = \Pr\{X_t = y | X_0 = x\}, \forall x, y \in R$. It is easy to verify that $M(G, \lambda)$ is (a) *irreducible* and (b) *aperiodic*. The irreducibility of $M(G, \lambda)$ follows from the observation that any radiocoloring x may be transformed to any other radiocoloring y by sequentially assigning new colors to the vertices V in ascending sequence; before assigning a new color c to vertex v it is necessary to recolor all vertices $u > v$ that have color c. If we assume that $\lambda \geq 2\Delta + 26$ colors are given, removing the color c from this set, we are left with $\geq 2\Delta + 25$ for the coloring of the rest of the graph. The algorithm presented in Ref. [17] shows that the remaining graph can by radiocolored with a set of colors of this size. Hence, color c can be assigned to v.

Aperiodicity follows from the fact that the loop probabilities are $P(x, x) \neq 0, \forall x \in R$.

Thus, the finite Markov chain $M(G, \lambda)$ is *ergodic*, i.e., it has a stationary distribution $\pi : R \to [0, 1]$ such that $\lim_{t \to \infty} P^t(x, y) = \pi(y), \forall x, y \in R$. Now if $\pi' : R \to [0, 1]$ is any function satisfying "local balance," i.e., $\pi'(x)P(x, y) = \pi'(y)P(y, x)$ then if $\sum_{x \in R} \pi'(x) = 1$ it follows that π' is indeed the stationary distribution. In our case $P(y, x) = P(x, y)$, thus the stationary distribution of $M(G, \lambda)$ is *uniform*.

12.3.4 Rapid Mixing

The efficiency of any approach like this to sample radiocolorings crucially depends on the rate of convergence of $M(G, \lambda)$ to stationarity. There are various ways to define closeness to stationarity but all are essentially equivalent in this case and we will use the "variation distance" at time t with respect to initial vertex x:

$$\delta_x(t) = \max_{S \subseteq R} \left| P^t(x, S) - \pi(S) \right| = \frac{1}{2} \sum_{y \in R} \left| P^t(x, y) - \pi(y) \right|$$

where $P^t(x, S) = \sum_{y \in S} P^t(x, y)$ and $\pi(S) = \sum_{x \in S} \pi(x)$.

Note that this is a *uniform bound* over all events $S \subseteq R$ of the difference of probabilities of event S under the stationary and t-step distributions.

The *rate of convergence to stationarity* from initial vertex x is

$$\tau_x(\epsilon) = \min\{t : \delta_x(t') \leq \epsilon, \forall t' \geq t\}$$

Our strategy is to use the coupling method, i.e., construct a coupling for $M = M(G, \lambda)$, i.e., a stochastic process (X_t, Y_t) on $R \times R$ such that each of the processes (X_t), (Y_t), considered in isolation, is a faithful copy of M. We will arrange a joint probability space for (X_t), (Y_t) so that, far from being independent, the two processes tend to *couple* so that $X_t = Y_t$ for t large enough. If coupling can occur rapidly (independently of the initial states X_0, Y_0), we can infer that M is rapidly mixing, because the variation distance of M from the stationary distribution is bounded above by the probability that (X_t) and (Y_t) *have not coupled* by time t.

The key result we use here is the *Coupling Lemma* (see Ref. [22] and Chapter 4 by Jerrum [7]), which apparently makes its first explicit appearance in the work of Aldous [23], Lemma 3.6 (see also Diaconis [24], Chapter 4, Lemma 5).

Lemma 12.1

Suppose that M is a countable, ergodic Markov chain with transition probabilities $P(\cdot, \cdot)$ and let $((X_t, Y_t), t \in \mathbb{N})$ be a coupling of M. Suppose further that $t : (0, 1] \to \mathbb{N}$ is a function such that $\Pr(X_{t(\epsilon)} \neq Y_{t(\epsilon)}) \leq \epsilon, \forall \epsilon \in (0, 1]$, uniformly over the choice of initial state (X_0, Y_0). Then the mixing time $\tau(\epsilon)$ of M is bounded above by $t(\epsilon)$. ◇

The transition $(X_t, Y_t) \to (X_{t+1}, Y_{t+1})$ in the coupling is defined by the following experiment:

(1) Select $v \in V$ u.a.r.
(2) Compute a permutation $g(G, X_t, Y_t)$ of C according to a procedure to be explained below.
(3) Choose a color $c \in C$ u.a.r.

(4) In the radiocoloring X_t (respectively Y_t) recolor vertex v with color c (respectively $g(c)$) to get a new radiocoloring X' (respectively Y').
(5) If X' (respectively Y') is a (valid) radiocoloring then $X_{t+1} = X'$ (respectively $Y_{t+1} = Y'$), else let $X_{t+1} = X_t$ (respectively $Y_{t+1} = Y_t$).

Note that whatever procedure is used to select the permutation g, the distribution of $g(c)$ is *uniform*, thus (X_t) and (Y_t) are both faithful copies of M.

We now remark that any set of vertices $F \subseteq V$ can have the same color in the graph G^2 only if they can have the same color in some radiocoloring of G. Thus, given a proper coloring of G^2 with λ' colors, we can construct a proper radiocoloring of G by giving the values (new colors) $1, 3, \ldots, 2\lambda' - 1$ in the color classes of G^2. Note that this transformation preserves the number of colors (but not the span).

Now let $A = A_t \subseteq V$ be the set of vertices on which the colorings of G^2 implied by X_t, Y_t agree and $Dim = D_t \subseteq V$ be the set on which they disagree. Let $d'(v)$ be the number of edges incident at v in G^2 that have one point in A and one in Dim. Clearly, if m' is the number of edges of G^2 spanning A, D, we get $\sum_{v\in A} d'(v) = \sum_{v\in D} d'(v) = m'$.

The procedure to compute $g(G, X_t, Y_t)$ is as follows:

(a) If $v \in D$ then g is the identity.
(b) If $v \in A$ then proceed as follows: Denote by N the set of neighbors of v in G^2. Define $C_x \subseteq C$ to be the set of all colors c, such that some vertex in N receives c in radiocoloring Y_t but no vertex in N receives c in radiocoloring Y_t. Let C_y be defined as C_x with the roles of X_t, Y_t interchanged. Observe $C_x \cap C_y = \emptyset$ and $|C_x|, |C_y| \leq d'(v)$. Let, w.l.o.g., $|C_x| \leq |C_y|$. Choose any subset $C'_y \subseteq C_y$ with $|C'_y| \leq |C_x|$ and let $C_x = \{c_1, \ldots, c_r\}$, $C'_y = \{c'_1, \ldots, c'_r\}$ be enumerations of C_x, $C_{y'}$ coming from the orderings of X_t, Y_t. Finally, let g be the permutation $(c_1, c'_1), \ldots, (c_r, c'_r)$, which interchanges the color sets C_x, $C_{y'}$ and leaves all other colors fixed.

It is clear that $|D_{t+1}| - |D_t| \in \{-1, 0, 1\}$.

(i) Consider first the probability that $|D_{t+1}| = |D_t| + 1$. For this event to occur, the vertex v selected in step (1) of the procedure for g must lie in A and hence we follow (b). If the new radiocolorings are to disagree at vertex v then the color c selected in line (3) must be an element of C_y. But $|C_y| \leq d'(v)$ hence

$$\Pr\{|D_{t+1}| = |D_t| + 1\} \leq \frac{1}{n}\sum_{v\in A}\frac{d'(v)}{\lambda} = \frac{m'}{\lambda \cdot n} \tag{12.6}$$

(ii) Now consider the probability that $|D_{t+1}| = |D_t| - 1$. For this to occur, the vertex v must lie in Dim and hence the permutation g selected in line (2) is the identity. For X_{t+1}, Y_{t+1} to agree at v, it is enough that color c selected in step (3) is different from all the colors that X_t, Y_t imply for the neighbors of v in G^2. The number of colors c that satisfy this is (by our previous results) at least $\lambda - 2(2\Delta + 25) + d'(v)$ hence,

$$\begin{aligned}\Pr\{|D_{t+1}| = |D_t| - 1\} &\geq \frac{1}{n}\sum_{v\in D}\frac{\lambda - 2(2\Delta + 25) + d'(v)}{\lambda}\\ &\geq \frac{\lambda - 2(2\Delta + 25)}{\lambda n}|D| + \frac{m'}{\lambda n}\end{aligned} \tag{12.7}$$

Define now $\alpha = \frac{\lambda - 2(2\Delta+25)}{\lambda n}$ and $\beta = \frac{m'}{\lambda n}$. So

$$\Pr\{|D_{t+1}| = |D_t| + 1\} \leq \beta$$

and $\Pr\{|D_{t+1}| = |D_t| - 1\} \geq \alpha|D_t| + \beta$

Given $\alpha > 0$, i.e. $\lambda > 2(2\Delta + 25)$, from Eq. (12.6) and Eq. (12.7), we get

$$\begin{aligned}E(|D_{t+1}|) &\leq \beta(|D_t| + 1) + (\alpha|D_t| + \beta)(|D_t| - 1) + (1 - \alpha|D_t| - 2\beta)|D_t|\\ &= (1 - \alpha)|D_t|\end{aligned}$$

Thus, from Bayes, we get $E(|D_{t+1}|) \leq (1-\alpha)^t |D_0| \leq n(1-\alpha)^t$
and since $|D_t|$ is a nonnegative random variable, we get, by the Markov inequality, that

$$\Pr\{D_t \neq 0\} \leq n(1-\alpha)^t \leq ne^{-\alpha t}$$

So, we note that, $\forall\, \epsilon > 0, \Pr\{D_t \neq \emptyset\} \leq \epsilon$ provided that $t \geq \frac{1}{\alpha} \ln\left(\frac{n}{\epsilon}\right)$ thus proving Theorem 12.2.

Theorem 12.2

Let G be a planar graph of maximum degree Δ on n vertices. Assuming $\lambda \geq 2(2\Delta + 25)$ the convergence time $\tau(\epsilon)$ of the Markov chain $M(G, \lambda)$ is bounded above by

$$\tau_x(\epsilon) \leq \frac{\lambda}{\lambda - 2(2\Delta + 25)} \;\; n \ln\left(\frac{n}{\epsilon}\right)$$

regardless of the initial state x. □

12.3.5 An FPRAS for Radiocolorings with λ Colors

We first provide the following definition.

Definition 12.5

A randomized approximation scheme for radiocolorings with λ colors of a planar graph G is a probabilistic algorithm that takes as input the graph G and an error bound $\epsilon > 0$ and outputs a number Y (a random variable) such that

$$\Pr\{(1-\epsilon)\, |R_\lambda(G)| \leq Y \leq (1+\epsilon)|R_\lambda(G)|\} \geq \frac{3}{4}$$

Such a scheme is said to be fully polynomial *if it runs in time polynomial in n and ϵ^{-1}. We abbreviate such schemes to* FPRAS.

The technique we employ is as in Ref. [18] and is fairly standard in the area. By using it we get the following theorem.

Theorem 12.3

There is an FPRAS for the number of radiocolorings of a planar graph G with λ colors, provided that $\lambda > 2(2\Delta + 25)$, *where Δ is the maximum degree of G.*

Proof

Recall that $R_\lambda(G)$ is the set of all radiocolorings of G with λ colors. Let m be the number of edges in G and let

$$G = G_m \supseteq G_{m-1} \supseteq \cdots \supseteq G_1 \supseteq G_0$$

be any sequence of graphs where G_{i-1} is obtained by G_i by removing a single edge. We can always erase an edge whose one node is of degree at most 5 in G_i. Clearly

$$|R_\lambda(G)| = \frac{|R_\lambda(G_m)|}{|R_\lambda(G_{m-1})|} \cdot \frac{|R_\lambda(G_{m-1})|}{|R_\lambda(G_{m-2})|} \cdots \frac{|R_\lambda(G_1)|}{|R_\lambda(G_0)|} \cdot |R_\lambda(G_0)|$$

But $|R_\lambda(G_0)| = \lambda^n$ for all kinds of colorings. The standard strategy is to estimate the ratio

$$\rho_i = \frac{|R_\lambda(G_i)|}{|R_\lambda(G_{i-1})|}$$

for each i, $1 \leq i \leq m$.

Suppose that graphs G_i, G_{i-1} differ in the edge $\{u, v\}$, which is present in G_i but not in G_{i-1}. Clearly, $R_\lambda(G_i) \subseteq R_\lambda(G_{i-1})$. Any radiocoloring in $R_\lambda(G_{i-1}) \setminus R_\lambda(G_i)$ assigns either the same color to u, v or the color values of u, v differ by only 1. Let $deg(v) \leq 5$ in G_i. So, we now have to recolor u with one of at least $\lambda - (2\Delta + 25)$, i.e., at least $2\Delta + 25$, colors (from Section 5 of Ref. [18]). Each radiocoloring of

$R_\lambda(G_i)$ can be obtained in at most one way by our algorithm of the previous section as the result of such a perturbation, thus

$$\frac{1}{2} \leq \frac{2\Delta + 25}{2(\Delta + 1) + 25} \leq \rho_i < 1 \tag{12.8}$$

To avoid trivialities, assume $0 < \epsilon \leq 1$, $n \geq 3$ and $\Delta > 2$.

Let $Z_i \in \{0, 1\}$ be the random variable obtained by simulating the Markov chain $M(G_{i-1}, \lambda)$ from any certain fixed initial state for

$$T = \frac{\lambda}{\lambda - 2(2\Delta + 25)} n \ln\left(\frac{4nm}{\epsilon}\right)$$

steps and returning to 1 if the final state is a member of $R_\lambda(G_i)$ and 0 else. Let $\mu_i = E(Z_i)$. By our theorem of rapid mixing, we have

$$\rho_i - \frac{\epsilon}{4m} \leq \mu_i \leq \rho_i + \frac{\epsilon}{4m}$$

and by Eq. (12.8), we get

$$\left(1 - \frac{\epsilon}{2m}\right)\rho_i \leq \mu_i \leq \left(1 + \frac{\epsilon}{2m}\right)\rho_i$$

As our estimator for $|R_\lambda(G)|$ we use

$$Y = \lambda^n Z_1 Z_2 \cdots Z_m$$

Note that $E(Y) = \lambda^n \mu_1 \mu_2 \cdots \mu_m$. But

$$Var(Y) \leq \frac{Var(Z_1 Z_2 \cdots Z_m)}{(\mu_1 \mu_2 \cdots \mu_m)^2} = \prod_{i=1}^{m}\left(1 + \frac{Var(Z_i)}{\mu_i^2}\right) - 1$$

By using standard techniques (as in Ref. [18]) one can easily show that Y satisfies the requirements for an FPRAS for the number of radiocolorings of graph G with λ colors $|R_\lambda(G)|$. □

13.1 Introduction

The spread of computer networks, from sensor networks to the Internet, creates an ever-growing need for efficient *distributed* algorithms. In such scenarios, familiar combinatorial structures such as spanning trees and dominating sets are often useful for a variety of tasks. Others, like maximal independent sets, turn out to be a very useful primitive for computing other structures. In a distributed setting, where transmission of messages can be orders of magnitude slower than local computation, the expensive resource is communication. Therefore, the running time of an algorithm is given by the number of communication rounds that are needed by the algorithm. This will be made precise below.

In what follows we will survey a few problems and their solutions in a distributed setting: dominating sets, edge and vertex colorings, matchings, vertex covers, and minimum spanning trees. These problems were chosen for a variety of reasons: they are fundamental combinatorial structures; computing them is useful in distributed settings; and they serve to illustrate some interesting techniques and methods.

Randomization, whose virtues are well known to people coping with parallel and distributed algorithms, will be a recurrent theme. In fact, only rarely it has been possible to develop deterministic distributed algorithms for nontrivial combinatorial optimization problems. Here, in the section on vertex covers, we will discuss a novel and promising approach based on the primal-dual methodology to develop efficient, distributed deterministic algorithms. One of the main uses of randomization in distributed scenarios is to break the symmetry. This is well illustrated in Section 13.2. discussing dominating sets. Often, the analysis of simple randomized protocols requires deep results from probability theory. This will be illustrated in Section 13.3, where martingale methods are used to analyze some simple, and yet almost optimal, distributed algorithms for edge coloring. The area of distributed algorithms for graph problems is perhaps unique in complexity theory because it is possible to derive several nontrivial absolute lower bounds (that is, not relying on special complexity assumptions such as $\mathsf{P} \neq \mathsf{NP}$). This will be discussed in Section 13.6.

Let us then define the computation model. We have a message-passing, synchronous network: vertices are processors, edges are communication links, and the network is synchronous. Communication proceeds in synchronous *rounds*: in each round, every vertex sends messages to its neighbors, receives messages from its neighbors, and does some amount of local computation. It is also assumed that each vertex has a unique identifier. In the case of randomized algorithms each node of the network has access to its own source of random bits. *In this model, the running time is the number of communication rounds.* This will be our notion of "time." As remarked, this is a very reasonable first approximation since typically sending a message is orders of magnitude slower than performing local computation.

Although we place no limits on the amount of local computation, the algorithms we describe perform polynomial-time local computations only. Under the assumption that local computations are polynomial time several of the algorithms that we describe are "state of the art," in the sense that their approximation guarantee is the same, or comparable, to that obtainable in a centralized setting. It is remarkable that this can be achieved in a distributed setting.

The model is in some sense orthogonal to the Parallel Random Access Machine (PRAM) model for parallel computation where a set of polynomially many, synchronous processors access a shared memory. There communication is free: any two processors can communicate in constant time via the shared memory. In the distributed model, in contrast, messages are routed through the network and therefore the cost of sending a message is at least proportional to the length of the shortest path between the two nodes. On the other hand, local computation is inexpensive, while this is the expensive resource in the PRAM model.

Note that there is a trivial universal algorithm that always works: The network elects a leader which then collects the entire topology of the network, computes the answers, and notifies them to the other nodes. This will take a time proportional to the diameter of the network, which can be as large as n, the number of nodes. In general, we will be looking for algorithms that take polylogarithmically, in n, many communication rounds, regardless of the diameter of the network. Such algorithms will be called *efficient.*

Note the challenge here: if a protocol runs for t rounds then each processor can receive messages from nodes at distance at most t. For small values of t this means that the network is computing a global function of itself by relying on local information alone.

13.2 Small Dominating Sets

In this section we study the minimum dominating set (MDS) problem. The advent of wireless networks gives a new significance to the problem since (connected) dominating sets are the structure of choice to set up the routing infrastructure of such ad hoc networks, the so-called backbone (see, for instance, Ref. [1] and references therein). In the sequel we describe a nice algorithm from Ref. [2] for computing small dominating sets. The algorithm is in essence an elegant parallelization of the well-known greedy heuristic for set cover [3,4]. Randomness is a key ingredient in the parallelization. The algorithm computes, on any input graph, a dominating set of size at most $O(\log \Delta)opt$, where as customary Δ denotes the maximum degree of the graph and opt is the smallest size of a dominating set in the input graph. By "computing a dominating set" we mean that at the end of the protocol every vertex decides whether it is in the dominating set or not. The algorithm was originally developed for the PRAM model but, as we will show, it can be implemented distributively. It is noteworthy that the approximation bound is essentially the "best possible" under the assumption that every node performs a polynomially bounded computation during every round. "Best possible" means that there exists a constant $c > 0$ such that a $c \log n$-approximation would imply that $\mathsf{P} = \mathsf{NP}$ [5], while a $(c \ln n)$-approximation, for a constant $c < 1$, would imply that NP could be solved exactly by means of slightly superpolynomial algorithms [6,7].

We shall then describe a surprisingly simple deterministic algorithm that, building on top of the dominating set algorithm, computes a "best possible" connected dominating set, in $O(\log n)$ additional communication rounds [8].

There are other nice algorithms to compute dominating sets efficiently in a distributed setting. The algorithm in Ref. [9] is a somewhat different parallelization of the greedy algorithm, while Ref. [10] explores an interesting trade-off between the number of rounds of the algorithm and the quality of the approximation that it achieves. This paper makes use of LP-based methods, an issue that we will explore in Section 13.5.

13.2.1 Greedy

Let us start by reviewing the well-known greedy heuristic for set cover. Greedy repeatedly picks the set of minimum unit cost, creating a new instance after every choice by removing the points just covered. More formally, let (X, F, c) be a set cover instance, where X is a ground set of elements and $F := \{S_i : S_i \subseteq X, i \in [m]\}$ is a family of nonempty subsets of X with positive costs $c(S) > 0$. The goal is to select a subfamily of minimum cost that covers the ground set. The cost of a subfamily is the sum of the costs of each set in the subfamily.

Dominating set is a special case of set cover. A graph G with positive weights $c(u)$, $u \in V(G)$, can be viewed as a set system $\{S_u : u \in V(G)\}$ with $S_u := N(u) \cup \{u\}$, where $N(u)$ is the set of neighbors of u, and $c(S_u) := c(u)$.

Given a set cover instance $I := (X, F, c)$, let $c(e) := \min_{e \in S \in F} \frac{c(S)}{|S|}$ be the *cost* of the element $e \in X$. This is the cheapest way to cover e where we do the accounting in the following natural way: when we pick a set, its cost is distributed equally to all elements it covers. An algorithm A may pick a certain set S' at this stage, then in this accounting scheme, each element $e \in S'$ pays the *price* $p(e) := \frac{c(S')}{|S'|}$. Once set s' is picked, we create a new instance I' with ground set $X' := X - \hat{S}$ and set system F' whose sets are defined as $S'_i := S_i - \hat{S}$. The new costs coincide with the old ones: $c(S') = c(S)$, for all $S \in F'$. The algorithm continues in the same fashion until all elements are covered.

Greedy selects a set $\hat{S}$ at each stage that realizes the minimum unit cost, i.e., $p(e) = c(e)$ at each stage. In other words, greedy repeatedly selects the set that guarantees the smallest unit price. For the discussion to follow concerning the distributed version of the algorithm it is important to notice that each element e is assigned a price tag $p(e)$ only once, at the time when it is covered by greedy. For a subset $A \subseteq X$, let $g(A) := \sum_{e \in A} p(e)$. Then $g(X)$, the sum of the unit prices, is the total cost incurred by greedy. The crux of the analysis is the next lemma.

Lemma 13.1

For any set S, $g(S) \leq H_{|S|} c(S)$ where $H_k := 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{k}$ is the kth harmonic number.

Proof

Sort the elements of S according to the time when they are covered by greedy, breaking ties arbitrarily. Let $e_1, e_2, \cdots, e_k$ be this numbering. When greedy covers e_i it must be that $p(e_i) \leq \frac{c(S)}{k-i}$. The claim follows. □

Clearly we have that $g(A \cup B) \leq g(A) + g(B)$. Denoting with C^* an optimal cover, we have, by Lemma 13.1,

$$g(X) = g\left(\cup_{S \in C^*} S\right) \leq \sum_{S \in C^*} g(S) \leq \sum_{S \in C^*} H_{|S|} c(S) \leq \max_S H_{|S|} \sum_{S \in C^*} c(S) \leq \max_S H_{|S|} opt$$

It is well known that $\log k \leq H_k \leq \log k + 1$. In the case of the dominating set the bound becomes

$$g(X) \leq H_{\Delta+1} opt = O(\log \Delta) opt$$

where Δ is the maximum degree of the graph.

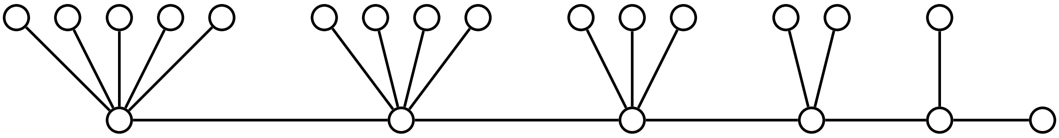

FIGURE 13.1 Example of lower-bound graph for $k = 6$. The number of nodes is $n = k(k+1)/2 = \Theta(k^2)$. The bottom nodes are selected by greedy, one by one from left to right. The number of rounds is $k - 1$.

13.2.2 Greedy Hordes

We now proceed to parallelize greedy. Figure 13.1 shows that the number of steps taken by greedy can be $\Omega(\sqrt{n})$. The problem lies in the fact that at any stage there is just one candidate set that gives the minimum unit cost $\hat{c}$. It is to get around this problem that we introduce the following notion. A *candidate* is any set S such that

$$\hat{c} \leq \frac{c(S)}{|S|} \leq 2\hat{c} \tag{13.1}$$

Let us modify greedy in such a way that, at any step, it selects any set satisfying this condition. With this modification, the solution computed by greedy will still be at most $O(\log n)opt$ since the algorithm pays at most twice the smallest unit price the overall we lose only a factor of 2 in the approximation.

Suppose now that the algorithm is modified in such a way that it adds to the solution all candidates satisfying Eq. (13.1). With this modification, the graphs of Figure 13.1 will be covered in $O(\log n)$ steps. But as the example of the clique shows (all the nodes are selected) this increase in speed destroys the approximation guarantee. This is because the key requirement of the sequential greedy procedure is violated. In the sequential procedure, the price $p(e)$ is paid only once, at the time when e is covered. If we do things in parallel we need to keep two conflicting requirements in mind: picking too many sets at once can destroy the approximation guarantee, but picking too few can result in slow progress. And we must come up with a charging scheme to distribute the costs among the elements in a manner similar to the sequential case.

Rajagopalan and Vazirani solved this problem by devising a scheme that picks enough sets to make progress but at the same time retains the parsimonius accounting of costs like in the sequential version. Specifically, for every set S selected by greedy, the cost $c(S)$ will be distributed among the elements of a subset $T \subset S$ of at least $|S|/4$ elements. Crucially, the elements of T will be charged only once. If we can do this then we will lose another factor of 4 in the approximation guarantee with respect to greedy, all in all losing a factor of 8.

The scheme works as follows: line up the candidate sets satisfying Eq. (13.1) on one side and all the elements on the other. The elements are thought of as *voters* and cast their vote for one of the candidate sets containing them by an *election*. An election is conducted as follows:

- A random permutation of the candidates is computed.
- Among all the candidate sets that contain it, each voter votes for that set which has the lowest number in the permutation.
- A candidate is elected if it obtains at least $\frac{1}{4}$ of the votes of its electorate. Elected candidates enter the set cover being constructed.

The cost of the set can now be distributed equally among the elements that voted for it, i.e., at least a quarter of the elements.

Let us now describe the distributed implementation of this scheme in the specific case of the set system corresponding to the dominating set problem. During the execution nodes can be in four different states:

- They can be *free*. Initially all vertices are free.
- They can be *dominated*.

- They can be *dominators.* Dominators are added to the dominating set and removed from the graph.
- They can be *out.* Vertices are out when they are dominated and have no free neighbors. These vertices are removed from the graph since they can play no useful role.

The algorithm is a sequence of $\log \Delta$ *phases* during which the following invariant is maintained, with high probability. At the beginning of phase i, $i = 1, 2, \ldots, \log \Delta$, the maximum degree of the graph is at most $\Delta/2^{i-1}$. The candidates during phase i are all those vertices whose degree is in the interval $(\Delta/2^i, \Delta/2^{i-1}]$ i.e., they satisfy condition (13.1). Note that candidates can be free or dominated vertices. The voters are those free nodes that are adjacent to a candidate. This naturally defines a bipartite graph with candidates on one side, voters on the other, and edges that represent domination relationships. Each phase consists of a series of $O(\log n)$ elections. A free vertex can appear on both sides, since a free vertex can dominate itself. We shall refer to the neighbors of a candidate c in the bipartite graph as the *electorate* of c, and to the neighbors of a voter v as the *pool* of v. Elections are carried out and elected candidates enter the dominating set.

Step 1 of each election seems to require global synchronization, but a random permutation can be generated if the value of n is known. If each element picks a random number between 1 and n^k then with probability $1 - 1/n^{k-1}$ all choices will be distinct. Thus, the probability that there is a collision is negligible during the entire execution of the algorithm.

After every election, nodes are removed for two different reasons. Elected nodes disappear from the candidate side of the bipartition, while their neighbors disappear from the other side since they are no more free. In the analysis we will show that after one election the expected number of edges that disappear from the bipartite graph is a constant fraction of the total. This automatically implies that the total number of elections to remove all edges from the graph is $O(\log n)$ with overwhelming probability. More precisely, for any $c > 0$ there is $\alpha > 0$ such that, the probability that the bipartite graph is nonempty after $\alpha \log n$ elections is at most n^{-c} [11,12]. It follows that α can be chosen in such a way that the probability that some phase does not end successfully is negligible.

A voter v is *influential* for a candidate c if at least $\frac{3}{4}$ of the voters in c's electorate have degree no greater than that of v. Let $d(v)$ denote the degree of v.

Lemma 13.2

For any two voters v and w, $d(v) \geq d(w)$, in c's electorate, $\mathsf{Pr}[w \textit{ votes } c \mid v \textit{ votes } c] \geq \frac{1}{2}$.

Proof

Let N_b denote the number of neighbors that v and w have in common, let N_v the number of neighbors of v that are not neighbors of w, and N_w the number of neighbors of w that are not neighbors of v. Then,

$$\mathsf{Pr}[w \text{ votes } c \mid v \text{ votes } c] = \frac{\mathsf{Pr}[w \text{ votes } c, v \text{ votes } c]}{\mathsf{Pr}[v \text{ votes } c]} = \frac{N_v + N_b}{N_v + N_b + N_w} \geq \frac{1}{2} \qquad \square$$

Lemma 13.3

Let v be an influential voter for c. Then, $\mathsf{Pr}[c \textit{ is elected} \mid v \textit{ votes } c] \geq \frac{1}{6}$.

Proof

Let $X :=$ (# votes for c) and $Y := c - X$ where, with abuse of notation we use c to denote the size of c's electorate. Then, by Lemma 13.2

$$\mathsf{E}[X \mid v \text{ votes } c] \geq \sum_{w:\, d(w) \leq d(v)} \mathsf{Pr}[w \text{ votes } c \mid v \text{ votes } c] \geq \frac{3}{8}c$$

Applying Markov's inequality to Y we get

$$\begin{aligned}\mathsf{Pr}[c \text{ not elected} \mid v \text{ votes } c] &= \mathsf{Pr}[X < c/4 \mid v \text{ votes } c] = \mathsf{Pr}[Y \geq 3c/4 \mid v \text{ votes } c] \\ &\leq \frac{4\,\mathsf{E}[Y \mid v \text{ votes } c]}{3c} = \frac{4(c - \mathsf{E}[X \mid v \text{ votes } c])}{3c} \leq \frac{5}{6}\end{aligned}$$

The claim follows. □

Lemma 13.4

Fix a phase and let m denote the total number of edges in the bipartite graph at any stage in this phase. Let X denote the number of edges removed from the bipartite graph after one election. Then, $\mathsf{E}[X] \geq \frac{m}{24}$.

Proof

An edge vc is *good* if v is influential for c. By definition, at least $\frac{1}{4}$ of the edges are good. Then,

$$\begin{aligned}
\mathsf{E}[X] &= \sum_{vc} \mathsf{Pr}[c \text{ is elected, } v \text{ votes } c]d(v) \\
&\geq \sum_{vc \text{ good}} \mathsf{Pr}[c \text{ is elected, } v \text{ votes } c]d(v) \\
&\geq \sum_{vc \text{ good}} \mathsf{Pr}[v \text{ votes } c]\ \mathsf{Pr}[c \text{ is elected} \mid v \text{ votes } c]d(v) \\
&= \sum_{vc \text{ good}} \mathsf{Pr}[c \text{ is elected} \mid v \text{ votes } c] \\
&\geq \frac{m}{24} \quad \text{by Lemma 13.3}
\end{aligned}$$

□

As remarked, this lemma implies that, with high probability, $O(\log n)$ rounds are sufficient for every phase. The resulting running time is $O(\log n \log \Delta)$ communication rounds, while the approximation guarantee is $O(\log \Delta)$. Vertices must know n to compute a permutation and to run the correct number of elections, and they must know Δ to decide whether they are candidates at the current phase. Alternatively, if only the value of n is known, the algorithm can execute $O(\log n)$ phases, for a total of $O(\log^2 n)$ many rounds.

13.2.3 Small Connected Dominating Sets

In this section we develop an efficient distributed algorithm for computing "best possible" connected dominating sets. Again, by this we mean that the protocol computes a connected dominating set of size at most $O(\log \Delta)$ times the optimum. Nowadays, connected dominating sets are quite relevant from the application point of view since they are the solution of choice for setting up the backbones of self-organizing networks such as ad hoc and sensor networks (see Ref. [1] and references therein). A backbone is a subnetwork that is in charge of administering the traffic inside a network.

What is remarkable from the algorithmic point of view is that connectivity is a strong global property, and yet we will be able to obtain it by means of a distributed algorithm that relies on local information alone. The overall strategy can be summarized as follows:

- Compute a small dominating set.
- Connect it up using a sparse spanning network.

We saw in the previous section how to take care of step 1. To connect a dominating set we can proceed as follows. Let D be the dominating set in the graph G created after step 1. Consider an auxiliary graph H with vertex set D and where any two $u, v \in D$ that are at distance 1, 2, or 3 in G are connected by an edge in H. It is easy to see that H is connected if G is (which we assume). Every edge in H corresponds to a path with 0, 1, or 2 vertices in G. If we inserted all such vertices we would still have a dominating set, since adding vertices can only improve domination. The resulting set would however be too large in general, since H can have as many as $|D|^2$ edges, each contributing with two vertices. The best way to connect D up would be to compute a spanning tree T. If we could do this, adding to D all vertices lying on paths corresponding to the edges of T, we would obtain the desired approximation since $E(T) = |D| - 1$ and recalling that $|D|$ is a $O(\log \Delta)$-approximation. Therefore, denoting with D^* and C^* an optimal dominating and connected dominating set, respectively, we would have (with some abuse of notation) that $|D \cup V(T)| \leq 3|D| \leq O(\log \Delta)|D^*| \leq O(\log \Delta)|C^*|$.

The problem however is that, as we discuss in Section 13.6.1, computing a spanning tree takes time $\Omega(\sqrt{n})$. In what follows we show a very simple algorithm that computes, in $O(\log |V(G)|)$ many communication rounds, a network $S \subset H$ such that (a) S is connected, (b) $|E(S)| = O(|D|)$, and (c) $V(S) = D$. In words, S is a sparse connected network that spans the whole of D with linearly many edges. If we can compute such an S than we will have a connected dominating set of size at most $O(\log \Delta)$ times the optimum. S will not be acyclic but this is actually a positive thing since it makes S more resilient to failures. In fault-prone environments such as ad hoc and sensor networks this kind of redundancy is actually very useful. The key to computing S is given by the following lemma (see, for instance Ref. [13, Lemma 15.3.1]). Recall that the *girth* of a graph G is the length of the shortest cycle in G.

Lemma 13.5

Let $G = (V, E)$ be a graph of girth g, and let $m := |E|$ and $n := |V|$. Then, $m \leq n + n^{1+2/(g-1)}$.

Proof

Assume $g = 2k + 1$ and let $d := \frac{m}{n}$. Consider the following procedure. As long as there is a vertex whose degree is less than d, remove it. Every time we remove a vertex the new minimum degree is at least as large as the old one. Therefore, this procedure ends with a graph whose minimum degree is at least d. Now pick any vertex in this graph and start a breadth first search. This generates a tree in which the root has at least d children and every other node has at least $d - 1$ children. Moreover, assigning level 0 to the root, this tree is a real tree up to and including level $k - 1$, i.e., no two vertices of this Breadth-First Search (BFS) exploration coincide up to that level. Therefore,

$$n \geq 1 + d + d(d-1) + \cdots + d(d-1)^{k-1} \geq (d-1)^k$$

Recalling the definition of d, the claim follows. The proof for the case $g = 2k$ is analogous. □

Note that if $g = 2\log n + 1$ then $m \leq 3n$. Define a cycle to be *small* if it is of length at most $2\log n + 1$. The following amazingly simple protocol removes all small cycles while, crucially, preserving connectivity:

- If an edge is the smallest in some small cycle, it is deleted.

Assume that every edge in the graph has a unique identifier. An edge is smaller than another edge if its identifier is smaller than that of the other edge. It is clear that every small cycle is destroyed. The next lemma shows that connectivity is preserved.

Lemma 13.6

The above protocol preserves connectivity.

Proof

Sort the edges by increasing IDs and consider the following sequential procedure. At the beginning all edges are present in the graph. At step i edge e_i is considered. If e_i is in a small cycle then it is removed. This breaks all small cycles and preserves connectivity, since an edge is removed only when there is another path connecting its endpoints. The claim follows by observing that the sequential procedure and the distributed protocol remove the same set of edges. □

To implement the protocol we only need to determine the small cycles to which an edge belongs. This can be done by a BFS of depth $O(\log n)$ starting from every vertex. If edges do not have distinct IDs to start with they can be generated by selecting a random number in the range $[m^3]$, which ensures that all IDs are distinct with overwhelming probability. This requires the value of n or m to be known. This sparsification technique appears to be quite effective in practice [1].

13.3 Coloring: The Extraordinary Career of a Trivial Algorithm

Consider the following sequential greedy algorithm to color the vertices of an input graph with $\Delta + 1$ colors, where Δ is the maximum degree: pick a vertex, give it a color not assigned to any of its neighbors; repeat until all vertices are colored. In general, Δ can be quite far from the optimal value $\chi(G)$ but it should not be forgotten that the chromatic number is one of the most difficult combinatorial problems to approximate [14–16].

In this section we will see how efficient distributed implementations of this simple algorithm lead to surprisingly strong results for vertex and especially edge coloring. Consider first the following distributed implementation. Each vertex u is initially given a list of colors $L_u := \{1, 2, \ldots, \Delta + 1\}$. Computation proceeds in rounds, until the graph is colored. One round is as follows: each uncolored vertex u picks a tentative color $t_u \in L_u$; if no neighboring vertex has chosen the same tentative color, t_u becomes the final color of u, and u stops. Otherwise L_u is updated by removing from it all colors assigned to neighbors of u at the current round. We shall refer to this as the *trivial algorithm*. It is apparent that the algorithm is distributed.

The trivial algorithm is clearly correct. An elementary, but nontrivial analysis shows that the probability that an uncolored vertex colors itself in one round is at least $\frac{1}{4}$ [17]. As we discussed in the previous section, this implies that the algorithm will color the entire network within $O(\log n)$ communication rounds, with high probability.

The following slight generalization is easier to analyze. At the beginning of every round, uncolored vertices are *asleep* and wake up with probability p. The vertices that wake up execute the round exactly as described earlier. At the end of the round, uncolored vertices go back to sleep. In other words, the previous algorithm is obtained by setting $p = 1$. In the sequel we will refer to this generalization as the (generalized) trivial algorithm. Luby analyzed this algorithm for $p = \frac{1}{2}$ [18]. Heuristically, it is not hard to see why the algorithm makes progress in this case. Assume u is awake. The expected number of neighbors of u that wake up is $d(u)/2 \leq |L_u|/2$.

In the worst case, these neighbors will pick different colors and all these colors will be in L_u. Even then, u will have probability at least $\frac{1}{2}$ to pick a color that creates no conflict. Thus, with probability $\frac{1}{2}$ a vertex wakes up and, given this, with probability at least $\frac{1}{2}$ it colors itself. The next proposition formalizes this heuristic argument.

Proposition 13.1

When $p = \frac{1}{2}$ the probability that an uncolored vertex colors itself in one round is at least $\frac{1}{4}$.

Proof

Let t_u denote the tentative color choice of a vertex u.

$$\begin{aligned}
\Pr[u \text{ does not color} \mid u \text{ wakes up}] &= \Pr[\exists v \in N(u)\ t_u = t_v \mid u \text{ wakes up}] \\
&\leq \sum_{v \in N(u)} \Pr[t_u = t_v \mid u \text{ wakes up}] \\
&= \sum_{v \in N(u)} \Pr[t_u = t_v \mid u \text{ and } v \text{ wake up}] \Pr[v \text{ wakes up}] \\
&= \sum_{v \in N(u)} \frac{|L_u \cap L_v|}{|L_v||L_u|} \frac{1}{2} \leq \sum_{v \in N(u)} \frac{1}{|L_u|} \frac{1}{2} \leq \frac{1}{2}
\end{aligned}$$

Therefore,

$$\Pr[u \text{ colors itself}] = \Pr[u \text{ colors itself} \mid u \text{ wakes up}] \Pr[u \text{ wakes up}] \geq \frac{1}{4} \qquad \square$$

Note that the trivial algorithm works just as well if the lists are initialized as $L_u := \{1, 2, \ldots, d(u) + 1\}$, for all $u \in V(G)$, for any value of $p > 0$. Interestingly, in practice, with $p = 1$ the trivial algorithm is much faster than Luby's one. In fact, experimentally, the speed of the algorithm increases regularly and monotonically as p tends to 1 [19].

In the distributed model we can simulate the trivial algorithm for the line graph with constant-time overhead. In this case, the algorithm will be executed by the edges rather than the vertices, each edge e having its own list L_e. In this fashion we can compute edge colorings that are approximated by a factor of 2 (since $2\Delta - 1$ colors are used). It is a challenging open problem whether an $O(\Delta)$-approximation can be computed deterministically in the distributed model. The best known result so far is an $O(\Delta \log n)$-approximation [20]. But the real surprise is that the trivial algorithm computes near-optimal edge colorings!

Vizing's theorem shows that every graph G can be edge colored sequentially in polynomial time with Δ or $\Delta + 1$ colors (see, for instance, Ref. [21]). The proof is in fact a polynomial-time sequential algorithm for achieving a $\Delta + 1$ coloring. Thus edge coloring can be well approximated. It is a very challenging open problem whether colorings as good as these can be computed fast in a distributed model.

If the edge lists L_e's are initialized to contain just a bit more than Δ colors, say $|L_e| = (1 + \epsilon)\Delta$ for all e, then the trivial algorithm will edge color the graph within $O(\log n)$ communication rounds. Here ϵ can be any fixed, positive constant. Some lists can run out of colors and, consequently, the algorithm can fail, but this happens with a probability that goes to 0 as n, the number of vertices, grows. All this is true, provided that the minimum degree $\delta(G)$ is large enough, i.e., $\delta(G) \gg \log n$ [22,23]. For Δ-regular graphs the condition becomes $\Delta \gg \log n$.

In fact, the trivial algorithm has in store more surprises. If the input graph is Δ-regular and has no triangles, it colors the vertices of the graph using only $O(\Delta / \log \Delta)$ colors. This is in general optimal, since there are infinite families of triangle-free graphs that need these many colors [24]. Again, the algorithm fails with negligible probability, provided that $\Delta \gg \log n$. For the algorithm to work, the value of p must be set to a value that depends on the round: small initially, it grows quickly to 1 [25].

The condition $\Delta \gg \log n$ appears repeatedly. The reason is that these algorithms are based on powerful martingale inequalities and this condition is needed to make them work. These probabilistic inequalities are the subject of the next section.

13.3.1 Coloring with Martingales

Let $f(X_1, \ldots, X_n)$ be a function for which we can compute $\mathsf{E}[f]$, and let the X_i's be independent. Assume moreover that the following Lipshitz condition (with respect to the Hamming distance) holds:

$$|f(X) - f(Y)| \leq c_i \tag{13.2}$$

whenever $X := (x_1, \ldots, x_n)$ and $Y := (y_1, \ldots, y_n)$ differ only in the ith coordinate. Then, f is sharply concentrated around its mean:

$$\Pr[|f - \mathsf{E}[f]| > t] \leq 2e^{-2t^2/\Sigma_i c_i^2} \tag{13.3}$$

This is the simplest of a series of powerful concentration inequalities dubbed the method of bounded differences (MOBD) [26]. The method is based on martingale inequalities (we refer the reader to the thorough and quite accessible treatment in Ref. [12]). In words, if a function does not depend too much on any coordinate then it is almost constant.

To appreciate the power and ease of use of Eq. (13.3) we derive the well-known Chernoff–Hoeffding bound (see, among others Refs. [12,27,28]). This bound states that if $X := \sum_{i=1}^{n} X_i$ is the sum of independent, binary random variables $X_i \in \{0, 1\}$, then X is concentrated around its mean: $\Pr[|X - \mathsf{E}[X]| > t] \leq 2e^{-2t^2/n}$. This captures the well-known fact that if a fair coin is flipped many times we expect HEADS to occur roughly 50% of the time, and this bound gives precise probability estimates of deviating from the mean. This bound can be recovered from Eq. (13.3) simply by defining $f := X$ and by noticing that condition (13.2) holds with $c_i = 1$.

We now apply the MOBD to the analysis of the trivial algorithm in a simplified setting. Let us assume that the network is a triangle-free, d-regular graph. We analyze what happens to the degree of a node after the first round. The probability with which an edge colors itself is $\left(1 - \frac{1}{d}\right)^{2d-2} \sim \frac{1}{e^2}$. Therefore, denoting with f the new degree of vertex u, we have that $\mathsf{E}[f] = \Theta(d)$. At first blush it may seem that the value of f depends on the tentative color choices of $\Theta(d^2)$ edges: those incident on u and the edges incident on them. But it is possible to express f as a function of $2d$ variables only, as follows. For every $v \in N(u)$ consider the bundle of $d - 1$ edges incident on v that are not incident on u, and treat this bundle as a single random variable, denoted as B_v. B_v is a random vector with $d-1$ components, each specifying the tentative color choice of an edge incident on v (except uv). Furthermore, for every edge $e = uv$, let X_e denote e's color choice. Thus, f depends on d variables of type X_e and on d variables of type B_v. What is the effect of these variables on f? If we change the value of a fixed X_e, and keep all remaining variables the same, this color change can affect at most two edges (one of which is e itself). The resulting c_e is 2. The cumulative effect of the first d variables of type X_e is therefore $4d$.

Note now that since the network is triangle-free, changing the value of a bundle B_v can only affect the edge uv the bundle is incident to. Thus, the effect of changing B_v while keeping everything else fixed is 1. Summing up, we get a total effect of $\sum_i c_i^2 = 5d$. Plugging in this value in Eq. (13.3), for $t = \epsilon d$, where $1 > \epsilon > 0$ we get, $\Pr[|f - \mathsf{E}[f]| > \epsilon d] \leq 2e^{-2\epsilon^2 d/5}$. We can see here why it is important to have $d \gg \log n$. With this condition, the bound is strong enough to hold for all vertices and all rounds simultaneously. In fact, a value $d = \Theta(\log n)$ would seem to be enough, but the error terms accumulate as the algorithm progresses. To counter this cumulative effect, we must have $d \gg \log n$.

This establishes that the graph stays almost regular after one round (and in fact at all times), with high probability. For the full analysis one has to keep track of several other quantities besides vertex degrees, such as the size of the color lists. While the full analysis of the algorithm is beyond the scope of this survey, this simple example already clarifies some of the issues. For instance, if the graph is not triangle-free, then the effect of a bundle can be much greater than 1. To cope with this, more powerful inequalities, and a more sophisticated analysis, are needed [12,22,23,29]. We remark that in general these inequalities do not even require the variables X_i to be independent. In fact, only the following bounded difference condition is required:

$$|\mathsf{E}[f|X_1, \ldots, X_{i-1}, X_i = a] - |\mathsf{E}[f|X_1, \ldots, X_{i-1}, X_i = b]| \leq c_i$$

If this condition holds for all possible choices of a and b, and for all i, then Eq. (13.3) follows. What is behind this somewhat contrived definition is the fact that the sequence $Y_i := \mathsf{E}[f|X_1, \ldots, X_{i-1}, X_i]$ is a martingale (the so-called Doob martingale). A martingale is simply a sequence of random variables $Z_0, Z_1, \ldots, Z_n$ such that $\mathsf{E}[Z_i|Z_0, \ldots, Z_{i-1}] = Z_i$, for $i = 1, 2, \ldots, n$. A typical example of a martingale is a uniform random walk in the integer lattice, where a particle can move left, right, up, or down with equal probability. If Z_i denotes the distance of the particle from the origin, the expected distance after one step stays put. A close relative of the Chernoff–Hoeffding bound, known as Azuma's inequality, states that if a martingale sequence $Z_0, Z_1, \ldots, Z_n$ satisfies the bounded difference condition $|Z_i - Z_{i-1}| \leq c_i$ for $i = 1, 2, \ldots, n$, then it is unlikely that Z_n is far from Z_0:

$$\Pr[|Z_n - Z_0| > t] \leq 2e^{-2t^2/\Sigma_i c_i^2} \tag{13.4}$$

In words, if a martingale sequence does not make big jumps, then it is unlikely to stray afar from its starting point. This is true for the random walk; it is very unlikely that after n steps the particle will be far from the origin. Note that for a Doob martingale $Y_0 = \mathsf{E}[f]$ and $Y_n = f$, so that Eq. (13.4) becomes Eq. (13.3).

To see the usefulness of this more awkward formulation, let us drop the assumption that the network is triangle-free and analyze again what happens to the vertex degrees, following the analysis from Ref. [29]. As observed this introduces the problem that the effect of bundles can be very large: changing the value of B_v can affect the new degree by as much as $d-1$. We will therefore accept the fact that the new degree of a vertex is a function of $\Theta(d^2)$ variables, but we will be able to bound the effect of edges at distance one from the vertex. Fix a vertex v and let $N^1(v)$ denote the set of "direct" edges—i.e., the edges incident on v—and let $N^2(v)$ denote the set of "indirect edges" that is, the edges incident on a neighbor of v. Let $N^{1,2}(v) := N^1(v) \bigcup N^2(v)$. Finally, let $T := (T_{e_1}, \ldots, T_{e_m})$, $m = |E(G)|$, be the random vector specifying the tentative color choices of the edges in the graph G. With this notation, the number of edges successfully colored at vertex v is a function $f(T_e, e \in N^{1,2}(v))$ (to study f or the new degree is the same: if f is concentrated so is the new degree).

Let us number the variables so that the direct edges are numbered *after* the indirect edges (this will be important for the calculations to follow). We need to compute

$$\lambda_k := |\mathsf{E}[\mathsf{f} \mid \boldsymbol{T}_{\mathsf{k}-1}, \mathsf{T}_\mathsf{k} = \mathsf{c}_\mathsf{k}] - \mathsf{E}[\mathsf{f} \mid \boldsymbol{T}_{\mathsf{k}-1}, \mathsf{T}_\mathsf{k} = \mathsf{c}'_\mathsf{k}]| \tag{13.5}$$

We decompose f as a sum to ease the computations later. Introduce the indicator functions f_e, $e \in E$: $f_e(\boldsymbol{c})$ is 1 if edge e is successfully colored in coloring $\boldsymbol{c}$, and 0 otherwise. Then $f = \sum_{v \in e} f_e$. Hence we are reduced, by linearity of expectation, to computing for each $e \in N^1(v)$, $|\mathsf{Pr}[f_e = 1 \mid \boldsymbol{T}_{k-1}, T_k = c_k] - \mathsf{Pr}[f_e = 1 \mid \boldsymbol{T}_{k-1}, T_k = c'_k]|$.

To compute a good bound for λ_k in Eq. (13.5), we shall lock together two distributions Y and Y'. Y is distributed as $\boldsymbol{T}$ conditioned on $\boldsymbol{T}_{k-1}$, $T_k = c_k$, and Y', while Y' is distributed as $\boldsymbol{T}$ conditioned on $\boldsymbol{T}_{k-1}$, $T_k = c'_k$. We can think of $\boldsymbol{Y'}$ as identically equal to $\boldsymbol{Y}$ except that $\boldsymbol{Y'}_k = c'_k$. Such a pairing (Y, Y') is called a *coupling* of the two different distributions $[T|\boldsymbol{T}_{k-1}, T_k = c_k]$ and $[T|\boldsymbol{T}_{k-1}, T_k = c'_k]$. It is easily seen that by the independence of all tentative colors, the marginal distributions of $\boldsymbol{Y}$ and $\boldsymbol{Y'}$ are exactly the two conditioned distributions $[\boldsymbol{T} \mid \boldsymbol{T}_{k-1}, T_k = c_k]$ and $[\boldsymbol{T} \mid \boldsymbol{T}_{k-1}, T_k = c'_k]$, respectively. Now let us compute $|\mathsf{E}[\mathsf{f}(\boldsymbol{Y}) - \mathsf{f}(\boldsymbol{Y'})]|$.

First, let us consider the case when $e_1, \ldots, e_k \in N^2(v)$, i.e., only the choices of indirect edges are exposed. Let $e_k = (w, z)$, where w is a neighbor of v. Then, for a direct edge $e \neq vw$, $f_e(\boldsymbol{y}) = f_e(\boldsymbol{y'})$ because in the joint distribution space, $\boldsymbol{y}$ and $\boldsymbol{y'}$ agree on all edges incident on e. So we only need to compute $|\mathsf{E}[\mathsf{f}_{\mathsf{vw}}(\boldsymbol{Y}) - \mathsf{f}_{\mathsf{vw}}(\boldsymbol{Y'})]|$. To bound this simply, we observe first that $f_{vw}(\boldsymbol{y}) - f_{vw}(\boldsymbol{y'}) \in [-1, 1]$ and second that $f_{vw}(\boldsymbol{y}) = f_{vw}(\boldsymbol{y'})$ unless $y_{vw} = c_k$ or $y_{vw} = c'_k$. Thus we can conclude that $\mathsf{E}[\mathsf{f}_{\mathsf{vw}}(\boldsymbol{Y}) - \mathsf{f}_{\mathsf{vw}}(\boldsymbol{Y'})]| \leq \mathsf{Pr}[\mathsf{Y}_\mathsf{e} = \mathsf{c}_\mathsf{k} \vee \mathsf{Y}_\mathsf{e} = \mathsf{c}'_\mathsf{k}] \leq \frac{2}{\mathsf{d}}$.

In fact, one can do a tighter analysis using the same observations. Let us denote $f_e(\boldsymbol{y}, y_{w,z} = c_1, y_e = c_2)$ by $f_e(c_1, c_2)$. Note that $f_{vw}(c_k, c_k) = 0$ and similarly $f_{vw}(c'_k, c'_k) = 0$. Hence

$$\begin{aligned}\mathsf{E}[\mathsf{f}_\mathsf{e}(\boldsymbol{Y}) - \mathsf{f}_\mathsf{e}(\boldsymbol{Y'}) \mid \mathsf{z}] &= (f_{vw}(c_k, c_k) - f_{vw}(c'_k, c_k))\mathsf{Pr}[Y_e = c_k] \\ &\quad + (f_{vw}(c_k, c'_k) - f_{vw}(c'_k, c'_k))\mathsf{Pr}[Y_e = c'_k] \\ &= (f_{vw}(c_k, c'_k) - f_{vw}(c'_k, c_k))\frac{1}{d}\end{aligned}$$

(Here we used the fact that the distribution of colors around v is unaffected by the conditioning around z and that each color is equally likely.) Hence $|\mathsf{E}[\mathsf{f}_\mathsf{e}(\boldsymbol{Y}) - \mathsf{f}_\mathsf{e}(\boldsymbol{Y'})]| \leq \frac{1}{\mathsf{d}}$.

Now let us consider the case when $e_k \in N^1(v)$, i.e., choices of all indirect edges and of some direct edges have been exposed. In this case, we merely observe that f is Lipshitz with constant 2: $|f(\boldsymbol{y}) - f(\boldsymbol{y'})| \leq 2$ whenever $\boldsymbol{y}$ and $\boldsymbol{y'}$ differ in only one coordinate. Hence we can easily conclude that $|\mathsf{E}[\mathsf{f}(\boldsymbol{Y}) - \mathsf{f}(\boldsymbol{Y'})]| \leq 2$.

Overall, $\lambda_k \leq 1/d$ for an edge $e_k \in N^2(v)$, and $\lambda_k \leq 2$ for an edge $e_k \in N^1(v)$. Therefore, we get

$$\sum_k \lambda_k^2 = \sum_{e \in N^2(v)} \frac{1}{d^2} + \sum_{e \in N^1(v)} 4 \leq 4d + 1$$

We thus arrive at the following sharp concentration result by plugging into Eq. (13.3): Let v be an arbitrary vertex and let f be the number of edges successfully colored around v in one stage of the trivial algorithm. Then,

$$\mathsf{Pr}[|f - \mathsf{E}[\mathsf{f}]| > t] \leq 2\exp\left(-\frac{t^2}{2d + \frac{1}{2}}\right)$$

Since $\mathsf{E}[f] = \Theta(d)$, this is a very strong bound.

13.4 Matchings

Maximum matching is probably one of the best studied problems in computer science: given a weighted undirected graph $G = (V, E)$, compute a subset of pairwise nonincident edges (*matching*) of maximum cost. For simplicity, we will focus on the the cardinality version of the problem, where all the edges have weight 1.

It is not hard to show that a maximum matching cannot be computed efficiently (i.e., in polylogarithmic time) in a distributed setting.

Lemma 13.7

Any distributed maximum matching algorithm requires $\Omega(n)$ rounds.

Proof

Consider the following *mailing problem*: let P be a path of $n = 2k + 1$ nodes, and let ℓ and r be the left and right endpoints of the path, respectively. Moreover, let c be the *central* node of the path. Nodes ℓ and r receive the same input bit b, and the problem is to forward b to the central node c. Clearly, this process takes at least k rounds.

Now assume by contradiction that there exists a $o(n)$ distributed maximum matching protocol $\mathcal{M}$. We can use $\mathcal{M}$ to solve the mailing problem above in the following way. All the nodes run $\mathcal{M}$ on the auxiliary graph $P(b)$ obtained from P by removing the edge incident to ℓ if $b = 1$, and the edge incident to r otherwise. If $b = 1$ ($b = 0$), the edge on the left (right) of v must belong to the (unique) maximum matching. This way c can derive the value of the input bit b in $o(n) = o(k)$ rounds, which is a contradiction. □

Fischer et al. [30] described a parallel algorithm to compute a near-optimal matching in arbitrary graphs. Their algorithm can be easily turned into a distributed protocol to compute a $k/(k + 1)$-approximate solution in polylogarithmic time, for any fixed positive integer $k > 0$. A crucial step in the algorithm by Fischer et al. is computing (distributively) a maximal independent set. Since this subproblem is rather interesting by itself in the distributed case, in Section 13.4.1 we will sketch how it can be solved efficiently. In Section 13.4.2 we will describe and analyze the algorithm by Fischer et al.

13.4.1 Distributed Maximal Independent Set

Recall that an *independent set* of a graph is a subset of pairwise nonadjacent nodes. No deterministic protocol is currently known for the problem. Indeed, this is one of the main open problems in distributed algorithms. Luby [31] and independently Alon et al. [32] gave the first distributed randomized algorithms to compute a maximal independent set. Here we will focus on Luby's result, as described in Kozen's book [33].

As the algorithm by Fischer et al., Luby's algorithm was originally thought for a parallel setting, but it can be easily turned into a distributed algorithm. It is worth noticing that transforming an efficient parallel algorithm into an efficient distributed algorithm is not always trivial. For example, there is a deterministic parallel version of Luby's algorithm, while, as mentioned above, no efficient deterministic distributed algorithm is known for the maximal independent set problem.

Luby's algorithm works in stages. In each stage, one (not necessarily maximal) independent set I is computed, and the nodes I are removed from the graph together with all their neighbors. All the edges incident to deleted nodes are also removed. The algorithm ends when no node is left. At the end of the algorithm a maximal independent set is given by the union of the independent sets I computed in the different stages.

It remains to describe how each independent set I is computed. Each node v in the (current) graph independently becomes a *candidate* with probability $\frac{1}{2d(v)}$. Then, for any two adjacent candidates, the one of lower degree is discarded from S (ties can be broken arbitrarily). The remaining candidates form the set I.

Each stage can be trivially implemented with a constant number of communication rounds. The expected number of rounds is $O(\log n)$. More precisely, in each stage at least a constant expected fraction of the (remaining) edges are removed from the graph.

A crucial idea in Luby's analysis is the notion of good nodes: a node v is *good* if at least one-third of its neighbors have degree not larger than v. In particular, this implies

$$\sum_{u \in N(v)} \frac{1}{2d(u)} \geq \frac{1}{6} \tag{13.6}$$

Otherwise v is *bad*. Although there might be few good nodes in a given graph, the edges incident to at least one good node are a lot. Let us call an edge *good* if it is incident to at least one good node, and *bad* otherwise. The following lemma holds.

Lemma 13.8

At least one-half of the edges are good.

Proof

Direct all the edges toward the endpoint of higher degree, breaking ties arbitrarily. Consider any bad edge e directed toward a given (bad) node v. By definition of bad nodes, the out-degree of v is at least twice its own in-degree. Thus we can uniquely map e into a pair of edges (either bad or good) leaving v. Therefore, the edges are at least twice as many as the bad edges. □

Thus it is sufficient to show that in a given stage each good node is removed from the graph with constant positive probability.

Lemma 13.9

Consider a node v in a given stage. Node v belongs to I with probability $\frac{1}{4d(v)}$.

Proof

Let $L(v) = \{u \in N(v) \mid d(u) \geq d(v)\}$ be the neighbors of v of degree not smaller than $d(v)$. Then

$$Pr(v \notin I \mid v \in S) \leq \sum_{u \in L(v)} Pr(u \in S \mid v \in S) = \sum_{u \in L(v)} Pr(u \in S) \leq \sum_{u \in L(v)} \frac{1}{2d(u)} \leq \sum_{u \in L(v)} \frac{1}{2d(v)} \leq \frac{1}{2}$$

Hence $Pr(v \in I) = Pr(v \in I \mid v \in S)\ Pr(v \in S) \geq \frac{1}{2}\frac{1}{2d(v)} = \frac{1}{4d(v)}$. □

Lemma 13.10

Let v be a good node in a given stage. Node v is discarded in the stage considered with probability at least $1/36$.

Proof

We will show that $v \in N(I) = \cup_{u \in I} N(u)$ with probability at least $1/36$. The claim follows. If v has a neighbor u of degree at most 2, by Lemma 13.9, $Pr(v \in N(I)) \geq Pr(u \in I) \geq \frac{1}{4d(u)} = \frac{1}{8}$.

Now assume that all the neighbors of v have degree 3 or larger. It follows that, for every neighbor u of v, $\frac{1}{2d(u)} \leq \frac{1}{6}$. Hence by Eq. (13.6) there exists a subset $M(v)$ of neighbors of v such that $\frac{1}{6} \leq \sum_{u \in M(v)} \frac{1}{2d(u)} \leq \frac{1}{3}$. Thus

$$\begin{aligned}
Pr(v \in N(I)) &\geq Pr(\exists\, u \in M(v) \cap I) \\
&\geq \sum_{u \in M(v)} Pr(u \in I) - \sum_{u,w \in M(v),\ u \neq w} Pr(u \in I \wedge w \in I) \\
&\geq \sum_{u \in M(v)} \frac{1}{4d(u)} - \sum_{u,w \in M(v),\ u \neq w} Pr(u \in S \wedge w \in S) \\
&\geq \sum_{u \in M(v)} \frac{1}{4d(u)} - \sum_{u,w \in M(v),\ u \neq w} Pr(u \in S) Pr(w \in S) \\
&\geq \sum_{u \in M(v)} \frac{1}{4d(u)} - \sum_{u \in M(v)} \sum_{w \in M(v)} \frac{1}{2d(u)} \frac{1}{2d(w)} \\
&= \left(\frac{1}{2} - \sum_{w \in M(v)} \frac{1}{2d(w)}\right) \sum_{u \in M(v)} \frac{1}{2d(u)} \geq \left(\frac{1}{2} - \frac{1}{3}\right)\frac{1}{6} = \frac{1}{36}
\end{aligned}$$

□

13.4.2 The Distributed Maximum Matching Algorithm

Consider an arbitrary matching M of a graph $G = (V, E)$. A node is *matched* if it is the endpoint of some edge in M, and *free* otherwise. An *augmenting path* P with respect to M is a path (of odd length) whose endpoints are free and whose edges are alternatively inside and outside M. The reason of the name is that we can obtain a matching M' of cardinality $|M| + 1$ from M, by removing from M all the edges which are also in P, and by adding to M the remaining edges of P (in other words, M' is the symmetric difference $M \oplus P$ of M and P).

The algorithm by Fischer et al. is based on the following two lemmas by Hopcroft and Karp [34]. Let two paths be *independent* if they are node-disjoint. Note that a matching can be augmented along several augmenting paths simultaneously, provided that such paths are independent.

Lemma 13.11

If a matching is augmented along a maximal set of independent shortest augmenting paths, then the shortest augmenting paths length grows.

Lemma 13.12

Suppose a matching M does not admit augmenting paths of length $2k - 1$ *or smaller. Then the size of M is at least a fraction* $\frac{k}{k+1}$ *of the maximum matching size.*

Proof

Let M^* be a maximum matching. The symmetric difference $M' = M \oplus M^*$ contains $|M^*| - |M|$ independent augmenting paths with respect to M. Since each of these paths contains at least k edges of M, $|M^*| - |M| \leq |M|/k$. The claim follows. □

We are now ready to describe and analyze the approximate maximum matching algorithm by Fischer et al. The algorithm proceeds in stages. In each stage i, $i \in \{1, 2, \ldots, k\}$, the algorithm computes a maximal independent set P_i of augmenting paths of length $2i - 1$ with respect to the current matching M. Then M is augmented according to P_i. Stage i can be implemented by simulating Luby's algorithm on the auxiliary graph induced by the augmenting paths considered, where the nodes are the paths and the edges are the pairs of nonindependent paths. In particular, Luby's algorithm takes $O(\log n^{2i})$ rounds in expectation in the auxiliary graph, where each such round can be simulated within $O(i)$ rounds in the original graph. Note that, by Lemma 13.11, at the end of stage i there are no augmenting paths of length $2i - 1$ or smaller. It follows from Lemma 13.12 that at the end of the kth stage the matching computed is $\frac{k}{k+1}$-approximate. The total expected number of rounds is trivially $O(k^3 \log n)$. The following theorem summarizes the discussion above.

Theorem 13.1

For every integer $k > 0$, *there is a distributed algorithm which computes a matching of cardinality at least* $\frac{k}{k+1}$ *times the maximum matching cardinality within* $O(k^3 \log n)$ *communication rounds in expectation.*

Wattenhofer and Wattenhofer [35] gave a $O(\log^2 n)$ randomized algorithm to compute a constant approximation in the weighted case. In the deterministic case weaker results are available. This is mainly due to the fact that we are not able to compute maximal independent sets deterministically. Hańćkowiak et al. [36,37] described an efficient distributed deterministic algorithm to compute a maximal matching. Recall that any maximal matching is a 2-approximation for the maximum matching problem. Recently, a 1.5 deterministic distributed approximation algorithm was described in Ref. [38].

13.5 LP-Based Distributed Algorithms

It might come as a surprise that LP-based methods find their application in a distributed setting. In this section we describe some primal-dual algorithms for vertex cover problems that give "state-of-the-art" approximations. In general, it seems that the primal-dual method, one of the most successful techniques in approximation algorithms, when applied to graph algorithms exhibits "local" properties that makes it amenable to a distributed implementation. The best way to explain what we mean is to work out an example.

We will illustrate the method by considering the *vertex cover* problem: given an undirected graph $G = (V, E)$, with positive weights $\{c(v)\}_{v \in V}$, compute a minimum-cost subset V' of nodes such that each edge is incident to at least one node in V'. This *NP*-hard problem is approximable within 2 [39], and not approximable within 1.1666 unless P = NP [40]. In the centralized case there is a primal-dual 2-approximation algorithm. The distributed implementation we give yields a $2 + \epsilon$ approximation, where ϵ can be any fixed constant greater than 0. The number of communication rounds of the algorithm is $O(\log n \log \frac{1}{\epsilon})$.

The sequential primal-dual algorithm works as follows. We formulate the problem as an integer program (IP):

$$\begin{aligned} \min \quad & \sum_{v \in V} c(v) \cdot x_v && && \text{(IP)} \\ \text{s.t.} \quad & x_v + x_u \geq 1 && \forall e = (u, v) \in E && (13.7) \\ & x_v \in \{0, 1\} && \forall v \in V && (13.8) \end{aligned}$$

The binary indicator variable x_v, for each $v \in V$, takes value 1 if $v \in V'$, and 0 otherwise.

We now let (LP) be the standard LP relaxation obtained from (IP) by replacing the constraints (13.8) by $x_v \geq 0$ for all $v \in V$. In the linear programming dual of (LP) we associate a variable α_e with constraints (13.7) for every $e \in E$. The linear programming dual (D) of (LP) is then

$$\begin{aligned} \max \quad & \sum_{e \in E} \alpha_e && && \text{(D)} \\ \text{s.t.} \quad & \sum_{e=(u,v) \in E} \alpha_e \leq c(v) && \forall v \in V && (13.9) \\ & \alpha_e \geq 0 && \forall e \in E && (13.10) \end{aligned}$$

The starting primal and dual solutions are obtained by setting to 0 all the variables x_v and α_e. Observe that the dual solution is feasible while the primal one is not. We describe the algorithm as a continuous process. We let all the variables α_e grow at uniform speed. As soon as one constraint of type (13.9) is satisfied with equality (it becomes *tight*), we set the corresponding variable x_v to 1, and we freeze the values α_e of the edges incident to v. The α-values of frozen edges do not grow more, so that the constraint considered remains tight. The process continues until all edges are frozen. When this happens the primal solution becomes feasible. To see why, suppose not. But then there is an edge $e = uv$ which is not covered, i.e., $x_u = x_v = 0$. This means that the constraints corresponding to u and v are not tight and α_e can continue to grow, a contradiction.

Thus the set $V' := \{u : x_u = 1\}$ is a cover. Its cost is upper-bounded by twice the cost of the dual solution:

$$\sum_{v \in V} c(v)\, x_v = \sum_{v \in V'} c(v) \leq \sum_{v \in V'} \sum_{e=(u,v) \in E} \alpha_e \leq 2 \sum_{e \in E} \alpha_e$$

Thus the solution computed is 2-approximate by weak duality.

The continuous process above can be easily turned into a discrete one. Let $c'(v)$ be the difference between the right- and the left-hand side of constraints (13.9) in a given instant of time (*residual weight*):

$$c'(v) = c(v) - \sum_{e=(u,v) \in E} \alpha_e$$

Moreover, let $d'(v)$ be the current number of nonfrozen (*active*) edges incident to v. The idea is to raise in each step the dual value α_e of all the active edges by the minimum over all nodes v such that $x_v = 0$ of the quantity $c'(v)/d'(v)$. This way, in each step at least one extra node enters the vertex cover.

There is a simple-minded way to turn the algorithm above into a distributed algorithm: each node v maintains the quantities $c'(v)$ and $d'(v)$. A node is *active* if $c'(v) > 0$ and $d'(v) > 0$, that is if v and at least one of its neighbors are not part of the vertex cover. In each round each active node v sends a *proposal* $c'(v)/d'(v)$ to all its active neighbors. Then it decreases $c'(v)$ by the minimum of all the proposals sent and received. If $c'(v)$ becomes 0, v enters the vertex cover. Otherwise, if $d'(v)$ becomes 0, v halts since all its neighbors already belong to the vertex cover.

The main drawback of this approach is that it is very slow. In fact, it may happen that in each step a unique node enters the vertex cover, thus leading to a linear number of rounds. Khuller et al. [41] showed how to circumvent this problem by losing something in the approximation. Here we will present a simplified version of their algorithm and analysis (which was originally thought for weighted set cover in a parallel setting). The idea is to slightly relax the condition for a node v to enter the vertex cover: it is sufficient that the residual weight $c'(v)$ falls below $\epsilon\, c(v)$, for a given (small) constant $\epsilon > 0$.

Theorem 13.2

The algorithm above computes a $\frac{2}{1-\epsilon}$-approximate vertex cover within $O(\log n \log \frac{1}{\epsilon})$ rounds.

Proof

The bound on the approximation easily follows by adapting the analysis of the primal-dual centralized approximation algorithm:

$$(1-\epsilon)\, apx = \sum_{v \in V'} (1-\epsilon)\, c(v) \leq \sum_{v \in V'} \sum_{e=(u,v) \in E} \alpha_e \leq 2 \sum_{e \in E} \alpha_e \leq 2\, opt$$

To bound the number of rounds we use a variant of the notion of good nodes introduced in Section 13.4.1. Consider the graph induced by the active nodes in a given round, and call the corresponding edges *active*. Let us direct all the active edges toward the endpoint which makes the smallest proposal. A node is *good* if its in-degree is at least one-third of its (total) degree. By basically the same argument as in Section 13.4.1, at least one-half of the edges are incident to good nodes. Moreover, the residual weight of a node which is good in a given round decreases by at least one-third in the round considered. As a consequence, a node can be good in at most $\log_{3/2} \frac{1}{\epsilon}$ rounds (after those many rounds it must enter the vertex cover).

We will show next that the total number of active edges halves every $O(\log \frac{1}{\epsilon})$ rounds by means of a potential function argument. It follows that the total number of rounds is $O(\log m \log \frac{1}{\epsilon}) = O(\log n \log \frac{1}{\epsilon})$. Let us associate $2 \log_{3/2} \frac{1}{\epsilon}$ credits to each edge, and thus $2m \log_{3/2} \frac{1}{\epsilon}$ credits to the whole graph. When a node v is good in a given step, we remove one credit from each edge incident to it. Observe that an active edge e in a given round must have at least two credits left. This is because otherwise one of the endpoints of e would already belong to the vertex cover, and thus e could not be active. By m_j we denote the number of active edges in round j. Recall that in each round at least one-half of the edges are incident to a good node, and such edges loose at least one credit each in the round considered. Thus the total number of credits in round j decreases by a quantity g_j which satisfies $g_j \geq m_j/2$. Consider an arbitrary round i, and let k be the smallest integer such that $m_{i+k} < m_i/2$ (or $i+k$ is the last round). It is sufficient to show that $k = O(\log \frac{1}{\epsilon})$. In each round j, $j \in \{i, i+1, \ldots, i+k-1\}$, the number of edges satisfies $m_j \geq m_i/2$. The total number of credits at the beginning of round i is at most $2m_i \log_{3/2} \frac{1}{\epsilon}$, and the algorithm halts when no credit is left. Therefore,

$$2m_i \log_{3/2} \frac{1}{\epsilon} \geq \sum_{j=i}^{i+k-1} g_j \geq \sum_{j=i}^{i+k-1} \frac{m_j}{2} \geq \sum_{j=i}^{i+k-1} \frac{m_i}{4} = k\frac{m_i}{4} \quad \Rightarrow \quad k \leq 8 \log_{3/2} \frac{1}{\epsilon} = O\left(\log \frac{1}{\epsilon}\right) \quad \square$$

By choosing $\epsilon = 1/(nC+1)$, where C is the maximum weight, the algorithm by Khuller et al. computes a 2-approximate vertex cover within $O(\log n \log(nC))$ rounds. Recently, Grandoni et al. [42] showed how to achieve the same task in $O(\log(nC))$ rounds by means of randomization. They reduce the problem to the computation of a maximal matching in an auxiliary graph of nC nodes (to have an idea of the

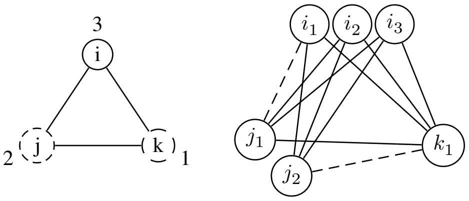

FIGURE 13.2 A weighted graph G (on the left) with the corresponding auxiliary graph $\widetilde{G}$. A maximal matching M of $\widetilde{G}$ is indicated via broken lines. The nodes of G such that all the corresponding nodes in $\widetilde{G}$ are matched form a 2-approximate vertex cover.

reduction, see Figure 13.2). Such matching can be computed in $O(\log(nC))$ rounds via the randomized, distributed maximal matching algorithm by Israeli and Itai [43]. The authors also show how to keep small the message size and the local computation time by computing the matching *implicitly*.

The *capacitated* vertex cover problem is the generalization of the vertex cover problem where each node v can cover only a limited number $b(v) \leq d(v)$ of edges incident to it. Grandoni et al. [44] showed how to compute within $O(\frac{\log nC}{\epsilon})$ rounds an $(2 + \epsilon)$-approximate solution, if any, which violates the capacity constraints by a factor at most $(4 + \epsilon)$. They also proved that any distributed constant approximation algorithm must violate the capacity constraints by a factor at least 2. This, together with the known lower bounds on the approximation of (classical) vertex cover, shows that their algorithm is the best possible modulo constants. The algorithm by Grandoni et al. builds up on a primal-dual centralized algorithm developed for the purpose, which computes a 2 approximation with a factor 2 violation of the capacity constraints. Turning such primal-dual algorithm into a distributed protocol is far more involved than in the case of classical vertex cover.

13.6 What Can and Cannot Be Computed Locally?

This fundamental question in distributed computing was posed by Naor and Stockmeyer [45]. Here, "locally" means that the nodes of the network use information available locally from a neighborhood that can be reached in time much smaller than the size of the network. For many natural distributed network problems such as leader election and consensus the parameter determining the time complexity is not the number of vertices, but the network *diameter* D, which is the maximum distance (number of hops) between any two nodes [46]. A natural question is whether other fundamental primitives can be computed in $O(D)$ time in a distributed setting. If the model allows messages of unbounded size, then there is a trivial affirmative answer to this question: collect all the information at one vertex, solve the problem locally and then transmit the result to all vertices. The problem is therefore only interesting in the more realistic model where we assume that each link can transmit only B bits in any time step (B is usually taken to be a constant or $O(\log n)$).

A landmark negative result in this direction was that of Linial [47] which investigated the time complexity of various global functions of a graph computed in a distributed setting. Suppose that n processors are arranged in a ring and can communicate only with their immediate neighbors. Linial showed that a three-coloring of the n-cycle requires time $\Omega(\log^* n)$. This result was extended to randomized algorithms by Naor [48]: any probabilistic algorithm for three-coloring the ring must take at least $\frac{1}{2}\log^* n - 2$ rounds, otherwise the probability that all processors are colored legally is less than $\frac{1}{2}$. The bound is tight (up to a constant factor) in light of the deterministic algorithms of Cole and Vishkin [49].

There has been surprisingly little continuation of work in this direction until fairly recently. Garay et al. [50] gave an algorithm of complexity $O(D + \sqrt{n}\log n)$ to compute a minimum spanning tree (MST) of a graph on n vertices with diameter D. Similar bounds were attained by other methods, but none managed to break the $\sqrt{n}$ barrier, leading to the suspicion that it might be impossible to compute the MST in time $o(\sqrt{n})$ and so this problem is fundamentally harder than the other paradigm problems. The issue was finally settled by Peleg and Rubinovich [51], who showed a $\Omega(\sqrt{n})$ lower bound on the problem (up to log factors). Subsequently, Elkin [52] improved the lower bound and also extended it to distributed approximation algorithms. Kuhn et al. [53] gave lower bounds on the complexity of computing the minimum vertex cover (MVC) and the MDS of a graph: in k communication rounds, the MVC and MDS can only be approximated to factors of $\Omega(n^{ck^2}/k)$ and $\Omega(\Delta^{1/k}/k)$ (where Δ is the maximum degree of the graph). Thus, the number of rounds required to reach a constant or even a polylog approximation is at least $\Omega(\sqrt{\log n/\log\log n})$ and $\Omega(\log\Delta/\log\log\Delta)$. The same lower bounds also apply to the construction of maximal matchings and maximal independent sets via a simple reduction.

13.6.1 A Case Study: Minimum Spanning Tree

Here, we give a self-contained exposition of the lower bound for the MST problem due to Refs. [51,52]. We will give the full proof of a bound somewhat weaker than the optimal result of Elkin to convey the underlying ideas more clearly. The basic idea is easy to explain using the example of Peleg and Rubinovich [51] (see Figure 13.3). The network consists of m^2 country road and one highway. Each country road has m toll stations and between every two successive toll station are m towns. The highway has m toll stations with no towns in between. Each toll station number i on each country road is connected to the corresponding highway toll station. The left end of the country road i is labelled s_i and its right end r_i. The left end of the highway is labelled s and the right end r. This is the basic underlying graph. Note that there are $\Theta(m^4)$ vertices and the diameter is $\Theta(m)$.

As for the weights, every edge along the highway or on the country roads has weight 0. The roads connecting the toll stations on the country roads to the corresponding toll stations on the highway have weight ∞ *except for the first and last toll stations.* The toll station connections at the right end between each r_i and r are all 1. At the left end, between each s_i and s, they take either the value 0 or ∞.

What does the MST of this network look like? First, we may as well include the edges along the highway and each path since these have zero cost. Also the intermediate connecting edges have weight ∞ and so are excluded. That leaves us with the connecting edges on the left and on the right. The choice here depends on the weights on the left connecting edges. There are m connecting edges from the left vertex s. If the edge (s, s_i) has weight ∞, then we must exclude this and include the matching connection (r_i, r) at the right end. In contrast, if edge (s, s_i) has weight 0, then we must include this and exclude the corresponding edge (r_i, r) at the right to r. Thus there are m^2 decisions made at s depending on the weights of the corresponding edges, and these decisions must be conveyed to r to pick the corresponding complementary edges. How quickly can these m^2 bits be conveyed from s to r? Clearly, it would take very long to route along the country roads, and so one must use the highway edges instead. Each highway edge can forward only B bits at any time step. So, heuristically, transporting the m^2 bits takes $\Omega(m^3/B)$ steps.

To make this heuristic argument formal, Peleg and Rubinovich introduced a *mailing problem* to be solved on a given network. In the example above, the *sender* s has m^2 bits that need to be transported to the *receiver* r. At each step one can forward B bits along any edge. How many steps do we need to correctly route the m^2 bits from the sender to the receiver? It is easy to see that there is a reduction from the mailing problem to that of computing the MST: for each of the input bits at s, set the weights on the connecting edges accordingly: the weight (s, s_i) is ∞ if the input bit i is 1 and 0 otherwise. Now compute the MST. Then, if vertex r notices that the edge (r_i, r) is picked in the MST, it decodes i

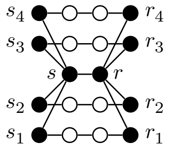

FIGURE 13.3 MST lower bound graph for $m = 2$. The black nodes are the toll stations and the white nodes are the towns.

as 1 and as 0 otherwise. This will correctly solve the mailing problem, due to the structure of the MST discussed above. Thus, a lower bound on the mailing problem implies the same lower bound on the MST problem.

In fact by a slight change, the correspondence can be extended from exact to approximation algorithms. Elkin [52] introduced the *corrupted mail* problem. Here there are Γ bits at the sender exactly $\alpha\Gamma$ of which are 1's, where α and Γ are parameters. In the example above, $\Gamma = m^2$. The receiver should get Γ bits delivered to it, but these are allowed to be somewhat corrupted. The restrictions are (a) any input bit that was 1 must be transmitted correctly without corruption and (b) the total number of 1's delivered can be at most $\beta\Gamma$, where $\beta \geq \alpha$ is another parameter. Consider solving the (α, β) corrupted mail problem on the Peleg–Rubinovich example. As in the reduction before, the vertex s sets the weights on the left connections according to its input and so exactly $\alpha\Gamma$ connections have weight ∞, and the rest 0. The optimal MST has weight exactly $\alpha\Gamma$ obtained by picking the corresponding right connections. Now, instead of the optimal MST, suppose we apply a protocol to compute a β/α approximation. This approximate MST can have weight at most $\beta\Gamma$, and it must include the connection edges at r paired with the infinite weight edges at s. Thus, if r sets its bits as before corresponding to which of its connections are in the approximate MST, we get a correct protocol for the (α, β) corrupted mail problem. Thus a lower bound for the (α, β) corrupted mail problem implies the same lower bound for a $\frac{\beta}{\alpha}$-approximate MST.

We are thus left with the task of proving a lower bound for the corrupted mail problem. Let the *state* $\psi(v, t)$ of a vertex v at some time t denote the sequence of messages it has received up to this time. Consider the start vertex s at time 0: this can be in any of $\binom{\Gamma}{\alpha\Gamma}$ states corresponding to the input it receives. At this time, on the other hand, the vertex r (and indeed, any other vertex) is in a fixed state (having received no messages at all). As time progresses and messages are passed, the set of possible states that other vertices are in expands. Eventually, the set of possible states that vertex r is in must be large enough to accommodate the output corresponding to all the possible inputs at s. Each possible state of r with at most $\beta\Gamma$ 1's can be the correct answer to at most $\binom{\beta\Gamma}{\alpha\Gamma}$ input configurations at s. Hence, the set of output states at r must be at least $\binom{\Gamma}{\alpha\Gamma}/\binom{\beta\Gamma}{\alpha\Gamma} \geq (1/e\beta)^{\alpha\Gamma}$.

Now, we will argue that it must take a long time for any protocol, before enough messages arrive at r for the set of its possible states to have this size. Consider the *tail sets* T_i, $i \geq 1$ which consist of the tail of each country road from vertex i until the end, and the corresponding fragment of the highway consisting of the vertices $h_{\lceil i/m \rceil m}$ until h_{m^2}. Also, set $T_0 := V \setminus \{h_0\}$. For a subset of vertices U, let $\mathcal{C}(U, t)$ denote the set of all possible vectors of states of the vertices in U at time t, and let $\rho(U, t) := |\mathcal{C}(U, t)|$. Note that $\rho(T_0, 0) = 1$ although $\rho(\{s\}, 0) = \binom{\Gamma}{\alpha\Gamma}$.

We now focus on how set of configurations of the tail sets T_i grow in time. Fix a configuration $C \in \mathcal{C}(T_t, t)$. How many configurations in $\mathcal{C}(T_{t+1}, t+1)$ can this branch into? The tail set T_{t+1} is connected to the rest of the graph by one highway edge f and by m^2 path edges. Each of the path edges carries a unique message determined by the state of the left endpoint in configuration C. The state of the left endpoint of the highway edge f is not determined by C and hence there could be a number of possible messages that could be relayed along it. However, because of the restriction that at most B bits can be transmitted along an edge at any time step, the total number of possible behaviors observable on edge f at this time step is at most $2^B + 1$. Thus the configuration C can branch off into at most $2^B + 1$ possible configurations $C' \in \mathcal{C}(T_{t+1}, t+1)$. Thus we have argued that for $0 \leq t < m^2$, $\rho(T_{t+1}, t+1) \leq (2^B + 1)\rho(T_t, t)$. By induction, this implies that for $0 \leq t < m^2$, $\rho(T_t, t) \leq (2^B + 1)^t$. Thus finally, we have, that if t^* is the time at which the protocol ends, then either $t^* \geq m^2$, or $(1/e\beta)^{\alpha\Gamma} \leq \rho(\{r\}, t^*) \leq \rho(T_{t^*}, t^*) \leq (2^B + 1)^{t^*}$. Hence, $t^* \geq \min(m^2, \alpha\Gamma \log(\frac{1}{e\beta})/(B + 1))$.

Recalling that $\Gamma = m^2$ in our specific graph, and taking β to be a constant such that $\beta e < 1$, $t^* = \Omega(\alpha m^2/B)$, or, in terms of the number of vertices $n = \Theta(m^4)$ of the graph, $t^* = \Omega(\alpha\sqrt{n}/B)$. If we have a $H := \beta/\alpha$ approximation algorithm for the MST, this implies that $t^* = \Omega(\sqrt{n}/HB)$, implying the trade-off $t^* H = \Omega(\sqrt{n}/B)$ between time and approximation. Elkin [52] improves the lower bound for t^* to $t^* = \Omega\left(\sqrt{n/B}/H\right)$, implying the time-approximation trade-off $t^{*2}H = \Omega\left(\sqrt{n/B}\right)$, and gives a protocol achieving this trade-off.

13.6.2 The Role of Randomization in Distributed Computing

Does randomization help in a distributed setting? This is a fundamental open question in distributed computing. For some of the problems discussed, such as three-coloring on a ring, we have noted that matching lower bounds hold for randomized algorithms. By the usual application of Yao's Minimax Theorem, Elkin's lower bound also applies to randomized algorithms. For the problem of computing maximal matchings and maximal independent sets, there are simple randomized algorithms, whereas the result of Kuhn et al. [53] shows a superpolylog lower bound for deterministic algorithms. A classification of problems by the degree to which randomization helps is an interesting open problem.

Empirical Analysis of Randomized Algorithms

Holger H. Hoos

Thomas Stützle
Free University of Brussels

14.1 Introduction

Heuristic algorithms are often difficult to analyse theoretically; this holds in particular for advanced, randomised algorithms that perform well in practice, such as high-performance stochastic local search (SLS) procedures (also known as metaheuristics) [1]. Furthermore, for various reasons, the practical applicability of the theoretical results that can be achieved is often very limited. Some theoretical results are obtained under idealised assumptions that do not hold in practical situations—as is the case, for example, for the well-known convergence result for simulated annealing [2]. Also, most complexity results apply to worst-case behaviour, and average-case results, which are fewer and typically much harder to prove, are often based on instance distributions that are unlikely to be encountered in practice. Finally, theoretical bounds on the run times of heuristic algorithms are typically asymptotic and do not reflect the actual behaviour accurately enough for many purposes, in particular, for comparative performance analyses. For these reasons, researchers (and practitioners) typically use empirical methods when analysing or evaluating heuristic algorithms.

In many ways, the issues and considerations arising in the empirical analysis of algorithmic behaviour are quite similar to those commonly encountered in experimental studies in biology, physics or any other empirical science. Fundamentally, to investigate a complex phenomenon of interest, the classical scientific cycle of observation, hypothesis, prediction and experiment is followed to obtain a model that explains the phenomenon. Different from natural phenomena, algorithms are completely specified and mathematically defined at the lowest level; still, in many cases, this knowledge is insufficient for theoretically deriving all relevant aspects of their behaviour. In this situation, empirical approaches, based on computational experiments, are often not only the sole way of assessing a given algorithm, but also have the potential to provide insights into practically relevant aspects of algorithmic behaviour that appear to lie well beyond the reach of theoretical analysis.

Some general goals are common to all empirical studies: *Reproducibility* ensures that experiments can be repeated with the same outcome; it requires that all relevant experimental conditions and protocols are specified clearly and in sufficient detail. In the empirical analysis of algorithmic behaviour, reproducibility is greatly facilitated by the fact that actual computations can in principle be replicated exactly. However, complications can arise when dealing with randomised algorithms or randomly generated input data, in which case statistical significance and sample sizes can become critical issues (despite the fact that typically, pseudo-random number generators are used to implement random processes). *Comparability* with past and future related results ensure that empirical results are useful in the context of larger scientific endeavours. To achieve this goal, experiments have to be designed in such a way that their results can be meaningfully compared to those from relevant previous works and facilitate comparisons with related results expected from future experiments. Finally, perhaps the main goal of any empirical study is to gain *insight and understanding*; this implies that experiments should be designed in such a way that their outcome is likely to shed light on important, previously open questions regarding the phenomenon of interest. In the empirical analysis of algorithms, in many cases these questions are of the form 'Algorithm A has property X', and in particular, 'Algorithm A performs better than Algorithm B'.

14.2 Decision Algorithms

Many computational problems take the form of *decision problems*, in which solutions are characterised by a set of logical conditions. As an example, consider the following decision variant of the travelling salesman problem (TSP): given an edge-weighted graph and a real number b, does there exist a Hamiltonian cycle (i.e., a round trip that visits every vertex exactly once) with total weight at most b? Other well-known examples of decision problems include the propositional satisfiability problem (SAT), the graph colouring problem and certain types of scheduling problems.

A *decision algorithm* is an algorithm that takes as an input an instance of a given decision problem and determines whether the instance is *soluble*, i.e., whether it has a solution. In most cases, if a solution is found, that solution is also returned by the algorithm. Note that this notion of a decision algorithm includes algorithms that may be incomplete, i.e., may fail to return a correct result within bounded time, or even incorrect, i.e., sometimes return erroneous results. In the following, we will focus on decision algorithms that are correct, but incomplete; this captures most heuristic decision algorithms, including, for example, almost all SLS algorithms for SAT.

14.2.1 Analysis on Single Instances

The primary performance metric for complete (and correct) decision algorithms is typically *run time*, i.e., the time required for solving a given problem instance. For incomplete algorithms, it may happen that, although the given problem instance is soluble, a solution cannot be found. (In this case, the algorithm may not terminate, or signal failure, for example, by returning 'no solution found'.) Obviously, such cases need to be noted; by further analysing them, valuable insights into weaknesses of the algorithm (or errors in its implementation) can be obtained.

Run time is typically measured in terms of CPU time (rather than wall-clock time) to minimise the impact of other processes that are running concurrently (e.g., system processes). Obviously, CPU time measurements are always based on a concrete implementation and run-time environment, i.e., machine and operating system; to facilitate reproducibility and comparability, a specification of the run-time environment (comprising at least the processor type and model, clock speed and amount of RAM, as well as the operating system, including version number) should be given along with any CPU time result.

It is often desirable to further abstract from details of the implementation and run-time environment, especially in the context of comparative performance studies. This can be achieved using *operation counts*, which reflect the number of elementary operations that are considered to contribute significantly towards an algorithm's performance, and *cost models*, which relate the cost of these operations (typically in terms of run time per execution) relative to each other or absolute in terms of CPU time for a given implementation and run-time environment [3]. For SLS algorithms, a commonly used operation count is the number of local search steps. When measuring performance in terms of operation counts, care should be taken to select elementary operations whose cost per step is constant or close to constant within and between runs of the algorithm on the same instance. In this situation, operation counts and CPU-time measurements are related to each other by scaling with a constant factor that only depends on the given problem instance. Using operation counts and an associated cost model rather than CPU-time measurements as the basis for empirical studies often gives a clearer and more detailed picture of algorithmic performance.

While performance analysis of deterministic decision algorithms on a single problem instance consists of a simple run-time measurement, matters are slightly more involved if the algorithm under consideration is randomised. In that case, the run time of an algorithm A applied to a given problem instance π corresponds to a random variable $RT_{A,\pi}$; the probability distribution of $RT_{A,\pi}$ is called the *run-time distribution* (*RTD*) *of A on π*. Clearly, the run-time behaviour of an algorithm A on a given problem instance π is completely and precisely characterised by the respective RTD. Furthermore, this RTD can be estimated based on run-time measurements obtained from multiple independent runs of A on π. For sufficiently high numbers of runs, the *empirical RTDs* thus obtained approximate the underlying theoretical RTD arbitrarily accurately. In practice, empirical RTDs based on 20–100 runs are sufficient for most purposes (this will be further discussed later in this chapter).

Graphical representations of empirical RTDs are often useful; plots of the respective cumulative distribution functions (CDFs) are easily obtained (see Ref. [1]) and, unlike histograms, show the underlying data in full detail. They also make it easy to read quantiles and quantile ratios (such as the median and quartile ratio) directly off the plots; these basic descriptive statistics provide the basis for quantitative analyses and many statistical tests, which are discussed later. Compared to averages and empirical standard deviations, medians and quantile ratios have the advantage of being less sensitive with respect to outliers. Given the fact that the RTDs of many randomised heuristic algorithms show very large variability, the stability of basic descriptive statistics can become an important consideration. For the same reason, empirical RTDs are often best presented in the form of semi-log or log-log plots. Figure 14.1 shows an example of a typical empirical RTD plot.

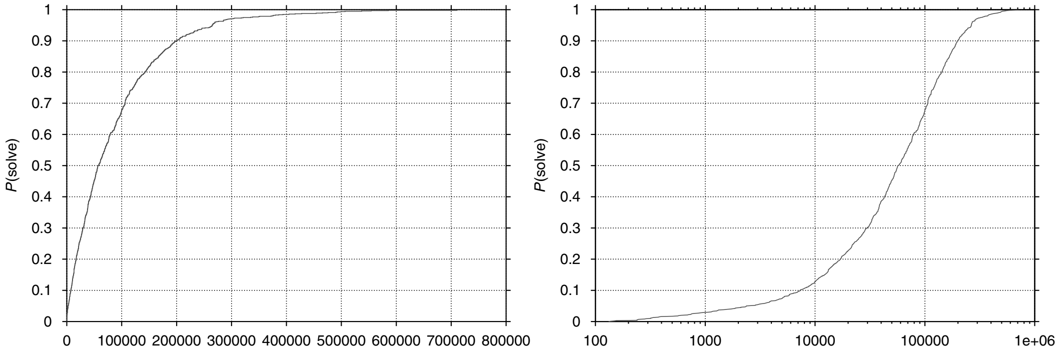

FIGURE 14.1 *Left*: Example of an empirical run-time distribution of an SLS algorithm for SAT applied to a hard problem instance; *right*: semi-log plot of the same RTD. P(solve) denotes the probability for finding a solution within the given run time.

14.2.2 Analysis on Instance Ensembles

Typically, the behaviour of heuristic algorithms is analysed on a set or ensemble of instances. The selection of such benchmark sets is an important factor in the design of an empirical study, and the use of inadequate benchmark sets can lead to questionable results and misleading conclusions. Although the criteria for benchmark selection depend significantly on the problem domain under consideration, on the hypotheses and goals of the empirical study and on the algorithms being analysed, there are some general principles and guidelines, which can be summarised as follows (for more details, see Ref. [1]): Benchmark sets should contain a diverse collection of problem instances, ideally including instances from real-world applications as well as artificially crafted and randomly generated instances; the instances should typically be intrinsically hard or difficult to solve for a broad range of algorithms. Furthermore, to facilitate the reproducibility of empirical analyses and the comparability of results between studies, it is important to use established benchmark sets (in particular those available from public benchmark libraries, such as ORLIB [4], TSPLIB [5] or SATLIB [6]), and to make newly created test-sets available to other researchers.

The basic approach to the empirical evaluation of an algorithm on a given ensemble of problem instances is to perform the same type of analysis described in the previous section on each individual instance. For small ensembles, it is often possible to analyse and report the results of this analysis for all instances, for example, in the form of tables or multiple RTD plots. When dealing with bigger ensembles, such as benchmark sets obtained from random instance generators, it becomes important to characterise the performance of a given algorithm on individual instances as well as across the entire ensemble. The latter can be achieved by aggregrating the results obtained on all individual instances into a so-called *search cost distribution* (*SCD*). For a deterministic algorithm applied to a given benchmark set, the empirical SCD is obtained from the run-time measurements on each individual problem instance. Analogous to RTDs, SCDs are typically best analysed qualitatively by means of CDF plots and quantitatively by means of basic descriptive statistics, such as quantiles and quantile ratios. For randomised decision algorithms, SCDs can be computed based on the median (or mean) run times for each individual instance; this means that each point in the SCD plot corresponds to a statistic of an entire RTD. It is often appropriate to also analyse in more detail a small set of RTDs that have been carefully selected in such a way that they representatively illustrate the variation in algorithm behaviour across the ensemble.

In many cases, it is also of considerable interest to investigate the dependence of algorithmic performance on certain instance features, such as problem size. This is often done by studying the correlation between the feature value for a given problem instance and the corresponding run time (or RTD) across the ensemble, for example, by means of simple correlation plots or using appropriate statistics, such as the Pearson correlation coefficient, and possibly also significance tests. The issues faced in this context are very similar to those arising in the comparative analysis of multiple algorithms on instance ensembles and will be further discussed in Section 14.2.4. In terms of qualitative analyses, choosing an appropriate graphical representation, such as a semilogarithmic plot for the functional dependence of mean cost on problem size, is often the key for easily detecting interesting behaviour (e.g., exponential scaling).

14.2.3 Comparative Analysis on Single Instances

In many empirical studies, the main goal is to establish the superiority of one heuristic algorithm over another. The most basic form of this type of analysis is the comparative analysis between two decision algorithms on a single problem instance. If both algorithms are deterministic, this amounts to a straightforward comparison between the respective run-time measurements. Clearly, in the case of incomplete algorithms or prematurely terminated runs, it needs to be noted if one or both algorithms failed to solve the given problem instance.

If at least one of the algorithms is randomised, the situation is slightly more complicated. Intuitively, an algorithm A shows superior performance compared to another algorithm B on a given problem instance π if for no run time, A has a lower solution probability than B, and there are some run times for which the solution probability of A is higher than that of B. In that case, we say that *A probabilistically dominates B*

TABLE 14.1 Upper Bounds on the Performance Differences Detectable by the Mann–Whitney U-Test for Various Sample Sizes (Number of Runs per RTD)

Significance Level 0.05, power 0.95		Significance Level 0.01, power 0.99	
Sample size	m_1/m_2	Sample size	m_1/m_2
3010	1.1	5565	1.1
1000	1.18	1000	1.24
122	1.5	225	1.5
100	1.6	100	1.8
32	2	58	2
10	3	10	3.9

Notes: m_1/m_2 denotes the ratio between the medians of the two given RTDs. The values in this table have been obtained using a standard procedure based on adjusting the statistical power of the two-sample t-test to the Mann–Whitney U-test using a worst-case Pitman asymptotic relative efficiency (ARE) value of 0.864.

on π (see Ref. [1]). A probabilistic domination relation holds between two decision algorithms on a given problem instance if, and only if, their respective cumulative RTD graphs do not cross each other. This provides a simple method for graphically checking probabilistic domination between two SLS algorithms on individual problem instances. The concept of probabilistic domination also applies to situations where one of A and B is deterministic, since in terms of analysing run-time behaviour, deterministic decision algorithms can be seen as special cases of randomised decision algorithms that have degenerate RTDs whose CDFs are simple step functions. In situations where a probabilistic domination relation does not hold, that is, there is a crossover between the respective RTD graphs, which of the two given algorithms is preferable in terms of higher-solution probability depends on the time the algorithms are allowed to run.

Statistical tests can be used to assess the significance of empirically measured performance differences between randomised algorithms. In particular, the *Mann–Whitney U-test* (or, equivalently, the *Wilcoxon rank sum test*) can be used to determine whether the medians of two given RTDs are equal [7]; a rejection of this null hypothesis indicates significant performance differences. The widely used t-test compares the means of two populations, but it requires the assumption that the given samples are normally distributed with identical variance—an assumption which is usually not met when analysing individual RTDs. The more specific hypothesis whether the theoretical RTDs of two decision algorithms are identical can be tested using the *Kolmogorov–Smirnov test for two independent samples* [7].

An important question arising in comparative performance analyses of randomised algorithms is that of sample size: How many independent runs should be performed when measuring the respective empirical RTDs? Generally, the ability of statistical tests to correctly distinguish situations in which the given null hypothesis is correct from those where it is incorrect crucially depends on sample size. This is illustrated in Table 14.1, which shows the performance differences between two given RTDs that can be detected by the Mann–Whitney U-test for standard significance levels and power values in dependence of sample size. (The significance level and power value indicate the maximum probabilities that the test incorrectly rejects or accepts the null hypothesis that the medians of the given RTDs are equal, respectively.)

In cases where probabilistic domination does not hold, the previously mentioned statistical tests are still applicable. However, they do not capture interesting and potentially important performance differences that can be easily seen from the respective RTD graphs. Such an example is depicted in Figure 14.2.

14.2.4 Comparative Analysis on Instance Ensembles

Comparative performance analyses of two decision algorithms on ensembles of problem instances are based on the same data used in the comparative analysis on the respective single instances. When dealing with two deterministic decision algorithms, A and B, this results in pairs of run times for each problem instance. In many cases, particularly when evaluating algorithms on big and diverse benchmark sets, there will be cases where A performs better than B and vice versa. In such situations it can be beneficial to use

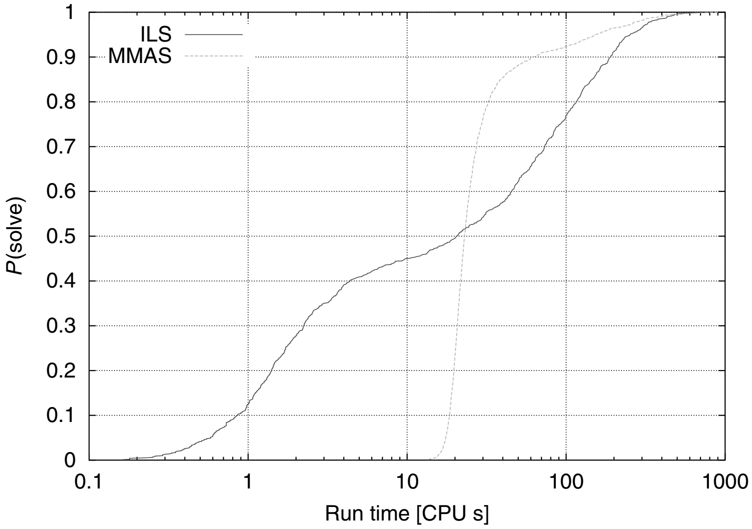

FIGURE 14.2 RTDs for two SLS algorithms for the TSP that for a given benchmark instance are required to find an optimal solution. Between 20 and 30 CPU s the two RTDs cross over.

statistical tests to assess the significance of the observed performance differences; this is particularly the case for benchmark sets obtained from random instance generators. The *binomial sign test* as well as the *Wilcoxon-matched pairs signed-rank test* determine whether the median of the paired differences is statistically significantly different from zero, indicating that one algorithm performs better than the other [7]. The Wilcoxon test is more sensitive, but requires the assumption that the distribution of the paired differences is symmetric. The well-known *t-test for two dependent samples* requires assumptions on the normality and homogeneity of variance of the underlying distributions of search cost over the given instance ensembles, which are typically not satisfied when dealing with the run times of heuristic algorithms.

If one or both of the given algorithms are randomised, the same tests can be applied to RTD statistics, such as the median (or mean) run time. However, this approach does not capture qualitative differences in performance, particularly as given in cases where there is no probabilistic domination of one algorithm over the other, and may suffer from inaccuracies due to a lack of statistical stability of the underlying RTD statistics. Therefore, additional analyses should be performed. In particular, the statistical significance of the performance differences (such as median run time) on each individual problem instance should be investigated using an appropriate test (such as the Mann–Whitney U-test). Furthermore, for each instance it should be checked whether a probabilistic domination relation holds; based on this information, the given instance ensemble can be partitioned into three subsets: (i) those instances on which A probabilistically dominates B, (ii) those on which B probabilistically dominates A, and (iii) those for which probabilistic domination is not observed. The relative sizes and contents of these partitions give a rather realistic and detailed picture of the algorithms' relative performance on the given set of instances.

Particularly for large instance ensembles, it is often useful to study the correlation between the performance of algorithms A and B across the given set of instances. This type of analysis can help to expose (and ultimately, remedy) weaknesses of an algorithm and to refine claims about its relative superiority for certain types of problem instances. For qualitative analyses of performance correlation, scatter plots can be used in which each instance is represented by one point, whose coordinates correspond to the performance of A and B applied to that instance. Performance measures used in this context are typically run time in case of deterministic algorithms, and RTD statistics, such as the median run time, otherwise. It should be noted that in the case of randomised algorithms, statistical instability of RTD statistics due to sampling error limits the accuracy of performance measurements. An example of such an analysis is shown in Figure 14.3.

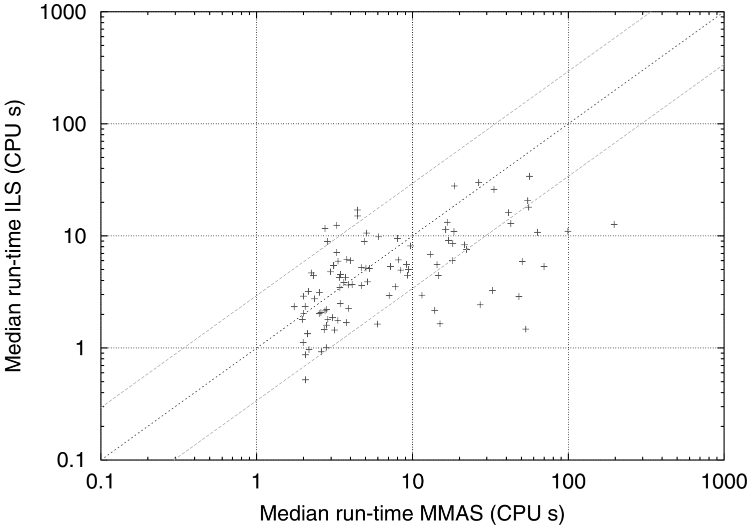

FIGURE 14.3 Correlation between the median run times required by two high-performance SLS algorithms for finding optimal solutions to a set of 100 TSP instances of 300 cities each; each median was measured across 10 runs per algorithm. The band between the two outer lines indicates performance differences that cannot be assumed to be statistically significant for the given sample size of the underlying RTDs.

Quantitatively, the correlation can be summarised using the empirical correlation coefficient. When the nature of an observed performance correlation seems to be regular (e.g., a roughly linear trend in the scatter plot), a simple regression analysis can be used to model the corresponding relationship in the algorithms' performance. It is often useful to perform correlation analyses on log-transformed data; this facilitates capturing general polynomial relationships.

To test the statistical significance of an observed performance correlation, nonparametric tests, such as *Spearman's rank order test* or *Kendall's tau test*, can be employed [7]. These tests determine whether there is a significant monotonic relationship in the performance data. They are preferable over tests based on Pearson's product-moment correlation coefficient, which require the assumption that the two random variables underlying the performance data stem from a bivariate normal distribution. (This assumption is often violated when dealing with run times of heuristic algorithms over instance ensembles.)

14.3 Optimisation Algorithms

In many situations, the objective of a computational problem is to find a solution that is optimal with respect to some measure of quality or cost. An example of such an *optimisation problem* is the widely studied TSP: given an edge-weigthed graph G, find a Hamiltonian cycle with minimal total weight, i.e., a shortest round trip that visits every vertex of G exactly once. Another example is MAX-SAT, the optimisation variant of the SAT problem, where the objective is to find an assignment of truth values to the propositional variables in a given formula F in conjunctive normal form such that a maximal number of clauses of F are simultaneously satisfied.

The measure to be optimised in an optimisation problem is called the *objective function*, and the term *solution quality* is used to refer to the objective function value of a given candidate solution. In most cases, solution qualities take the form of real numbers, and the goal is to find a candidate with either minimal or maximal solution quality. Optimisation problems can include additional logical conditions that any candidate solution needs to satisfy to be deemed *valid* or *feasible.* In the case of the TSP, such a logical condition states that to be considered a valid solution, a path in the given graph must be a Hamiltonian cycle. Logical conditions can always be integrated into the objective function in such a way that valid solutions are characterised by objective function values that exceed a specific threshold in solution quality.

An *optimisation algorithm* is an algorithm that takes as an input an instance of a given optimisation problem and returns a valid solution (or may determine that no valid solution exists). Optimisation algorithms that are theoretically guaranteed to find an optimal solution for any soluble problem instance within bounded time are called *complete* or *exact*; algorithms that are guaranteed to always return a solution that is within a specific constant factor of an optimal solution are called *approximation algorithms*.

When evaluating the performance of optimisation algorithms (theoretically or empirically), it is often useful to study the ratio between the solution quality achieved by the algorithm, q, and the optimal solution quality for the given problem instance, q^*. This performance measure is called the *approximation ratio*; formally, to be uniformly applicable to minimisation and maximisation problems, it is defined as $r := \max\{q/q^*, q^*/q\}$. When used in the empirical analysis of optimisation algorithms, solution qualities are often expressed in percent deviation from the optimum; this measure of *relative solution quality* is defined as $q' := (r - 1) \times 100$. For most heuristic optimisation algorithms, in particular for those based on SLS methods, there is a trade-off between run time and solution quality: the longer the algorithm is run, the better solutions are produced. The characterisation of this trade-off is of significant importance in the empirical analysis of optimisation algorithms.

14.3.1 Analysis on Single Instances

As in the case of decision algorithms, the empirical analysis of a deterministic optimisation algorithm on a single problem instance is rather straightforward, and many of the same considerations (particularly with respect to measuring run times and failure to produce valid solutions) apply. Run time / solution quality trade-offs are characterised by the development of solution quality over time, in the form of so-called *solution quality over time (SQT) curves*; these represent for each point in time t the quality of the best solution seen up to time t (the so-called *incumbent solution*) and are hence always monotone.

A slightly more complicated situation arises when dealing with randomised optimisation algorithms. Following the same approach as for randomised decision algorithms, run time is considered a random variable; in addition, a second random variable is used to capture solution quality, and the joint probability distribution of these two random variables characterises the behaviour of the algorithm on a given problem instance precisely and completely. For a given algorithm and problem instance, this probability distribution is called the *bivariate RTD of A on π* [1]; it can be visualised in the form of a cumulative distribution surface, each point of which represents the probability that A applied to π reaches (or exceeds) a certain solution quality bound within a certain amount of time (see Figure 14.4).

Empirical bivariate RTDs can be easily determined from multiple *solution quality traces*, each of which represents the development of solution quality over time for a single run of the algorithm on the given problem instance. A solution quality trace usually consists of pairs (t, q) for each point in time t at which an improvement in the incumbent solution, i.e., a new best solution quality q within the current run, has been achieved. As in the case of the (univariate) RTDs for decision algorithms, a sufficient number of independent runs (i.e., solution quality traces) on any given problem instance is required for measuring reasonably accurate empirical bivariate RTDs; obviously, the same holds for basic descriptive RTD statistics on the solution quality obtained within a given run time, or the run time required for reaching a given solution quality.

Multivariate probability distributions are more difficult to handle than univariate distributions. Therefore, rather than working directly with bivariate RTDs, it is often preferable to focus on the (univariate) distributions of the run time required for reaching a given solution quality threshold instead. These *qualified run-time distributions (QRTDs)* are the marginals of a given bivariate RTD for a specific bound on solution quality; intuitively, they correspond to cross-sections of the respective two-dimensional cumulative RTD graph for fixed solution quality values (see Figure 14.4). QRTDs directly characterise the ability of an SLS algorithm for an optimisation problem to solve the associated decision problems for the given solution quality bound. They are particularly useful for analysing an algorithm's ability to find optimal, close-to-optimal or feasible solutions and can be studied using exactly the same techniques as those

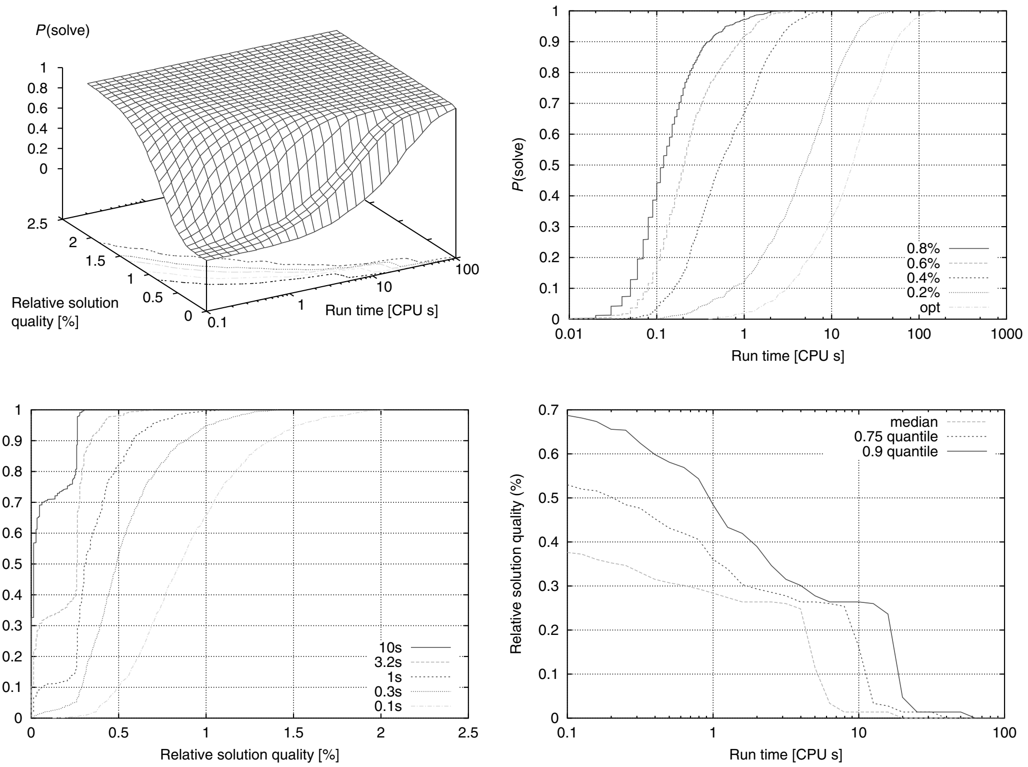

FIGURE 14.4 *Top left*: Bivariate RTD for an SLS algorithm applied to a TSP benchmark instance; the other plots give different views on the same distribution; *top right*: QRTDs for various relative solution quality bounds (percentage deviation from optimum); *bottom left*: SQDs for various run-time bounds (in CPU s); and *bottom right*: SQT curves for various SQD quantiles.

applied to the (univariate) RTDs of decision algorithms. A detailed picture of the behaviour of a randomised optimisation algorithm on a single problem instance can be obtained by analysing series of qualified RTDs for increasingly tight solution quality thresholds. The solution quality bounds used in a QRTD analysis are typically derived from knowledge of optimal solutions or bounds on the optimal solution quality; the latter case includes bounds obtained from long runs of heuristic optimisation algorithms.

Another commonly used way of studying the behaviour of randomised optimisation algorithms on a given problem instance is to analyse the distribution of solution qualities obtained over multiple independent runs with a fixed time bound. Technically, these so-called *solution quality distributions* (*SQDs*) are the marginals of the underlying bivariate RTDs for a fixed run-time bound. They correspond to cross-sections of the two-dimensional cumulative RTD graph for fixed run-time values; in this sense, they are orthogonal to QRTDs (see Figure 14.4). Again, these univariate distributions can be studied using essentially the same techniques as for analysing the RTDs of decision algorithms.

Closely related to SQDs are the *asymptotic solution quality distributions* obtained in the limit for arbitrarily long run times. For complete and probabilistically approximately complete optimisation algorithms, which are guaranteed to find an optimal solution to any given problem instance with arbitrarily high probability given sufficiently long run time, the asymptotic SQDs are degenerate distributions whose probability mass is completely concentrated on the optimal solution quality of the given problem instance. When dealing with randomised optimisation algorithms with an algorithm-dependent termination criterion, such as randomised iterative improvement methods that terminate upon reaching a local minimum, it is often also useful to study *termination time distributions (TTDs)*, which characterise the distribution of the time until termination over multiple independent runs.

Finally, the SQT curves described earlier in the context of characterising run time / solution quality trade-offs for deterministic optimisation algorithms can be generalised to randomised algorithms. This is done by replacing the uniquely defined solution quality values obtained by a deterministic algorithm for any given run-time bound by statistics of the respective SQDs in the randomised case. Although historically, this type of analysis has most commonly used SQT curves based on mean solution quality values, it is often preferable to use SQTs that reflect the development of SQD quantiles (such as the median) over time, since these tend to be statistically more stable than means. SQTs based on SQD quantiles also offer the advantage that they directly correspond to horizontal sections or contour lines of the underlying bivariate RTD surfaces. Combinations of such SQTs can be very useful for summarising certain aspects of a complete bivariate RTD; they are particularly well suited for analysing trade-offs between run time and solution quality (see Figure 14.4). However, the investigation of individual SQTs offers a fairly limited view of an optimisation algorithm's run-time behaviour in which important details can be easily missed and should therefore be complemented with other approaches, such as QRTD or SQD analysis. All these analyses can be carried out on the same set of solution quality traces collected over multiple indendent runs of the algorithm.

14.3.2 Comparative Analysis on Single Instances

The basic approach used for the comparative analysis of two (or more) optimisation algorithms on a single problem instance is analogous to that for decision algorithms. Often, a fixed target solution quality is used in this context, in which case the analysis involves the QRTDs of the algorithms with respect to that solution quality bound. Alternatively, a bound on run time can be used, and the respective SQDs can be compared using the same methods as in the case of RTDs for decision algorithms. (It may be noted that the SQDs of high-performance algorithms for high run times typically have much lower variance than QRTDs.)

Both of these methods do not take into account trade-offs between run time and solution quality. To capture such trade-offs, it is useful to extend the concept of domination introduced earlier for decision algorithms. We first note that in the case of two deterministic optimisation algorithms, A and B, this is straightforward: A dominates B on a given problem instance π if A gives consistently better solution quality than B for any run time. This implies that the respective SQT curves do not cross each other. In the case of crossing SQTs, which of the two algorithm is preferable in terms of solution quality achieved depends on the time the algorithms are allowed to run.

When generalised to randomised algorithms, this leads to the concept of *probabilistic domination*. Analogous to the case of randomised decision algorithms, probabilistic domination between two randomised optimisation algorithms holds if, and only if, their (bivariate) cumulative RTD surfaces do not cross each other. Note that this implies that there is no crossover between any SQDs for the same run-time bound, or between any QRTDs for any solution quality bound. In practice, probabilistic domination can be tested based on a series of QRTDs for different solution quality bounds (or SQDs for various run-time bounds). This does not require substantial experimental overhead, since the solution quality traces underlying empirical QRTDs for the best solution quality bound also contain all the information for QRTDs for lower-quality bounds. When probabilistic domination does not hold, the run-time/solution quality trade-offs between the given algorithms can be characterised using the same data. In many cases, the results from empirical performance comparisons between randomised optimisation algorithms can be conveniently summarised using SQT curves over multiple SQD statistics (e.g., median and additional quantiles) in combination with SQD plots for selected run times.

14.3.3 Analysis on Instance Ensembles

The considerations arising when extending the analyses described in the previous sections to ensembles of problem instances are essentially the same as in the case of decision algorithms (see Sections 14.2.2 and 14.2.4). It is convienent (and in some special cases sufficient) to perform the analysis for a single solution quality or run-time bound, in which case the methodology is analogous to that for decision algorithms. However, in most cases, run time / solution quality trade-offs need to be considered. This can be achieved by analysing SCDs or performance correlations for multiple solution quality or run-time bounds in addition to a more detailed analysis for carefully selected individual instances.

In the analysis of optimisation algorithms on instance ensembles, it is typically much preferable to use relative rather than absolute solution qualities. This introduces a slight complication when dealing with benchmark instances for which (provably) optimal solution qualities are unknown. To deal with such instances, theoretically or empirically determined bounds on the optimal solution quality, including best solution qualites achieved by high-performance heuristic algorithms, are often used. In this context, particularly when conducting performance comparisons related to the ability of various algorithms to find optimal or close-to-optimal solutions, it is very important to ensure that the bounds used in lieu of provably optimal solutions are as tight as possible.

14.4 Advanced RTD-Based Analysis

The measurement of RTDs for decision and optimisation problems can serve not only as a first step in the descriptive and comparative analysis of algorithm behaviour, as shown in the previous sections, but it can also form the basis of more advanced analysis techniques, for example, for examining scaling behaviour or performance robustness with respect to an algorithm's parameter settings. In what follows, we briefly outline such types of analyses; while our discussion is focused on RTDs for decision algorithms or, equivalently, on QRTDs for optimisation algorithms, many of its aspects can be extended in a straightforward way to the analysis of SQDs for optimisation algorithms.

14.4.1 Scaling with Instance Size

An important question is how an algorithm's performance scales with the size of the given problem instance. One approach to studying scaling behaviour is to base the analysis on individual instances of various sizes. However, since there is often very substantial variation in run time between instances of the same size, scaling studies are better based on ensembles of instances for each size. Then, the set of techniques discussed in the previous section can be applied by first measuring RTDs on individual instances; next, SCDs can be derived from appropriately chosen statistics of these RTDs, as discussed in Section 14.2.2; and finally, various statistics of these SCDs can be analysed in dependence of instance size.

As a first step, it is often useful to analyse the scaling data graphically. In this context, the use of semi-log or log-log plots can be very helpful: in particular, exponential scaling of mean or median search cost is reflected in a linear relationship between instance size and the logarithm of run time, while a linear relationship between the logarithms of both, instance size and run time is indicative of polynomial scaling. To analyse scaling behaviour in more detail, function fitting techniques, such as statistical regression, can be used. A simple example of an empirical scaling analysis is given in Figure 14.5.

Additional support for observed or conjectured scaling behaviour can be obtained by interpolation experiments, where for instance sizes that are in the range of the previously analysed instance ensembles additional data points are measured, or by extrapolation experiments, where an empirically fitted scaling function is used to predict the SCD statistics for larger instance sizes and deviations from the predicted values are analysed to possibly further refine the hypothesis on the scaling behaviour.

14.4.2 Impact of Parameter Settings

Many heuristic algorithms have one or more parameters that control their behaviour; as an example, consider the tabu tenure parameter in tabu search, a well-known SLS method (see also Chapters 19 and 23). The settings of such control parameters often have a significant yet theoretically poorly understood impact on the performance of the respective algorithm, which can be empirically studied by analysing the variation of an algorithm's RTD (or RTD statistics) in response to changes in its parameter settings. Often, the data required for this type of parameter sensitivity analysis is readily available from experiments conducted to optimise parameter settings for achieving peak performance.

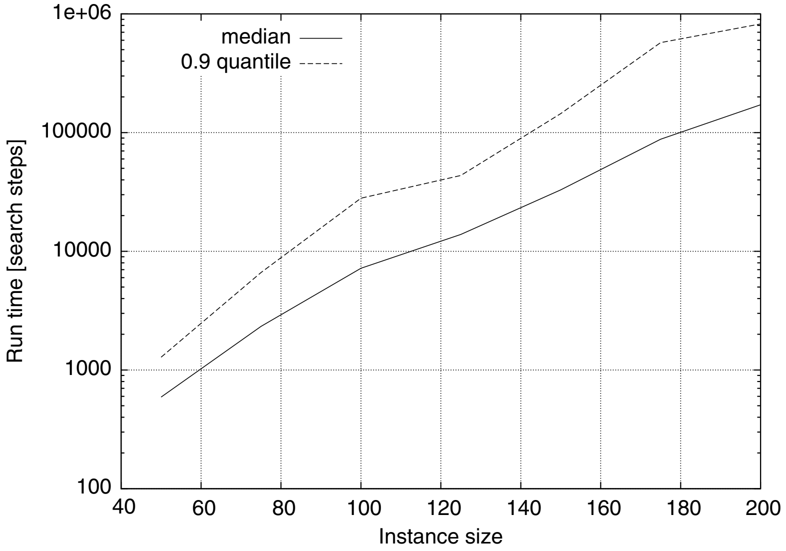

FIGURE 14.5 Scaling of the median and the 0.9 percentile for the search cost of solving SAT-encoded graph colouring instances with an SLS algorithm. Both statistics show evidence of exponential scaling.

It should be noted that in the case of randomised algorithms, the variation of run time for a fixed parameterisation and problem instance often depends on the parameter settings and should therefore be studied. For many SLS algorithms, suboptimal parameter values can cause search stagnation and extremely high variability in run time; in such situations, larger sample sizes may be required for obtaining reasonably accurate estimates of RTD statistics. Furthermore, for many heuristic algorithms with multiple parameters, the effects of various parameters are typically not independent, and experimental design techniques have to be employed for studying the nature and strength of these parameter dependencies.

Another important aspect of investigating parameter-dependent algorithmic performance deals with consistency across instance ensembles, i.e., with the question to which degree the impact of parameter settings is similar across the instances in a given ensemble. One way of approaching this issue is to treat different parameterisations like different algorithms, and to use the methods for comparative performance analysis on instance ensembles from Section 14.2.4 (in particular, correlation analysis of RTD statistics). Consistency of performance-optimising parameter settings is often of particular interest. When consistent behaviour across an ensemble is not observed, it may still be possible to relate aspects of parameter-dependent run-time behaviour to specific characteristics of the instances. Such characteristics could be of purely syntactic nature (such as instance size or clauses/variables ratio for SAT instances) or they may be based on some deeper semantic properties (such as search space features in the case of SLS algorithms).

The need for manually tuning parameters can cause problems in practical applications of heuristic algorithms as well as in their empirical analysis. In particular, comparative performance analyses can yield misleading results when parameter settings have been tuned unevenly (i.e., more effort has been spent in optimising parameter settings for one of the algorithms). To alleviate these problems, automatic tuning techniques have been proposed [8,9]. Furthermore, mechanisms for adapting parameter values while solving a given problem instance have been used with considerable success, in particular in the context of reactive search methods (see Chapter 21).

14.4.3 Stagnation Detection

Intuitively, a randomised heuristic decision algorithm shows stagnation behaviour if for long runs, the probability of finding a solution can be improved by restarting the algorithm at some appropriately chosen cut-off time. For search algorithms, this effect may be due to the inability of the algorithm to trade off

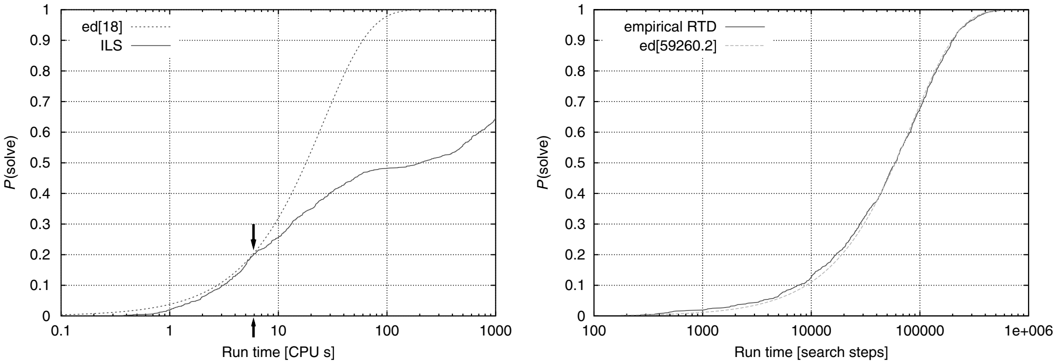

FIGURE 14.6 *Left*: Empirical QRTD of an iterated local search algorithm for finding the optimal solution of TSPLIB instance pcb442 (ILS); comparison with an exponential distribution ($\mathtt{ed}[m] = 1 - 2^{-\mathtt{run\,time}/m}$) reveals severe stagnation behaviour. *Right*: Best fit of an empirical RTD by an exponential distribution. The fit passes a χ^2 goodness-of-fit test at a significance level of $\alpha = 0.05$.

effectively exploration of the search space and exploitation of previous search experience, and may be related to the algorithm getting trapped in specific areas of the search space.

Interestingly, it is relatively straightforward to detect such stagnation behaviour from an empirical RTD. It is easy to see that only for RTDs that are identical to an exponential distribution, a well-known probability distribution from statistics, such restarts do not result in any performance loss or improvement [11] (essentially, this is due to the memory-less property of the exponential distribution). This insight provides the basis for detecting stagnation situations by comparing empirical RTDs of a given algorithm to exponential distributions. Stagnation behaviour is present if there is an exponential distribution whose CDF graph meets that of the empirical RTD from below but never crosses it. This situation is illustrated in Figure 14.6 (left pane); the arrows indicate the optimal cut-off time for a static restart strategy, which can also be determined from the RTD.

In general, the detection of stagnation situations using the RTD-based methodology can be a key element in the systematic development of randomised heuristic algorithms; for example, in the case of SLS algorithms, the occurrence of search stagnation often indicates the need for additional or stronger diversification mechanisms. (For further details, see Chapter 4 of Ref. [1].)

14.4.4 Functional Characterisation of Empirical RTDs

It is often useful (though not always possible) to characterise empirical RTDs by means of simple mathematical functions. For example, the RTDs of many high-performance SLS algorithms are well approximated by exponential distributions (see, e.g., Ref. [11]). Such characterisations are not only useful in the context of stagnation analysis (as explained in the previous section), but also provide detailed and often very accurate summarisations of an algorithm's run-time behaviour. Furthermore, they can help in gaining insights into an algorithm's properties by providing a basis for modelling its behaviour mathematically.

In the context of functional RTD characterisations, it is particularly appealing to model empirical RTDs using parameterised continuous probability distributions known from statistics. This can be done using standard fitting techniques to determine suitable parameter values; the quality of the resulting approximations can be evaluated using goodness-of-fit tests, such as the χ^2 test or the Kolmogorov–Smirnov test [7]. (For an illustration, see right pane of Figure 14.6.) The same methods can be used for functionally characterising other empirical data, such as SQDs or SCDs.

When dealing with large instance ensembles, the fitting and testing process needs to be automated. This way, more general hypotheses regarding an algorithm's run-time behaviour can be investigated empirically. Like any empirical approach, this method cannot be used for proving universal results on an algorithms' behaviour on an entire (infinite) class of problem instances, but it can be very useful in formulating, refining or falsifying hypotheses on such results.

14.5 Extensions

Most empirical analyses of heuristic algorithms in the literature focus on "classical" $\mathcal{NP}$-hard problems. It is clear, however, that sound empirical methodologies are equally important when tackling conceptually more involved types of problems, such as multiobjective, dynamic or stochastic optimisation problems.

Multiobjective problems. In multiobjective problems, several, typically conflicting optimisation criteria need to be considered simultaneously. For these problems, a common goal is to identify the set of *Pareto-optimal solutions* [12], i.e., solutions for which there exists no alternative that is strictly better with respect to all optimisation criteria. Such multiobjective problems arise in many engineering and business applications, and heuristic algorithms are widely used for solving them [13,14]. The behaviour of these algorithms can be analysed empirically using a suitably generalised notion of multivariate RTDs. Since the dimensionality of the RTDs to be measured in this case is equal to the number of objective functions plus one, data collection and analysis are considerably more complex than in the case of single-objective optimisation problems. While we are not aware of any studies based on these multivariate RTDs, the marginal distributions obtained when keeping the computation time fixed have received considerable attention. The analysis of these so-called *attainment functions* has been proposed by Fonseca et al. [15] and has been acknowledged as one of the few approaches for a correct analysis of the performance of randomised algorithms for multiobjective optimisation [16].

Dynamic problems. In many applications, some aspects of a given problem instance may change while trying to find or implement a solution. Such dynamic problems are encountered, for example, in many distribution problems, where traffic situations can change as a result of congested or blocked routes. Two common goals in dynamic problems are to minimise the delay in recovering solutions (of a certain quality) after a change in the problem instance has occurred and to miminise disruptions of the current solution, i.e., the amount of modifications required to adapt the current solution to the changed situation. The empirical analysis of heuristic (and in particular, randomised) algorithms for both of these situations can be handled using relatively straightforward extensions of the RTD-based methodology. In the case of dynamic optimisation problems, tradeoffs between solution quality and the amount of disruption can be studied using the same techniques as for static multiobjective problems. Also, particularly for dynamic optimisation problems where changes occur rather frequently, it can be useful to analyse the development of solution quality (or, for randomised algorithms, SQDs) over time, using suitable generalisations of the RTD-based techniques for static optimisation problems.

Stochastic problems. In some practical applications, important properties of solutions are subject to statistical variation. For many stochastic optimisation problems, variations in the quality of a given solution are caused by random changes (or uncertainty) in solution components that are characterised in the form of probability distributions; for example, in stochastic routing problems, the costs associated with using certain connections may be specified by Gaussian distributions. A typical goal when solving stochastic optimisation problems is to find a solution with optimal *expected quality*. In some cases, the expected quality of a solution can be determined analytically, and algorithms for such problems can be analysed using the same empirical methods as described for conventional deterministic problems. In other cases, approximation or sampling methods have to be used for estimating the quality of candidate solutions. While in principle, the techniques described in this chapter can be extended to these cases, empirical analyses (as well as algorithm development) are more involved; for example, when measuring empirical SQDs, a trade-off arises between the number of algorithm runs and the number of samples used to estimate the quality of incumbent solutions.

14.6 Further Reading

The use of principled and advanced techniques for the empirical analysis of deterministic and randomised heuristic algorithms is gaining increasing acceptance among researchers and practitioners. In this chapter, we have described the analysis of RTDs as a core technique for the empirical investigation and characterisation of randomised algorithms [17]. While RTDs have been previously reported in the literature [18–20], they have typically been used for purely descriptive purposes or in the context of investigating the parallelisation speed-up achievable by performing multiple independent runs of a sequential algorithm. A more detailed description of the RTD-based methodology is given in Chapter 4 of Ref. [1]. RTD-based methods are now being used increasingly widely for the empirical study of a broad range of SLS algorithms for numerous combinatorial problems [21–29].

SQDs of randomised heuristic optimisation algorithms have been occasionally reported in the literature; they have been used, for example, to obtain results on the scaling of SLS behaviour [30]. SQDs can also be used for estimating optimal solution qualities for combinatorial optimisation problems [31,32]. SCDs over ensembles of problem instances have been measured and characterised for deterministic, complete algorithms for binary constraint satisfaction problems and SAT [33,34].

There is a growing body of work on general issues in empirical algorithmics. Several articles provide guidelines for the experimental study of mathematical programming software [35,36] and heuristic algorithms [37], with the aim of increasing the reproducibility of results. General guidelines for the experimental analysis of algorithms have also been proposed by McGeoch and Moret [38–40]. Johnson [41] gives an overview of guidelines and potential pitfalls in empirical algorithmics research. A more scientific approach to experimental studies of algorithms in optimisation has been advocated by Hooker [42,43], who emphasised the need for formulating and empirically investigating hypotheses about algorithm properties and behaviour rather than limiting the experimental study of algorithms to simplistic performance comparisons.

At the core of any empirical approach to investigating the behaviour and performance of randomised algorithms are statistical methods. Cohen's book [44] provides a good introduction to empirical methods in computing science with an emphasis on algorithms and applications in artificial intelligence. The handbook by Sheskin [7] is an excellent source for detailed information on statistical tests and their application, while Siegel et al. [45] and Conover [46] provide more specialised introductions to nonparametric statistics. For an introduction to the important topic of experimental design and data analysis we refer to the books of Dean and Voss [47] and Montgomery [48].

Reductions That Preserve Approximability

15.1 Introduction

The technique of transforming a problem into another in such a way that the solution of the latter entails, somehow, the solution of the former is a classical mathematical technique that has found wide application in computer science since the seminal works of Cook [1] and Karp [2], who introduced particular kinds of transformations (called *reductions*) with the aim of studying the computational complexity of combinatorial decision problems. The interesting aspect of a reduction between two problems consists in its twofold application: on the one hand it allows to transfer positive results (resolution techniques) from one problem to the other and, on the other hand, it may also be used for deriving negative (hardness) results. In fact, as a consequence of such seminal work, by making use of a specific kind of reduction, the polynomial-time *Karp-reducibility*, it has been possible to establish a complexity partial order among decision problems, which, for example, allows us to state that, modulo polynomial-time transformations, the SATISFIABILITY problem is as hard as thousands of other combinatorial decision problems, even though the precise complexity level of all these problems is still unknown.

Strictly associated with the notion of reducibility is the notion of completeness. Problems that are complete in a complexity class via a given reducibility are, in a sense, the hardest problems of such class. Besides, given two complexity classes **C** and $\mathbf{C}' \subseteq \mathbf{C}$, if a problem Π is complete in **C** via reductions that belong (preserve membership) to $\mathbf{C}'$, to establish whether $\mathbf{C}' \subset \mathbf{C}$, it is "enough" to assess the actual complexity of Π (informally, we say that Π is a candidate to separate **C** and $\mathbf{C}'$).

In this chapter we will show that an important role is played by reductions also in the field of approximation of hard combinatorial optimization problems. In this context, the kind of reductions which will be applied are called *approximation preserving reductions*. Intuitively, in the most simple case, an approximation preserving reduction consists of two mappings f and g: f maps an instance x of problem Π into an instance $f(x)$ of problem Π', g maps back a feasible solution y of Π' into a feasible solution $g(y)$ of Π with the property that $g(y)$ is an approximate solution of problem Π whose quality is almost as good as the quality of the solution y for problem Π'. Clearly, again in this case, the role of an approximation preserving reduction is twofold: on the one hand it allows to transfer an approximation algorithm from problem Π' to problem Π; on the other, if we know that problem Π cannot be approximated beyond a given threshold, such limitation applies also to problem Π'.

Various kinds of approximation-preserving reducibilities will be introduced in this chapter and we will show how they can be exploited in a positive way, to transform solution heuristics from a problem to another and how, on the contrary, they may help in proving negative, inapproximability results.

It is well known that **NP**-hard combinatorial optimization problems behave in a very different way with respect to approximability and can be classified accordingly. While for some problems there exist polynomial-time approximation algorithms that provide solutions with a constant approximation ratio w.r.t. the optimum solution, for some other problems even a remotely approximate solution is computationally hard to achieve. Analogous to what happens in the case of the complexity of decision problems, approximation-preserving reductions allow to establish a partial order among optimization problems in terms of approximability properties, independently from the actual level of approximation that for such problems can be achieved (and that in some cases is still undefined). Approximation-preserving reductions can also be used to define complete problems which play an important role in the study of possible separations between approximation classes. The discovery that a problem is complete in a given approximation class provides a useful insight in understanding what makes a problem not only computationally hard but also resilient to approximate solutions.

As a final remark on the importance of approximation-preserving reductions, let us observe that such reductions require some correspondence between the combinatorial structure of two problems be established. This is not the case for reductions between decision problems. For example, in such a case, we see that all **NP**-complete decision problems turn out to be mutually interreducible by means of polynomial-time reduction while when we consider the corresponding optimization problems, the different approximability properties come to evidence. As a consequence, we can say that approximation-preserving reductions are also a useful tool to analyze the deep relation existing between combinatorial structure of problems and the hardness of approximation.

The rest of this chapter is organized as follows. The next section is devoted to basic definitions and preliminary results concerning reductions among combinatorial optimization problems. In Section 15.3 we provide the first, simple example of approximation-preserving reducibility, namely the *linear reducibility*, that while not as powerful as the reducibilities that will be presented in the sequel is widely used in practice. In Section 15.4, we introduce the reducibility that, historically, has been the first to be introduced, *the strict reducibility* and we discuss the first completeness results based on reductions of such kind. Next, in Section 15.5, we introduce AP-reducibility, and in Section 15.6 we discuss more extensive completeness results in approximation classes. In Section 15.7, we present a new reducibility, called FT-reducibility, that allows to prove the polynomial-time approximation scheme (**PTAS**)-completeness of natural NP-optimization (**NPO**) problems. Finally, in Section 15.8, we present other reductions with the specific aim of proving further inapproximability results. The last two sections of the chapter contain conclusions and references.

In this chapter we assume that the reader is familiar with the basic notions of computational complexity regarding both decision problems and combinatorial optimization problems, as they are defined in Chapter 1.

15.2 Basic Definitions

Before introducing the first examples of reductions between optimization problems, let us recall the definitions of the basic notions of approximation theory and of the most important classes of optimization problems, characterized in terms of their approximability properties. First of all we introduce the class **NPO** which is the equivalent, for optimization problems, of the class of decision problems **NP**.

Definition 15.1

An **NP** optimization problem, **NPO**, Π *is defined as a four-tuple* $(\mathcal{I}, Sol, m, \text{goal})$ *such that*

- $\mathcal{I}$ *is the set of* instances *of* Π *and it can be recognized in polynomial time;*
- *given* $x \in \mathcal{I}$, $Sol(x)$ *denotes the set of* feasible solutions *of* x*; for any* $y \in Sol(x)$, $|y|$ *(the size of* y*) is polynomial in* $|x|$ *(the size of* x*); given any* x *and any* y *polynomial in* $|x|$, *one can decide in polynomial time if* $y \in Sol(x)$*;*
- *given* $x \in \mathcal{I}$ *and* $y \in Sol(x)$, $m(x, y)$ *denotes the value of* y *and can be computed in polynomial time;*
- goal $\in \{min, max\}$ *indicates the* type *of optimization problem.*

Given an **NPO** problem $\Pi = (\mathcal{I}, \text{Sol}, m, \text{goal})$ an optimum solution of an instance x of Π is usually denoted $y^*(x)$ and its measure $m(x, y^*(x))$ is denoted by $\text{opt}(x)$.

Definition 15.2

Given an **NPO** *problem* $\Pi = (\mathcal{I}, Sol, m, \text{goal})$, *an* approximation algorithm A *is an algorithm that given an instance* x *of* Π *returns a feasible solution* $y \in Sol(x)$. *If* A *runs in polynomial time with respect to* $|x|$, A *is called a* polynomial-time approximation algorithm *for* Π.

The quality of the solution given by an approximation algorithm $\mathtt{A}$ for a given instance x is usually measured as the ratio $\rho_A(x)$, *approximation ratio*, between the value of the approximate solution, $m(x, A(x))$, and the value of the optimum solution $opt(x)$. For minimization problems, therefore, the approximation ratio is in $[1, \infty)$, while for maximization problems it is in $[0, 1]$.

Definition 15.3

An **NPO** *problem* Π *belongs to the class* **APX** *if there exist a polynomial-time approximation algorithm* A *and a value* $r \in \mathbb{Q}$ *such that, given any instance* x *of* Π, $\rho_{\mathtt{A}}(x) \leq r$ *(resp.,* $\rho_{\mathtt{A}}(x) \geq r$*) if* Π *is a minimization problem (resp., a maximization problem). In such a case,* A *is called an* r*-approximation algorithm.*

Examples of combinatorial optimization problems belonging to the class **APX** are MAX SATISFIABILITY, MIN VERTEX COVER, and MIN EUCLIDEAN TSP.

In some cases, a stronger form of approximability for **NPO** problems can be obtained by a PTAS that is a family of algorithms $\mathtt{A}_r$ such that, given any ratio $r \in \mathbb{Q}$, the algorithm $\mathtt{A}_r$ is an r-approximation algorithm whose running time is bounded by a suitable polynomial p as a function of $|x|$.

Definition 15.4

An **NPO** *problem* Π *belongs to the class* **PTAS** *if there exists a* **PTAS** A_r *such that, given any* $r \in \mathbb{Q}$, $r \neq 1$, *and any instance* x *of* Π, $\rho_{\mathtt{A}_r}(x) \leq r$ *(resp.,* $\rho_{\mathtt{A}_r}(x) \geq r$*) if* Π *is a minimization problem (resp., a maximization problem).*

Among the problems in **APX** listed above, the problem MIN EUCLIDEAN TSP can be approximated by means of a **PTAS** and hence belongs to the class **PTAS**. Moreover, other examples of combinatorial optimization problems belonging to the class **PTAS** are MIN PARTITIONING and MAX INDEPENDENT SET ON PLANAR GRAPHS.

Finally, a stronger form of approximation scheme can be used for particular problems in **PTAS**, such as, for example, MAX KNAPSACK or MIN KNAPSACK. In such cases, in fact, the running time of the algorithm A_r is uniformly polynomial in r as made precise in the following definition.

Definition 15.5

An **NPO** *problem* Π *belongs to the class fully polynomial-time approximation scheme* **(FPTAS)** *if there exists a* **PTAS** A_r *such that, given any* $r \in \mathbb{Q}$, $r \neq 1$, *and any instance* x *of* Π, $\rho_{\mathtt{A}_r}(x) \leq r$ *(resp.,* $\rho_{\mathtt{A}_r}(x) \geq r$*) if* Π *is a minimization problem (resp., a maximization problem) and, furthermore, there exists a two variate polynomial* q *such that the running time of* $A_r(x)$ *is bounded by* $q(x, 1/(r-1))$ *(resp.,* $q(x, 1/(1-r))$ *in case of maximization problems).*

It is worth remembering that under the hypothesis that **P** $\neq$ **NP** all the above classes form a strict hierarchy that is **FPTAS** $\subset$ **PTAS** $\subset$ **APX** $\subset$ **NPO**.

Let us note that there also exists other notorious approximability classes, as **Poly-APX**, **Log-APX**, **Exp-APX**, the classes of problems approximable within ratios that are, respectively, polynomials (or inverse of polynomials if goal = max), logarithms (or inverse of logarithms), exponentials (or inverse of exponentials) of the size of the input. The best studied among them is the class **Poly-APX**. Despite their interest for sake of conciseness these classes are not dealt in the chapter.

When the problem of characterizing approximation algorithms for hard optimization problems was tackled, soon the need arose for a suitable notion of reduction that could be applied to optimization problems to study their approximability properties [3]:

> What is it that makes algorithms for different problems behave in the same way? Is there some stronger kind of reducibility than the simple polynomial reducibility that will explain these results, or are they due to some structural similarity between the problems as we define them?

Approximation preserving reductions provide an answer to the above question. Such reductions have an important role when we wish to assess the approximability properties of an **NPO** optimization problem and locate its position in the approximation hierarchy. In such a case, in fact, if we can establish a relationship between the given problem and other known optimization problems, we can derive both positive information on the existence of approximation algorithms (or approximation schemes) for the new problem or, on the other side, negative information, showing intrinsic limitations to approximability. With respect to reductions between decision problems, reductions between optimization problems have to be more elaborate. Such reductions, in fact, have to map both instances and solutions of the two problems, and they have to preserve, so to say, the optimization structure of the two problems.

The first examples of reducibility among optimization problems were introduced by Ausiello et al. in Refs. [4,5] and by Paz and Moran in Ref. [6]. In particular, in Ref. [5], the notion of *structure preserving reducibility* is introduced and for the first time the completeness of MAX WSAT (weighted-vertex SAT) in the class of **NPO** problems is proved. Still it took a few more years until suitable notions of approximation preserving reducibilities were introduced by Orponen and Mannila in Ref. [7]. In particular, their paper presented the strict reduction (see Section 15.4) and provided the first examples of natural problems who are complete under approximation preserving reductions: (MIN WSAT, MIN 0-1 LINEAR PROGRAMMING, and MIN TSP).

Before introducing specific examples of approximation preserving reduction in the next sections, let us explain more formally how reductions between optimization problems can be defined, starting from the notion of *basic reducibility* (called R-reducibility in the following, denoted $\leq_{\mathsf{R}}$) which underlays most of the reducibilities that will be later introduced.

Definition 15.6

Let Π_1 and Π_2 be two **NPO** *maximization problems. Then we say that $\Pi_1 \leq_{\mathsf{R}} \Pi_2$ if there exist two polynomial-time computable functions f, g that satisfy the following properties:*

- $f : \mathcal{I}_{\Pi_1} \to \mathcal{I}_{\Pi_2}$ *such that* $\forall x_1 \in \mathcal{I}_{\Pi_1}$, $f(x_1) \in \mathcal{I}_{\Pi_2}$; *in other words, given an instance x_1 in Π_1, f allows to build an instance $x_2 = f(x_1)$ in Π_2;*
- $g : \mathcal{I}_{\Pi_1} \times \mathrm{Sol}_{\Pi_2} \to \mathrm{Sol}_{\Pi_1}$ *such that,* $\forall (x_1, y_2) \in (\mathcal{I}_{\Pi_1} \times \mathrm{Sol}_{\Pi_2}(f(x_1)))$, $g(x_1, y_2) \in \mathrm{Sol}_{\Pi_1}(x_1)$; *in other words, starting from a solution y_2 of the instance x_2, g determines a solution $y_1 = g(x_1, y_2)$ of the initial instance x_1.*

As we informally said in the introduction, the aim of an approximation preserving reduction is to guarantee that if we achieve a certain degree of approximation in the solution of problem Π_2, then a suitable degree of approximation is reached for problem Π_1. As we will see, the various notions of approximation preserving reducibilities that will be introduced in the following, essentially differ in the mapping that is established between the approximation ratios of the two problems.

Before closing this section, let us introduce the notion of *closure* of a class of problems under a given type of reducibility. In what follows, given two **NPO** problems Π and Π', and a reducibility X, we will generally use the notation $\Pi \leq_{\mathsf{X}} \Pi'$ to indicate that Π reduces to Π' via reduction of type X.

Definition 15.7

*Let **C** be a class of **NPO** problems and X a reducibility. Then, the closure* $\overline{\mathbf{C}}^{\mathsf{X}}$ *of **C** under X is defined as:* $\overline{\mathbf{C}}^{\mathsf{X}} = \{\Pi \in \boldsymbol{NPO} : \exists \Pi' \in \mathbf{C}, \Pi \leq_{\mathsf{X}} \Pi'\}$.

15.3 The Linear Reducibility

The first kind of approximation preserving reducibility that we want to show is a very natural and simple transformation among problems which consists of two linear mappings: one between the values of the optimum solutions of the two problems and one between the errors of the corresponding approximate solutions, the *linear reducibility* (L-reducibility, denoted $\leq_{\mathsf{L}}$).

Definition 15.8

Let Π_1 *and* Π_2 *be two problems in **NPO**. Then, we say that* $\Pi_1 \leq_{\mathsf{L}} \Pi_2$*, if there exist two functions* f *and* g *(basic reduction) and two constants* $\alpha_1 > 0$ *and* $\alpha_2 > 0$ *such that* $\forall x \in \mathcal{I}_{\Pi_1}$ *and* $\forall y' \in \mathrm{Sol}_{\Pi_2}(f(x))$*:*

- $\mathrm{opt}_{\Pi_2}(f(x)) \leq \alpha_1 \, \mathrm{opt}_{\Pi_1}(x)$;
- $|m_{\Pi_1}(x, g(y')) - \mathrm{opt}_{\Pi_1}(x)| \leq \alpha_2 |m_{\Pi_2}(f(x), y') - \mathrm{opt}_{\Pi_2}(f(x))|$.

This type of reducibility has been introduced in Ref. [8] and has played an important role in the characterization of the hardness of approximation. In fact it is easy to observe that the following property holds.

Fact 15.1

Given two problems Π *and* Π'*, if* $\Pi \leq_{\mathsf{L}} \Pi'$ *and* $\Pi' \in$ ***PTAS****, then* $\Pi \in$ ***PTAS****. In other words, the* L*-reduction preserves membership in* ***PTAS****.*

Example 15.1

MAX 3-SAT $\leq_{\mathsf{L}}$ MAX 2-SAT. *Let us consider an instance* ϕ *with* m *clauses (w.l.o.g., let us assume that all clauses consist of exactly three literals); let* l_i^1, l_i^2, *and* l_i^3 *be the three literals of the* i*th clause,* $i = 1, \ldots, m$. *To any clause we associate the following 10 new clauses, each one consisting of at most two literals:* $l_i^1, l_i^2, l_i^3, l_i^4, \bar{l}_i^1 \vee \bar{l}_i^2, \bar{l}_i^1 \vee \bar{l}_i^3, \bar{l}_i^2 \vee \bar{l}_i^3, l_i^1 \vee \bar{l}_i^4, l_i^2 \vee \bar{l}_i^4, l_i^3 \vee \bar{l}_i^4$, *where* l_i^4 *is a new variable. Let* C_i' *be the conjunction of the 10 clauses derived from clause* C_i. *The formula* $\phi' = f(\phi)$ *is the conjunction of all clauses* C_i', $i = 1, \ldots, m$, i.e., $\phi' = f(\phi) = \wedge_{i=1}^{m} C_i'$ *and it is an instance of* MAX 2-SAT.

It is easy to see that all truth assignments for ϕ' *satisfy at most seven clauses in any* C_i'. *On the other side, for any truth assignment for* ϕ *satisfying* C_i, *the following truth assignment for* l_i^4 *is such that the extended truth assignment satisfies exactly seven clauses in* C_i': *if exactly one (resp., all) of the variables* l_i^1, l_i^2, l_i^3 *is (resp., are) set to true, then* l_i^4 *is set to false (resp., true); otherwise (exactly one literal in* C_i *is set to false),* l_i^4 *can be indifferently true or false. Finally, if* C_i *is not satisfied (*l_i^1, l_i^2, *and* l_i^3 *are all set to false), no truth assignment for* l_i^4 *can satisfy more than six clauses of* C_i' *while six are guaranteed by setting* l_i^4 *to false. This implies that* $\mathrm{opt}(\phi') = 6m + \mathrm{opt}(\phi) \leq 13\, \mathrm{opt}(\phi)$ *(since* $m \leq 2\, \mathrm{opt}(\phi)$, *see Lemma 15.2 in Section* 15.6.2).

Given a truth assignment for ϕ', *we consider its restriction* $\tau = g(\phi, \tau')$ *on the variables of* ϕ*; for such assignment* τ *we have:* $m(\phi, \tau) \geq m(\phi', \tau') - 6m$. *Then,* $\mathrm{opt}(\phi) - m(\phi, \tau) = \mathrm{opt}(\phi') - 6m - m(\phi, \tau) \leq \mathrm{opt}(\phi') - m(\phi', \tau')$. *This means that the reduction we have defined is an* L*-reduction with* $\alpha_1 = 13$ *and* $\alpha_2 = 1$.

L-reductions provide a simple way to prove hardness of approximability. An immediate consequence of the reduction that has been shown above and of Fact 15.1 is that, since MAX 3-SAT does not allow a PTAS (see Chapter 17) so does MAX 2-SAT. The same technique can be used to show the nonexistence of PTAS for a large class of optimization problems, among others MAX CUT, MAX INDEPENDENT SET-B (i.e., MAX INDEPENDENT SET on graphs with bounded degree), and MIN VERTEX COVER.

Before closing this section, let us observe that the set of 10 2-SAT clauses that we have used in Example 15.1 for constructing the 2-SAT formula $\phi' = f(\phi)$, is strongly related to the bound on approximability established in the example. Really, the proof of the result is based on the fact that at least six out of the 10 clauses can always be satisfied while exactly seven out of 10 can be satisfied, if and only if the original 3-SAT clause is satisfied. A combinatorial structure of this kind, which allows to transfer (in)approximability results from a problem to another, is called a *gadget* (see Ref. [9]). The role of gadgets in approximation-preserving reductions will be discussed further in Section 15.8.

15.4 Strict Reducibility and Complete Problems in NPO

As we informally said in the introduction, an important characteristic of an approximation preserving reduction from a problem Π_1 to a problem Π_2 is that the solution y_1 of problem Π_1 produced by the mapping g should be at least as good as the original solution y_2 of problem Π_2. This property is not necessarily true for any approximation preserving reduction (it is easy to observe that, for example, L-reductions do not always satisfy it), but it is true for the most natural reductions that have been introduced in the early phase of approximation studies: the *strict reductions* [7].

In the following, we present the strict reducibility (S-reducibility, denoted $\leq_S$) referring to minimization problems, but the definition can be trivially extended to all types of optimization problems.

Definition 15.9

*Let Π_1 and Π_2 be two **NPO** minimization problems. Then, we say that $\Pi_1 \leq_S \Pi_2$ if there exist two polynomial-time computable functions f, g that satisfy the following properties:*

- *f and g are defined as in a basic reduction;*
- $\forall x \in \mathcal{I}_{\Pi_1}, \forall y \in \mathrm{Sol}_{\Pi_2}(f(x)), \rho_{\Pi_2}(f(x), y) \geq \rho_{\Pi_1}(x, g(x, y))$.

It is easy to observe that the S-reducibility preserves both membership in **APX** and in **PTAS**.

Proposition 15.1

*Given two minimization problems Π_1 and Π_2, if $\Pi_1 \leq_S \Pi_2$ and $\Pi_2 \in$ **APX** (resp., $\Pi_2 \in$ **PTAS**), then $\Pi_1 \in$ **APX** (resp., $\Pi_2 \in$ **PTAS**).*

Example 15.2

Consider the MIN-WEIGHTED VERTEX COVER *problem in which the weights of vertices are bounded by a polynomial $p(n)$ and let us prove that this problem S reduces to the unweighted* MIN VERTEX COVER *problem. Let us consider an instance $(G(V, E), \vec{w})$ of the former and let us see how it can be transformed into an instance $G'(V', E')$ of the latter. We proceed as follows: for any vertex $v_i \in V$, with weight w_i, we construct an independent set W_i of w_i new vertices in V'; next, for any edge $(v_i, v_j) \in E$, we construct a complete bipartite graph among the vertices of the independent sets W_i and W_j in G'. This transformation is clearly polynomial since the resulting graph G' has $\sum_{i=1}^{n} w_i \leq np(n)$ vertices.*

Let us now consider a cover C' of G' and, w.l.o.g., let us assume it is minimal w.r.t. inclusion (in case it is not, we can easily delete vertices until we reach a minimal cover). We claim that at this point C' has the form: $\cup_{j=1}^{\ell} W_{i_j}$, i.e., there is an ℓ such that C' consists of ℓ independent sets W_i. Suppose that the claim is not true. Let us consider an independent set W_k which is only partially included in C' (that is a nonempty portion W_k' of it belongs to C'). Let us also consider all independent sets W_p that are entirely or partially included in C' and moreover are connected by edges to the vertices of W_k. Two cases may arise: (i) all considered sets W_p have their vertices included in C'; in this case the existence of W_k' would contradict the minimality of C'; (ii) among the considered sets W_p there is at least one set W_q out of which only a nonempty portion W_q' is included in C'; in this case, since the subgraph of G' induced by $W_k \cup W_q$ is a complete bipartite graph, the *edges connecting the vertices of $W_p \setminus W'_p$ with the vertices of $W_q \setminus W'_q$ are not covered by C' and this would contradict the assumption that C' is a cover of G'. As a consequence, the size of C' satisfies $|C'| = \sum_{j=1}^{\ell} w_{i_j}$ and the function g of the reduction can then be defined as follows:* if C' is a cover of G' and if $W_i, i = 1, \ldots, \ell$, are the independent sets that form C', then a cover C for G contains all corresponding vertices $v_1, \ldots, v_\ell$ of V. *Clearly g can be computed in polynomial time.*

From these premises we can immediately infer that the same approximation ratio that is guaranteed for A on G' is also guaranteed by g on G. The shown reduction is hence an S-reduction.

An immediate corollary of the strict reduction shown in the example is that the approximation ratio 2 for MIN VERTEX COVER (that we know can be achieved by various approximation techniques, see Ref. [10]) also holds for the weighted version of the problem, dealt in Example 15.2.

The S-reducibility is indeed a very strong type of reducibility: in fact it requires a strong similarity between two optimization problems and it is not easy to find problems that exhibit such similarity. The interest for the S-reducibility arises mainly from the fact that by making use of reductions of this kind, Orponen and Mannila have identified the first optimization problem that is complete in the class of **NPO** minimization problems: the problem MIN WSAT. Let us consider a Boolean formula in conjunctive normal form ϕ over n variables $x_1, \ldots, x_n$ and m clauses. Any variable x_i has a positive weight $w_i = w(x_i)$. Let us assume that the truth assignment that puts all variables to *true* is feasible, even if it does not satisfy ϕ. Besides, let us assume that t_i is equal to 1 if τ assigns value *true* to the ith variable and 0 otherwise. We want to determine the truth assignment τ of ϕ which minimizes $\sum_{i=1}^{n} w_i t_i$. The problem MAX WSAT can be defined in similar terms. In this case, we assume that the truth assignment that puts all variables to *false* is feasible and we want to determine the truth assignment τ that maximizes $\sum_{i=1}^{n} w_i t_i$. In the variants MIN W3-SAT and MAX W3-SAT, we consider that all clauses contain exactly three literals.

The fact that MIN WSAT is complete in the class of **NPO** minimization problems under S-reductions implies that this problem does not allow any constant-ratio approximation (unless **P** = **NP**) [5–7]. In fact, due to the properties of S-reductions, if a problem which is complete in the class of **NPO** minimization problems was approximable then all **NPO** minimization problems would. Since it is already known that some minimization problems in **NPO** do not allow any constant-ratio approximation algorithm (namely MIN TSP on general graphs), then we can deduce that (unless **P** = **NP**) no complete problem in the class of NPO minimization problems allows any constant-ratio approximation algorithm.

Theorem 15.1

MIN WSAT *is complete in the class of minimization problems belonging to* **NPO** *under S-reductions.*

Proof

The proof is based on a modification of Cook's proof of the **NP**-completeness of SAT [1]. Let us consider a minimization problem $\Pi \in$ **NPO**, the polynomial p which provides the bounds relative to problem Π (see Definition 15.1) and an instance x of Π. The following nondeterministic Turing machine M (with two output tapes T_1 and T_2) generates all feasible solutions $y \in \mathrm{Sol}(x)$ together with their values:

- generate y, such that $|y| \leq p(|x|)$;
- if $y \notin \mathrm{Sol}(x)$, then reject; otherwise, write y on output tape T_1, $m(x, y)$ on output tape T_2, and accept.

Let us now consider the reduction that is currently used in the proof of Cook's theorem (see Ref. [11]) and remember that such reduction produces a propositional formula in conjunctive normal form that is satisfied if and only if the computation of the Turing machine accepts. Let ϕ_x be such formula and $x_n, x_{n-1}, \ldots, x_0$ the variables of ϕ_x that correspond to the cells of tape T_2 where M writes the value $m(x, y)$ in binary (w.l.o.g., we can assume such cells to be consecutive), such that a satisfying assignment of ϕ_x, x_i is *true* if and only if the $(n - i)$-th bit of $m(x, y)$ is equal to 1. Given an instance x of Π the function f of the S-reduction provides an instance of MIN WSAT consisting of the pair (ϕ_x, ψ), where $\psi(x) = \psi\ (x_i) = 2^i$, for $i = 0, \ldots, n$ and $\psi(x) = 0$, for any other variable x in ϕ_x.

The function g of the S-reduction is defined as follows. For any instance x of Π and any solution $\tau' \in \mathrm{Sol}(f(x))$ (i.e., any truth assignment τ' which satisfies the formula ϕ_x [for simplicity we only consider the case in which the formula ϕ_x is satisfiable]), we recover from ϕ_x the representation of the solution y written on tape T_1. Besides, we have that $m(x, g(x, \tau')) = \sum_{\tau'(x_i)=\mathbf{true}} 2^i = m((\phi_x, \psi), \tau')$, where by $\tau'(x_i)$ we indicate the value of variable x_i according to the assignment τ'. As a consequence, $m(x, g(x, \tau')) = m(f(x), \tau')$ and henceforth, $r(x, g(x, \tau')) = r(f(x), \tau')$, and the described reduction is an S-reduction. □

After having established that MIN WSAT is complete for **NPO** minimization problems under the S-reducibility we can then proceed to find other complete problems in this class.

Let us consider the following definition of the MIN 0-1 LINEAR PROGRAMMING problem (the problem MAX 0-1 LINEAR PROGRAMMING can be defined analogously). We consider a matrix $A \in \mathbb{Z}^{m\times n}$ and two vectors $\vec{b} \in \mathbb{Z}^m$ and $\vec{w} \in \mathbb{N}^n$. We want to determine a vector $\vec{y} \in \{0, 1\}^n$ that verifies $A\vec{y} \geq \vec{b}$ and minimizes the quantity $\vec{w} \cdot \vec{y}$.

Clearly, MIN 0-1 LINEAR PROGRAMMING is an **NPO** minimization problem. The reduction from MIN WSAT to MIN 0-1 LINEAR PROGRAMMING is a simple modification of the standard reduction among the corresponding decision problems. Suppose that the following instance of MIN 0-1 LINEAR PROGRAMMING, consisting of a matrix $A \in \mathbb{Z}^{m\times n}$ and two vectors $\vec{b} \in \mathbb{Z}^m$ and $\vec{w} \in \mathbb{N}^n$, is the image $f(x)$ of an instance x of MIN WSAT and suppose that $\vec{y}$ is a feasible solution of $f(x)$ whose value is $m(f(x), \vec{y}) = \vec{w} \cdot \vec{y}$. Then, $g(x, \vec{y})$ is a feasible solution of x, that is a truth assignment τ, whose value is $m(x, \tau) = \sum_{i=1}^{n} w_i t_i$ where t_i is equal to 1 if τ assigns value *true* to the ith variable and 0 otherwise. Since we have $\sum_{i=1}^{n} w_i t_i = \vec{w} \cdot \vec{y}$, it is easy to see that the reduction (f, g, c), where c is the identity function, is an S-reduction[1] and, as a consequence, MIN 0-1 LINEAR PROGRAMMING is also complete in the class of **NPO** minimization problems.

It is not difficult to prove that an analogous result holds for maximization problems, that is, MAX WSAT is complete under S-reductions in the class of **NPO** maximization problems.

At this point of the chapter we still do not have the technical instruments to establish a more powerful result, that is, to identify problems which are complete under S-reductions for the entire class of **NPO** problems. To prove such a result we need to introduce a more involved kind of reducibility, the AP-reducibility (see Section 15.5). In fact, by means of AP-reductions MAX WSAT can itself be reduced to MIN WSAT and vice versa (see Ref. [12]) and therefore it can be shown that (under AP-reductions) both problems are indeed **NPO**-complete.

15.5 AP-Reducibility

After the seminal paper by Orponen and Mannila [7], research on approximation preserving reducibility was further developed (see, e.g., Refs. [13–15]); nevertheless, the beginning of the structural theory of approximability of optimization problems can be traced back to the fundamental paper by Crescenzi and Panconesi [16] where reducibilities preserving membership in **APX** (A-reducibility), **PTAS** (P-reducibility), and **FPTAS** (F-reducibility) were studied and complete problems for each of the three kinds of reducibilities were shown, respectively in **NPO**, **APX**, and **PTAS**. Unfortunately, the problems which are proved complete in **APX** and **PTAS** in this paper are quite artificial.

Along a different line of research, during the same years, the study of logical properties of optimization problems has led Papadimitriou and Yannakakis [8] to the syntactic characterization of an important class of approximable problems, the class **Max-SNP**. Completeness in **Max-SNP** has been defined in terms of L-reductions (see Section 15.3) and natural complete problems (e.g., MAX 3-SAT, MAX 2-SAT, and MIN VERTEX COVER-B) have been found. The relevance of such an approach is related to the fact that it is possible to prove that **Max-SNP**-complete problems do not allow PTAS (unless $\mathbf{P} = \mathbf{NP}$).

[1] Note that, in this case, the reduction is also a linear reductions with $\alpha_1 = \alpha_2 = 1$.

The two approaches have been reconciled by Khanna et al. [17], where the closure of syntactically defined classes with respect to an approximation preserving reduction were proved equal to the more familiar computationally defined classes. As a consequence of this result, any Max-SNP-completeness result appeared in the literature can be interpreted as an APX-completeness result. In this paper a new type of reducibility is introduced, the E-reducibility. With respect to the L-reducibility, in the E-reducibility the constant α_1 is replaced by a polynomial $p(|x|)$. This reducibility is fairly powerful since it allows to prove that MAX 3-SAT is complete for **APX-PB** (the class of problems in **APX** whose values are bounded by a polynomial in the size of the instance) such as MAX 3-SAT. However, it remains somewhat restricted because it does not allow the transformation of **PTAS** problems (such as MAX KNAPSACK) into problems belonging to **APX-PB**.

The final answer to the problem of finding the suitable kind of reducibility (powerful enough to establish completeness results both in **NPO** and **APX**) is the AP-reducibility introduced by Crescenzi et al. [12].

In fact, the types of reducibility that we have introduced so far (linear and strict reducibilities) suffer from various limitations. In particular, we have seen that strict reductions allow us to prove the completeness of MIN WSAT in the class of **NPO** minimization problems, but are not powerful enough to allow the identification of problems which are complete for the entire class **NPO**. Besides, both linear and strict reductions, in different ways, impose strong constraints on the values of the solutions of the problems among which the reduction is established.

In this section, we provide the definition of the AP-reducibility (denoted $\leq_{\mathsf{AP}}$) and we illustrate its properties. Completeness results in **NPO** and in **APX** based on AP-reductions are shown in Section 15.6.

Definition 15.10

*Let Π_1 and Π_2 be two minimization **NPO** problems. An AP-reduction between Π_1 and Π_2 is a triple (f, g, α), where f and g are functions and α is a constant, such that, for any $x \in \mathcal{I}_{\Pi_1}$ and $r > 1$:*

- *$f(x, r) \in \mathcal{I}_{\Pi_2}$ is computable in time $t_f(|x|, r)$ polynomial in $|x|$ for a fixed r; $t_f(n, \cdot)$ is nonincreasing;*
- *for any $y \in \mathrm{Sol}_{\Pi_2}(f(x, r))$, $g(x, y, r) \in \mathrm{Sol}_{\Pi_1}(x)$ is computable in time $t_g(|x|, y, r)$ which is polynomial both in $|x|$ and in $|y|$ for an fixed r; $t_g(n, n, \cdot)$ is nonincreasing;*
- *for any $y \in \mathrm{Sol}_{\Pi_2}(f(x, r))$, $\rho_{\Pi_2}(f(x, r), y) \leq r$ implies $\rho_{\Pi_1}(x, g(x, y, r)) \leq 1 + \alpha(r - 1)$.*

It is worth underlining the main differences of AP-reductions with respect to the reductions introduced until now. First, with respect to L-reductions the constraint that the optimum values of the two problems are linearly related has been dropped. Second, with respect to the S-reductions we allow a weaker relationship to hold between the approximation ratios achieved for the two problems. Besides, an important condition which is needed in the proof of APX-completeness is that, in AP-reductions, the two functions f and g may depend on the approximation ratio r. Such extension is somewhat natural since there is no reason to ignore the quality of the solution we are looking for, when reducing one optimization problem to another and it plays a crucial role in the completeness proofs. However, since in many applications such knowledge is not required, whenever functions f and g do not use the dependency on r, we will avoid specifying this dependency. In other words, we will write $f(x)$ and $g(x, y)$ instead of $f(x, r)$ and $g(x, y, r)$, respectively.

Proposition 15.2

*Given two minimization problems Π_1 and Π_2, if $\Pi_1 \leq_{\mathsf{AP}} \Pi_2$ and $\Pi_2 \in$ **APX** (resp., $\Pi_2 \in$ **PTAS**), then $\Pi_1 \in$ **APX** (resp., $\Pi_1 \in$ **PTAS**).*

As a last remark, let us observe that the S-reducibility is a particular case of AP-reducibility, corresponding to the case in which $\alpha = 1$. More generally, the AP-reducibility is sufficiently broad to encompass almost all known approximation preserving reducibilities while maintaining the property of establishing a linear relation between performance ratios: This is important to preserve membership in all approximation classes.

15.6 NPO-Completeness and APX-Completeness

15.6.1 NPO-Completeness

In the preceding section, we have announced that by means of a suitable type of reduction we can transform an instance of MAX WSAT into an instance of MIN WSAT. This can now be obtained by making use of AP-reductions. By combining this result with Theorem 15.1 and with the corresponding result concerning the completeness of MAX WSAT in the class of **NPO** maximization problems, we can assemble the complete proof that MIN WSAT is complete for the entire class **NPO** under AP-reductions. The inverse reduction, from MIN WSAT to MAX WSAT can be shown in a similar way, leading to the proof that also MAX WSAT is complete for the entire class **NPO** under AP-reductions.

Theorem 15.2

MAX WSAT *can be AP-reduced to* MIN WSAT *and vice versa.*

Proof (Sketch)

The proof works as follows. First a simple reduction can be defined which transforms a given instance ϕ of MAX WSAT into an instance ϕ' of MIN WSAT with α depending on r. Such reduction can then be modified into a real AP-reduction in which α is a constant, not depending on r, while, of course, the functions f and g will depend on r. We limit ourselves to describing the first step. The complete proof can be found in Ref. [18].

Let ϕ be the formula produced in the reduction proving the completeness of MAX WSAT for the class of NPO maximization problems. Then, $f(\phi)$ be the formula $\phi \wedge \alpha_1 \wedge \cdots \wedge \alpha_s$, where α_i is $z_i \equiv (\overline{v}_1 \wedge \cdots \wedge \overline{v}_{i-1} \wedge v_i)$, $z_1, \ldots, z_s$ are new variables with weights $w(z_i) = 2^i$ for $i = 1, \ldots, s$, and all other variables (even the v variables) have zero weight. If τ is a satisfying truth assignment for $f(\phi)$, let $g(\phi, \tau)$ be the restriction of τ to the variables that occur in ϕ. This assignment clearly satisfies ϕ. Note that exactly one among the z variables is *true* in any satisfying truth assignment of $f(\phi)$. If all z variables were *false*, then all v variables would be *false*, which is not allowed. However, it is clearly not possible that two z variables are *true*. Hence, for any feasible solution τ of $f(\phi)$, we have that $m(f(\phi), \tau) = 2^i$, for some i with $1 \leq i \leq s$. This finally implies that $2^s/m(f(\phi), \tau) \leq m(\phi, g(\phi, \tau)) < 2.2^s/m(f(\phi), \tau)$. This is particularly true for the optimal solution (observe that any satisfying truth assignment for ϕ can be easily extended to a satisfying truth assignment for $f(\tau)$). Thus, after some easy algebra, the performance ratio of $g(\phi, \tau)$ with respect to ϕ verifies $r(\phi, g(\phi, \tau)) > 1/(2r(f(\phi), \tau))$.

The reduction satisfies the approximation preserving condition with a factor $\alpha = (2r - 1)/(r - 1)$. To obtain a factor α not depending on r, the reduction can be modified by introducing 2^k more variables for a suitable integer k. □

Other problems that have been shown **NPO**-complete are MIN (MAX) W3-SAT and MIN TSP [7]. As it has been observed before, as a consequence of their **NPO**-completeness under approximation preserving reductions, for all these problems any r-approximate algorithm with constant r does not exist unless **P** = **NP**.

15.6.2 APX-Completeness

As it has been mentioned above, the existence of an **APX**-complete problem has already been shown in Ref. [16] (see also Ref. [19]), but the problem that is proved complete in such framework is a rather artificial version of MAX WSAT. The reduction used in such a result is called P-reduction. Unfortunately, no natural problem has been proved complete in **APX** using the same approach. In this section, we prove the **APX**-completeness under AP-reduction of a natural and popular problem: MAX 3-SAT. The proof is crucially based on the following two lemmas (whose proofs are not provided in this paper).

The first lemma is proved in Ref. [20] and is based on a powerful algebraic technique for the representation of propositional formulæ (see also Ref. [18]), while the second one states a well-known property of propositional formulæ and is proved in Refs. [3,18].

Lemma 15.1

There is a constant $\epsilon > 0$ and two functions f_s and g_s such that, given any propositional formula ϕ in conjunctive normal form, the formula $\psi = f_s(\phi)$ is a conjunctive normal form formula with at most three literals per clause which satisfies the following property: for any truth assignment T' satisfying at least a portion $1 - \epsilon$ of the maximum number of satisfiable clauses in ψ, $g_s(\phi, T')$ satisfies ϕ if and only if ϕ is satisfiable.

Lemma 15.2

Given a propositional formula in conjunctive normal form, at least one-half of its clauses can always be satisfied.

Theorem 15.3

MAX 3-SAT *is **APX**-complete.*

Proof (Sketch)

As it has been done in the case of the proofs of **NPO**-completeness, we split the proof in two parts. First, we show that MAX 3-SAT is complete in the class of **APX** maximization problems and then we show that any **APX** minimization problem can be reduced to an **APX** maximization problem. To make the proof easier, we adopt the convention used in Ref. [18]. The approximation ratio of a maximization problem in this context will be defined as the ratio between the value of the optimum solution opt(x) and the value of the approximate solution $m(x, \mathtt{A}(x))$. For both maximization and minimization problems, therefore, the approximation ratio is in $[1, \infty)$. Let us first observe that MAX 3-SAT $\in$ **APX** since it can be approximated up to the ratio 0.8006 [9].

Now we can sketch the proof that MAX 3-SAT is hard for the class of maximization problems in **APX**. Let us consider a maximization problem $\Pi \in$ **APX**. Let $\mathtt{A}_\Pi$ be a polynomial-time r_Π-approximation algorithm for Π. To construct an AP-reduction, let us define the parameter α as follows: $\alpha = 2(r_\Pi \log r_\Pi + r_\Pi - 1) \times((1 + \epsilon)/\epsilon)$, where ϵ is the constant of Lemma 15.1. Let us now choose $r > 1$ and let us consider the following two cases: $1 + \alpha(r - 1) \geq r_\Pi$ and $1 + \alpha(r - 1) < r_\Pi$.

In the case $1 + \alpha(r - 1) \geq r_\Pi$, given any instance x of Π and given any truth assignment τ for MAX 3-SAT, we trivially define $f(x, r)$ to be the empty formula and $g(x, \tau, r) = \mathtt{A}_\Pi(x)$. It can easily be seen that $r(x, g(x, \tau, r)) \leq r_\Pi \leq 1 + \alpha(r - 1)$ and the reduction is an AP-reduction.

Let us then consider the case $1 + \alpha(r - 1) < r_\Pi$ and let us define $r_n = 1 + \alpha(r - 1)$; then, $r = ((r_n - 1)/\alpha) + 1$. If we define $k = \lceil \log_{r_n} r_\Pi \rceil$, we can partition the interval $[m(x, \mathtt{A}_\Pi(x)), r_\Pi m(x, \mathtt{A}_\Pi(x))]$ in the following k subintervals: $[m(x, \mathtt{A}_\Pi(x)), r_n m(x, \mathtt{A}_\Pi(x))]$, $[r_n^i m(x, \mathtt{A}_\Pi(x)), r_n^{i+1} m(x, \mathtt{A}_\Pi(x))]$, $i = 1, \ldots, k-2$, $[r_n^{k-1} m(x, \mathtt{A}_\Pi(x)), r_\Pi m(x, \mathtt{A}_\Pi(x))]$. Then we have $m(x, \mathtt{A}_\Pi(x)) \leq \text{opt}(x) \leq r_\Pi m(x, \mathtt{A}_\Pi(x)) \leq r_n^k m(x, \mathtt{A}_\Pi(x))$, i.e., the optimum value of instance x of Π belongs to one of the subintervals.

Note that by definition $k < (r_\Pi \log r_\Pi + r_\Pi - 1)/(r_n - 1)$ and by making use of the definitions of α, r, and k, we obtain $r < (\epsilon/(2k(1 + \epsilon))) + 1$.

For any $i = 0, 1, \ldots, k - 1$, let us consider an instance x of Π and the following nondeterministic algorithm, where p is the polynomial that bounds the value of all feasible solutions of Π:

- guess a candidate solution y with value at most $p(|x|)$;
- if $y \in \text{Sol}_\Pi(x)$ and $m_\Pi(x, y) \leq r_n^{i+1} m(x, \mathtt{A}_\Pi(x))$, then return *yes*, otherwise return *no*.

Applying once again the technique of Theorem 15.1, we can construct k propositional formulæ $\phi_0, \phi_1, \ldots, \phi_{k-1}$ such that for any truth assignment τ_i satisfying ϕ_i, $i = 0, 1, \ldots, k - 1$, in polynomial time we can build a feasible solution y of the instance x with $m_\Pi(x, y) \geq r_n^i m(x, \mathtt{A}_\Pi(x))$.

Hence, the instance ψ of MAX 3-SAT that we consider is the following: $\psi = f(x, r) = \wedge_{i=0}^{k-1} f_s(\phi_i)$, where f_s is the function defined in Lemma 15.1; w.l.o.g., we can suppose that all formulæ $f_s(\phi_i)$, $i = 0, \ldots, k - 1$, contain the same number of clauses.

Denote by T a satisfying truth assignment of ψ achieving approximation ratio r and by r_i the approximation ratio guaranteed by τ over $f_s(\phi_i)$. By Lemma 15.2 we get $m(r_i - 1)/(2r_i) \leq \text{opt}(\psi) - m(\psi, T) \leq km(r - 1)/r$. Using this expression for $i = 0, \ldots, k - 1$, we have $m(r_i - 1)/2r_i \leq km(r - 1)/r$, which implies $1 - (2k(r - 1)/r) \leq 1/r_i$ and, finally, $r_i \leq 1 + \epsilon$.

Using Lemma 15.1 again, we derive that, for $i = 0, \ldots, k-1$, the truth assignment $\tau_i = g_s(\phi_i, \tau)$ (where g_s is as defined in Lemma 15.1) satisfies ϕ_i if and only if ϕ_i is satisfiable. Let us call i^* the largest i for which τ_i satisfies ϕ_i; then, $r_n^{i^*} m(x, \mathtt{A}_\Pi(x)) \leq \mathrm{opt}_\Pi(x) \leq r_n^{i^*+1} m(x, \mathtt{A}_\Pi(x))$. Starting from τ_{i^*}, we can then construct a solution y for Π whose value is at least $r_n^{i^*} m(x, \mathtt{A}_\Pi(x))$. This means that y guarantees an approximation ratio r_n. In other words, $r(x, y) \leq r_n = 1 + \alpha(r-1)$ and the reduction (f, g, α) that we have just defined (where g consists in applying g_s, determining i^* and constructing y starting from τ_{i^*}) is an AP-reduction.

Since Π is any maximization problem in **APX**, the completeness of MAX 3-SAT for the class of maximization problems in **APX** follows.

We now turn to the second part of the theorem. In fact, we still have to prove that all minimization problems in **APX** can be AP-reduced to maximization problems and, henceforth, to MAX 3-SAT.

Let us consider a minimization problem $\Pi \in$ **APX** and an algorithm $\mathtt{A}$ with approximation ratio r for Π; let $k = \lceil r \rceil$. We can construct a maximization problem $\Pi' \in$ **APX** and prove that $\Pi \leq_{\mathsf{AP}} \Pi'$. The two problems have the same instances and the same feasible solutions, while the objective function of Π' is defined as follows: given an instance x and a feasible solution y of x, $m_{\Pi'}(x, y) = (k+1)m_\Pi(x, \mathtt{A}(x)) - km_\Pi(x, y)$, if $m_\Pi(x, y) \leq m_\Pi(x, \mathtt{A}(x))$, $m_{\Pi'}(x, y) = m_\Pi(x, \mathtt{A}(x))$, otherwise.

Clearly, $m_\Pi(x, \mathtt{A}(x)) \leq \mathrm{opt}_{\Pi'}(x) \leq (k+1)m_\Pi(x, \mathtt{A}(x))$ and, by definition of Π', the algorithm $\mathtt{A}$ is also an approximation algorithm for this problem with approximation ratio $k+1$; therefore, $\Pi' \in$ **APX**. The reduction from Π to Π' can now be defined as follows: for any instance x of Π, $f(x) = x$; for any instance x of Π and for any solution y of instance $f(x)$ of Π', $g(x, y) = y$, if $m_\Pi(x, y) \leq m_\Pi(x, \mathtt{A}(x))$, $g(x, y) = \mathtt{A}(x)$, otherwise $\alpha = k+1$. Note that f and g do not depend on the approximation ratio r.

We now show that the reduction we have just defined is an AP-reduction. Let y be an r'-approximate solution of $f(x)$; we have to show that the ratio $r_\Pi(x, g(x, y))$ of the solution $g(x, y)$ of the instance x of Π is smaller than, or equal to, $1 + \alpha(r'-1)$. We have the following two cases: $m_\Pi(x, y) \leq m_\Pi(x, \mathtt{A}(x))$ and $m_\Pi(x, y) > m_\Pi(x, \mathtt{A}(x))$.

In the case $m_\Pi(x, y) \leq m_\Pi(x, \mathtt{A}(x))$, we can derive $m_\Pi(x, y) \leq (1 + \alpha(r'-1))\,\mathrm{opt}_\Pi(x)$. In other words, $r_\Pi(x, g(x, y)) = r_\Pi(x, y) \leq 1 + \alpha(r'-1)$.

In the case $m_\Pi(x, y) > m_\Pi(x, \mathtt{A}(x))$, since $\alpha \geq 1$, we have $r_\Pi(x, g(x, y)) = r_\Pi(x, \mathtt{A}(x)) = r_{\Pi'}(x, y) \leq r' \leq 1 + \alpha(r'-1)$.

In conclusion, all minimization problems in **APX** can be AP-reduced to maximization problems in APX and all maximization problems in **APX** can be AP-reduced to MAX 3-SAT. Since the AP-reduction is transitive, the **APX**-completeness of MAX 3-SAT is proved. □

15.6.3 Negative Results Based on APX-Completeness

Similar to what we saw for completeness in **NPO**, also completeness in **APX** implies negative results in terms of approximability of optimization problems. In fact if we could prove that an **APX**-complete problem admits a PTAS, then so would all problems in **APX**. However, it is well known that, unless **P** = **NP**, there are problems in **APX** that do not admit a PTAS (one example for all, MIN SCHEDULING ON IDENTICAL MACHINES, see Ref. [18]), therefore, under the same complexity theoretic hypothesis, no **APX**-complete problem admits a PTAS.

As a consequence of the results in the previous subsection, we can therefore assert that, unless **P** = **NP**, MAX 3-SAT does not admit a PTAS, neither do all other optimization problems that have been shown **APX**-complete (MAX 2-SAT, MIN VERTEX COVER, MAX CUT, MIN METRIC TSP, etc.).

Note that the inapproximability of MAX 3-SAT has been proved by Arora et al. [20] in a breakthrough paper by means of sophisticated techniques based on the concept of *probabilistically checkable proofs*, without any reference to the notion of **APX**-completeness. This fact, though, does not diminish the relevance of approximation preserving reductions and the related completeness notion. In fact, most results that state the nonexistence of PTAS for **APX** optimization problems have been proved starting from MAX 3-SAT, via approximation preserving reductions that allow to carry over the inapproximability results from one problem to another. Second, it is worth noting that the structure of approximation classes with respect to approximation preserving reductions is richer than it appears from this chapter. For example, beside complete problems, other classes of problems can be defined inside approximation classes, identifying the so called *intermediate* problems (see Ref. [18]).

15.7 FT-Reducibility

As we have already pointed out in Section 15.5, **PTAS**-completeness has been studied in Ref. [16] under the so-called F-reduction, preserving membership in **FPTAS**. Under this type of reducibility, a single problem, a rather artificial version of MAX WSAT has been shown **PTAS**-complete. In fact, F-reducibility is quite restrictive since it mainly preserves optimality, henceforth, existence of a **PTAS**-complete polynomially bounded problem is very unlikely.

In Ref. [21], a more "flexible" type of reducibility, called FT-reducibility has been introduced. It is formally defined as follows.

Definition 15.11

Let Π and Π' be two maximization integer-valued problems. Then, Π FT-reduces to Π' (denoted by $\Pi \leq_{\mathrm{FT}} \Pi'$) if, for any $\epsilon > 0$, there exist an oracle $\bigcirc_\alpha^{\Pi'}$ for Π' and an algorithm $\mathtt{A}_\epsilon$ calling $\bigcirc_\alpha^{\Pi'}$ such that

- *$\bigcirc_\alpha^{\Pi'}$ produces, for any $\alpha \in [0, 1]$ and for any instance x' of Π', a feasible solution $\bigcirc_\alpha^{\Pi'}(x')$ of x' that is an $(1 - \alpha)$-approximation;*
- *for any instance x of Π, $y = \mathtt{A}_\epsilon(\bigcirc_\alpha^{\Pi'}, x) \in \mathrm{Sol(x)}$; furthermore the approximation ratio of y is at least $(1 - \epsilon)$;*
- *if $\bigcirc_\alpha^{\Pi'}(\cdot)$ runs in time polynomial in both $|f(x)|$ and $1/\alpha$, then $\mathtt{A}_\epsilon(\bigcirc_\alpha^{\Pi'}(f(x)), x)$ is polynomial in both $|x|$ and $1/\epsilon$.*

For the case where at least one among Π and Π' is a minimization problem it suffices to replace $1 - \epsilon$ or/and $1 - \alpha$ by $1 + \epsilon$ or/and $1 + \alpha$, respectively.

As one can see from Definition 15.11, FT-reduction is somewhat different from the other ones considered in this chapter and, in any case, it is not conformal to Definition 15.6. In fact, it resembles a Turing-reduction. Clearly, FT-reduction transforms an FPTAS for Π' into an FPTAS for Π, i.e., it preserves membership in **FPTAS**. Note also that the F-reduction, as it is defined in Ref. [16], is a special case of the FT-reduction, since the latter explicitly allows multiple calls to oracle $\bigcirc$ while for the former this fact is not explicit.

Theorem 15.4

*Let Π' be an **NP**-hard problem in **NPO**. If $\Pi' \in$ **NPO-PB** (the class of problems in **NPO** whose values are bounded by a polynomial in the size of the instance), then any **NPO** problem FT reduces to Π'. Consequently, (i) $\overline{\mathbf{PTAS}}^{\mathrm{FT}} = \mathbf{NPO}$ and (ii) any **NP**-hard polynomially bounded problem in **PTAS** is **PTAS**-complete under FT-reductions.*

Proof (Sketch)

We first prove the following claim: *if an **NPO** problem Π' is **NP**-hard, then any **NPO** problem Turing reduces (see Ref. [18]) to Π'.*

To prove this claim, let Π be an **NPO** problem and q be a polynomial such that $|y| \leqslant q(|x|)$, for any instance x of Π and for any feasible solution y of x. Assume that the encoding $n(y)$ of y is binary. Then $0 \leq n(y) \leq 2^{q(|x|)} - 1$. We consider problem $\hat{\Pi}$ which is the same as Π up to its value that is defined by $m_{\hat{\Pi}}(x, y) = 2^{q(|x|)+1} m_{\Pi}(x, y) + n(y)$. If $m_{\hat{\Pi}}(x, y_1) \geq m_{\hat{\Pi}}(x, y_2)$, then $m_{\Pi}(x, y_1) \geq m_{\Pi}(x, y_2)$. So, if a solution y is optimal for x, with respect to $\hat{\Pi}$, it is so with respect to Π. Remark now that $\hat{\Pi}$ and its evaluation version $\hat{\Pi}_e$ are equivalent since given the value of an optimal solution y, one can determine $n(y)$ (hence y) by computing the remainder of the division of this value by $2^{q(|x|)+1}$. Since Π' is **NP**-hard, it can be shown that one can solve the evaluation problem $\hat{\Pi}_e$, henceforth $\hat{\Pi}$ if one can solve, the (constructive) problem Π' and the claim is proved.

We now prove the following claim: *let* $\Pi' \in$ ***NPO-PB****; then, any* ***NPO*** *problem Turing-reducible to* Π' *is also FT-reducible to* Π'.

To prove this second claim, let Π be an **NPO** problem and suppose that there exists a Turing-reduction between Π and Π'. Let $\bigcirc_{\alpha}^{\Pi'}$ be as in Definition 15.11. Moreover, let p be a polynomial such that for any instance x' of Π' and for any feasible solution y' of x', $m(x', y') \leqslant p(|x'|)$. Let x be an instance of Π. The Turing-reduction claimed gives an algorithm solving Π using an oracle for Π'. Consider now this algorithm where we use, for any query to the oracle with the instance x' of Π', the approximate oracle $\bigcirc_{\alpha}^{\Pi'}(x')$, with $\alpha = 1/(p(|x'|) + 1)$. This algorithm is polynomial and produces an optimal solution, since a solution y' being an $(1 - (1/(p(|x'|) + 1)))$-approximation for x' is an optimal one. So, the claim is proved.

From the combination of the above claims the theorem is easily derived. □

Observe finally that MAX PLANAR INDEPENDENT SET and MIN PLANAR VERTEX COVER are in both PTAS [22] and **NPO-PB**. So, the following theorem concludes this section.

Theorem 15.5

MAX PLANAR INDEPENDENT SET *and* MIN PLANAR VERTEX COVER *are* ***PTAS****-complete under FT-reductions.*

15.8 Gadgets, Reductions, and Inapproximability Results

As it has been pointed out already in Section 15.3, in the context of approximation preserving reductions, we call *gadget* a combinatorial structure which allows to transfer approximability (or inapproximability) results from a problem to another. A classical example is the set of 10 2-SAT clauses that we have used in Example 15.1 for constructing the 2-SAT formula starting from a 3-SAT formula. Although gadgets are used since the seminal work of Karp on reductions among combinatorial problems, the study of gadgets has been started in Refs. [9,23]; from the latter derive most of the results discussed in this section.

To understand the role of gadgets in approximation preserving reductions, let us first go back to linear reductions and see what are the implications on the approximation ratio of two problems Π and Π', deriving from the fact that $\Pi \leq_{\mathrm{L}} \Pi'$. Suppose Π and Π' are minimization problems, f, g, α_1, and α_2 are the functions and constants that define the linear reduction, x is an instance of problem Π, $f(x)$ is the instance of problem Π' determined by the reduction, and y is a solution of $f(x)$. Then, the following relationship holds between the approximation ratios of Π and Π': $r_{\Pi}(x, g(x, y)) \leq 1 + \alpha_1\alpha_2(r_{\Pi'}(f(x), y) - 1)$, and, therefore, we have that $r_{\Pi'} \leq 1 + (r - 1)/(\alpha_1\alpha_2)$ implies $r_{\Pi} \leq r$.

In the particular case of the reduction between MAX 3-SAT and MAX 2-SAT, we have $\alpha_1\alpha_2 = 13$ and, therefore, we can infer the following results on the approximability upper bounds and lower bounds of the two problems, which may be proved by a simple calculation:

- Since it is known that MAX 2-SAT can be approximated with the ratio 0.931 [24], then MAX 3-SAT can be approximated with ratio 0.103.
- Since it is known that MAX 3-SAT cannot be approximated beyond the threshold 7/8, then MAX 2-SAT cannot be approximated beyond the threshold 103/104.

Although better bounds are now known for these problems (see Karloff and Zwick [25]), it is important to observe that the above given bounds may be straightforwardly derived from the linear reduction between the two problems and are useful to show the role of gadgets. In such reduction, the structure of the gadget is crucial (it determines the value α_1) and it is clear that better bounds could be achieved if the reduction could make use of "smaller" gadgets. In fact, in Ref. [9], by cleverly constructing a more sophisticated type of gadget (in which, in particular, clauses have real weights), the authors derive a 0.801 approximation algorithm for MAX 3-SAT, improving on previously known bounds.

Based on Ref. [23], in Ref. [9] the notion of α gadget (i.e., gadget with performance α) is abstracted and formalized with reference to reductions among constraint satisfaction problems. In the same paper, it is shown that, under suitable circumstances, the search for (possibly optimum) gadgets to be used in approximation preserving reductions, can be pursued in a systematic way by means of a computer program. An example of the results that may be achieved in this way is the following.

Let PC_0 and PC_1 be the families of constraints over three binary variables defined as $\text{PC}_i(a, b, c) = 1$, if $a \oplus b \oplus c = i$, $\text{PC}_i(a, b, c) = 0$, otherwise, and let DICUT be the family of constraints corresponding to directed cuts in a graph. There exists optimum 6.5 gadgets (automatically derived by the computer program) reducing PC_0 and PC_1 to DICUT. As a consequence, for any $\epsilon > 0$, MAX DICUT is hard to approximate to within $12/13 + \epsilon$.

15.9 Conclusion

A large number of other approximation preserving reductions among optimization problems, besides those introduced in this chapter, have been introduced throughout the years. Here we have reported only the major developments. Other overviews of the world of approximation preserving reductions can be found in Refs. [12,26].

As we have already pointed out in Section 15.2, we have not dealt in this chapter with approximability classes beyond **APX**, even if intensive studies have been performed, mainly for **Poly APX**. In Ref. [17], completeness results are established, under the E-reduction, for **Poly-APX-PB** (the class of problems in **Poly APX** whose values are bounded by a polynomial in the size of the instance). Indeed, as we have already discussed in Section 15.5, use of restrictive reductions as the E-reducibility, where the functions f and g do not depend on any parameter ϵ seems very unlikely to be able to handle **Poly-APX**-completeness. As it is shown in Ref. [21] (see also Chapter 16), completeness for the whole **Poly APX** can be handled, for instance, by using PTAS-reduction, a further relaxation of the AP-reduction where the dependence between the approximation ratios of Π and Π' is not restricted to be linear [27]. Under PTAS-reduction, MAX INDEPENDENT SET is **Poly-APX**-complete [21].

Before concluding, it is worth noting that a structural development (based on the definition of approximability classes, approximation preserving reductions, and completeness results), analogous to the one that has been carried on for the classical approach to the theory of approximation, has been elaborated also for the differential approach (see Chapter 16 for a survey). In Refs.[21,28] the approximability classes **DAPX**, **Poly-DAPX** and **DPTAS** are introduced, suitable approximation preserving reductions are defined and complete problems in **NPO**, **DAPX**, **Poly-DAPX**, and **DPTAS**, under such kind of reductions, are shown.

16.1 Introduction

In this chapter we introduce the so-called differential approximation ratio as a measure of the quality of the solutions obtained by approximation algorithms. After providing motivations and basic definitions we show examples of optimization problems for which the evaluation of approximation algorithms based on the differential ratio appears to be more meaningful than the usual approximation ratio used in the classical approach to approximation algorithms. Finally, we discuss some structural results concerning approximation classes based on the differential ratio. Throughout the chapter we make use of the notations introduced in Chapter 15. Also, given an approximation algorithm $\mathtt{A}$ for an **NP** optimization problem Π (the class of these problems is called **NPO**), we denote by $m_{\mathtt{A}}(x, y)$, the value of the solution y computed by $\mathtt{A}$ on instance x of Π. When clear from the context, reference to $\mathtt{A}$ will be omitted. The definitions of most of the problems dealt in this chapter can be found in Refs. [1,2]; also, for graph-theoretic notions, interested readers are referred to Ref. [3].

In several cases, the commonly used approximation measure (called *standard approximation ratio* in what follows) may not be very meaningful in characterizing the quality of approximation algorithms. This happens, in particular, when the ratio of $m(x, y_w)$, the value of the worst solution for a given input x, to the value of the optimum solution $\text{opt}(x)$ is already bounded (above, if $\text{goal}(\Pi) = \min$, below, otherwise). Consider, for instance, the basic maximal matching algorithm for MIN VERTEX COVER that achieves approximation ratio 2. In this algorithm, given a graph $G(V, E)$, a maximal[1] matching M of G is computed and the endpoints of the edges in M are added in the solution for MIN VERTEX COVER. If M is perfect (almost any graph, even relatively sparse, admits a perfect matching [4]), then the whole of V will be included in the cover, while an optimum cover contains at least a half of V. So, in most cases, the absolutely worst solution (that one could compute without using any algorithm) achieves approximation ratio 2.

The remark above is just one of the drawbacks of the standard approximation ratio. Various other drawbacks have been also observed, for instance, the artificial dissymmetry between "equivalent"

[1] With respect to inclusion.

minimization and maximization problems (e.g., MAX CUT and MIN CLUSTERING, see Ref. [5]) introduced by the standard approximation ratio. The most blatant case of such dissymmetry is the one appearing when dealing with the approximation of MIN VERTEX COVER and MAX INDEPENDENT SET (given a graph, a vertex cover is the complement of an independent set with respect to the vertex set of the graph). In other words, using linear programming vocabulary, the objective function of the former is an affine transformation of the objective function of the latter. This equivalence under such simple affine transformation does not reflect in the approximability of these problems in the classical approach: the former problem is approximable within constant ratio, in other words it belongs to the class **APX** of problems that are approximable within constant ratios (see Chapter 15 for definitions of approximability classes based on the standard approximation paradigm; the ones based on the differential paradigm are defined analogously in this chapter, see Section 16.5), while the latter is inapproximable within ratio $\Omega(n^{\epsilon-1})$, for any $\epsilon > 0$ (see Ref. [6] and Chapter 17). In other words, the standard approximation ratio is unstable under affine transformations of the objective function.

To overcome these phoenomena, several researchers have tried to adopt alternative approximation measures not suffering from these inconsistencies. One of them is the ratio $\delta(x, y) = (\omega(x) - m(x, y))/(\omega(x) - \text{opt}(x))$, called differential ratio in the sequel, where $\omega(x)$ is the value of a worst solution for x, called *worst value*. It will be formally dealt in the next sections. It has been used rather punctually and without following a rigorous axiomatic approach until the paper in Ref. [7] where such an approach is formally defined. To our knowledge, differential ratio is introduced in Ref. [8] in 1977, and Refs. [9–11] are, to our knowledge, the most notable cases in which this approach has been applied. It is worth noting that in Ref. [11], a weak axiomatic approach is also presented.

Finally, let us note that several other authors that have also recognized the methodological problems implied by the standard ratio, have proposed other alternative ratios. It is interesting to remark that, in most cases, the new ratios are very close, although with some small or less small differences, to the differential ratio. For instance, in Ref. [12], for studying MAX TSP, it is proposed that the ratio $d(x, y, z_r) = |\,\text{opt}(x) - m(x, y)|/|\,\text{opt}(x) - z_r|$, where z_r is a positive value computable in polynomial time, called *reference value*. It is smaller than the value of any feasible solution of x, hence smaller than $\omega(x)$ (for a maximization problem a worst solution is the one of the smallest feasible value). The quantities $|\,\text{opt}(x) - m(x, y)|$ and $|\,\text{opt}(x) - z_r|$ are called *deviation* and *absolute deviation*, respectively. The approximation ratio $d(x, y, z_r)$ depends on both x and z_r, in other words, there exist a multitude of such ratios for an instance x of an **NPO** problem, one for any possible value of z_r. Consider a maximization problem Π and an instance x of Π. Then, $d(x, y, z_r)$ is increasing with z_r, so, $d(x, y, z_r) \leq d(x, y, \omega(x))$. In fact, in this case, for any reference value z_r: $r(x, y) \geq 1 - d(x, y, z_r) \geq 1 - d(x, y, \omega(x)) = \delta(x, y)$, where r denotes the standard approximation ratio for Π. When $\omega(x)$ is computable in polynomial time, $d(x, y, \omega(x))$ is the smallest (tightest) over all the d-ratios for x. In any case, if for a given problem, one sets $z_r = \omega(x)$, then $d(x, y, \omega(x)) = 1 - \delta(x, y)$ and both ratios have the natural interpretation of estimating the relative position of the approximate solution-value in the interval worst solution-value—optimal value.

16.2 Toward a New Measure of Approximation Paradigm

In Ref. [7], the task of adopting is undertaken, in an axiomatic way, an approximation measure founded on both intuitive and mathematical links between optimization and approximation. It is claimed there that a "consistent" ratio must be *order preserving* (i.e., the better the solution the better the approximation ratio achieved) and *stable under affine transformation of the objective function*. Furthermore, it is proved that no ratio function of two parameters—for example, m, opt—can fit this latter requirement. Hence, it is proposed what will be called *differential approximation ratio*[2] in what follows. Problems related by affine transformations of their objective functions are called *affine equivalent*.

[2] This notation is suggested in Ref. [7]; another notation drawing the same measure is *z-approximation* suggested in Ref. [13].

Consider an instance x of an **NPO** problem Π and a polynomial-time approximation algorithm $\mathtt{A}$ for Π, the differential approximation ratio $\delta_{\mathtt{A}}(x, y)$ of a solution y computed by $\mathtt{A}$ in x is defined by: $\delta_{\mathtt{A}}(x, y) = (\omega(x) - m_{\mathtt{A}}(x, y))/(\omega(x) - \mathrm{opt}(x))$, where $\omega(x)$ is the value of a worst solution for x, called *worst value*. Note that for any goal, $\delta_{\mathtt{A}}(x, y) \in [0, 1]$ and, moreover, the closer $\delta_{\mathtt{A}}(x, y)$ to 1, the closer $m_{\mathtt{A}}(x, y)$ to $\mathrm{opt}(x)$. By definition, when $\omega(x) = \mathrm{opt}(x)$, i.e., all the solutions of x have the same value, then the approximation ratio is 1. Note that, $m_{\mathtt{A}}(x, y) = \delta_{\mathtt{A}}(x, y)\,\mathrm{opt}(x) + (1 - \delta_{\mathtt{A}}(x, y))\omega(x)$. So, differential approximation ratio measures how an approximate solution is placed in the interval between $\omega(x)$ and $\mathrm{opt}(x)$.

We note that the concept of the worst solution has a status similar to the optimum solution. It depends on the problem itself and is defined in a nonconstructive way, i.e., independently of any algorithm that could build it. The following definition for worst solution is proposed in Ref. [7].

Definition 16.1

*Given an **NPO** problem $\Pi = (\mathcal{I}, \mathrm{Sol}, m, \mathrm{goal})$, a worst solution of an instance x of Π is defined as an optimum solution of a new problem $\bar{\Pi} = (\mathcal{I}, \mathrm{Sol}, m, \overline{\mathrm{goal}})$, i.e., of an **NPO** problem having the same sets of instances and of instances and of feasible solutions and the same value-function as Π but its goal is the inverse w.r.t. Π, i.e., $\overline{\mathrm{goal}} = \min$ if $\mathrm{goal} = \max$ and vice versa.*

Example 16.1

The worst solution for an instance of MIN VERTEX COVER or of MIN COLORING is the whole vertex set of the input graph, while for an instance of MAX INDEPENDENT SET the worst solution is the empty set. However, if one deals with MAX INDEPENDENT SET with the additional constraint that a feasible solution has to be maximal with respect to inclusion, the worst solution of an instance of this variant is a *minimum–maximal independent set*, i.e., an optimum solution of a very well-known combinatorial problem, the MIN INDEPENDENT DOMINATING SET. Also, the worst solution for MIN TSP is a "heaviest" Hamiltonian cycle of the input graph, i.e., an optimum solution of MAX TSP, while for MAX TSP the worst solution is the optimum solution of a MIN TSP. The same holds for the pair MAX SAT, MIN SAT.

From Example 16.1, one can see that, although for some problems a worst solution corresponds to some trivial input parameter and can be computed in polynomial time (this is, for instance, the case with MIN VERTEX COVER, MAX INDEPENDENT SET, MIN COLORING, etc.), several problems exist for which determining a worst solution is as hard as determining an optimum one (as for MIN INDEPENDENT DOMINATING SET, MIN TSP, MAX TSP, MIN SAT, MAX SAT, etc.).

Remark 16.1

Consider the pair of affine equivalent problems MIN VERTEX COVER, MAX INDEPENDENT SET, *and an input graph $G(V, E)$ of order n. Denote by $\tau(G)$ the cardinality of a minimum vertex cover of G and by $\alpha(G)$, the stability number of G. Obviously, $\tau(G) = n-\alpha(G)$. Based upon what has been discussed above, the differential ratio of some vertex cover C of G is $\delta(G, C) = (n-|C|)/(n-\tau(G))$. Since the set $S = V \setminus C$ is an independent set of G, its differential ratio is $\delta(G, S) = (|S| - 0)/(\alpha(G) - 0) = (n - |C|)/(n - \tau(G)) = \delta(G, C)$.*

As we have already mentioned, the differential ratio, although not systematically, has been used several times by many authors, before and after [7], in various contexts going from mathematical (linear or nonlinear) programming [14–16] to pure combinatorial optimization [9,10,13,17,18]. Sometimes the use of the differential approach has been disguised by considering the standard approximation ratio of affine transformations of a problem. For instance, to study differential approximation of BIN PACKING, one can deal with standard approximation of the problem of maximizing the number of unused bins; for MIN COLORING, the affinely equivalent problem is the one of maximizing the number of unused colors, for MIN SET COVER, the problem consists in maximizing the number of unused sets, etc.

16.3 Differential Approximation Results for Some Optimization Problems

In general, no systematic way allows to link results obtained in standard and differential approximation paradigms when dealing with minimization problems. In other words, there is no evident transfer of positive or inapproximability results from one framework to the other. Hence, a "good" differential approximation result does not signify anything for the behavior of the approximation algorithm studied, or of the problem itself, when dealing with the standard framework, and vice versa. Things are somewhat different for maximization problems with positive solution-values. In fact, considering an instance x of a maximization problem Π and a solution $y \in \text{Sol}(x)$ that is a δ-differential approximation, we immediately get:

$$\frac{m(x, y) - \omega(x)}{\text{opt}(x) - \omega(x)} \geq \delta \Longrightarrow \frac{m(x, y)}{\text{opt}(x)} \geqslant \delta + (1 - \delta)\frac{\omega(x)}{\text{opt}(x)} \overset{\omega(x)\geqslant 0}{\Longrightarrow} \frac{m(x, y)}{\text{opt}(x)} \geqslant \delta$$

So, positive results are transferred from differential to standard approximation, while transfer of inapproximability thresholds is done in the opposite direction.

Fact 16.1

Approximation of a maximization **NPO** *problem* Π *within differential approximation ratio* δ*, implies its approximation within standard approximation ratio* δ*.*

Fact 16.1 has interesting applications. The most immediate of them deals with the case of maximization problems with worst-solution values 0. There, standard and approximation ratios coincide. In this case, the differential paradigm inherits the inapproximability thresholds of the standard one. For instance, the inapproximability of MAX INDEPENDENT SET within $n^{\epsilon-1}$, for any $\epsilon > 0$ [6], also holds in the differential approach.

Furthermore, since MAX INDEPENDENT SET and MIN VERTEX COVER are affine equivalent, henceforth differentially equiapproximable, the negative result for MAX INDEPENDENT SET is shared, in the differential paradigm, by MIN VERTEX COVER.

Corollary 16.1

Both MAX INDEPENDENT SET *and* MIN VERTEX COVER *are inapproximable within differential ratios* $n^{\epsilon-1}$*, for any* $\epsilon > 0$*, unless* $\mathbf{P} = \mathbf{NP}$*.*

Note that differential equi-approximability of MAX INDEPENDENT SET and MIN VERTEX COVER makes that, in this framework the latter problem is not constant approximable but inherits also the positive standard approximation results of the former one [19–21].

In what follows in this section, we mainly focus ourselves on three well-known **NPO** problems: MIN COLORING, BIN PACKING, TSP in both minimization and maximization variants, and MIN MULTIPROCESSOR SCHEDULING. As we will see, approximabilities of MIN COLORING and MIN TSP are radically different from the standard paradigm (where these problems are very hard) to the differential one (where they become fairly well approximable). For the first two of them, differential approximability will be introduced by means of more general problem that encompasses both MIN COLORING and BIN PACKING, namely, the MIN HEREDITARY COVER.

16.3.1 Min Hereditary Cover

Let π be a nontrivial *hereditary* property[3] on sets and C a ground set. A π-covering of C is a collection $\mathcal{S} = \{S_1, S_2, \ldots, S_q\}$ of subsets of C (i.e., a subset of 2^C), any of them verifying π and such that $\cup_{i=1}^{q} S_i = C$.

[3] A property is hereditary if whenever it is true for some set, it is true for any of its subsets; it is nontrivial if it is true for infinitely many sets and false for infinitely many sets also.

Then, MIN HEREDITARY COVER consists, given a property π, a ground set C and a family $\mathcal{S}$ including *any* subset of C verifying π, of determining a π-covering of minimum size. Observe that, by definition of the instances of MIN HEREDITARY COVER, singletons of the ground sets are included in any of them and are always sufficient to cover C. Henceforth, for any instance x of the problem, $\omega(x) = |C|$.

It is easy to see that, given a π-covering, one can yield a π-partition (i.e., a collection $\mathcal{S}$ where for any $S_i, S_j \in \mathcal{S}$, $S_i \cap S_j = \emptyset$) of the same size, by greedily removing duplications of elements of C. Henceforth, MIN HEREDITARY COVER or MIN HEREDITARY PARTITION are, in fact, the same problem. MIN HEREDITARY COVER has been introduced in Ref. [22] and revisited in Ref. [13] under the name MIN COVER BY INDEPENDENT SETS. Moreover, in the former paper, using a clever adaptation of the local improvement methods of Ref. [23], a differential ratio 3/4 for MIN HEREDITARY COVER has been proposed. Based on Ref. [24], this ratio has been carried to 289/360 by Ref. [13].

A lot of well-known **NPO** problems are instantiations of MIN HEREDITARY COVER. For instance, MIN COLORING becomes a MIN HEREDITARY COVER problem, considering as ground set the vertices of the input graph and as set system, the set of the independent sets[4] of this graph. The same holds for the partition of the covering of a graph by subgraphs that are planar, or by degree-bounded subgraphs, etc. Furthermore, if any element of C is associated with a weight and a subset S_i of C is in $\mathcal{S}$ if the total weight of its members is at most 1, then one recovers BIN PACKING.

In fact, an instance of MIN HEREDITARY COVER can be seen as a virtual instance of MIN SET COVER, even if there is no need to make it always explicit. Furthermore, the following general result links MIN k-SET COVER (the restriction of MIN SET COVER to subsets of cardinality at most k) and MIN HEREDITARY COVER (see Ref. [25] for its proof in the case of MIN COLORING; it can be easily seen that extension to the general MIN HEREDITARY COVER is immediate).

Theorem 16.1

If MIN k-SET COVER *is approximable in polynomial time within differential approximation ratio δ, then* MIN HEREDITARY COVER *is approximable in polynomial time within differential approximation ratio* $\min\{\delta, k/(k+1)\}$.

16.3.1.1 Min Coloring

MIN COLORING has been systematically studied in the differential paradigm. Subsequent papers [(18,23, 24,26–29)] have improved their differential approximation ratio from 1/2 to 289/360. This problem is also a typical example of a problem that behaves in completely different ways when dealing with the standard or the differential paradigms. Indeed, dealing with the former one, MIN COLORING is inapproximable within ratio $n^{1-\epsilon}$, for any $\epsilon > 0$, unless problems in **NP** can be solved by slightly superpolynomial deterministic algorithms (see Ref. [1] and Chapter 17).

As we have seen previously, given a graph $G(V, E)$, MIN COLORING can be seen as a MIN HEREDITARY COVER problem considering $C = V$ and taking for $\mathcal{S}$ the set of the independent sets of G. According to Theorem 16.1 and Ref. [24], where MIN 6-SET COVER is proved approximable within differential ratio 289/360, one can derive that it is also approximable within differential ratio 289/360. Note that any result for MIN COLORING also holds for the minimum vertex-partition (or covering) into cliques problem since an independent set in some graph G becomes a clique in the complement $\bar{G}$ of G (in other words, this problem is also an instantiation of MIN HEREDITARY COVER). Furthermore, in Refs. [26,27], a differential ratio preserving reduction is devised between minimum vertex-partition into cliques and minimum edge-partition (or covering) into cliques. So, as in the standard paradigm, all these three problems have identical differential approximation behavior.

Finally, it is proved in Ref. [30] that MIN COLORING is **DAPX**-complete (see also Section 16.5.3.1); consequently, unless **P** = **NP**, it cannot be solved by polynomial-time differential approximation schemata. This derives immediately that neither MIN HEREDITARY COVER belongs to **DPTAS**, unless **P** = **NP**.

[4] It is well known that the independence property is hereditary.

16.3.1.2 Bin Packing

We now deal with another very well-known **NPO** problem, the BIN PACKING. According to what has been discussed above, BIN PACKING being a particular case of MIN HEREDITARY COVER, it is approximable within differential ratio 289/360. In what follows in this section, we refine this result by first presenting an approximation preserving reduction transforming any standard approximation ratio ρ into differential approximation ratio $\delta = 2 - \rho$. Then, based on this reduction we show that BIN PACKING can be solved by a polynomial-time differential approximation schema [31]; in other words, BIN PACKING $\in$ **DPTAS**. This result draws another, although less dramatical than the one in Section 16.3.1.1, difference between standard and differential approximation. In the former paradigm, BIN PACKING is solved by an *asymptotic* polynomial-time approximation schema, more precisely within standard approximations ratio $1 + \epsilon + (1/\operatorname{opt}(L))$, for any $\epsilon > 0$ ([32]), but it is **NP**-hard to approximate it by a "real" polynomial-time approximation schema [2].

Consider a list $L = \{x_1, \ldots, x_n\}$, instance of BIN PACKING, assume, without loss of generality, that items in L are rational numbers ranged in decreasing order and fix an optimum solution B^* of L. Observe that $\omega(L) = n$. For the purposes of this section, a bin i will be denoted either by b_i, or by explicit listing of the numbers placed in it; finally, any solution will be alternatively represented as union of its bins.

Theorem 16.2

From any algorithm achieving standard approximation ratio ρ for BIN PACKING, *can be derived an algorithm achieving differential approximation ratio $\delta = 2 - \rho$.*

Proof (Sketch)

Let k^* be the number of bins in B^* that contain a single item. Then, it is easy to see that there exists an optimum solution $\bar{B}^* = \{x_1\} \cup \cdots \cup \{x_{k^*}\} \cup \bar{B}_2^*$ for L, where any bin in $\bar{B}_2^*$ contains at least two items. Furthermore, one can show that, for any optimum solution $\hat{B} = \{b_j : j = 1, \ldots, \operatorname{opt}(L)\}$ and for any set $J \subset \{1, \ldots, \operatorname{opt}(L)\}$, the solution $B_J = \{b_j \in B : j \in J\}$ is optimum for the sublist $L_J = \cup_{j \in J} b_j$.

Consider now Algorithm SA achieving standard approximation ratio ρ for BIN PACKING, denote by SA(L) the solution computed by it, when running on an instance L (recall that L is assumed ranged in decreasing order), and run the following algorithm, denoted by DA in the sequel, which uses SA as subprocedure:

1. for $k = 1$ to n set: $L_k = \{x_{k+1}, \ldots, x_n\}$, $B_k = \{x_1\} \cup \cdots \cup \{x_k\} \cup \mathtt{SA}(L_k)$;
2. output $B = \operatorname{argmin}\{|B_k| : k = 0, \ldots, n-1\}$.

Let $\bar{B}^*$ be the optimum solution claimed above. Then, $\bar{B}_2^*$ is an optimum solution for the sublist L_{k^*}. Observe that Algorithm SA called by DA has also been executed on L_{k^*} and denote by B_{k^*} the solution so computed by DA. The solution returned in step 2 verifies $|B| \leq |B_{k^*}|$. Finally, since any bin in $\bar{B}_2^*$ contains at least two items, $|L_{k^*}| = n - k^* \geq 2\operatorname{opt}(L_{k^*})$. Putting all this together, we get $\delta_{\mathtt{DA}}(L, B) = (n - |B|)/(n - \operatorname{opt}(L)) \geq (|L_{k^*}| - |B_{k^*}|)/(|L_{k^*}| - \operatorname{opt}(L_{k^*})) \geq 2 - \rho$. □

In what follows, denote by SA any polynomial algorithm approximately solving BIN PACKING within (fixed) constant standard approximation ratio ρ, by ASCHEMA(ϵ) the asymptotic polynomial-time standard approximation schema of Ref. [32], parameterized by $\epsilon > 0$, and consider the following algorithm, DSCHEMA (L is always assumed ranged in decreasing order):

1. fix a constant $\epsilon > 0$ and set $\eta = \lfloor 2(\rho - 1 + \epsilon)/\epsilon^2 \rfloor$;
2. for $k = n - \eta + 1, \ldots, n$ build list L_{k-1} where L_{k-1} is as in step 1 of Algorithm DA (Theorem 16.2);
3. for any list L_i computed in step 2 above, perform an exhaustive search on L_i, denote by E_i the solution so computed, and set $B_i = \{\{x\} : x \in L \setminus L_i\} \cup E_i$;
4. store B, the smallest of the solutions computed in Step 3;
5. run DA both with SA and ASCHEMA$(\epsilon/2)$, respectively, as subprocedures on L;
6. output the best among the three solutions computed in steps 4 and 5.

Theorem 16.3 (**Demange et al. [31]**)

Algorithm `DSCHEMA` *is a polynomial-time differential approximation schema for* BIN PACKING. *So,* BIN PACKING $\in$ ***DPTAS***.

Proof (Sketch)

Since ρ and ϵ do not depend on n, neither does η, computed at step 1. One can then show that when dealing with a list L such that $|L_{k^*+1}| \leq \eta$, BIN PACKING can be solved in polynomial time when η is a fixed constant. However, assuming $|L_{k^*+1}| \geq \eta$, then, one can prove that, if $\text{opt}(L_{k^*+1}) \leq \epsilon|L_{k^*+1}|/(\rho_{\texttt{SA}} - 1 + \epsilon)$, the approximation ratio of algorithm `DA`, when calling `SA` as subprocedure, is $\delta \geq 1 - \epsilon$ while, if $\text{opt}(L_{k^*+1}) \geq \epsilon|L_{k^*+1}|/(\rho_{\texttt{SA}} - 1 + \epsilon)$, then the approximation ratio of algorithm `DA`, when calling `ASCHEMA`$(\epsilon/2)$ as subprocedure, is also $\delta \geq 1 - \epsilon$. So, when $|L_{k^*+1}| \geq 2(\rho - 1 + \epsilon)/\epsilon^2$, step 5 of `DSCHEMA` achieves differential approximation ratio $1 - \epsilon$. Putting things together derives the result. □

Let us note that, as we will see in Section 16.5.4, BIN PACKING is **DPTAS**-complete; consequently, unless $\mathbf{P} = \mathbf{NP}$ it is inapproximable by fully polynomial-time differential approximation schemata. Inapproximability of BIN PACKING by such schemata has also been shown independently in Ref. [19].

16.3.2 Traveling Salesman Problems

MIN TSP is one of the most paradigmatic problems in combinatorial optimization and one of the hardest one to approximate. Indeed, unless $\mathbf{P} = \mathbf{NP}$, no polynomial algorithm can guarantee, on an edge-weighted complete graph of size n when no restriction is imposed to the edge weights, standard approximation ratio $O(2^{p(n)})$, for any polynomial p. As we will see in this section things are completely different when dealing with differential approximation where MIN TSP $\in$ **DAPX**. This result draws another notorious difference between the two paradigms.

Consider an edge-weighted complete graph of order n, denoted by K_n, and observe that the worst MIN TSP-solution in K_n is an optimum solution for MAX TSP. Consider the following algorithm (originally proposed by Monnot [33] for MAX TSP) based upon a careful patching of the cycles of a minimum-weight 2-matching[5] of K_n:

- compute $M = (C_1, C_2, \ldots, C_k)$; denote by $\{v_i^j : j = 1, \ldots, k, \ i = 1, \ldots, |C_j|\}$, the vertex set of C_j; if $k = 1$, return M;
- for any C_j, pick arbitrarily four consecutive vertices v_i^j, $i = 1, \ldots, 4$; if $|C_j| = 3$, $v_4^j = v_1^j$; for C_k (the last cycle of M), pick also another vertex, denoted by u that is the other neighbor of v_1^k in C_k (hence, if $|C_k| = 3$, then $u = v_3^k$ while if $|C_k| = 4$, then $u = v_4^k$);
- if k is even (odd), then set:

$$-R_1 = \cup_{j=1}^{k-1}\{(v_2^j, v_3^j)\} \cup \{(v_1^k, v_2^k)\},\ A_1 = \{(v_1^k, v_3^1), (v_2^1, v_2^2)\} \cup_{j=1}^{(k-2)/2} \{(v_3^{2j}, v_3^{2j+1}), (v_2^{2j+1}, v_2^{2j+2})\}$$

$$(R_1 = \cup_{j=1}^{k}\{(v_2^j, v_3^j)\},\ A_1 = \{(v_2^k, v_3^1)\} \cup_{j=1}^{(k-1)/2} \{(v_2^{2j-1}, v_2^{2j}), (v_3^{2j}, v_3^{2j+1})\}),\ T_1 = (M \setminus R_1) \cup A_1;$$

$$-R_2 = \cup_{j=1}^{k-1}\{(v_1^j, v_2^j)\} \cup \{(u, v_1^k)\},\ A_2 = \{(u, v_2^1), (v_1^1, v_1^2)\} \cup_{j=1}^{(k-2)/2} \{(v_2^{2j}, v_2^{2j+1}), (v_1^{2j+1}, v_1^{2j+2})\}$$

$$(R_2 = \cup_{j=1}^{k}\{(v_1^j, v_2^j)\},\ A_2 = \{(v_1^k, v_2^1)\} \cup_{j=1}^{(k-1)/2} \{(v_1^{2j-1}, v_1^{2j}), (v_2^{2j}, v_2^{2j+1})\}),\ T_2 = (M \setminus R_2) \cup A_2;$$

$$-R_3 = \cup_{j=1}^{k-1}\{(v_3^j, v_4^j)\} \cup \{(v_2^k, v_3^k)\},\ A_3 = \{(v_2^k, v_4^1), (v_3^1, v_3^2)\} \cup_{j=1}^{(k-2)/2} \{(v_4^{2j}, v_4^{2j+1}), (v_3^{2j+1}, v_3^{2j+2})\}$$

$$(R_3 = \cup_{j=1}^{k}\{(v_3^j, v_4^j)\},\ A_3 = \{(v_3^k, v_4^1)\} \cup_{j=1}^{(k-1)/2} \{(v_3^{2j-1}, v_3^{2j}), (v_4^{2j}, v_4^{2j+1})\}),\ T_3 = (M \setminus R_3) \cup A_3;$$

- output T the best among T_1, T_2, and T_3.

[5] A minimum-weight 2-matching is a minimum total weight partial subgraph of K_n any vertex of which has degree at most 2; this computation is polynomial, see, for example, Ref. [34]; in other words, a 2-matching is a collection of paths and cycles, but when dealing with complete graphs a 2-matching can be considered as a collection of cycles.

As proved in Ref. [33], the set $(M \setminus \cup_{i+1}^{3} R_i) \cup_{i+1}^{3} A_i$ is a feasible solution for MIN TSP, the value of which is a lower bound for $\omega(K_n)$; furthermore, $m(K_n, T) \leq (\sum_{i=1}^{3} m(K_n, T_i))/3$. Then, a smart analysis, leads to the following theorem (the same result has been obtained, by a different algorithm working also for negative edge weights, in Ref. [13]).

Theorem 16.4 (Monnot [33])

MIN TSP *is differentially 2/3-approximable.*

Notice that MIN TSP, MAX TSP, MIN METRIC TSP, and MAX METRIC TSP are all affine equivalent (see Ref. [35] for the proof; for the two former problems, just replace weight $d(i, j)$ of edge (v_i, v_j) by $M - d(i, j)$, where M is some number greater than the maximum edge weight). Hence, the following theorem holds.

Theorem 16.5

MIN TSP, MAX TSP, MIN METRIC TSP, *and* MAX METRIC TSP *are differentially 2/3-approximable.*

A very famous restrictive version of MIN METRIC TSP is the MIN TSP12, where edge weights are all either 1 or 2. In Ref. [36], it is proved that this version (as well as, obviously, MAX TSP 12) is approximable within differential ratio 3/4.

16.3.3 Min Multiprocessor Scheduling

We now deal with a classical scheduling problem, the MIN MULTIPROCESSOR SCHEDULING [37], where we are given n tasks $t_1, \ldots, t_n$ with (execution) time lengths $l(t_j)$, $j = 1, \ldots, n$, polynomial with n, that have to be executed on m processors, and the objective is to partition these tasks on the processors in such a way that the occupancy of the busiest processor is minimized. Observe that the worst solution is the one where all the tasks are executed in the same processor; so, given an instance x of MIN MULTIPROCESSOR SCHEDULING, $\omega(x) = \sum_{j=1}^{n} l(t_j)$. A solution y of this problem will be represented as a vector in $\{0, 1\}^{mn}$, the nonzero components y_j^i of which correspond to the assignment of task j to processor i.

Consider a simple local search algorithm that starts from some solution and improves it upon any change of the assignment of a single task from one processor to another. Then the following result can be obtained [38].

Theorem 16.6

MIN MULTIPROCESSOR SCHEDULING *is approximable within differential ratio $m/(m+1)$.*

Proof (Sketch)

Assume that both tasks and processors are ranged with decreasing lengths and occupancies, respectively. Denote by $l(p_i)$, the total occupancy of processor p_i, $i = 1, \ldots, m$. Then, $\text{opt}(x) \geq l(t_1)$ and $l(p_1) = \sum_{j=1}^{n} y_j^1 l(t_j) = \max_{i=1,\ldots,} m\{l(p_i) = \sum_{j=1}^{n} y_j^i l(t_j)\}$. Denote, w.l.o.g., by $1, \ldots, q$, the indices of the tasks assigned to p_1. Since y is a local optimum, it verifies, for $i = 2, \ldots, m$, $j = 1, \ldots, q$: $l(t_j) + l(p_i) \geq l(p_1)$. We can assume $q \geq 2$ (on the contrary y is optimum). Then, adding the preceding expression for $j = 1, \ldots, q$, we get $l(p_i) \geq l(p_1)/2$. Also, adding $l(p_1)$ with the preceding expression for $l(p_i)$, $i = 2, \ldots, m$, we obtain $\omega(x) \geq (m+1)l(p_1)/2$. Putting all this together we finally get $m(x, y) = l(p_1) \leq (m\,\text{opt}(x)/(m+1)) + (\omega(x)/(m+1))$. □

16.4 Asymptotic Differential Approximation Ratio

In any approximation paradigm, the notion of asymptotic approximation (dealing, informally, with a class of "interesting" instances) is pertinent. In the standard paradigm, the asymptotic approximation ratio is defined on the hypothesis that the interesting (from an approximation point of view) instances of the simple problems are the ones whose values of the optimum solutions tend to ∞ (because, in the opposite case,[6] these problems, called *simple* [39], are polynomial). In the differential approximation framework, on the contrary, the size (or the value) of the optimum solution is not always a pertinent hardness criterion (see Ref. [40] for several examples about this claim). Henceforth, in Ref. [40], another hardness criterion, *the number* $\sigma(x)$ *of the feasible values of* x, has been used to introduce the *asymptotic differential approximation ratio.* Under this criterion, the asymptotic differential approximation ratio of an algorithm $\mathtt{A}$ is defined as

$$\delta_{\mathtt{A}}^{\infty}(x, y) = \lim_{k \to \infty} \inf_{\substack{x \\ \sigma(x) \geq k}} \left\{ \frac{\omega(x) - m(x, y)}{\omega(x) - \mathrm{opt}(I)} \right\} \tag{16.1}$$

Let us note that $\sigma(x)$ is motivated by, and generalizes, the notion of the *structure of the instance* introduced in Ref. [9]. We also notice that the condition $\sigma(x) \geq k$ characterizing "the sequence of unbounded instances" (or "limit instances") cannot be polynomially verified.[7] But in practice, for a given problem, it is possible to directly interpret condition $\sigma(x) \geq k$ by means of the parameters $\omega(x)$ and opt(x) (note that $\sigma(x)$ is not a function of these values). For example, for numerous cases of discrete problems, it is possible to determine, for any instance x, a step $\pi(x)$ defined as the least variation between two feasible values of x. For example, for BIN PACKING, $\pi(x) = 1$. Then, $\sigma(x) \leq ((\omega(x) - \mathrm{opt}(x))/\pi(x)) + 1$. Therefore, from Eq. (16.1):

$$\delta_{\mathtt{A}}^{\infty}(x, y) \geq \lim_{k \to \infty} \inf_{\substack{x \\ \frac{\omega(x) - \mathrm{opt}(x)}{\pi(x)} \geq k-1}} \left\{ \frac{\omega(x) - m(x, y)}{\omega(x) - \mathrm{opt}(x)} \right\}$$

Whenever π can be determined, condition $(\omega(x) - \mathrm{opt}(x))/\pi(x) \geq k - 1$ can be easier to evaluate than $\sigma(x) \geq k$, and in this case, the former condition is used (this is not senseless since we try to bound below the ratio).

The adoption of $\sigma(x)$ as hardness criterion can be motivated by considering a class of problems, called *radial problems* in Ref. [40], that includes many well-known combinatorial optimization problems, as BIN PACKING, MAX INDEPENDENT SET, MIN VERTEX COVER, MIN COLORING, etc. Informally, a problem Π is radial if, given an instance x of Π and a feasible solution y for x, one can, in polynomial time, on the one hand, deteriorate y as much as one wants (up to finally obtain a worst-value solution) and, on the other, greedily improve y to obtain (always in polynomial time) a suboptimal solution (eventually the optimum one).

Definition 16.2

A problem $\Pi = (\mathcal{I}, \mathrm{Sol}, m, \mathrm{goal})$ *is radial if there exists three polynomial algorithms* ξ, ψ, *and* ϕ *such that, for any* $x \in \mathcal{I}$:

1. ξ *computes a feasible solution* $y^{(0)}$ *for* x;
2. *for any feasible solution* y *of* x *strictly better (in the sense of the value) than* $y^{(0)}$, *algorithm* ϕ *computes a feasible solution* $\phi(y)$ *(if any) with* $m(x, \phi(y))$ *strictly worse than* $m(x, y)$;
3. *for any feasible solution* y *of* x *with value strictly better than* $m(x, y^{(0)})$, *there exists* $k \in \mathbb{N}$ *such that* $\phi^k(y) = y^{(0)}$ *(where* ϕ^k *denotes the k-times iteration of* ϕ*);*
4. *for a solution* y *such that, either* $y = y^{(0)}$, *or* y *is any feasible solution of* x *with value strictly better than* $m(x, y^{(0)})$, $\psi(y)$ *computes the set of ancestors of* y, *defined by* $\psi(y) = \phi^{-1}(\{y\}) = \{z : \phi(z) = y\}$ *(this set being eventually empty).*

Let us note that the class of radial problems includes in particular the well-known class of *hereditary* problems for which any subset of a feasible solution remains feasible. In fact, for a hereditary (maximization) problem, a feasible solution y is a subset of the input data, for any instances x, $y^{(0)} = \emptyset$, and for any other feasible solution y, $\phi(y)$ is just obtained from y by removing a component of y. The hereditary notion deals with problems for which a feasible solution is a subset of the input data, while the radial notion allows problems for which solutions are also second-order structures of the input data.

[6] The case where optimum values are bounded by fixed constants.

[7] The same holds for the condition opt$(x) \geq k$ induced by the hardness criterion in the standard paradigm.

Proposition 16.1 **(Demange and Paschos [40])**

Let κ be a fixed constant and consider a radial problem Π such that, for any instance x of Π of size n, $\sigma(x) \leq \kappa$. Then, Π is polynomial-time solvable.

16.5 Structure in Differential Approximation Classes

What has been discussed in the previous sections makes it clear which the entire theory of approximation, which tries characterize and classify problems with respect to their approximability hardness, can be redone in the differential paradigm. There exist problems having several differential approximability levels and inapproximability bounds. What follows further confirms this claim. It will be shown that the approximation paradigm we deal with allows to devise its proper tools and to use them to design an entire structure for the approximability classes involved.

16.5.1 Differential NPO-Completeness

Obviously, the *strict* reduction of Ref. [41] (see also Chapter 15), can be identically defined in the framework of the differential approximation; for clarity, we denote this derivation of the strict reduction by D-reduction. Two **NPO** problems will be called D-equivalent if there exist D-reductions from any of them to the other one.

Theorem 3.1 in Ref. [41] (where the differential approximation ratio is mentioned as a possible way of estimating the performance of an algorithm), based upon an extension of Cook's proof [42] of SAT **NP**-completeness to optimization problems, works also when the differential ratio is dealt instead of the standard one. Furthermore, solution *triv*, as defined in Ref. [41] is indeed a worst solution for MIN WSAT. However, the following proposition holds.

Proposition 16.1 **(Ausiello et al. [43])**

MAX WSAT *and* MIN WSAT *are D-equivalent.*

Proof (Sketch)

With any clause $\ell_1 \vee \cdots \vee \ell_t$ of an instance ϕ of MAX WSAT, we associate in the instance ϕ' of MIN WSAT the clause $\bar{\ell}_1 \vee \cdots \vee \bar{\ell}_t$. Then, if an assignment y satisfies the instance ϕ, the complement y' of y satisfies ϕ', and vice versa. So, $m(\phi, y) = \sum_{i=1}^{n} w(x_i) - m(\phi', y')$, for any y'. Thus, $\delta(\phi, y) = \delta(\phi', y')$. The reduction from MIN WSAT to MAX WSAT is completely analogous. □

In a completely analogous way, as in Proposition 16.1, it can be proved that MIN 0-1 INTEGER PROGRAMMING and MAX 0-1 INTEGER PROGRAMMING are also D-equivalent. Putting all the above together the following holds.

Theorem 16.7

MAX WSAT, MIN WSAT, MIN 0-1 INTEGER PROGRAMMING, *and* MAX 0-1 INTEGER PROGRAMMING *are **NPO**-complete under D-reducibility.*

16.5.2 The Class 0-DAPX

Informally, the class 0-DAPX is the class of NPO problems for which the differential ratio of any polynomial-time algorithm is *equal* to 0. In other words, for any such algorithm, there exists an instance on which it will compute its worst solution. Such situation draws the worst case for the differential approximability of a problem. Class 0-DAPX is defined in Ref. [43] by means of a reduction called G-reduction. It can be seen as a particular kind of the GAP-reduction [1,44,45].

Definition 16.3

A problem Π is said to be G-reducible to a problem Π', if there exists a polynomial reduction that transforms any δ-differential approximation algorithm for Π', $\delta > 0$, into an optimum (exact) algorithm for Π.

Let Π be an **NP**-complete decision problem and Π' an **NPO** problem. The underlying idea for $\Pi \leq_{\mathrm{G}} \Pi'$ in Definition 16.3 is, starting from an instance of Π, to construct instances for Π' that have only two distinct feasible values and to prove that any differential δ-approximation for Π', $\delta > 0$, could distinguish between positive instances and negative instances for Π. Note finally that the G-reduction generalizes both the D-reduction of Section 16.5.1 and the strict reduction of Ref. [41].

Definition 16.4

***0-DAPX** is the class of **NPO** problems Π' for which there exists an **NP**-complete problem Π G-reducible to Π'. A problem is said to **0-DAPX**-hard, if any problem in **0-DAPX** G reduces to it.*

An obvious consequence of Definition 16.4 is that ***0-DAPX** is the class of **NPO** problems Π for which approximation within any differential approximation ratio $\delta > 0$ would entail $\mathbf{P} = \mathbf{NP}$.*

Proposition 16.3 (Bazgan and Paschos [46])

MIN INDEPENDENT DOMINATING SET $\in$ ***0-DAPX**.*

Proof (Sketch)

Given an instance ϕ of SAT with n variables $x_1, \ldots, x_n$ and m clauses $C_1, \ldots, C_m$, construct a graph G, instance of MIN INDEPENDENT DOMINATING SET associating with any positive literal x_i a vertex u_i and with any negative literal $\bar{x}_i$ a vertex v_i. For $i = 1, \ldots, n$, draw edges (u_i, v_i). For any clause C_j, add in G a vertex w_j and an edge between w_j and any vertex corresponding to a literal contained in C_j. Finally, add edges in G to obtain a complete graph on $w_1, \ldots, w_m$. An independent set of G contains at most $n + 1$ vertices. An independent dominating set containing the vertices corresponding to true literals of a nonsatisfiable assignment and one vertex corresponding to a clause not satisfied by this assignment, is a worst solution of G of size $n + 1$. If ϕ is satisfiable then $\mathrm{opt}(G) = n$. If ϕ is not satisfiable then $\mathrm{opt}(G) = n + 1$. So, any independent dominating set of G has cardinality either n or $n + 1$. □

By analogous reductions, restricted versions of optimum-weighted satisfiability problems are proved **0-DAPX** in Ref. [47].

Finally, the following relationship between **NPO** and **0-DAPX** holds.

Theorem 16.8 (Ausiello et al. [43])

*Under D-reducibility, **NPO**-complete = **0-DAPX**-complete $\subseteq$ **0-DAPX**.*

If, instead of D, a stronger reducibility is considered, for instance, by allowing f and/or g to be multivalued in the strict reduction, then, under this type of reducibility, it can be proved that **NPO**-complete = **0-DAPX** [43].

16.5.3 DAPX- and Poly-DAPX-Completeness

In this section we address the problem of completeness in the classes **DAPX** and **Poly-DAPX**. For this purpose, we first introduce a differential approximation schemata preserving reducibility, originally presented in Ref. [43], called DPTAS-reducibility.

Definition 16.5

*Given two **NPO** problems Π and Π', Π DPTAS reduces to Π' if there exist a (possibly) multivalued function $f = (f_1, f_2, \ldots, f_h)$, where h is bounded by a polynomial in the input length, and two functions g and c, computable in polynomial time, such that*

- *for any $x \in \mathcal{I}_\Pi$, for any $\epsilon \in (0, 1) \cap \mathbb{Q}$, $f(x, \epsilon) \subseteq \mathcal{I}_{\Pi'}$;*
- *for any $x \in \mathcal{I}_\Pi$, for any $\epsilon \in (0, 1) \cap \mathbb{Q}$, for any $x' \in f(x, \epsilon)$, for any $y \in \mathrm{sol}_{\Pi'}(x')$, $g(x, y, \epsilon) \in \mathrm{sol}_\Pi(x)$;*
- *$c : (0, 1) \cap \mathbb{Q} \rightarrow (0, 1) \cap \mathbb{Q}$;*
- *for any $x \in \mathcal{I}_\Pi$, for any $\epsilon \in (0, 1) \cap \mathbb{Q}$, for any $y \in \cup_{i=1}^{h} \mathrm{sol}_{\Pi'}(f_i(x, \epsilon))$, $\exists j \leqslant h$ such that $\delta_{\Pi'}(f_j(x, \epsilon), y) \geqslant 1 - c(\epsilon)$ implies $\delta_\Pi(x, g(x, y, \epsilon)) \geqslant 1 - \epsilon$.*

16.5.3.1 DAPX-Completeness

If one restricts her/himself to problems with polynomially computable worst solutions, then things are rather simple. Indeed, given such a problem $\Pi \in$ **DAPX**, it is affine equivalent to a problem Π' defined on the same set of instances and with the same set of solutions but, for any solution y of an instance x of Π, the measure for solution y with respect to Π' is defined as $m_{\Pi'}(x, y) = m_{\Pi}(x, y) - \omega(x)$. Affine equivalence of Π and Π' ensures that $\Pi' \in$ **DAPX**; furthermore, $\omega_{\Pi'}(x) = 0$. Since, for the latter problem, standard and differential approximation ratios coincide, it follows that $\Pi' \in$ **APX**. MAX INDEPENDENT SET is **APX**-complete under PTAS-reducibility [48], a particular kind of the AP-reducibility seen in Chapter 15. So, Π' PTAS reduces to MAX INDEPENDENT SET. Putting together affine equivalence between Π and Π', PTAS-reducibility between Π' and MAX INDEPENDENT SET, and taking into account that composition of these two reductions is an instantiation of DPTAS-reduction, we conclude the **DAPX**-completeness of MAX INDEPENDENT SET.

However, things become much more complicated, if one takes into account problems with nonpolynomially computable worst solutions. In this case, one needs more sophisticated techniques and arguments. We informally describe here the basic ideas and the proof schema in Ref. [43]. It is first shown that any DAPX problem Π is reducible to MAX WSAT-B by a reduction transforming a polynomial-time approximations schema for MAX WSAT-B into a polynomial-time differential approximation schema for Π. For simplicity, denote this reduction by S–D. Next, a particular **APX**-complete problem Π' is considered, say MAX INDEPENDENT SET-B. MAX WSAT-B, that is in **APX**, is PTAS-reducible to MAX INDEPENDENT SET-B. MAX INDEPENDENT SET-B is both in **APX** and in **DAPX** and, moreover, standard and differential approximation ratios coincide for it; this coincidence draws a trivial reduction called ID-reduction. It trivially transforms a differential polynomial-time approximation schema into a standard polynomial-time approximation schema. The composition of the three reductions specified (i.e., the S–D-reduction from Π to MAX WSAT-B, the PTAS-reduction from MAX WSAT-B to MAX INDEPENDENT SET-B, and the ID-reduction) is a DPTAS-reduction transforming a polynomial-time differential approximation schema for MAX INDEPENDENT SET-B into a polynomial-time differential approximation schema for Π, i.e., MAX INDEPENDENT SET-B is **DAPX**-complete under DPTAS-reducibility.

Also, by standard reductions that turn out to be DPTAS-reductions also, the following can be proved [30,43].

Theorem 16.9

MAX INDEPENDENT SET-B, MIN VERTEX COVER-B, *for fixed* B, MAX k-SET PACKING, MIN k-SET COVER, *for fixed k, and* MIN COLORING *are **DAPX**-complete under DPTAS-reducibility.*

16.5.3.2 Poly-DAPX-Completeness

Recall that a maximization problem $\Pi \in$ **NPO** is *canonically hard for **Poly-APX*** [49], if and only if there exist a polynomially computable transformation T from 3SAT to Π, two constants n_0 and c and a function F, hard for **Poly**,[8] such that, given an instance x of 3SAT on $n \geqslant n_0$ variables and a number $N \geqslant n^c$, the instance $x' = T(x, N)$ belongs to $\mathcal{I}_{\Pi}$ and verifies the following three properties: (i) if x is satisfiable, then $\text{opt}(x') = N$; (ii) if x is not satisfiable, then $\text{opt}(x') = N/F(N)$; (iii) given a solution $y \in \text{sol}_{\Pi}(x')$ such that $m(x', y) > N/F(N)$, one can polynomially determine a truth assignment satisfying x.

Based on DPTAS-reducibility and the notion of canonical hardness, the following is proved in Ref. [30].

Theorem 16.10

*If a (maximization) problem $\Pi \in$ **NPO** is canonically hard for **Poly-APX**, then any problem in **Poly-DAPX** DPTAS reduces to Π.*

[8] The set of functions from $\mathbb{N}$ to $\mathbb{N}$ is bounded by a polynomial; a function $f \in$ **Poly** is hard for Poly, if and only if there exists three constants k, c, and n_0 such that, for any $n \geqslant n_0$, $f(n) \leqslant kF(n^c)$.

As it is shown in Ref. [49], MAX INDEPENDENT SET is canonically hard for **Poly-APX**. Furthermore, MIN VERTEX COVER is affine equivalent to MAX INDEPENDENT SET. Henceforth, use of Theorem 16.10 immediately derives the following result.

Theorem 16.11

MAX INDEPENDENT SET *and* MIN VERTEX COVER *are complete for* ***Poly-DAPX*** *under DPTAS-reducibility.*

16.5.4 DPTAS-Completeness

Completeness in **DPTAS** (the class of **NPO** problems that are approximable by polynomial time differential approximation schemata) is tackled by means of a kind of reducibility preserving membership in **DFPTAS**, which is called DFT-reducibility in Ref. [30]. This type of reducibility is the differential counterpart of the FT-reducibility introduced in Section 15.7 of Chapter 15 and can be defined in an exactly similar way. Based on DFT-reducibility, the following theorem holds ([30]; its proof is very similar to the one of Theorem 15.4 in Chapter 15). Before stating it, we need to introduce the class of diameter polynomially bounded problems that is a subclass of the radial problems seen in Section 16.4. An **NPO** problem Π is *diameter polynomially bounded* if and only if, for any $x \in \mathcal{I}_{\Pi}$, $|\operatorname{opt}(x) - \omega(x)| \leqslant q(|x|)$. The class of diameter polynomially bounded **NPO** problems will be denoted by **NPO-DPB**.

Theorem 16.12 (Bazgan et al. [30])

*Let Π' be an **NP**-hard problem **NPO-DPB**. Then, any problem in **NPO** is DFT reducible to Π'. Consequently, (i) the closure of **DPTAS** under DFT-reductions is the whole **NPO** and (ii) any **NP**-hard problem in **NPO-DPB** $\cap$ **DPTAS** is **DPTAS**-complete under DFT-reductions.*

Consider now MIN PLANAR VERTEX COVER, MAX PLANAR INDEPENDENT SET, and BIN PACKING. They are all **NP**-hard and in **NPO-DPB**. Furthermore, they are all in **DPTAS** (for the first two problems, this is derived by the inclusion of MAX PLANAR INDEPENDENT SET in **PTAS** proved in Ref. [50]; for the third one, see Section 16.3.1.2). So, the following theorem holds and concludes this section [30].

Theorem 16.13

MAX PLANAR INDEPENDENT SET, MIN PLANAR VERTEX COVER, *and* BIN PACKING *are* ***DPTAS****-complete under DFT-reducibility.*

16.6 Discussion and Final Remarks

As we have already claimed in the beginning of Section 16.5, the entire theory of approximation can be reformulated in the differential paradigm. This paradigm has the diversity of the standard one, it has a nonempty scientific content and, to our opinion, it represents in some sense a kind of revival for the domain of the polynomial approximation.

Since the work in Ref. [7], a great number of paradigmatic combinatorial optimization problems has been studied in the framework of the differential approximation. For instance, KNAPSACK has been studied in Ref. [7] and revisited in and Ref. [13]. MAX CUT, MIN CLUSTER, STACKER CRANE, MIN DOMINATING SET, MIN DISJOINT CYCLE COVER, and MAX ACYCLIC SUBGRAPH have been dealt in Ref. [13]. MIN FEEDBACK ARC SET is also studied in Ref. [38] together with MIN FEEDBACK NODE SET. MIN VERTEX COVER and MAX INDEPENDENT SET are studied in Refs. [7,13]. MIN COLORING is dealt in Ref. [18,23,24, 26–30], while MIN WEIGHTED COLORING (where the input is a vertex-weighted graph and the weight of a color is the weight of the heaviest of its vertices) is studied in Ref. [51] (see also Ref. [52]). MIN INDEPENDENT DOMINATING SET is dealt in Ref. [46]. BIN PACKING is studied in Refs. [27,31,40,53]. MIN SET COVER, under several assumptions on its worst value, is dealt in Refs. [7,13,54], while MIN WEIGHTED SET COVER is dealt in Refs. [27,54]. MIN TSP and MAX TSP, as well as, several famous variants of them, MIN METRIC TSP, MAX METRIC TSP, MIN TSPab (the most famous restrictive case of this problem is MIN TSP12), and MAX TSPab are studied in Refs. [13,33,35,36,55]. STEINER TREE problems under several assumptions on the form of the input graph and on the edge weights are dealt in Ref. [56]. Finally, several optimum satisfiability and constraint satisfaction problems (as MAX SAT, MAX E2SAT, MAX 3SAT, MAX E3SAT, MAX EkSAT, MIN SAT, MIN kSAT, MIN EkSAT, MIN 2SAT, and their corresponding constraint satisfaction versions) are studied in Ref. [57].

Dealing with structural aspects of approximation, besides the existing approximability classes (defined rather upon combinatorial arguments) two logical classes have been very notorious in the standard paradigm. These are **Max-NP** and **Max-SNP**, originally introduced in Ref. [58] (see also Chapters 15 and 17). Their definitions, independent from any approximation ratio consideration, make that they can identically be considered also in differential approximation. In the standard paradigm, the following strict inclusions hold: **PTAS** $\subset$ **Max-SNP** $\subset$ **APX** and **MAX-NP** $\subset$ **APX**. As it is proved in Ref. [57], MAX SAT $\notin$ **DAPX**, unless **P** $=$ **NP**. This, draws an important structural difference in the landscape of approximation classes in the two paradigms, since an immediate corollary of this result is that **MAX-NP** $\not\subset$ **DAPX**. Position of **Max-SNP** in the differential landscape is not known yet. It is conjectured, however, that **MAX-SNP** $\not\subset$ **DAPX**. In any case, formal relationships of **Max-SNP** and **Max-NP** with the other differential approximability classes deserve further study.

Hardness of Approximation

Mario Szegedy
Rutgers University

17.1 Introduction

This chapter is devoted to the core theory of inapproximability. Undoubtedly, the most fundamental part of the theory, with its numerous consequences, is the probabilistically checkable proofs (PCPs) theorem, which asserts that MAX-3SAT is NP-hard to approximate within a factor of $1 + \epsilon$ (for some $\epsilon > 0$). In Section 17.9 we sketch a recently obtained short proof to it [1].

Our survey places particular emphasis on the various kinds of reductions that are employed in the theory. We would like to convey our conviction that the entire theory is the study of these reductions and their compositions. We have found it important to introduce the reader to the proof and code-checking intuition. These play a key role in the theory, have been guiding its development, and even today, when alternative interpretations are available, still prove to be indispensable when trying to obtain stronger results.

Unfortunately, we had to make sacrifices to keep the size of the chapter within limits. We discuss only a handful of specific optimization problems. We could not have possibly opened the treasure chest of ad hoc inapproximability reductions, there are just so many of them. We have also omitted discussing how the syntax of optimization problems can often give a guideline to their (in)-approximability status. This subject, called the syntactic versus semantic view of (in)-approximability, is under heavy investigation and several advances have been reported recently [2,3]. We have found no room to convey recent excitement about the unique game conjecture and its consequences [4,5]. Finally, the chapter is concerned only with NP optimization problems. Probabilistic debate systems [6] and inapproximability of #P problems are out of the scope of this survey.

17.2 NP Optimization: Approximability and Inapproximability

Optimization problems are either *maximization* or *minimization* problems:

$$OPT(x) = \max_{y \in D(x)} F(x, y) \qquad \text{(maximization problem)}$$
$$OPT(x) = \min_{y \in D(x)} F(x, y) \qquad \text{(minimization problem)}$$

where $x \in \{0, 1\}^*$ is a string describing the input and $F(x, y)$ is a real-valued function (we often also assume nonnegativity). The *witness* y comes from a set that may depend on the input.

One may think of max and min as quantifiers. In analogy with NP, the class NPO is the set of those optimization problems for which $F(x, y)$ and the relation $y \in D(x)$ are polynomial-time computable. Here, the polynomial is in terms of $|x|$, the input length. We may get rid of the sometimes annoying $y \in D(x)$ domain condition by setting $F(x, y)$ definitely smaller (larger) than $OPT(x)$ if $y \notin D(x)$. This, however, might add extra complexity to the calculation of $F(x, y)$. NPO consists of NP maximization and NP minimization problems. To turn an NP maximization (minimization) problem into an NP problem we just augment the input with a threshold value and ask if OPT is larger (smaller) than the threshold.

While some important optimization problems are not in NPO, most of those that come from real life are. Examples are abundant: coloring, allocation, scheduling, Steiner tree problems, TSP, linear and quadratic programming, knapsack, vertex cover, etc. All of these examples (except linear programming) are NP-hard, and the best we can hope is to find quick approximate solution for them.

Approximation Ratio

Let $x \to A(x)$ $(\forall x : A(x) \in D(x))$ be a map. This map is said to *approximate* $OPT(x) = \max_{y \in D(x)} F(x, y)$ to within a factor of $r(x) \geq 1$ if

$$\forall x : OPT(x) \leq r(x) F(x, A(x))$$

The best such $r(x)$ is also called the *approximation ratio* achieved by A. If there is a polynomial-time computable A that achieves approximation ratio $r(x)$, we say that *OPT* is *approximable* within a factor of $r(x)$. When we seek to approximate OPT, we often choose $r(x)$ to be a function of the input length. If the input is a graph, $r(x)$ is typically chosen to be a function of the number of vertices or edges, but we could also make it dependent on the maximal degree, the girth, etc. When *OPT* is a minimization problem the bound in the above definition is replaced by $F(x, A(x)) \leq OPT(x) r(x)$. (In the literature sometimes $1/r(x)$ is called the approximation ratio. The two definitions can be told apart, since in our definition $r(x)$ is always greater than 1.)

Example 17.1 (Set cover)

Let x describe a polynomial size set system $\mathcal{S}$ (say, by listing the elements of each set in $\mathcal{S}$), let y describe a subsystem $\mathcal{S}' \subseteq \mathcal{S}$, and let $y \in D(x)$ iff $\cup \mathcal{S}' = \cup \mathcal{S}$. The set cover problem is asking to find $y \in D(x)$ such that $|\mathcal{S}'|$ is minimized. It can be shown that there is a polynomial-time algorithm that approximates the set cover problem within a factor of $1 + \ln |\cup \mathcal{S}|$.

Inapproximability

For the above example Feige has shown that set cover cannot be approximated within a factor of $(1 - \epsilon) \ln |\cup \mathcal{S}|$ in P for any fixed $\epsilon > 0$ unless $NP \subseteq DTIME(n^{\log \log n})$ [7]. In general, a statement that there is no polynomial-time algorithm for *OPT* with approximation ratio $r(x)$ under some complexity theoretic hypothesis is referred to as an *inapproximability result*, where $r(x)$ is called *inapproximability ratio*.

Feige's result is sharp in the sense that the set cover is approximable in polynomial time within a ratio of $C \ln |\cup \mathcal{S}|$ if and only if $C \geq 1$ (under our complexity theoretic hypothesis). Thus, $\ln |\cup \mathcal{S}|$ may be viewed as the approximation boundary of the set cover problem. In general, we call a function $r(x)$ an *approximation boundary* of problem OPT if OPT is polynomial-time approximable within a factor of $r(x)C$ for any $C > 1$, but OPT is (conditionally) hard to approximate within a factor of $r(x)C$ for any $C < 1$. The above is sometimes understood in the logarithmic sense, i.e., when $r(x)C$ is replaced by $r(x)^C$. The latter is clearly a weaker condition. For many NPO problems a type of *dichotomy* holds: approximating them beyond their approximation boundary is NP-hard. (The other alternative could be that the complexity of approximating them gradually increases as $r(x)$ decreases.)

For a long time no approximation boundaries were known for major NPO problems. The appearance of the theory of probabilistically checkable proofs (PCP theory) has changed this situation. In its rise, numerous exact inapproximability results (including the one above by Feige) were proven. This theory is the subject of our next sections.

17.2.1 The Emergence of the PCP Theory

Motivated by Graham's [8] exact bounds on the performance of various bin packing heuristics, Johnson [9] gave algorithms for the Subset Sum, the Set Cover, and the MAX k-SAT problems with guarantees on their performances ($1 + o(1)$, $O(\log |S|)$, $2^k/(2^k - 1)$, respectively). He also gave inapproximability results, but unfortunately they referred only to specific algorithms. Nevertheless, he has brought up the issue of classifying NPO problems by the best approximation ratio achievable for them in polynomial time. Although the goal was set, only a handful of inapproximability results existed. Sahni and Gonzalez [10] proved the inapproximability of the non-metric traveling salesman and some other problems (under $P \neq NP$). Garey and Johnson [11] introduced *gap amplification* techniques to show that the chromatic number of a graph cannot be approximated to within a factor of $2 - \epsilon$ unless $P = NP$, and an approximation algorithm for the max clique within *some* constant factor could be turned into an algorithm which approximates max clique within *any* constant factor.

The old landscape of approximation theory of NPO radically changed when in 1991 Feige et al. [12] for the first time used Babai et al.'s characterization of NEXP in terms of multiprover interactive proof systems [13] to show that approximating the clique within any constant factor is hard for NTIME($n^{1/\log\log n}$). Simultaneously, Papadimitriou and Yannakakis [14] defined a subclass of NPO, what they called MAXSNP, in which problems have an elegant logical description and can be approximated within a constant factor. They also showed that if MAX3SAT, vertex cover, MAX CUT, and some other problems in the class, could be approximated in polynomial time with an arbitrary precision, the same would hold for all problems in MAXSNP. They established this fact by reducing MAXSNP to these problems in an *approximation preserving* manner. They called their special reduction L-reduction and considered MAXSNP-completeness with respect to it a strong indication that a problem does not have *polynomial-time approximation scheme* (PTAS) (i.e., a sequence of polynomial-time algorithms achieving $1 + 1/k$ accuracy for $k = 1, 2, \ldots$). Their work showed great insight. What was missing was a relation between MAXSNP-completeness and usual hardness assumptions such as $P \neq NP$. In 1992, Arora et al. [15] showed that MAX3SAT is hard to approximate within a factor of $1 + \epsilon$ for some $\epsilon > 0$ unless $P = NP$. Their proof relied on PCPs, and employed several intricate arguments. They took techniques from Refs. [13,16–18], in particular, the important "proof recursion" idea of Arora and Safra [17]. The term PCP was also coined in the latter article. Rapid development came on the heals of these results:

1. Inapproximability of NPO problems.
2. Construction of approximation algorithms achieving optimal or near-optimal ratios (e.g., Ref. [19]).
3. A bloom of approximation preserving reductions and discovery of new (in)approximability classes.

PCP theory has turned out to be the key ingredient in determining the approximation boundaries of many NPO problems. Some problems remain open, like the Asymmetric Traveling Salesperson Problem, whose approximability status is not yet clarified. In a latest development, Dinur [1] gave a simplified proof for the ALMSS (Arora–Lund–Motwani–Sudan–Szegedy) theorem [20] (see a sketch in Section 17.9) eliminating much of the difficult algebra of the original proof.

17.3 Approximation-Preserving Reductions

Reduction is perhaps the most useful concept in algorithm design. Interestingly, it also turns out to be the most useful tool in proving computational hardness [21–23]. When in problem A Cook reduces to B, the hardness of B follows from the hardness of A. Unfortunately, Cook reduction does not ensure that if A is hard to approximate then B is hard to approximate. For reducing hardness of approximation new definitions are necessary.

Let $F_1(x, y)$ and $F_2(x', y')$ be functions that are to be optimized for y and y' (maximized or minimized in an arbitrary combination). Let $OPT_1(x)$ and $OPT_2(x')$ be the corresponding optimums. A Karp–Levin *reduction* involves two maps:

1. a polynomial-time map f to transform instances x of OPT_1 into instances $x' = f(x)$ of OPT_2 [Instance Transformation];
2. a polynomial-time map g to transform (input, witness) pairs (x', y') of OPT_2 into witnesses y of OPT_1.
   [Witness Transformation].

Observe that the witness transformation goes from OPT_2 to OPT_1. Let $opt_1 = OPT_1(x)$, $opt_2 = OPT_2(f(x))$, $appr_1 = F_1(x, g(f(x), y'))$, and $appr_2 = F_2(f(x), y')$.

The centerpiece of any *approximation-preserving* reduction scheme is a relation between these four quantities. This relation must express: "If $appr_2$ well approximates opt_2, then $appr_1$ well approximates opt_1." The first paper which defines an approximation preserving reduction was that of Orponen and Mannila [24]. Up to the present time more than eight notions of approximation preserving reductions exist differing only in the relation required between opt_1, opt_2, $appr_1$, and $appr_2$. For an example, consider the L-reduction of Papadimitriou and Yannakakis [14]. The required relations are $opt_2 \leq c_1 opt_1$ and $|appr_1 - opt_1| \leq c_2 |appr_2 - opt_2|$ for some constants c_1 and c_2. It easily follows from the next lemma, that L-reduction preserves PTAS.

Lemma 17.1

A reduction scheme preserves PTAS iff it enforces that

$$|appr_1 - opt_1|/opt_1 \rightarrow 0 \textit{ whenever } |appr_2 - opt_2|/opt_2 \rightarrow 0.$$

Proof

Here we only prove the "if" part. Assume we have a PTAS for OPT_2 and that OPT_1 reduces to OPT_2. To get a PTAS for $OPT_1(x)$ first we construct $f(x)$. Using the ϵ-approximation algorithm A_ϵ for OPT_2 we find a witness y' such that $(1 - \epsilon)OPT_2(f(x)) \leq F_2(f(x), y') \leq (1 + \epsilon)OPT_2(f(x))$. Hence $|F_2(f(x), y') - OPT_2(f(x))|/OPT_2(f(x)) \leq \epsilon$. When ϵ tends to 0, from the condition of the lemma we obtain that $|F_1(x, g(f(x), y')) - OPT_1(x)|/OPT_1(x)$ also tends to 0. Thus using f, g, and A_ϵ (for decreasing epsilon) we can build a sequence of algorithms that serves as a PTAS for OPT_1. □

The main advantage of approximation-preserving reductions is that they enable us to define large classes of optimization problems that behave in the same way with respect to approximation. A prominent example is MAXSNP: all problems in this class are constant-factor approximable, as shown via the L-reduction of Papadimitriou and Yannakakis.

17.4 Gap Problems, Karp Reductions, and the PCP Theorem

It soon became clear that besides approximation-preserving reductions, PCP theory also requires reductions between new types of problems, called *promise problems*. Promise problems are functions with three possible values: 0, 1, and "undefined." They occur as intermediate steps in reduction sequences from decision problems to functions. In PCP theory context Bellare et al. in Ref. [25] were the first to explain reductions through promise problems.

Let OPT be a minimization problem. Assume that for every input x we have two bounds: a lower bound $T_l(x)$ and an upper bound $T_u(x)$, both are polynomial-time computable in x. It is easy to see that if we can efficiently approximate $OPT(x)$ within a factor better than $r(x) = T_u(x)/T_l(x)$, then with only a polynomial (additive) overhead in the running time we can also solve:

- if $OPT(x) \geq T_u(x)$, the output is 0,
- if $OPT(x) \leq T_l(x)$, the output is 1,
- if $T_l(x) < OPT(x) < T_u(x)$, the output can be anything.

We call the above problem a *gap problem* and refer to it as $Gap(OPT, T_l, T_u)$. If OPT happens to be a maximization problem, the above definition stays valid, only the roles of 0 and 1 get exchanged.

Example 17.2

For graph G let $\chi(G)$ be the chromatic number of G. $OPT = \chi$ is a minimization problem. Let $T_l = 3$, $T_u = |V(G)|^{0.26}$, where $V(G)$ denotes the vertex set of the input graph. Karger, Motwani and Sudan solved $Gap(\chi, 3, |V(G)|^{0.26})$ in polynomial time. In fact, their algorithm well-colors any three chromatic graph using at most $|V(G)|^{0.26}$ colors. It is a famous open problem if for any $\epsilon > 0$ there is a polynomial-time algorithm that colors a three chromatic graph with $|V(G)|^{\epsilon}$ colors.

Witness giving condition: An algorithm for the problem $Gap(OPT, T_l, T_u)$, where OPT is an NP minimization problem, satisfies the Witness giving condition if for every x with $OPT(x) \leq T_l(x)$ the algorithm gives a "witness" y for which $F(x, y) < T_u(x)$. If OPT is a maximization problem then the witness giving condition requires that for every input x for which $OPT(x) \geq T_u(x)$, the algorithm computes a witness y for which $F(x, y) > T_l(x)$. Almost all polynomial-time solutions given to gap problems satisfy the witness giving condition.

Gap problems yield themselves to Karp reductions as explained below. For brevity we assume that OPT is an NP maximization problem.

Karp reduction from languages to gap problems

Let $L \subseteq \Sigma^*$ be a language. A Karp reduction from L to $Gap(OPT, T_l, T_u)$ is a polynomial-time map f from Σ^* to input instances of OPT such that

1. if $x \in L$, then $OPT(f(x)) \geq T_u(f(x))$;
2. if $x \notin L$, then $OPT(f(x)) \leq T_l(f(x))$.

For the above type of reduction the most prominent example is the PCP theorem:

Theorem 17.1 (PCP Theorem)

For some $\epsilon > 0$ it holds, that for every language $L \in NP$ there exists a polynomial-time computable function $f : \Sigma^* \to \{3CNF\ formulas\}$, such that

1. *if $x \in L$, then $f(x)$ is a formula in which all disjunctions are simultaneously satisfiable;*
2. *if $x \notin L$, then $f(x)$ is a formula in which one can satisfy at most $1 - \epsilon$ fraction of all clauses.*

Remark 17.1

The problem of maximizing the fraction of satisfied clauses of a 3CNF formula is called MAX-3SAT. *Formally, let $\phi = \bigwedge_{i=1}^{m}(y_{i,1}^{b_{i,1}} \vee y_{i,2}^{b_{i,2}} \vee y_{i,3}^{b_{i,3}})$ be a 3CNF formula. For an assignment y, define*

$$F(\phi, y) = |\{i \mid (y_{i,1}^{b_{i,1}} \vee y_{i,2}^{b_{i,2}} \vee y_{i,3}^{b_{i,3}})\textit{evaluates to true under assignment } y\}|/m.$$

Then $MAX\text{-}3SAT(\phi) = \max_y F(\phi, y)$.

We can restate Theorem 17.1 that any language in NP is Karp reducible to $Gap(MAX - 3SAT, 1 - \epsilon, 1)$.

Karp reduction between gap problems

Let OPT_1 and OPT_2 be maximization problems, T_l, T_u, T_l', T_u' polynomial-time computable functions. Let f be a polynomial-time computable function from the set of input instances for OPT_1 to the set of input instances for OPT_2 such that

1. if $OPT_1(x) \leq T_l(x)$, then $OPT(f(x)) \leq T_l'(f(x))$;
2. if $OPT_1(x) \geq T_u(x)$, then $OPT(f(x)) \geq T_u'(f(x))$.

Then f is a Karp reduction from $Gap(OPT_1, T_l, T_u)$ to $Gap(OPT_2, T_l', T_u')$. The above definition carries over without any difficulty to those cases when one or both of OPT_1 and OPT_2 are minimization problems. If such reduction exists and $Gap(OPT_1, T_l, T_u)$ is NP-hard then $Gap(OPT_2, T_l', T_u')$ is also NP-hard.

Example 17.3

For graphs G and H we denote by $G \times H$ their strong product: $V(G \times H) = V(G) \times V(H)$, $E(G \times H) = \{((u_1, v_1), (u_2, v_2)) \mid (u_1, u_2) \in E(\widehat{G}) \wedge (v_1, v_2) \in E(\widehat{H})\}$, where $\widehat{G}$ and $\widehat{H}$ are obtained from G and H by adding a loop to every node. Let $\omega(G)$ denote the maximum clique size of graph G. It is easy to see that $\omega(G \times H) = \omega(G)\omega(H)$. Let f be the map $G \to\ G \times G$ and let $l < u$ be arbitrary positive constants. The above implies that f is a Karp reduction from the gap problem $Gap(\omega, l, u)$ to $Gap(\omega, l^2, u^2)$.

The following scheme is a high-level description of the way we prove inapproximability results:

$$\begin{tikzcd}
\text{3SAT} \arrow[d, Rightarrow, "\text{PCP theorem (Karp reduction)}"] \\
\text{gap-3SAT} \arrow[d, Rightarrow, "\text{Karp reduction}"] \\
\text{Other gap problems} \arrow[d, Rightarrow, "\text{trivial}"] \\
\text{Corresponding inappr. results} \arrow[d, Rightarrow, "\text{Approx. preserving reduction}"] \\
\text{Inappr. results}
\end{tikzcd}$$

17.5 Probabilistic Verification: The FGLSS Graph

PCP theory grew out of the observation that probabilistic proof systems can be viewed as optimization problems. At the time of their discovery probabilistic proof systems were a surprising novelty. At the present time they represent a distinct contribution of the theory of computing to logic and mathematics. Their two origins are zero-knowledge proof systems [26]and Arthur–Merlin games [27].

Among all probabilistic proof systems, the so-called Multiprover interactive proof system (MIP) of Ben-Or et al. [28] is what we apply in the theory of PCPs. The polynomial-time randomized verifier of an MIP "interrogates" two (or more) noncommunicating all-powerful provers about the truth-hood of a statement. Instead of MIPs we consider a roughly equivalent system.

Probabilistic Oracle Machines (POM)

Let $M^y(x, r)$ be a probabilistic RAM with oracle y and random string r. M is said to accept a language L with completeness α and soundness β $(1 \geq \alpha > \beta \geq 0)$ iff

- if $x \in L$, then there is a y such that $Prob_r(M^y(x, r) = 1) \geq \alpha$;
- if $x \notin L$, then for every y it holds that $Prob_r(M^y(x, r) = 1) \leq \beta$.

The relevant parameters are the amount of randomness used ($|r|$), the query size (q), the completeness parameter (α), and the soundness parameter (β). The query size is the number of positions of y that M looks at for the worst-case input of size n. Every position of y contains an element of the Σ, the alphabet of y, which is assumed to be $\{0, 1\}$, unless otherwise said. If the alphabet size is larger, then $|\Sigma|$ is also a parameter. Recently, there is also an interest in minimizing the proof size, $|y|$ [1,29,30].

Probabilistically Checkable Proofs (PCP)

The witness y written on a POM machine's oracle tape is also called a *Probabilistically Checkable Proof.* The POM that checks the PCP is called a "PCP verifier." We use the terms "POM" and "PCP verifier" interchangeably. The latter term was born from an "anthropomorphic" interpretation of the verification process. We often speak in the first person when we describe the verifier's actions. Most PCP verifiers are nonadaptive: they ask all questions to the oracle at once.

To see the connection between proof systems and combinatorial optimization, let M be a POM with parameters $|r|$, q, α, β and consider the problem

$$OPT_M(x) = \max_y \text{Prob}_r(M^y(x, r))$$

Observe that if $x \in L$, then $OPT_M(x) \geq \alpha$ and if $x \notin L$, then $OPT_M(x) \leq \beta$, i.e., L Karp reduces to $Gap(OPT_M, \beta, \alpha)$. Thus, if L is NP-hard, approximating OPT_M within a factor better than α/β is also NP-hard. The significance of parameters $|r|$ and q will soon be clear.

Feige et al. have turned the $MIP = NEXP$ theorem of Babai, Fortnow, and Lund into an in-approximability result. It had to be scaled down first to the polynomial level, resulting in the statement: For an NP-complete language, L, there is a $C > 0$ and a probabilistic oracle machine M^* with query size randomness bounded by $(\log n)^C$, completeness parameter 1 and soundness parameter $1/n$. Hence OPT_{M^*} cannot be approximated by a factor of n. If this does not sound impressing, it is because computing OPT_{M^*} was not a frequently studied optimization problem. Feige et al. transformed OPT_{M^*} (or any OPT_M) into a maximum clique problem. Below we describe the transformation:

FGLSS (Feige–Goldwasser–Lovász–Safra–Szegedy) transformation

For a string $x \in \{0, 1\}^n$ and a probabilistic oracle machine $M^y(x, r)$ we define a graph $G_{x,M}$. The vertices of $G_{x,M}$ are ordered tuples (r, a) of 0-1 strings ($|a| = q$) such that M accepts if it has access to an oracle y that gives $a_1, a_2, \ldots, a_q$ for answers to the q subsequent queries of M, when we run it on inputs x and r. The main point is that given $a = a_1, a_2, \ldots, a_q$ we do not need the entire y to compute $M^y(x, r)$. Every oracle y that answers $a_1, a_2, \ldots, a_q$ to the k subsequent queries of $M^y(x, r)$ is said to be consistent with (r, a), as long as it also holds that $M^y(x, r)$ accepts. If $M^y(x, r)$ rejects, y is defined to be inconsistent with (r, a) for any a. Clearly, for fixed y and r if there is an a such that (r, a) is consistent with y, then this a is unique. For $r \neq r' \in \{0, 1\}^k$ and $a, a' \in \{0, 1\}^q$ we have an edge between (r, a) and (r', a') in $G_{x,M}$ if there is an oracle y consistent with both. The following is easy to see:

Lemma 17.2

Let $(r_1, a_1), (r_2, a_2), \ldots, (r_s, a_s)$ form a clique in $G_{x,M}$. Then there is an oracle y consistent with (r_i, a_i) for $1 \leq i \leq s$.

For a fixed oracle y the number of rs that are consistent with y (meaning that there exists an a such that (r, a) is consistent with y) is proportional with the probability over r that $M^y(x, r)$ accepts. Thus, $OPT_M(x)$ is proportional with the max clique size of $G_{x,M}$.

Since the number of all possible (r, a) pairs is $2^{|r|+q}$, graph $G_{x,M}$ has at most $2^{|r|+q}$ vertices. Applying this to the verifier M^* of Feige et al. we get that the number of vertices of G_{x,M^*} is at most $2^{2(\log n)^C}$. Since any algorithm that approximates OPT_{M^*} within a factor of n can solve NP, we can use any algorithm that approximates the max clique size of G_{x,M^*} within a factor of n to build an NP solver. The overhead is the cost of the FGLSS transformation, which is polynomial in the size of G_{x,M^*}. Expressing all parameters in terms of $N = |V(G_{x,M^*})|$, we get that for some constant C' the max clique problem of a graph with N nodes is not approximable in polynomial time within a factor of $2^{(\log N)^{1/C'}}$ unless $NP \subseteq DTIME(2^{(\log N)^{C'}})$. In [12,17,20,25,31–34] (starting with the original paper) the result was subsequently improved. The best current improvement is:

Theorem 17.2 (Zuckerman [34])

There are γ, $c > 0$ such that the maximal clique size of a graph with N nodes cannot be approximated within a factor of $\frac{N}{2^{(\log N)^{1-\gamma}}}$ in polynomial time unless NP $\subseteq DTIME(2^{(\log N)^c})$.

17.6 PCPs and Constraint Satisfaction Problems

We have seen that constructing a POM with small parameters has immediate inapproximability consequences. In Ref. [20] an even more dramatic consequence was found effecting the entire class MAXSNP:

Lemma 17.3

If for a language L there is a POM with perfect completeness, soundness $\gamma < 1$, logarithmic randomness and constant query size, then L Karp reduces to $Gap(MAX - 3SAT, \beta, 1)$ for some $\beta < 1$.

Indeed, let the POM in the lemma be $M^y(x, r)$. Since M queries at most $q = O(1)$ bits, for fixed x and r there is constant-size Boolean formula, $\Phi_{x,r}$ expressing if the verifier accepts or rejects the bits it views. We have

$$\max_y Prob(M^y(x, r) = 1) = \max_y |\{r|\Phi_{x,r}(y) = 1\}|/2^{|r|} \tag{17.1}$$

Constraint Satisfaction Problems (CSP)

The problem on the right-hand side of Eq. (17.1) is a MAX-CSP problem. A kCSP is a generalization of kSAT, where clauses can be any k-variable Boolean expressions. kCSPs are typically defined on Boolean variables, but it is easy to extend this definition to the case when the variables take values from a general constant-size alphabet Σ. In this case we talk about a $[k, \Sigma]$CSP.

Fact 17.1

Every PCP with completeness α, soundness γ, query size k, and witness-alphabet Σ can be turned into a $Gap(\mathrm{MAX} - [k, \Sigma]\mathrm{CSP}, \gamma, \alpha)$ instance.

In particular Eq. (17.1) reduces the L of Lemma 17.3 to $Gap(\mathrm{MAX} - [q, \Sigma]\mathrm{CSP}, \gamma, 1)$, where Σ is the alphabet of M. To prove Lemma 17.3 we need to reduce $Gap(\mathrm{MAX} - [q, \Sigma]\mathrm{CSP}, \gamma, 1)$ to $Gap(\mathrm{MAX} - 3\mathrm{SAT}, \gamma', 1)$. This is done by *gadgets* (in this case we have to transform little nondeterministic 3SAT formulas replacing the constraints of the k-CSP). Lemma 17.3 explains why we want to construct PCPs with constant number of check bits.

17.7 Codes and PCPs

Perhaps unexpectedly, when turning NP machines into POMs, it is not the machine, but rather the witness (or proof, in other words) that goes under a meaningful transformation. The old witness (let it be a coloring, a TSP tour, etc.) becomes a new and very interesting object, called PCP. (Of course, the machine needs to be adapted to the new checking task, but what motivates its actions is the presumed structure of the new witness.) To understand this better, let $\exists z \; N(x, z)$ be an NP machine, which we would like to transform into a POM that recognizes the same language. Without the loss of generality we can think of N as a machine for the chromatic number problem, x as a graph, and z as a coloring on the nodes. N verifies if z assigns different colors to all pairs of adjacent nodes in x.

Assume we manage to "encode" every witness (i.e., coloring) z into some string $y(x, z)$ (which may be viewed as a "probabilistically checkable version" of the same coloring) and design a probabilistic oracle machine $M^y(x, r)$ (also called checker or verifier) such that

1. if $N(x, z) = 1$, then $M^{y(x,z)}(x, r) = 1$ for every r.
2. for every x the string $y(x, z)$ (transformed from an original potential witness z) is an element of an error correcting code $\mathcal{C}_x$ that corrects δ fraction of errors.
3. if y is not δ-close to $\mathcal{C}_x$, then $Prob_r(M^y(x, r) = 1) \leq 0.5$.
4. if y is δ-close to some $y' \in \mathcal{C}_x$, but y' is not equal to some $y(x, z_0)$ for some z_0 for which $N(x, z_0) = 1$, then $Prob_r(M^y(x, r) = 1) \leq 0.5$.

Then M is a POM with completeness 1 and soundness 0.5 that recognizes the same language as N. The completeness property follows from 1. To see the soundness property assume that $\forall z \; N(x, z) = 0$. For some y how can $M^y(x, r)$ be accepting with probability greater than 0.5? From 3 we see that for this y has to be δ-close to the the code $\{y(x, z)|z\}$. But then there is a z_0 such that y is δ-close to z_0. Then 4 gives a contradiction, since $N(x, z_0) = 0$.

The above way of constructing PCPs gives a general philosophy. Point 3 calls for constructing codes such that a POM with small query size can tell with large certainty if a word is δ-far from a code word. In fact, the POM can be viewed as performing two procedures: (1) checking for closeness to the code and (2) given that y is close to the code, checking if it is an encoding of a witness that makes N accept. Sometimes these two tasks are merged together.

In Refs. [12,13,16] the technique to construct a PCP encoding code was *arithmetization.* When arithmetizing, the encoding function is the generalized Reed Solomon encoding. The PCP properties of this code are not straightforward. A technical detail, but important for the further developments, is that in these articles δ is not a constant, but rather inverse polylogarithmic.

In Ref. [17] the parameters were further reduced to $|q| = |r| = O(\log n)$ reaching an important milestone: NP was characterized for the first time as *PCP*$(\log n, \log n)$ (the two arguments are the number of the random bits and the number of the query bits).

In Ref. [20] the number of check bits had to be decreased to constant. Are there any error correcting codes over $\Sigma = \{0, 1\}$ that can be checked with constant number of queries even if we allow the code word to be exponentially long, and we do not require any additional properties? The answer is yes, and these codes play a fundamental role in the PCP theory.

Hadamard Code

Let $z \in \{0, 1\}^k$. We encode z as the sequence of all scalar products $had(z) = (z, v)_{v\in\{0,1\}^k}$. Here $(z, v) \overset{def}{=} \sum_i z_i v_i \bmod 2$. The above is known as the Hadamard encoding.

Lemma 17.4

Let $y = (y_v)_{v\in\{0,1\}^k}$ be any vector of length 2^k with elements from $\{0, 1\}$. Then

1. *If $y = had(z)$ for some $z \in \{0, 1\}^k$ then for every $v, t \in \{0, 1\}^k$ we have $y_v + y_t = y_{v+t}$.*
2. *If y is ϵ-far in Hamming distance from every word from the Hadamard code, then*

$$|\{(v, t)|y_v + y_t \neq y_{v+t}\}| \geq \epsilon\, 2^{2k}$$

The above lemma, which was first discovered with a slightly weaker constant by Blum et al. [18], gives a procedure to check membership in the Hadamard code: Pick $v, t \in \{0, 1\}^k$ randomly and independently, and reject if $y_v + y_t \neq y_{v+t}$. The lemma implies that if y is at least ϵ-far from all code words, the check gets rejected with probability at least ϵ. However, if it is a code word, the check gets accepted with probability 1. A further feature of the Hadamard code is that from any string y close to $had(z)$ we can recover any mod 2 subset-sum of the bits of z with high certainty, but we cannot easily recover nonlinear (in the two-element field arithmetic) functions of the encoded string. Arora et al. [20] employed the Hadamard encoding in their construction. The role of exponentially large codes in the PCP theory is made clearer in the next section.

We now describe another code, which is checkable with a constant number of bits and has the added nice feature that one can also recover any Boolean function of the encoded string with high certainty using only two queries. The checking procedure is remarkably efficient: three queries suffice. The code was invented by Bellare et al. [25] and was wonderfully analyzed by Hastad [35], who showed how this code plays a main role in obtaining sharp inapproximability results with it. It is also employed in the recent short proof for the PCP theorem.

The Long Code

Encode z ($z \in \{0, 1\}^k$) by the list of values that all Boolean functions take on z. We get *long*(z). Unlike the Hadamard code, the long code is nonlinear, although it is a subset of a Hadamard code. Since the number of Boolean functions that take k input bits is 2^{2^k}, the length of the long code is doubly exponential. The elements of the code are indexed by the names of the corresponding Boolean functions. There is another interpretation of the long code, which may be interesting. First encode z in unary and then encode $unary(z)$ with the Hadamard code. $long(z) = had(unary(z))$. If we have an abstract set S instead of $\{0, 1\}^k$ we may also encode its elements with the long code. Let $\mathcal{F}$ be the set of all functions $f : S \to \{0, 1\}$. For $z \in S$ we define $long_S(z) = (f(z))_{f\in\mathcal{F}}$, a string of length $2^{|S|}$.

Folding

If $y = long_S(z)$ then for every $f \in \mathcal{F}$ we have $y_{\neg f} = \neg y_f$. Let $s_0 \in S$ be an arbitrarily chosen element of S. For every f exactly one of $f(s_0)$, $\neg f(s_0)$ is 0. The folded long code $long'_S$ contains only those entries y_f of the long code for which $f(s_0) = 0$. Hence its words are from $2^{S\setminus\{s_0\}}$. When we describe a test for the folded long code it is often convenient to talk about y_f even when $f(s_0) \neq 0$. Under this, by definition, we mean $y_f = \neg y_{\neg f}$. To retrieve this value the tester needs to read only one bit from y. We call the above extension the *unfolding of y*. In PCP theory we always work with the folded code. Long code tests are studied by Fourier analytic techniques [31,35,36], and using the folded version gives nicer formulas. Also, if we unfold any string in $2^{S\setminus\{s_0\}}$ (not only a code word) then the unfolded string in 2^S will have Hamming weight exactly $2^{|S|-1}$.

Let $f_1 \vee f_2 \vee \cdots \vee f_l = 1$ and $y = long'(z)$ for some $z = \{0, 1\}^k$. Then $y_{f_1} \vee y_{f_2} \vee \cdots \vee y_{f_l} = 1$ must hold. This observation makes it possible to check $long'_s$ as follows:

Lemma 17.5 (Dinur [1])

For any finite set S the folded code $long'_S(z)$ can be checked looking at only three positions corresponding to functions whose OR is 1. *The first two functions of the triplet are randomly selected, while the third one is chosen by a random process (we do not give here the simple details) such that the OR of the three functions is* 1. *The procedure then accepts if $b_1 \vee b_2 \vee b_3 = 1$, where b_1, b_2, and b_3 are the three returned code bits. For the procedure the following holds:*

1. *If $y = long'_S(z)$, then y is accepted with probability* 1.
2. *If $dist(y, long'_S) > \delta$, then y is rejected with probability* 0.001δ.

17.8 Holographic Proofs and the Proof Recursion Idea

Babai et al. [16] have shown how to test randomly a (theorem, proof) pair without reading neither the theorem nor the proof. The theorem is assumed to be in an arbitrary error correcting format and the proof serves to check both the theorem and its format. When we say "proofs" and "theorems" normally we mean the corresponding notions of predicate calculus, but to understand this section one needs to think more generally (and in a sense, simpler). Ref. [16] considers *abstract proof systems*. In the most general case, the minimal requirement from a proof system is that it characterizes a set called *THEOREMS*, which comprises all "true statements." *THEOREMS* $\subseteq \{0, 1\}^*$ may be any language. The notion is merely syntactic. A slightly less minimal requirement is that *THEOREMS* be recursively enumerable. If so, then there is a polynomial-time machine N such that $x \in$ *THEOREMS* if and only if $\exists x\ N(x, y)$. Here, y can be arbitrarily long compared with x. We prefer to rename x and y and write the above as $\exists$ proof N(theorem, proof). We would like to emphasize that theorems and proofs are only strings. No semantics is attached to them. The only way to get convinced if a (theorem, proof) pair is valid if we run N on it.

The next step in Ref. [16] is to introduce the notion of "holographic" proof systems. Let us assume that the theorems of a conventional (nonholographic) abstract proof system form the set *THEOREMS*$_0$. Let $E_k : \{0, 1\}^k \to \{0, 1\}^{h(k)}$ be a family of efficiently computable error correcting encoding that correct δ fraction of errors. Let $E(x) = E_{|x|}(x)$. We define a new set

$$THEOREMS = \{E(x)|x \in THEOREMS_0\}$$

This transformation of the theorem set makes it error-resistant: Even if we delete or change a constant ($< \delta$) fraction of a theorem $\in$ *THEOREMS*, we can recover it using error correction. More importantly, if $THEOREMS_0$ is recursively enumerable (RE), then Ref. [16] shows how to build a "holographic proof system" for *THEOREMS* (below L stands for $THEOREMS_0$):

Theorem 17.3 (Babai et al. [16])

Let $E_k : \{0, 1\}^k \to \{0, 1\}^{h(k)}$ be a family of efficiently computable error correcting encodings that correct δ fraction of errors. For every $L \in RE$ with verifier N, there is a probabilistic oracle machine $M^{z,y}(k, r)$ (k is the length of the unencoded theorem, $z \in \{0, 1\}^{h(k)}$) such that

1. *If $x \in L$, $|x| = k$, then any witness y_0 for which $N(x, y_0) = 1$ can be turned into a witness y for M for which $M^{E(x),y}(k, r) = 1$ for every r. The transformation takes polynomial time in $|y_0|$.*
2. *Let $THEOREMS_k = \{E(x)|x \in L \cap \{0, 1\}^k\}$. For every z with $dist(z, THEOREMS_k) > \delta\, h(k)$ and for every y we have $Prob_r(M^{z,y}(k, r) = 1)) \leq 1/2$.*
3. *The query size and $|r|$ are only polylogarithmic in $|z| + |y|$.*

If we allow exponential blow-up in the parameters, then a much simpler holographic proof checker was found by Dinur [1], which she uses in her simple proof for the PCP theorem:

Assignment Tester of Dinur

Let F be an arbitrary Boolean function on k variables. Let $E : \{0, 1\}^k \to \{0, 1\}^l$ be an arbitrary encoding that corrects 10% of errors, and let

$$THEOREMS \overset{def}{=} \{E(x)|x \in \{0, 1\}^k;\quad F(x) = 1\}$$

The Dinur assignment tester is a holographic proof system for $z \in$ *THEOREMS*. Dinur's holographic proof for some $E(x) \in THEOREMS$ is simply $y = long'_{THEOREMS}(E(x))$. Given a candidate (z, y) for a (theorem, proof) pair, the verifier checks that the following hold:

1. y is close to some member of $long'_{THEOREMS}$;
2. assuming that the first condition holds, y is close to $long'_{THEOREMS}(z)$.

The second check is the reason why z of the true prover needs to come from an error correcting code. The first check is done as in Lemma 17.5. The second check is done by selecting a random index $1 \leq \rho \leq l$ and checking if the ρth bit of z is correctly encoded in y. For this the verifier picks a random $f : \{0, 1\}^l \to \{0, 1\}$ and checks if $y_f + y_{f+\pi_\rho} = z_\rho$, where π_ρ is the function that projects a word to its ρth bit: $w \to w_\rho$. Remark: π_ρ behaves as any other Boolean valued function on *THEOREMS*. In particular, the folded long code lets it to recover via the expression $y_f + y_{f+\pi_\rho}$, where f is arbitrary.

The verifier, instead of checking both 1 and 2, selects either 1 or 2 with 50% probability. If the above verification process is accepting with probability 0.999, then y is close to some $long'_{THEOREMS}(z')$. Also, z' is close to z in Hamming distance. This in turn means that z decodes to $x = E^{-1}(z')$, where $F(x) = 1$.

Reducing the Query Size

The query size of the above procedure is 3. As we see in the next section, it has a definite advantage to reduce the number of queries of the verifier to two even at the price of increasing the alphabet size to eight. To this end Dinur employs the following nice standard trick. To y we add another proof, y', that contains all the triplets of bits that are potentially read by the checking procedure. The alphabet of y' is $\{0, 1\}^3$. The verifier proceeds according to the same protocol as before, but when a check is to be performed, it reads the corresponding triplet, τ, from y'. To make sure that τ faithfully describes the corresponding three bits of $z \cup y$, it randomly selects one of the three bits of τ, compares it with the corresponding bit in $z \cup y$, and rejects if τ lies about it. The following is not hard to show:

Lemma 17.6

There is fixed $c > 0$ such that if z is δ-far from THEOREMS then for every y, y' the above 2-query verifier rejects $(z, y \cup y')$ with probability at least $c\delta$. On the other hand, if $z \in THEOREMS$ then there exist y, y' such that the verifier accepts $(z, y \cup y')$ with probability 1.

The holographic proof idea was slightly generalized in Refs. [1,10,37,38].

Proof Recursion

Arora and Safra [17] were the first to describe *proof recursion*, a method in PCP building to decrease the query size. Proof recursion builds on the holographic proof idea. Below we explain it in its simplest form. In this form proof recursion is used to decrease the size of the alphabet of the witness tape rather than the query size. In the process the query size should not increase by much. If the alphabet size is small but the query size is large, to do the proof recursion, we first need another transformation that trades query size for alphabet size by reducing the former and increasing the latter (see a simple example above). In general, if the query size is nonconstant, to achieve this trade-off may be quite technical.

Outer Verifier

Let M be a POM, called *outer verifier*, that makes a constant number of queries, but its witness is over a large alphabet, Σ_{big}. Let E be a binary error correcting encoding of Σ_{big} that corrects constant fraction of errors. From a witness $(y_i)_{1\leq i\leq m}$ we create another witness $(E(y_i))_{1\leq i\leq m}$, i.e., we encode every symbol of the witness (or proof) individually and concatenate the resulting code words.

Inner Verifier

To check the new witness we use a verifier that works under the holographic proof principles. Let us assume that the outer verifier for a random string r would read $y_{i_1}, y_{i_2}, \ldots, y_{i_q}$ and accept if some Boolean predicate $F(y_{i_1}, \ldots, y_{i_q})$ equals 1. Define:

$$THEOREMS = \{E(\sigma_1)E(\sigma_2)\ldots E(\sigma_q)|F(\sigma_1, \sigma_2, \ldots, \sigma_q) = 1\}$$

Note that if E corrects δ fraction of errors, then $E^q = E \times \cdots \times E$ still corrects δ/q fraction of errors, so *THEOREMS* is in an error correcting format (recall that by our assumption q is a constant). Therefore, a holographic proof checker capable of recognizing *THEOREMS* can be applied. (BFLS, D, and other constructions ensure the existence of such proof checkers for a wide range of parameters.) This proof checker, also called the *inner verifier*, needs to have access to a holographic proof besides $E(y_1)E(y_2)\ldots E(y_q)$.

Composed Verifier

We need to build an inner verifier for every fixed r as follows. The *composed verifier*, given r, first computes the indices of the check bits of the outer verifier, and the Boolean predicate F_r that represents the acceptance condition of the outer verifier for this r. From F_r it determines $THEOREMS_r$ and computes a random query of the associated inner verifier. For this the composed verifier uses an additional random string r' with length that agrees with the randomness required by the inner verifier. Then the composed verifier makes the queries. This is the only occasion when it reads anything from the witness tape. Thus the query and alphabet sizes of the composed verifier are that of the inner verifier. The composed proof itself is $(E(y_i))_{1\leq i\leq m} \cup \bigcup_r \text{holo}_r$, where holo_r is the holographic proof associated with random string r.

Building an outer verifier is not trivial, and it is a main technical component in Ref. [17]. Arora et al. [20] build a verifier that is both inner and outer, and which needs only logarithmic randomness and polylogarithmic query bits. They compose this verifier with itself a constant number of times. The verifier has a natural size parameter, which is set differently throughout the levels of composition. In particular, the size rapidly shrinks in every new iteration. For the last time they use a different inner verifier whose alphabet size is 2, and query size is constant similarly to Dinur's assignment tester. The latter was a novel idea at the time. To achieve significant improvement of the parameters in just a constant number of iterations the outer verifier must be very powerful, which makes the ALMSS [20] construction involved. To keep the number of iterations constant appeared to be necessary, because in their case every iteration of the proof recursion either added a constant to the query size or shrunk the completeness-soundness gap. In Refs. [1,38] gap-increasing reductions help to get around this. Shortly after Ref. [20] a powerful gap-increasing reduction, called *parallel repetition* was invented by Raz [39], and exploited in constructions to obtain sharp inapproximability results [35]. The parallel repetition, unlike the reductions in [1,38], which only add a constant to $|r|$, increases $|r|$ by a constant factor, so it can be used only (essentially) once without making $|r|$ superlogarithmic.

17.9 A Short Proof of the PCP Theorem

Before Refs. [1,38] several different proofs have been made for the PCP theorem, but their rough structure did not differ much. One of the nice features of the new proof is that it can be almost fully explained without mentioning PCPs, and talking only about Gap-CSPs (see Section 17.6). In particular, Dinur proves the following form of the PCP theorem:

Theorem 17.4

Let $\Sigma = \{0, 1\}^3$. *Then* $[2, \Sigma]$*CSP Karp reduces to Gap*$(MAX - [2, \Sigma]CSP, 0.9999, 1)$ *in polynomial time. (Note:* $[2, \Sigma]$*CSP is NP-complete.)*

For the rest of the section we fix $\Sigma = \{0, 1\}^3$.

Instance Size and Satisfiability Gap

For a CSP $\Phi = \bigwedge_{i=1}^{m} \Phi_i$, define the *instance size* as $|\Phi| = m$. The *satisfiability gap* of Φ is $\overline{\text{sat}}(\Phi) = \min_y |\{i|\Phi_i(y) = 0\}|/m$ (one minus the maximal fraction of the simultaneously satisfiable constraints). In words, Eq. (17.1) says

Let Φ be a $[k, \Sigma]$CSP instance. Either $\overline{\text{sat}}(\Phi) = 0$ (the formula is satisfiable) or $\overline{\text{sat}}(\Phi) \geq 1/|\Phi|$ (the formula is not satisfiable). The satisfiability gap cannot be smaller than $1/|\Phi|$ since if the formula is not satisfiable then at least one component of Φ is not satisfied under any assignment. Dinur constructs a reduction that enlarges this tiny gap to a constant, while keeping the gap of satisfiable instances 0. The reduction makes small progresses at a time.

It is sufficient to show that any $[2, \Sigma]$CSP instance Φ can be reduced in polynomial time to a $[2, \Sigma]$CSP instance Φ' with the following properties:

1. if Φ is satisfiable then Φ' is satisfiable.
2. $|\Phi'| \leq 10^{10^{10^{googol}}} |\Phi|$
3. $\overline{\text{sat}}(\Phi') \geq \min\{2\ \overline{\text{sat}}(\Phi),\ 0.0001\}$.

We say that a $[2, \Sigma]$CSP instance is d-regular, expanding, if the graph we obtain by replacing each constraint with the corresponding pair of variables is a d-regular expander. Let Φ be an arbitrary $[2, \Sigma]$CSP. Let $d = 11$ and t be a constant to be determined later. We obtain Φ' from Φ in three steps:

$$\begin{array}{lcl}
\Phi \in [2, \Sigma]\text{CSP} & \rightarrow & \text{(to improve on the structure)} \\
\Phi_{reg} \in d\text{-regular, expanding } [2, \Sigma]\text{CSP} & \rightarrow & \text{(to gain the gap)} \\
\Phi_{big} \in [2, \Sigma^{(d+1)^{\lceil \frac{t}{2} \rceil}}]\text{CSP} & \rightarrow & \text{(to reduce the alphabet size)} \\
\Phi' \in [2, \Sigma]\text{CSP} & &
\end{array}$$

Furthermore: (1) If Φ is satisfiable then so are Φ_{reg}, Φ_{big}, and Φ', (2) Each reduction increases the size of the instance only by a constant factor: $|\Phi_{reg}| \leq 30|\Phi|$, $|\Phi_{big}| = (d+1)^{\lceil \frac{t}{2} \rceil - 1}|\Phi_{reg}|$, $|\Phi'| \leq 2^{2^{31(d+1)^{\lceil \frac{t}{2} \rceil}}} |\Phi_{big}|$, and (3) The satisfiability gaps change as

$$\begin{aligned}
\overline{\text{sat}}(\Phi_{reg}) &\geq 0.1\ \overline{\text{sat}}(\Phi) \\
\overline{\text{sat}}(\Phi_{big}) &\geq \min\{200000\ \overline{\text{sat}}(\Phi_{reg}),\ 0.001\} \\
\overline{\text{sat}}(\Phi') &\geq 0.0001\ \overline{\text{sat}}(\Phi_{big})
\end{aligned}$$

Only for the $\Phi_{big} \rightarrow \Phi'$ reduction we need PCP ideas, although very little.

Reducing the Alphabet Size

In fact, Sections 17.7 and 17.8 have already prepared us to understand this reduction. Since $\Sigma = \{0, 1\}^3$, we can identify $\Sigma_{big} \overset{def}{=} \Sigma^{(d+1)^{\lceil \frac{t}{2} \rceil}}$ with $\{0, 1\}^{3(d+1)^{\lceil \frac{t}{2} \rceil}}$. If Φ_{big} is a positive instance (i.e., satisfiable), we encode each letter of the satisfying assignment with some encoding function $E : \{0, 1\}^{3(d+1)^{\lceil \frac{t}{2} \rceil}} \rightarrow \{0, 1\}^{30(d+1)^{\lceil \frac{t}{2} \rceil}}$ that corrects constant fraction of errors (from coding theory we know that such encoding exists). If v_i and v_j are two variables on which Φ_{big} has a constraint, we install a Dinur Assignment Tester (see the previous section, Lemma 17.6) which checks the property:

$$THEOREMS_{i,j} = \{(E(\sigma), E(\sigma'))|(\sigma, \sigma') \in \Sigma^2_{big} \text{ satisfy all constraints on } v_i, v_j\}$$

The proof, $(E(\sigma), E(\sigma'))$, is encoded, as required. A little detail is that the encoding is $E \times E$, rather than E, but $E \times E$ still corrects constant fraction of errors. Let us denote the holographic proof of this assignment tester by $\text{holo}_{i,j}$, and the set of all i, j pairs for which such a tester is built, by H. The properties of the Dinur Assignment Tester guarantee that when the constraint is satisfied, and the prover is faithful to the protocol, all tests are accepting. The tester looks at binary constraints over the alphabet $\Sigma = \{0, 1\}^3$, therefore, by Fact 17.1 it can be turned into a $[2, \{0, 1\}^3]$*CSP*. This CSP is made just for a single constraint of Φ_{big}. To obtain Φ' we unite the above sets for all constraints of Φ_{big}. The variables are all bits of all encoded variables of Φ_{big} together with $\bigcup_{i,j\in H} \text{holo}_{i,j}$.

Assume now that Φ_{big} is a negative instance. It takes a little argument to show that in this case the satisfiability gap of Φ' constructed above is at least $0.0001\overline{\text{sat}}(\Phi)_{big}$, *independently of t*. The transformation blows up the instance size by only a constant factor (dependent of t, but it is all right). These were all we wanted to achieve in this stage.

Making It Regular, Expanding

The $\Phi \rightarrow \Phi_{reg}$ reduction is even simpler. It is a fairly standard transformation which involves creating deg v clones of every node v of the constraint graph of Φ. We distribute the outgoing edges among the clones: Each clone remains connected to exactly one outgoing edge. For every v we fit a degree d' expander (say, with $d' = 5$) on its clones putting equality constraints on the new edges. This way we obtain a $d' + 1$-regular graph, which may not be an expander itself (recall that we did not have any assumption on the original graph). To ensure the expanding property, we now add new edges with empty constrains on them. The new edges form a degree d' expander on the entire vertex set. The final graph is $d = 2d' + 1$-regular and it is an expander. Throughout the whole construction we preserve multiple edges (possibly with different constraints).

Powering

The second reduction is a wonderful new addition to *PCP* theory and this is the one that really gains us the gap. We define an operation on binary constraint systems, called *powering*. Let G be a constraint graph and $t > 1$ be an integer. First we add a loop to each node (with an empty constraint). We denote the resulting graph with $G + I$. Then we construct $(G + I)^t$ in such a way that

- The vertices of $(G + I)^t$ are the same as the vertices of G.
- Edges: u and v are connected by k edges in $(G + I)^t$ iff the number of t steps paths from u to v in $G + I$ is exactly k.
- Alphabet: The alphabet of $(G + I)^t$ is $\Sigma^{(d+1)^{\lceil t/2 \rceil}}$, where every vertex specifies values for all of its neighbor reachable in $\lceil t/2 \rceil$ steps.
- Constraints: The constraint associated with an edge (u, v) of $(G+I)^t$ is satisfied iff the assignments for u and v are consistent with an assignment that satisfies all of the constraints induced by the $\lceil t/2 \rceil$ neighborhoods of u and v.

If G is satisfiable then $(G + I)^t$ is satisfiable as well. More importantly, powering has the following satisfiability gap enlarging property:

Lemma 17.7 (**Amplification Lemma** [1])

Let Σ be an arbitrary constant-size alphabet. There exists a constant $\gamma = \gamma(d, |\Sigma|) > 0$ such that for any $t > 0$ and for any d-regular expanding constraint graph G:

$$\overline{\text{sat}}((G + I)^t) \geq \gamma\sqrt{t} \min\left\{\overline{\text{sat}}(G), \frac{1}{t}\right\}$$

We define $\Phi_{big} = (\Phi_{reg} + I)^t$. Parameter t has to be chosen so that we get a large enough $\overline{\text{sat}}(\Phi_{big})/\overline{\text{sat}}(\Phi_{reg})$ ratio to compensate for the loss in the satisfiability gap in the first and third transformations, and even gaining a factor of 2 over that. This can be ensured because of Lemma 17.7.

Many of the stated properties of the reductions are intuitively clear, although some require nontrivial arguments. To get Theorem 17.4 we need to cycle through the reduction set $-log_2\alpha$ times (or, if we do not know α, more), where α is the satisfiability gap of the very first instance. $-log_2\alpha \leq \log m$, so the size of the final instance is polynomially bounded by that of the first, where the size of the latter is m.

Local Search, Neural Networks, and Metaheuristics

18
Local Search

Roberto Solis-Oba
The University of Western Ontario

18.1 Introduction

Typically, a combinatorial optimization problem involves a set E of elements (called *ground set*) and the goal is to arrange, group, order, or select a subset of elements from E that optimizes a given objective function. Classical examples of combinatorial optimization problems include the minimum spanning tree problem, the shortest paths problem, and the traveling salesman problem [1].

Local search is perhaps one of the most natural ways to attempt to solve a combinatorial optimization problem. The idea of local search is simple: Given a (probably not very good) solution s for a combinatorial optimization problem, try to improve the value of the solution by making "local changes" to s. A local change might involve, for example, adding elements from the ground set to s, removing elements from s, changing the way in which elements are grouped in s, or changing the order of the elements in s. If an improvement can be achieved in this manner, then a new solution s' is obtained. This process is continued until no further improvement can be obtained.

Local search has been successfully used to find good solutions for a large number of complex problems, the most famous of them probably being the traveling salesman problem [1]. The empirical performance of local search algorithms has been extensively studied for a large number of problems in scheduling, Very Large Scale Integration design, network design, distributed planning and production control, and many other fields [2]. Most of these studies concluded that local search is a good method for efficiently computing near-optimum solutions to problems of realistic sizes (see, e.g., Refs. [2,3]). In this chapter we explore the use of local search in the design of approximation algorithms with provable performance guarantee for NP-hard combinatorial optimization problems.

The idea of local search might be better understood by considering an example. In the *multiprocessor scheduling problem* the goal is to schedule a set $J = \{j_1, j_2, \dots, j_n\}$ of jobs into a group $M = \{M_1, M_2, \dots, M_m\}$ of m identical machines so that the completion time of the last job, also called the *makespan* of the schedule, is minimized. Each job j_i has a processing time p_i, and every machine can process only one job at a time. Furthermore, we assume that the processing of a job cannot be interrupted (i.e., preemptions are not allowed).

Let us consider a specific instance of the multiprocessor scheduling problem. Let $J = \{j_1, j_2, j_3, j_4, j_5, j_6\}$ with processing times $p_1 = 3$, $p_2 = 2$, $p_3 = 3$, $p_4 = 4$, $p_5 = 2$, and $p_6 = 1$, and $M = \{M_1, M_2, M_3\}$.

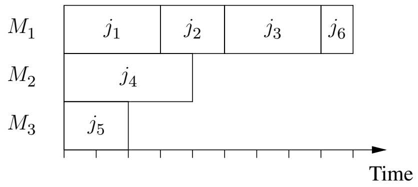

FIGURE 18.1 A schedule for J.

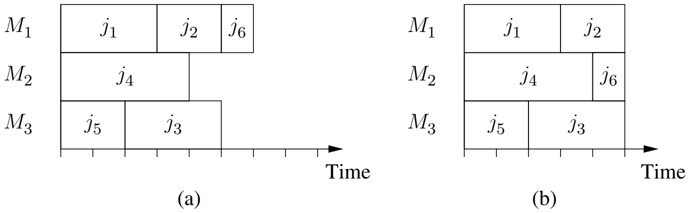

FIGURE 18.2 Local improvements for the solution in Figure 18.1.

A solution for this instance of the multiprocessor scheduling problem is shown in Figure 18.1. Machine M_1 processes jobs j_1, j_2, j_3, and j_6 requiring total processing time $3 + 2 + 3 + 1 = 9$. This is the *load* of machine M_1. The loads of M_2 and M_3 are 4 and 2, respectively. The makespan or length of this schedule is equal to the completion time of the last job, and it is also equal to the maximum machine load, namely 9.

We can make local changes to this solution to try to improve the makespan. For example, we could move a job from one machine with maximum load to a machine with minimum load. If, say, we move j_3 from M_1 to M_3, we get the solution shown in Figure 18.2(a) with makespan 8. As this solution is better than the first one, we keep it and try to further improve it. Now we can move j_6 to M_3 to get the solution depicted in Figure 18.2(b) with makespan 5.

This last solution cannot be improved by moving any one of the jobs to a different machine. In fact, one can show that this is an optimum solution for the problem since the total processing time of all the jobs is 15 and, thus, 3 machines need at least $15/3 = 5$ units of time to process them all.

18.1.1 Local Search and Combinatorial Optimization

Formally, a combinatorial optimization problem Π consists of a collection of instances $(\mathcal{S}, c)$. For each instance $(\mathcal{S}, c)$, $\mathcal{S}$ is the set of *feasible solutions*, and it consists of a family of subsets from a finite ground set E. The second component c of an instance is an objective function $c : \mathcal{S} \to I\!R$. The goal of a combinatorial optimization problem is to find a solution $s^* \in \mathcal{S}$ with minimum or maximum objective value, i.e.,

$$c(s^*) = \underset{s \in \mathcal{S}}{\texttt{optimum}}\, c(s)$$

where `optimum` is either `min` or `max`.

A *neighborhood function* $\mathcal{N} : \mathcal{S} \to 2^{\mathcal{S}}$ specifies for each solution $s \in \mathcal{S}$ a subset $\mathcal{N}(s)$ of neighbors of s, or solutions that are "close" to s. The local search algorithm that we informally described above is called the *iterative improvement* algorithm.

Algorithm IterativeImprovement ($\mathcal{S}$, $\mathcal{N}$, c)

In: Set $\mathcal{S}$ of feasible solutions, neighborhood function $\mathcal{N}$, and objective function c.
Out: A local optimum solution $s \in \mathcal{S}$ with respect to $\mathcal{N}$ and c.

```
1. Compute an initial feasible solution $s \in \mathcal{S}$.
2. while $\mathcal{N}(s)$ contains a better solution than $s$ do {
```

```
3.        Choose a solution $s' \in \mathcal{N}(s)$ with better value $c(s')$ than $c(s)$.
4.        Set $s \leftarrow s'$
  }
5. Output $s$.
```

The solution s computed by the algorithm has the best possible value among all the solutions in its neighborhood $\mathcal{N}(s)$

$$c(s) = \underset{s' \in \mathcal{N}(s)}{\texttt{optimum}}\, c(s') \tag{18.1}$$

Therefore, this solution s is called a *local optimum* with respect to $\mathcal{N}$ and c. The set of local optimum solutions in the feasible solution set $\mathcal{S}$ with respect to a neighborhood function $\mathcal{N}$ and objective function c is denoted as $\mathcal{L}_{\mathcal{N}c}(\mathcal{S})$. A local optimum solution is not necessarily a global optimum solution s^*. To see this, let us consider the same instance of the multiprocessor scheduling problem described above. For a feasible schedule s, the objective function $c(s)$ gives the makespan of the schedule. Let us use the same neighborhood function defined before, i.e., $\mathcal{N}(s)$ includes all solutions that can be obtained from s by moving a single job from a machine with maximum load to one with minimum load. This neighborhood function is called the *jump* of *move* neighborhood [4]. Let the initial solution be as shown in Figure 18.3.

Note that since M_1 and M_2 have maximum load, this solution is local optimum as moving a single job cannot decrease the makespan. The makespan of this local optimum solution is 6, while the global optimum solution of Figure 18.2(b) has makespan 5.

Given a combinatorial optimization problem Π with instances $(\mathcal{S}, c)$ and a local search algorithm A that uses neighborhood function $\mathcal{N}$, we define the *locality gap* α_A of A as the largest possible ratio between the value of a local optimum solution and a global optimum one

$$\alpha_A = \underset{(\mathcal{S},c)\in\Pi}{\texttt{max}} \left\{ \underset{s\in\mathcal{L}_{\mathcal{N}c}(\mathcal{S})}{\texttt{max}} \left\{ \frac{c(s)}{c(s^*)}, \frac{c(s^*)}{c(s)} \right\} : c(s^*) = \underset{s'\in\mathcal{S}}{\texttt{optimum}}\, c(s') \right\} \tag{18.2}$$

Therefore, if an algorithm A can compute in polynomial time a local optimum solution for a combinatorial optimization problem Π with respect to a given neighborhood function, then A is an approximation algorithm for Π with approximation ratio α_A.

18.1.2 The Complexity of Computing Local Optimum Solutions

There is a large number of combinatorial optimization problems and natural neighborhood functions for them, for which we do not know any polynomial-time algorithm for computing local optimum solutions. There has been a lot of research on characterizing the class of problems that admit polynomial-time algorithms for finding local optimum solutions. One of the most notable works in this area is the research by Johnson et al. [5], who introduced the complexity class PLS of Polynomial-time Local Search problems.

This class includes all those problems and associated neighborhood functions which admit polynomial-time algorithms for deciding whether a given feasible solution is locally optimum and, if not, computes a better solution in its neighborhood. There is a reduction among problems in the class PLS which defines a subclass of complete PLS problems. It is unknown whether there exists polynomial-time algorithms for computing local optimum solutions for PLS-complete problems.

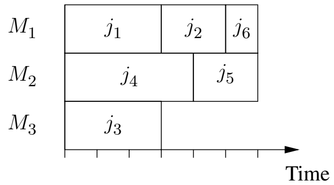

FIGURE 18.3 A local optimum solution with respect to the jump neighborhood and makespan objective function.

If we look closely at the IterativeImprovement algorithm described above, we note that its time complexity is dominated by the number of iterations of the while loop and by the time needed to search the neighborhood for a better solution. Given a combinatorial optimization problem, it is possible to scale the objective function c, so it yields integer values for all feasible solutions. Then, the IterativeImprovement algorithm will terminate in a pseudopolynomial number of iterations, since each iteration improves the value of the solution by an integral amount.

This observation led Orlin et al. [6] to study approximate locally optimum solutions: Given a value $\varepsilon > 0$, a solution s for an instance $(\mathcal{S}, c)$ of a combinatorial minimization problem is an *ε-local optimum* with respect to the neighborhood function $\mathcal{N}$ if

$$c(s) - c(s') \leq \varepsilon c(s') \quad \text{for all } s' \in \mathcal{N}(s)$$

Approximate locally optimum solutions can be defined in a similar manner for maximization problems. In Ref. [6] it is shown that every combinatorial optimization problem with a neighborhood function that can be efficiently searched has a fully polynomial-time algorithm for computing ε-local optimum solutions. This is a very interesting result, since as we show in Section 18.4, ε-local optimum solutions might be shown to be nearly global optimum.

18.1.3 Local Search in Approximation Algorithms

Despite its simplicity, local search has not been extensively used to design approximation algorithms. Among the reasons for this are that computing the locality gap of a local search algorithm is not easy, and for many problems natural local search algorithms have very large locality gaps leading to poor approximation algorithms. Consider, for example, the multiprocessor scheduling problem described above and the jump neighborhood function. Let us consider an instance of the problem, where J consists of an even number $n = km$ of jobs with unit processing times for some integer value $k > 0$, and let M consists of m machines. The solution shown in Figure 18.4 for this instance (half of the jobs are processed on machine M_1 and the other half on M_2) is a local optimum solution as moving a single job cannot decrease the makespan. An optimum solution, however, distributes the jobs evenly among all machines, and so it has makespan k. The locality gap of the IterativeImprovement algorithm with the jump neighborhood function is, then, at least $\frac{km/2}{k} = \frac{m}{2}$.

The problem with a local search algorithm based on the jump neighborhood is that it might get "trapped" in a local optimum solution of value far away from the optimum. If a neighborhood function is such that a local search algorithm always finds a global optimum solution, regardless of the initial solution, such a neighborhood function is called *exact*. For neighborhood functions that are not exact, getting trapped in a local optimum is a big problem, hence various local search techniques have been designed that can move a local search algorithm away from a local optimum solution. Variable-depth search, tabu search, simulated annealing, and genetic algorithms are among these techniques. In this chapter we consider only iterative improvement algorithms, as more complex local search techniques are much harder to analyze. In the sequel "local search" will mean iterative improvement.

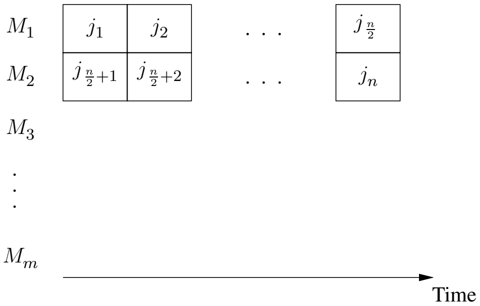

FIGURE 18.4 Instance showing a large locality gap for the jump neighborhood.

When designing an approximation algorithm using local search, if the locality gap of the algorithm with the selected neighborhood function is too large, we can try to improve it by selecting a different neighborhood function, and sometimes (as we show in the next section) by modifying the cost function.

Let us again consider the multiprocessor scheduling problem. Two other neighborhood functions that have been used for designing local search algorithms for this problem are the *swap* and *push* neighborhoods [4]. In the swap neighborhood, two jobs j_i and j_k on different machines are swapped (thus, interchanging their machine allocations). The push neighborhood allows moving a job j_i from its current machine M_j to a different one, M_h, and then it allows to recursively move from M_h those jobs with processing times smaller than p_i. It is not hard to find instances showing that, like the jump neighborhood, these two neighborhood functions have a large locality gap.

We could also define a *k-jump* neighborhood function, where up to k jobs are selected and moved to other machines. By selecting a sufficiently large value for k (e.g., by choosing $k = n$) we guarantee that the neighborhood function is exact and, therefore, that a local search algorithm based on such a neighborhood function will always find optimum solutions. The problem with this function is that given a solution s, the size of its neighborhood $|\mathcal{N}(s)|$ is exponential in k. Therefore, Step 3 of algorithm IterativeImprovement might require time that is exponential in k. The main challenge when designing a good local search approximation algorithm is to select a neighborhood function that yields small enough neighborhoods, so that deciding whether the current solution is a local optimum, or finding a better solution can be done efficiently, and such that the locality gap of the algorithm is small.

Computing the locality gap of a local search algorithm is, in general, not easy. We need to make use of the structural properties of local optimum solutions and relate them to the properties of global optimum solutions. In the next two sections we describe local search approximation algorithms for two NP-hard problems to illustrate this process. Sometimes it is a good idea to use Eq. (18.1) defining a local optimum solution to relate the value of local optimum and global optimum solutions. This idea is used in the last section of this chapter to design an approximation algorithm for the k-median problem.

18.2 An Approximation Algorithm for Multiprocessor Scheduling

As the example in Figure 18.4 shows, a local search algorithm for multiprocessor scheduling based on the jump neighborhood might return a solution that is much worse than the optimum. This happens when the algorithm gets trapped in a local optimum where several machines have the maximum load and the rest of them are idle. As in this case more than one machine has maximum load, moving a single job will not decrease the makespan of the schedule. However, by moving a job from a maximum load machine to an idle one, the number of machines with largest load will decrease. If we continue moving jobs away from machines with maximum load, eventually we might be able to decrease the makespan of the solution.

To force the IterativeImprovement algorithm to continue moving jobs away from machines with largest load, let us define a new objective function c' that assigns to every schedule s a pair $(c(s), d(s))$, where $c(s)$ is the makespan of s and $d(s)$ the number of machines with load $c(s)$. Given two solutions s and s', we let $c'(s) < c'(s)$ if $c(s) < c(s')$ or if $c(s) = c(s')$ and $d(s) < d(s')$.

Given a schedule s, its neighborhood $\mathcal{N}(s)$ has size at most $O(mn)$ since a neighbor of s can be obtained by moving any of the n jobs to any of the $m - 1$ machines which do not process it in s. Furthermore, we show below that the IterativeImprovement algorithm requires $O(n^2)$ iterations to find a local optimum solution. Thus, the time complexity of IterativeImprovement with the jump neighborhood is $O(mn^3)$.

We use the arguments presented in Ref. [7] to bound the number of iterations of the algorithm. Let $C_{\max}(i)$ and $C_{\min}(i)$ denote, respectively, the maximum and minimum machine loads at the beginning of the ith iteration. Let $\Delta(i) = C_{\max}(i) - C_{\min}(i)$. Since every iteration moves a job from a machine with maximum load to a machine with minimum load, then $C_{\max}(i)$ is a monotone nonincreasing function and $C_{\min}(i)$ a monotone nondecreasing function. Therefore, $\Delta(i)$ is also monotone nonincreasing.

We will bound the number of iterations by first bounding the maximum number of times that a job can be moved to other machines. Consider a job j_i that is moved to some machine M_k during the rth iteration. This means that $C_{\min}(r) = \ell(M_k, r)$, where $\ell(M_k, r)$ is the load of M_k at the beginning of the rth iteration. Then, assume that j_i is moved from M_k to some other machine at a later iteration $q > r$; thus, $C_{\max}(q) = \ell(M_k, q)$.

We need to consider two cases:

- Assume that no job is moved to machine M_k between iterations $r + 1$ and q. Then,

$$C_{\max}(q) = \ell(M_k, q) \leq \ell(M_k, r) + p_i = C_{\min}(r) + p_i \leq C_{\min}(q) + p_i$$

  The last inequality follows since $C_{\min}(i)$ is nondecreasing. Therefore,

$$p_i \geq C_{\max}(q) - C_{\min}(q) = \Delta(q)$$

  This implies that job j_i cannot be moved during the qth iteration since by moving j_i to a different machine the value of the objective function c' will not decrease.
- Therefore, at least one job needs to be moved to M_k during iterations $r+1, \ldots, q$. Let j_h be the last one of these jobs, and let j_h be moved to M_k during iteration u. Then, $C_{\min}(u) = \ell(M_k, u)$ and

$$C_{\max}(q) = \ell(M_k, q) \leq \ell(M_k, u) + p_h = C_{\min}(u) + p_h \leq C_{\min}(q) + p_h$$

  Hence,

$$p_h \geq C_{\max}(q) - C_{\min}(q) = \Delta(q)$$

  This implies that job j_h will not move during the following iterations.

From the above arguments, we conclude that a job j_i can move more than once, only if between any two consecutive moves at least one other job j_h gets fixed on some machine from which it will not move any further. Since at most $n - 1$ job movements can use j_h as the job that gets fixed, then the total number of job movements (and, thus, the total number of iterations of the algorithm) is $O(n^2)$.

Theorem 18.1

The IterativeImprovement algorithm with the jump neighborhood function and cost function c' always finds a schedule s with makespan at most $2 - \frac{1}{m}$ times the optimum one.

The proof of this theorem is essentially the same as Graham's proof for the performance ratio of his List scheduling algorithm [8]. Consider an instance $(\mathcal{S}, c)$ of the multiprocessor scheduling problem. The feasible set $\mathcal{S}$ is formed by all possible ways of scheduling the jobs J on the machines M. Let s^* be an optimum solution for this instance and let s be the local optimum solution computed by IterativeImprovement with the jump neighborhood and objective function c' (see Figure 18.5). Let M_i be a machine with maximum load $c(s)$ and let j_r be the last job processed by M_i.

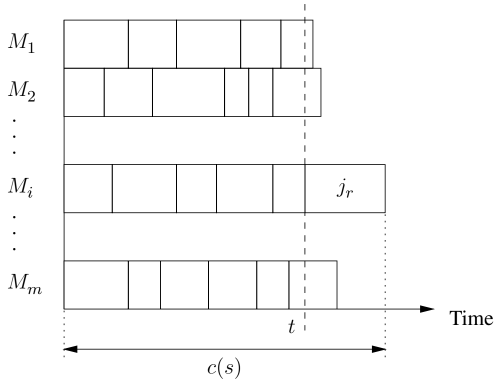

FIGURE 18.5 Solution computed by IterativeImprovement.

Let j_r start processing at time t, so $c(s) = t + p_r$. Since s is a local optimum solution, then every machine has load at least t. To see this, observe that if some machine M_k has load smaller than t, then moving j_r to M_k would decrease the cost $c'(s)$ of the solution. Since every machine's load is at least t, then

$$t \leq \frac{1}{m}\left(\sum_{j_i \in J} p_i - p_r\right) \leq c(s^*) - \frac{1}{m} p_r$$

as no schedule can process all jobs in J in time smaller than $\frac{1}{m}\sum_{j_i \in J} p_i$. Therefore,

$$\begin{aligned} c(s) = t + p_r &\leq c(s^*) - \frac{1}{m} p_r + p_r \\ &= c(s^*) + \left(1 - \frac{1}{m}\right) p_r \\ &\leq c(s^*) + \left(1 - \frac{1}{m}\right) c(s^*) \;\text{ as } p_r \leq c(s^*) \\ &= c(s^*)\left(2 - \frac{1}{m}\right) \end{aligned}$$

18.3 Finding Spanning Trees with Many Leaves

In this section we describe the local search algorithm of Lu and Ravi [9] for the *maximum leaves spanning tree problem*: Given an undirected graph $G = (V, E)$, find a spanning tree of G with maximum number of leaves. This problem is known to be NP-hard and MAX SNP-complete [10]. The algorithm of Lu and Ravi is simply the IterativeImprovement algorithm with the *exchange neighborhood function*, described below. The feasibility space $\mathcal{S}$ for this problem includes all spanning trees of the input graph G. For any spanning tree $s \in \mathcal{S}$, the objective function $c(s)$ gives the number of leaves in s.

Consider a spanning tree s. The exchange neighborhood of s is formed by all spanning trees that differ from s in a single edge, i.e.,

$$\mathcal{N}(s) = \{s' : s' \text{ is a spanning tree of G and } |s \cap s'| = n - 2\}$$

where n is the number of vertices of G. Here we view a spanning tree s as a collection of edges. Let $(u, v) \in E \setminus s$ be an edge that does not belong to the spanning tree s. Let s_{uv} be the unique path in s between vertices u and v. Note that if we add edge (u, v) to s we create a unique cycle, and by removing from this cycle any edge in s_{uv} we create a new spanning tree (see Figure 18.6). Since the path s_{uv} can have at most $n - 1$ edges, then the neighborhood $\mathcal{S}(s)$ of s has size at most $m(n - 1)$, where m is the number of edges in the graph. As this neighborhood function has polynomial size, Step 3 of algorithm IterativeImprovement can be performed in $O(mn)$ time.

Furthermore, each iteration of the algorithm increases the value of the solution s by at least 1. The initial solution s_0 must have at least 2 leaves, so $c(s_0) \geq 2$. Each iteration increases the value of the solution, and

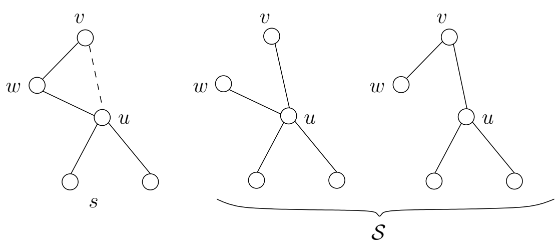

FIGURE 18.6 Neighborhood of spanning tree s. Edge (u, v) does not belong to s.

$c(s)$ cannot exceed $n-1$. Therefore, the maximum number of iterations that the while loop can perform is $n-3$. The time complexity of algorithm IterativeImprovement is, then, $O(mn^2)$. Now, let us compute the locality gap of the algorithm.

Theorem 18.2

The IterativeImprovement algorithm with the exchange neighborhood function has a locality gap of 10.

To prove the theorem we need to recall some basic properties of spanning trees. Let T be a spanning tree of a given graph $G = (V, E)$. A path in T containing only nodes of degree 2 in T is called a 2-*path.* For the rest of this section we use the convention that when referring to a tree T, the *degree* of a vertex u is the degree of u in T (not the degree of u in the graph G). So, for example, if u is a leaf of T we will say that the degree of u is 1.

Property 18.1

The number of nodes $N_3(T)$ of degree at least 3 in a spanning tree T of G is at most the number of leaves in T minus 2, i.e.,

$$N_3(T) \leq c(T) - 2$$

Proof

A spanning tree has maximum number of vertices of degree at least 3 if it is a full binary tree. In a full binary tree the number of leaves is one more than the number of internal nodes. Since in a full binary tree all internal nodes, except the root, have degree 3, then $c(T') = N_3(T') + 2$ for any binary tree T', and so

$$N_3(T) \leq c(T) - 2$$

for any spanning tree T of G. □

Property 18.2

The number $P_2(T)$ of 2-paths in any tree T is at most twice the number of leaves of T minus 3, i.e.,

$$P_2(T) \leq 2c(T) - 3$$

Proof

Let us choose a vertex of degree at least 3 as the root of T. Note that if the tree does not have any vertices of degree larger than 2 then T is a path, so $P_2(T) = 1$ and $c(T) = 2$.

A 2-path in T either connects a leaf or a vertex of degree at least 3 with its unique nearest ancestor of degree at least 3. Thus, every leaf and every node of degree at least 3 (except the root) has associated a unique 2-path, and so

$$P_2(T) \leq c(T) + N_3(T) - 1 \leq 2c(T) - 3$$ □

The last ingredient that we need to prove the theorem is the following lemma that relates the number of leaves in any spanning tree with the number of 2-paths in the local optimum tree s selected by the algorithm IterativeImprovement.

Lemma 18.1

Let T be a spanning tree of a graph $G = (V, E)$ and let s be the tree selected by IterativeImprovement. Let p be a 2-path of s. At most 4 vertices in p can be leaves in T.

Proof

We prove the lemma by contradiction. Assume that there is a 2-path p in s such that at least five of its vertices are leaves in T. Let w_1, w_2, w_3, w_4, and w_5 be five of the leaves of T that belong to p, as shown in Figure 18.7. Note that if two vertices u_i, u_j of p are not adjacent in p, then there cannot be an edge between them in G. This is because if such an edge exists, then adding (u_i, u_j) to s forms a unique cycle (see Figure 18.8); removing any edge of this cycle, other than (u_i, u_j), would increase the number of leaves

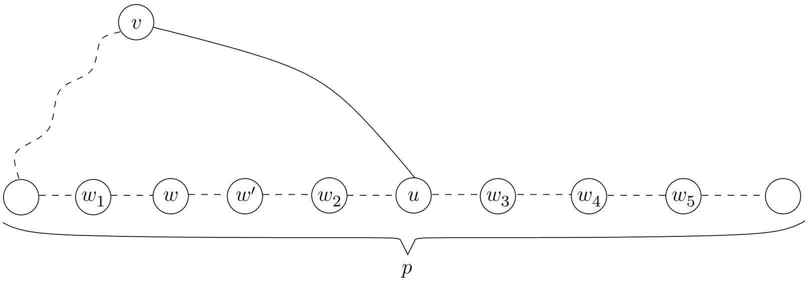

FIGURE 18.7 2-Path p of s. Edge (u, v) does not belong to s.

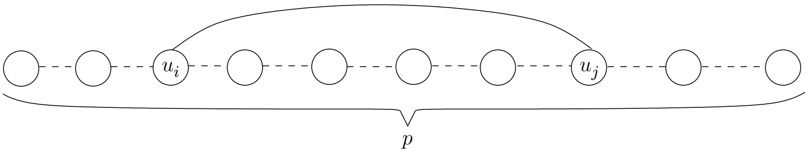

FIGURE 18.8 Cycle formed by the inclusion of edge (u_i, u_j) to p.

of s by 2, contradicting the assumption that s is a local optimum solution with respect to the exchange neighborhood.

Let us pick any vertex r not in p as the root of T. Let (u, v) be the first edge in the path from w_3 to r that does not belong to p (see Figure 18.7). Note that by the above argument, u and v cannot both belong to p. Without loss of generality let v not belong to p. Assume that the path s_{vw_3} in s from v to w_3 goes through vertices w_1 and w_2 (the other case, when such a path goes through w_4 and w_5 is similar). Adding edge (u, v) to s creates a unique cycle. Also, observe that u is an internal vertex in s, and thus, by adding (u, v) to s we decrease the number of leaves of s by at most 1. If we now remove from p any edge (w, w') in the path from w_1 to w_2 we create a new spanning tree s' in which w and w' are leaves, and so $c(s') \geq c(s) + 1$, contradicting the assumption that s is a local optimum solution. □

Now, we are ready to prove the theorem and to show that the IterativeImprovement algorithm with the exchange neighborhood has approximation ratio at most 10. Let s^* be a spanning tree of G with maximum number of leaves. Every leaf of s^* must be either

(a) a leaf of s; the total number of these leaves is at most $c(s)$,
(b) a vertex of degree at least 3 in s; there are at most $N_3(s) \leq c(s) - 2$ of these leaves by Property 18.1, or
(c) a vertex in a 2-path of s; by Lemma 18.1 and Property 18.2, the number of these leaves is at most $4P_2(s) \leq 8c(s) - 12$.

Combining (a)–(c), the number of leaves in s^* is

$$c(s^*) \leq c(s) + c(s) - 2 + 8c(s) - 12 \leq 10c(s)$$

Therefore,

$$\frac{c(s^*)}{c(s)} \leq 10$$

In Ref. [9] it is shown that by using more complex arguments, it can be proven that the locality gap of the algorithm is at most 5. Furthermore, by using a neighborhood function that allows the simultaneous exchange of two tree edges with two nontree edges, Lu and Ravi [9] show that the IterativeImprovement algorithm has locality gap 3.

18.4 Clustering Problems

In a clustering problem we are given a weighted graph $G = (V, E)$ and the goal is to partition the vertices of G into groups or clusters so that a certain objective function is optimized. Two classical clustering problems are the k-median problem and the facility location problem. In the k-median problem it is desired to partition the set of vertices V into k clusters, each with a distinguished vertex called a *center* or *median*, so that the sum of distances from the vertices to their clusters' medians is minimized.

Consider, for example, the weighted graph in Figure 18.9. If $k = 2$, then the two medians in an optimum solution are vertices 3 and 6. These two medians define a partition of the set of vertices, as each vertex must be in the same cluster as its nearest median (ties are broken arbitrarily); thus, the clusters are $\{1, 2, 3, 4, 8\}$ and $\{5, 6, 7, 9\}$. The sum of distances from the vertices to their nearest medians is $1+1+2+3+1+2+3 = 13$. A related problem is the *k-means* [11] problem where the goal is to minimize the sum of squared distances from the vertices to the medians.

In the facility location problem each vertex u of the graph has associated a cost $f(u)$ and the goal is to select a set F of vertices (and, thus, to partition G into $|F|$ clusters) so that the total cost $\sum_{u \in F} f(u)$ of the vertices in F plus the sum of distances from the vertices in $V \backslash F$ to F is minimized. Consider again the same graph of Figure 18.9. If the cost $f(u)$ of each vertex u is 3, then an optimum solution for the corresponding facility location problem is $F = \{3, 6\}$, and the cost of this solution is $3 + 3 + 13 = 19$.

Local search algorithms have been recently used to design good approximation algorithms for a variety of clustering problems including the k-median, k-means, and facility location problems [11–14]. In the next section we describe the algorithm of Arya et al. [15] for the metric version of the k-median problem.

18.4.1 Local Search Algorithm for the *k*-Median Problem

Consider a weighted graph $G = (V, E)$ in which the edge weight function $d : E \rightarrow \mathbb{R}$ satisfies the triangle inequality, i.e., for any three vertices $u, v, w \in V$, $d(u, v) + d(v, w) \geq d(u, w)$. The *metric k-median problem* is the k-median problem restricted to weighted graphs with weight functions that satisfy the triangle inequality.

Since a feasible solution for the k-median problem is a set $s \subseteq V$ of k vertices, the feasible set $\mathcal{S}$ consists of all subsets of k vertices. A natural way of defining the neighborhood of a solution s is through the use of the *swap operation.* A swap operation replaces one vertex in s with a vertex in $V \backslash s$, so $\mathcal{N}(s) = \{s' : s' = (s \backslash \{u\}) \cup \{v\}$ for every $u \in s$, $v \in V \backslash s\}$. For notational simplicity we denote the set $(s \backslash \{u\}) \cup \{v\}$ as $s - u + v$. The objective function $c(s) = \sum_{u \in V} d(u, s)$ gives the sum of distances from the vertices to the medians in the solution s. The distance $d(u, s)$ from a vertex u to the set s is defined as the distance from u to its closest median in the set s.

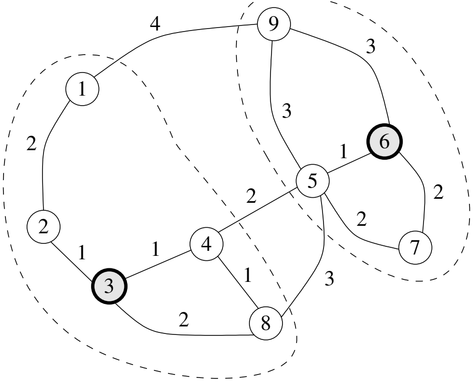

FIGURE 18.9 Clustering the vertices around vertices 3 and 6.

The size of the neighborhood $\mathcal{N}(s)$ of a solution s is $k(n-k)$. However, the number of iterations of the algorithm might not be polynomial in the size of the input. We show in the next section how to overcome this problem.

Theorem 18.3

The IterativeImprovement algorithm with the swap neighborhood has a locality gap of 5.

Let $s = \{s_1, s_2, \ldots, s_k\}$ be the solution computed by the algorithm. This set partitions the vertices V into k clusters $V_1, V_2, \ldots, V_k$, where all vertices in cluster V_i are closer to s_i than to any other median in s (ties are broken arbitrarily). Let $s^* = \{s_1^*, s_2^*, \ldots, s_k^*\}$ be an optimum solution, and let $V_1^*, V_2^*, \ldots, V_k^*$ be the partition induced by s^*. For any vertex $u \in V$ let $V_{\sigma(u)}$ denote its cluster in s and let $s_{\sigma(u)}$ be the median in cluster $V_{\sigma(u)}$. Then, the value $c(s)$ of solution s is $c(s) = \sum_{u \in V} d(u, s_{\sigma(u)})$.

Note that since s is a local optimum solution, then no swap operation can improve its value, i.e., for any pair of vertices $s_i \in s$, $v \in V \backslash s$,

$$c(s - s_i + v) \geq c(s) \tag{18.3}$$

To prove Theorem 18.3, first we will pair each median $s_i^* \in s^*$ with some median $\rho(s_i^*) \in s$ in such a way that no vertex in s is paired with more than two vertices of s^*. The pairing relation ρ is specified below. By inequality (18.3), for every vertex $s_i^* \in s^*$,

$$c(s - \rho(s_i^*) + s_i^*) - c(s) \geq 0 \tag{18.4}$$

and this inequality holds regardless of whether s_i^* is in s or not.

Observe that $c(s - \rho(s_i^*) + s_i^*)$ and $c(s)$ differ only by the contributions made by those vertices in $\rho(s_i^*)$'s cluster and s_i^*'s cluster to the values of the two solutions, as shown in Figure 18.10. Therefore,

$$0 \leq c(s - \rho(s_i^*) + s_i^*) - c(s) \leq \sum_{u \in V_i^*} (d(u, s^*) - d(u, s)) + \sum_{v \in V_{\sigma(\rho(s_i^*))} \backslash V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s)) \tag{18.5}$$

Adding inequalities (18.5) over all medians $s_i^* \in s^*$, we get

$$\begin{aligned} 0 &\leq \sum_{s_i^* \in s^*} (c(s - \rho(s_i^*) + s_i^*) - c(s)) \\ &\leq \sum_{s_i^* \in s^*} \sum_{u \in V_i^*} (d(u, s^*) - d(u, s)) + \sum_{s_i^* \in s^*} \sum_{v \in V_{\sigma(\rho(s_i^*))} \backslash V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s)) \end{aligned} \tag{18.6}$$

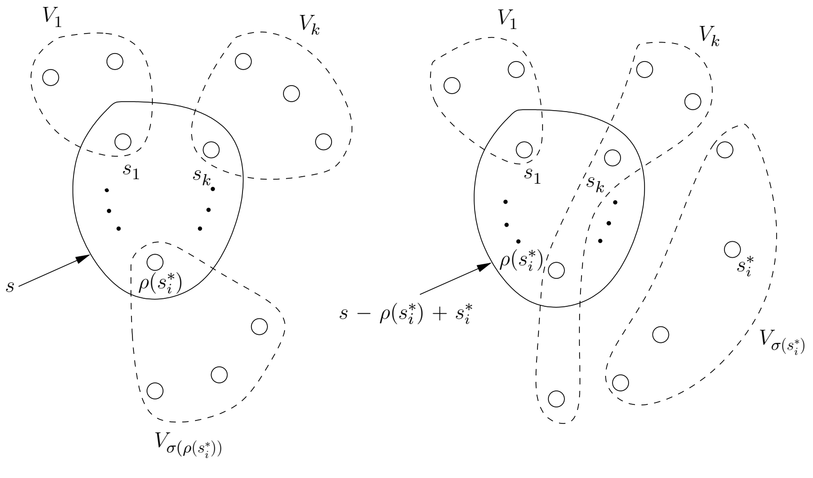

FIGURE 18.10 Solutions s and $s - \rho(s_i^*) + s_i^*$.

Let us look closely at the first term on the right-hand side of this last inequality. Since $\cup_{i=1}^{k} V_i^* = V$, then

$$\sum_{s_i^* \in s^*} \sum_{u \in V_i^*} (d(u, s^*) - d(u, s)) = \sum_{u \in V} d(u, s^*) - \sum_{u \in V} d(u, s) = c(s^*) - c(s) \tag{18.7}$$

The second term in the last inequality of (18.6) is more complicated, so we will spend most of the rest of this section showing that

$$\sum_{s_i^* \in s^*} \sum_{v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s)) \leq 4c(s^*) \tag{18.8}$$

Combining Eqs. (18.6)–(18.8) we get

$$0 \leq c(s^*) - c(s) + 4c(s^*) = 5c(s^*) - c(s)$$

From which it follows that

$$\frac{c(s)}{c(s^*)} \leq 5$$

as Theorem 18.3 claims. It just remains to prove inequality (18.8). The proof in Ref. [15] for the validity of this inequality is an elegant argument that exploits the fact that the edge weights satisfy the triangle inequality. First, let us define the relation ρ. We partition the set s of k medians into three groups, A_s, B_s, and C_s, as follows:

$$\begin{aligned} A_s &= \{s_i \in s : |V_i \cap V_j^*| \leq \frac{1}{2}|V_j^*| \text{ for all clusters } V_j^*,\ 1 \leq j \leq k\} \\ B_s &= \{s_i \in s : |V_i \cap V_j^*| > \frac{1}{2}|V_j^*| \text{ for exactly one cluster } V_j^*,\ 1 \leq j \leq k\} \\ C_s &= s \backslash (A_s \cup B_s) \end{aligned}$$

Observe that set B_s associates exactly one vertex s_j^* with each vertex $s_i \in B_s$. For each $s_i \in B_s$, we define the relation ρ as follows:

$$\rho(s_j^*) = s_i, \quad \text{where } s_j^* \text{ is such that } |V_i \cap V_j^*| > \frac{1}{2}|V_j^*|$$

For the remaining $|s| - |B_s|$ medians in s^*, the relation ρ associates them to vertices in A_s. Vertices in C_s are not mapped to any of the medians in the optimum solution. Note that for every vertex $s_i \in C_s$ there are at least two medians s_j^*, s_ℓ^* whose clusters share at least half of their vertices with s_i's cluster. Therefore, $|C_s| < \frac{1}{2}(|s| - |B_s|)$ and so $|A_s| \geq \frac{1}{2}(|s| - |B_s|)$.

Let $A_s = \{s_0, s_1, \ldots, s_{|A_s|-1}\}$ and let the, still, unmapped medians in s^* be $U^* = \{s_0^*, s_i^*, \ldots, s_{|s|-|B_s|-1}^*\}$. Then, for all $s_j^* \in U^*$ we define

$$\rho(s_j^*) = s_{j \bmod |A_s|}$$

Note that at most two medians of s^* are mapped to the same vertex of s.

Consider a pair $(\rho(s_i^*), s_i^*)$, and the swap operation that exchanges these two vertices transforming the solution s into $s - \rho(s_i^*) + s_i^*$. As Figure 18.10 shows, this swap modifies some of the clusters by reassigning some of the vertices in $V_{\sigma(\rho(s_i^*))}$ and V_i^*. The change in the cost of the solution (see inequality [18.5]) is

$$\sum_{u \in V_i^*} (d(u, s^*) - d(u, s)) + \sum_{v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s))$$

To find an upper bound for this value, we define a 1-1 and onto function $\pi : V \rightarrow V$ that for every median $s_i^* \in s^*$ maps vertices in its cluster V_i^* to V_i^*. The function is defined as follows. Fix a vertex $s_i^* \in s^*$. Sort the vertices in cluster V_i^* so that vertices in $V_i^* \cap V_j$ appear before vertices in $V_i^* \cap V_\ell$ for all

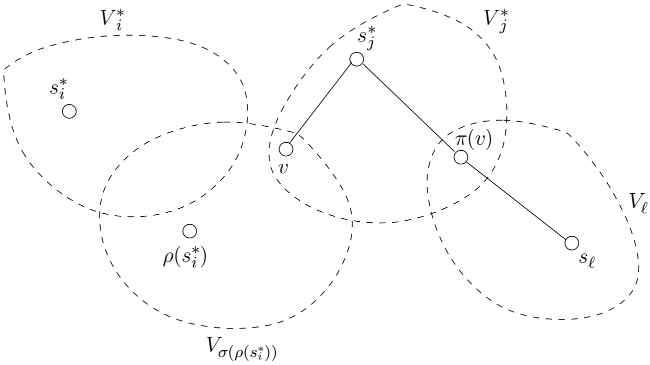

FIGURE 18.11 Reassigning vertices from $V_{\sigma(\rho(s_i^*))}$.

$1 \le j < \ell \le k$. Index the vertices in V_i^* in this order starting at 0. Let the vertices indexed in this manner be $v^*_{i0}, v^*_{i1}, \ldots, v^*_{i(p-1)}$, where $p = |V_i^*|$. Now, define

$$\pi(v^*_{ij}) = v^*_{ir}, \quad \text{where } r = \left(i + \left\lfloor \frac{p}{2} \right\rfloor\right) \bmod p, \quad \text{for all } 0 \le j \le d-1$$

Note that even when we do not know the optimum solution s^*, we know that such solution exists and, thus, this function also exists. Consider a vertex $v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*$ as depicted in Figure 18.11. Let v belong to cluster V_j^* in the optimum solution. Since $|V_{\sigma(\rho(s_i^*))} \cap V_j^*| \le \frac{1}{2}|V_j^*|$, then by the definition of π, we know that $\pi(v) \notin V_{\sigma(\rho(s_i^*))}$ and, thus, in solution s this vertex $\pi(v)$ belongs to some cluster $V_\ell \ne V_{\sigma(\rho(s_i^*))}$.

Since the swap operation that exchanges $\rho(s_i^*)$ and s_i^*, removes only one vertex, $\rho(s_i^*)$, from s, then $s_\ell \in s - \rho(s_i^*) + s_i^*$. Therefore,

$$d(v, s - \rho(s_i^*) + s_i^*) \le d(v, s_\ell)$$

Then, by the triangle inequality (see Figure 18.11),

$$\begin{aligned} d(v, s - \rho(s_i^*) + s_i^*) &\le d(v, s_\ell) \\ &\le d(v, s_j^*) + d(s_j^*, \pi(v)) + d(\pi(v), s_\ell) \\ &= d(v, s^*) + d(\pi(v), s^*) + d(\pi(v), s) \end{aligned}$$

Adding these inequalities for all vertices s_i^* as required on the left-hand side of Eq. (18.8) yields

$$\begin{aligned} &\sum_{s_i^* \in s^*} \sum_{v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s)) \\ &\quad \le \sum_{s_i^* \in s^*} \sum_{v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*} ((d(v, s^*) + d(\pi(v), s^*) \\ &\quad + d(\pi(v), s) - d(v, s)) \end{aligned}$$

Since $\cup_{s_i^* \in s^*} (V_{\sigma(\rho(s_i^*))} \setminus V_i^*) \subseteq V$ and ρ associates at most two vertices from s^* with any vertex in s, then

$$\begin{aligned} &\sum_{s_i^* \in s^*} \sum_{v \in V_{\sigma(\rho(s_i^*))} \setminus V_i^*} (d(v, s^*) + d(\pi(v), s^*) + d(\pi(v), s) - d(v, s)) \\ &\quad \le 2 \sum_{v \in V} (d(v, s^*) + d(\pi(v), s^*) \\ &\quad + d(\pi(v), s) - d(v, s)) \end{aligned}$$

Recall that the function π is 1-1 and onto, therefore,

$$\sum_{v\in V} d(v, s^*) = \sum_{v\in V} d(\pi(v), s^*) = c(s^*) \text{ and}$$
$$\sum_{v\in V} d(\pi(v), s) = \sum_{v\in V} d(v, s) = c(s)$$

Combining these inequalities yields

$$\sum_{s_i^*\in s^*} \sum_{v\in V_{\sigma(\rho(s_i^*))}\setminus V_i^*} (d(v, s - \rho(s_i^*) + s_i^*) - d(v, s)) \le 4c(s^*)$$

as required.

18.4.2 Approximate Local Optimum Solutions

Even when the locality gap of the above algorithm is at most 5, it is not an approximation algorithm, as the number of iterations needed by IterativeImprovement to find a local optimum solution might be superpolynomial. This is because the algorithm might potentially select as intermediate solutions a large fraction of all the subsets of k vertices in the input graph G.

To fix this problem we can change the stopping condition of the IterativeImprovement algorithm so it finishes as soon as it finds an approximate local optimum solution, i.e., when the solution s is such that every neighboring solution $s' \in \mathcal{N}(s)$ has value

$$c(s') > (1-\varepsilon)c(s)$$

for some accuracy $\varepsilon > 0$. By changing in this manner the condition of the while loop in Step 2 of the algorithm, we ensure that in each iteration the value of the solution decreases by at least a factor of $1-\varepsilon$. Therefore, the maximum number of iterations is $\log(c(s_0)/c(s^*))/\log(\frac{1}{1-\varepsilon})$, which is polynomial in the size of the input; s_0 is the initial solution selected in Step 1.

If we change the algorithm as described above, the analysis needs to change also, since now condition (18.4) does not hold, but the following one does:

$$c(s - \rho(s_i^*) + s_i^*) \ge (1-\varepsilon)c(s) \quad \text{for all } s_i^* \in s^*$$

Using this inequality in our analysis gives only a slight worsening in the locality gap (and, thus on the approximation ratio) of the algorithm, as now

$$\frac{c(s)}{c(s^*)} \le \frac{5}{1-3\varepsilon}$$

Arya et al. [15] show that by using the *p-swap* neighborhood which puts in the neighborhood $\mathcal{N}(s)$ of a solution s any subset s' of k vertices that differs from s in at most p vertices, the IterativeImprovement algorithms has locality gap $(3 + 2/p)$. To the date when this paper was written this was the best known approximation algorithm for the metric k-median problem.

Thomas Stützle
Free University of Brussels

19.1 Introduction

Stochastic local search (SLS) algorithms are among the most successful techniques for solving computationally hard problems from computing science, operations research and various application areas; examples range from propositional satisfiability, routing and scheduling problems to genome sequence assembly, protein structure prediction and winner determination in combinatorial auctions. Because of their versatility and excellent performance in combination with the fact that efficient implementations can often be achieved relatively easily, SLS methods enjoy an ever-increasing popularity among researchers and practitioners.

Local search techniques have a long history; they range from simple constructive and iterative improvement algorithms to rather complex methods that require significant fine-tuning, such as evolutionary algorithms (EAs) or simulated annealing (SA). The key idea behind local search is to iteratively expand or improve a current candidate solution by means of small modifications. Most local search algorithms make use of randomised decisions, for example, in the context of generating initial solutions or when determining search steps, and are therefore referred to as *stochastic local search algorithms.* (It may be noted that formally, deterministic local search algorithms can be seen as special cases of SLS algorithms, since deterministic decisions can be modelled using degenerate probability distributions.) To define an SLS algorithm, the following components have to be specified. (A formal definition can be found in Chapter 1 of the book by Hoos and Stützle [1].)

Search space: the set of *candidate solutions* (or *search positions*) for the given problem instance; candidate solutions typically consist of a number of discrete *solution components.*

Solution set: specifies all search positions that are considered to be (feasible) solutions of the given problem instance.

Neighbourhood relation: specifies the direct neighbours of each candidate solution s, i.e., the search positions that can be reached from s in one search step.

Memory states: used to hold information about the search mechanism beyond the search position (e.g., tabu tenure of solution components in tabu search (TS), or temperature in SA); there may be only a single, constant state in the case of algorithms that do not use memory, such as simple iterative improvement.

Initialisation function: specifies search initialisation in the form of a probability distribution over initial search positions and memory states.

```
Stochastic Local Search:
    determine initial search state
    While termination criterion is not satisfied:
        perform search step
        if necessary, update incumbent solution
    return incumbent solution or report failure
```

FIGURE 19.1 General outline of an SLS algorithm.

Step function: determines the computation of search steps by mapping each search position and memory state to a probability distribution over its neighbouring search positions and memory states.

Termination predicate: used to decide search termination based on the current search position and memory state.

Based on these components, SLS algorithms work as illustrated in Figure 19.1. When applied to optimisation problems, whose definition comprises an objective function that specifies the quality of solutions, SLS algorithms need to keep track of the best solution encountered during the search process, the so-called *incumbent solution*. For decision problems, the search process is usually terminated as soon as a solution for the given problem instance is found, and repeated updating of an incumbent solution is not required.

Among the components underlying any SLS algorithm, the neighbourhood relation and the step function are particularly important. Typically, neighbourhood relations have to be defined in a problem-specific way, and it is often difficult to predict which of the various choices that can be made in this context will result in the best performance. However, standard types of neighbourhood relations exist; particularly widely used are the so-called *k-exchange neighbourhoods*, in which two candidate solutions are direct neighbours if and only if they differ in at most k solution components. As an example, consider the 2-exchange neighbourhood for the (symmetric) travelling salesman problem (TSP), under which two candidate solutions are direct neighbours if one can be obtained from the other by replacing two edges of s by two alternate edges (see Figure 19.2). Every neighbourhood relation induces a *neighbourhood graph*, whose vertex set corresponds to the given search space, and in which each pair of neighbouring search positions is connected by an edge. Many important properties of the neighbourhood relation are reflected in the neighbourhood graph; for example, k-exchange neighbourhoods induce symmetric, k-regular neighbourhood graphs.

The step function defines how the search process moves from one search state to the next, where a *search state* is a combination of a search position and a memory state. Search steps are usually defined by means of a procedure that draws a sample from the probability distribution determined by the underlying step function; similar procedural specifications are used for the initialisation function and termination predicate. The search process is typically guided by an *evaluation function* that is used to heuristically assess or rank candidate solutions. For combinatorial optimisation problems, the objective function (which is part of the problem definition) is often also used as an evaluation function. In the case of combinatorial decision problems, however, there can be considerable freedom in choosing an appropriate evaluation function. Furthermore, some SLS methods use multiple evaluation functions or modify the evaluation function while searching. (For this reason, we do not explicitly specify a single evaluation function as a component of our formal definition of an SLS algorithm.)

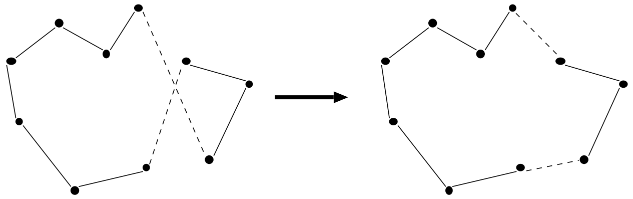

FIGURE 19.2 Example of a 2-exchange step for the symmetric TSP.

The concept of SLS, as defined above, provides a unifying framework for many different types of algorithms. In particular, it captures constructive algorithms, whose search space contains partial solutions of a given problem, i.e., candidate solutions that can be extended by adding solution components (such as edges in the case of the TSP). Consequently, search methods that are strongly based on constructive search procedures, such as greedy randomised adaptive search procedures (GRASP) [2,3] or ant colony optimisation (ACO) [4,5], fall under the general SLS framework. Similarly, population-based algorithms, which operate on ensembles of candidate solutions, are covered by our definition by considering search positions to consist of sets of individual candidate solutions. Note that in this case, step functions can be defined to model operations on populations, such as recombination in the case of EAs (see also Chapter 2 of Hoos and Stützle's book [1]).

Many SLS algorithms are based on generic methods for controlling and directing a simpler, subsidiary search process (such as an iterative improvement procedure, see Section 19.2), and substantial research efforts have been focused on the development and study of such general SLS methods, which are also commonly known as *metaheuristics* [6]. While high-level search strategies and mechanisms provide an important basis for developing SLS algorithms for a broad range of problems, it is important to keep in mind that other aspects, including the choice of the search space and neighbourhood relation as well as techniques for the efficient implementation of local search steps, are also crucial ingredients of high-performance SLS algorithms. Research in the area of SLS comprises all aspects of the design, implementation and analysis of SLS algorithms.

The remainder of this chapter provides an overview of widely used SLS methods for discrete combinatorial problems, including iterative improvement techniques (Section 19.2); so-called "simple" SLS methods (Section 19.3), including SA and tabu search, as well as the less widely known method of dynamic local search (DLS); hybrid SLS methods (Section 19.4), such as iterated local search (ILS) and GRASP; and population-based SLS methods (Section 19.5), in particular, ACO and EAs. The chapter closes with a brief discussion of some general issues and interesting research directions in the area of SLS.

19.2 Iterative Improvement

One of the most basic SLS methods is based on the idea of iteratively improving a candidate solution of the given problem with respect to an evaluation function. More precisely, the search is started from some initial position, and in each search step, the current candidate solution s is replaced with a neighbouring candidate solution s' with better evaluation function value. The search is terminated when a *local minimum* is reached, i.e., a candidate solution s with $g(s) \leq g(s')$ for all direct neighbours s' of s, where g is the evaluation function that is to be minimised. This SLS method is called *iterative improvement*; it is also known as *iterative descent* or *hill climbing* (the latter is motivated by an equivalent formulation where a given evaluation function is to be maximised).

Iterative improvement algorithms find local optima of a given evaluation function. Since local optima are defined with respect to a given neighbourhood relation N, it is quite obvious that the choice of N is of crucial importance for the performance of any iterative improvement procedure. While the use of larger neighbourhoods results in better quality local optima, the time complexity of determining improving search steps increases with neighbourhood size. For example, in the commonly used k-exchange neighbourhoods, each search position has $\mathcal{O}(n^k)$ direct neighbours (where n is the number of solution components in each candidate solution), i.e., the neighbourhood size is exponential in k, and the same holds for the time required for identifying improving neighbours in the worst case. This leads to a general trade-off between solution quality and run time of iterative improvement algorithms. In practice, search steps with quadratic or cubic time complexity can already lead to prohibitively high computation times when solving large problem instances.

The time complexity of local search steps can be significantly reduced using two generic techniques. Firstly, *caching and incremental updating techniques* can be used to significantly reduce the often considerable cost of computing from scratch the evaluation function values of all neighbours of the current search position in each search step. Instead, these values are stored and updated based on the actual effects of each search step (see also Chapter 1 of the book by Hoos and Stützle [1]). Secondly, the size of large neighbourhoods can be substantially reduced by excluding from consideration neighbours of the current candidate solution that are provably or likely nonimproving. Such *neighbourhood pruning techniques* have a long history; they include fixed radius searches, nearest neighbour lists, the use of so-called "don't look bits" in the context of the TSP [7], and reduced neighbourhoods in the case of the job-shop scheduling problem [8]. These techniques are essential for the design of high-performance SLS algorithms based on large neighbourhoods, but they can also lead to significant performance improvements when used in combination with smaller neighbourhoods.

Another factor that has a significant influence on the speed and performance of an iterative improvement algorithm is the mechanism used for determining the search steps—the so-called *pivoting rule* [9]. The two most widely used pivoting rules are best improvement and first improvement. *Iterative best improvement* chooses in each step one of the neighbouring search positions that results in a maximal possible improvement of the evaluation function value; ties can be broken randomly, based on the order in which the neighbourhood is examined or by using secondary criteria. *Iterative first improvement* examines the neighbourhood in some predefined order and performs the first improving search step encountered during this inspection. Clearly, the local optima found by this method depend on the order in which the neighbourhood is scanned. Instead of using predefined, fixed orders, it can be beneficial to examine the neighbourhood in random order, and repeated runs of such random-order first-improvement algorithms are often able to identify many different local optima, even when started from the same initial position [1].

Iterative first improvement usually requires more steps than iterative best improvement to reach local optima of comparable quality, but the individual improvement steps are typically found much faster, since in many cases, they do not require inspection of the entire neighbourhood. However, best-improvement algorithms often benefit more significantly from caching and incremental updating strategies, and as a result, are not always slower than first-improvement algorithms in reaching a local minimum. It may also be noted that to identify a candidate solution as a local optimum both, first- and best-improvement algorithms need to inspect the entire local neighbourhood; the time required for this final check (the so-called check-out time) can be reduced using "don't look bits" [7,10].

An interesting way of achieving a good trade-off between neighbourhood size and time complexity of local search steps is to use multiple neighbourhood relations. *Variable neighbourhood descent* (VND), a variant of a more general SLS method called variable neighbourhood search (VNS) [11,12], is an iterative improvement method that switches systematically between several neighbourhood relations N_1, N_2, ..., N_k, which are typically ordered according to increasing size. Starting from an initial candidate solution, VND performs iterative improvement using N_1. Once a local optimum w.r.t. N_1 is found, the search is continued in N_2. Generally, whenever a local optimum of N_i has been found, VND switches to N_{i+1}. However, as soon as an improvement has been achieved in any neighbourhood N_i (with $i > 1$), the search is continued using N_1. The idea underlying this mechanism is to use small neighbourhoods (which can be searched most efficiently) whenever possible. Variable neighbourhood descent terminates when a local optimum of N_k has been found. Empirical results have shown that VND algorithms are often significantly more efficient in finding high-quality local optima than simple iterative improvement algorithms using large neighbourhoods. It may be noted that other variants of the more general approach of variable neighbourhood search, such as basic VNS or skewed VNS [11,12], are conceptually more closely related to ILS (see Section 19.4).

Finally, a number of SLS algorithms use *very large-scale neighbourhoods* [13], whose size is often exponential in the size of the given problem instance. This type of neighbourhood usually has to be searched heuristically, which is the case in variable-depth search [14,15] and ejection chain algorithms [16]. However, there are specially structured neighbourhoods that can be searched exactly and efficiently using network-flow techniques or dynamic programming [17–21]. For an overview of these techniques we refer to Chapter 20 of this book.

19.3 “Simple” SLS Methods

Iterative improvement algorithms terminate when they reach a local optimum of the given evaluation function. In the following, we discuss several approaches that allow SLS algorithms to escape from local optima by occasionally accepting worsening search steps. The methods discussed in this section are “simple” in the sense that they are usually based on a single, fixed neighbourhood relation.

Randomised Iterative Improvement

One of the simplest ways to allow worsening search steps is to occasionally move to a randomly chosen neighbouring search position. In randomised iterative improvement (RII), this idea is implemented by switching probabilistically between two types of search steps within the same neighbourhood structure: iterative improvement steps and so-called *uninformed random walk steps*, in which a neighbour is chosen uniformly at random. More precisely, in each search step, an uninformed random walk step is performed with probability w_p, and an iterative improvement step is performed otherwise (i.e., with probability $1 - w_p$). The parameter w_p is called *walk probability* or *noise parameter*. Using this mechanism, arbitrarily long sequences of random walk steps can be performed, where the probability of r consecutive random walk steps is w_p^r. Extending an iterative improvement algorithm into an RII algorithm typically requires only few lines of code and introduces only one parameter. Despite their conceptual simplicity, RII algorithms can perform quite well; for example, they have provided the basis for GSAT with random walk, a well-known algorithm for the propositional satisfiability problem (SAT) [22]. However, there are relatively few RII algorithms, perhaps because more complex SLS algorithms often achieve better performance.

Probabilistic Iterative Improvement

Random walk steps, as performed in RII, may lead to significant deteriorations in evaluation function value. An attractive alternative is to base the acceptance of a worsening search step on the change in evaluation function caused by it; this is the key idea behind probabilistic iterative improvement (PII). At each step, PII selects a neighbouring candidate solution according to a function $p(g, s)$, which determines a probability distribution over the neighbourhood of S taking into account the evaluation function g. In practice, samples of this probability distribution can be taken as follows: first, a neighbour s' of the current search position s is selected uniformly at random; then, a decision is made whether s' is accepted as the new current search position. When minimising g, the probability of accepting s', $p_{accept}(T, s, s')$, is in many cases based on the following probability function:

$$p_{accept}(T, s, s') := \begin{cases} 1 & \text{if } g(s') < g(s) \\ \exp\left(\frac{g(s)-g(s')}{T}\right) & \text{otherwise} \end{cases} \tag{19.1}$$

where T is a parameter that determines the degree to which worsening search steps are likely to be accepted. This so-called *Metropolis condition* is frequently used in SA algorithms (discussed in the following), and in this context, the parameter T is called *temperature*. In fact, PII with the Metropolis condition is equivalent to constant-temperature SA, which has been shown to perform well if suitable temperature values are used [23,24].

Simulated Annealing

A natural generalisation of PII with the Metropolis condition is obtained by modifying the parameter T during the search; for example, by gradually decreasing T, the search process becomes increasingly greedy. This is the key idea underlying SA, an SLS method that is inspired by the annealing process of solids, and which has been independently proposed by Kirkpatrick et al. [25] and Cerný [26].

In each step of a standard SA algorithm, first, a neighbour s' of the current candidate solution s is chosen using a *proposal mechanism* (in the simplest case, this can be a uniform random choice from the local neighbourhood of s); next, a parameterised probabilistic *acceptance criterion* (e.g., the Metropolis condition—see Eq. (19.1)) is used to decide whether to perform a search step from s to s'. The way in which the temperature parameter T is modified during the search process is determined by the *annealing schedule*, a function that defines for each search step i a temperature value $T(i)$. Annealing schedules are usually specified in the form of an initial temperature T_0, the number of search steps performed at each temperature value (this is often chosen as a multiple of the neighbourhood size) and a temperature update scheme (e.g., geometric cooling according to $T_{k+1} := \alpha \cdot T_k$, where α is a parameter between 0 and 1). Obviously, the performance of an SA algorithm is highly dependent on its annealing schedule. SA algorithms frequently use special termination conditions, such as the *acceptance ratio* (i.e., the ratio of accepted versus proposed search steps) or the number of subsequent temperature values that have been used since the last improvement in the incumbent solution has been achieved.

Simulated annealing is one of the earliest and most prominent generic SLS methods. SA algorithms have been applied to a wide range of combinatorial problems; they have also been intensely studied analytically (giving rise to some interesting results, such as proofs regarding the convergence to optimal solutions) and experimentally. Many variants of SA have been proposed and studied, such as threshold accepting, where the probabilistic acceptance criterion is replaced by a deterministic mechanism [27]. For a more detailed discussion on SA we refer to Chapter 25 of this book.

Tabu Search

Differently from the previously discussed SLS methods, TS makes direct and systematic use of memory to guide the search process [28]. The key idea behind *simple* TS, the most basic TS variant, is to use short-term memory to prevent a subsidiary iterative improvement procedure from returning to recently visited search positions, which allows the search process to escape from local optima of the given evaluation function. When performing iterative improvement steps, only *permissible neighbours* of the current candidate solution are considered, i.e., neighbouring search positions that are not declared tabu. The tabu memory is updated after each search step, such that search steps cannot be undone for a fixed amount of time (*tabu tenure*). Typically, the tabu mechanism is implemented by storing with each solution component the time (in terms of step number) when it was last used in the current candidate solution, and to only permit solution components to be introduced by a search step for which the difference between this time stamp and the current time exceeds the tabu tenure. For example, in a simple TS algorithm based on the 2-exchange neighbourhood for the TSP, the edges removed in a 2-exchange step may not be reintroduced for *tt* subsequent search steps, where *tt* is the tabu tenure parameter. Many simple TS algorithms use an *aspiration criterion*, which allows a search step to a nonpermissible neighbour if it leads to an improvement in the incumbent solution.

The performance of simple TS algorithms can be very impressive, but usually depends strongly on the value of the tabu tenure parameter. Several extensions have been proposed that adjust the tabu tenure while running the search process; the best known example is reactive TS [29] (see also Chapter 21). Furthermore, additional intermediate and long-term memory mechanisms can be used to further improve the effectiveness of simple TS. These mechanisms aim to either intensify the search in particular regions of the search space or to diversify the search to prevent stagnation. For a detailed description of these techniques, we refer to the book by Glover and Laguna [28]. More detailed information on TS can also be found in Chapter 23 of this book.

Dynamic Local Search

A different approach for escaping from local optima provides the basis for DLS: Rather than explicitly using worsening search steps, DLS modifies the given evaluation function whenever its subsidiary local search procedure encounters a local optimum. More precisely, DLS works as follows. Initially, a subsidiary local search algorithm, typically an iterative improvement procedure, is executed until a local optimum s is encountered. At this point, the evaluation function is modified such that s is no longer a local optimum. Then, the subsidiary local search is run again until it reaches a local optimum of the modified evaluation function, at which point, further modifications of the evaluation function are performed. These phases of local search followed by evaluation function modifications are repeated until a termination criterion is satisfied.

The modifications to the evaluation function are typically achieved by means of *penalty weights* that are associated with individual solution components. The augmented evaluation function effectively used by the subsidiary local search algorithm is then of the form

$$g_p(s) := g(s) + \sum_{i \in C(s)} penalty(i) \tag{19.2}$$

where $g(s)$ is the original evaluation function, $C(s)$ the set of solution components of candidate solution s, and $penalty(i)$ the penalty of solution component i of s. At the beginning of the search process, all penalties are set to zero. DLS algorithms mainly differ in the way the penalty update is performed, for example, the usage of additive versus multiplicative increments or the selection of the solution components whose penalties are increased. Typically, when a local optimum s is encountered, penalties are only increased for solution components occurring in s. For example, in guided local search (GLS), a well-known family of DLS algorithms [30,31], the following penalty update mechanism is used. When encountering a local minimum s of g_p, GLS computes a utility value $u(i) := g_i(s)/(1+penalty(i))$ for each solution component i of s, where $g_i(s)$ is the contribution of i to the original evaluation (or objective) function. (For example, in the case of the TSP, the solution components are typically edges of the given graph, and $g_i(s)$ is the cost of edge i.) Then, only the penalties of solution components with maximal utility are increased. Note that the term $1 + penalty(i)$ in the denominator of the definition of $u(i)$ avoids overly frequent penalisation of solution components.

In addition to penalty increases in local optima, many DLS algorithms also occasionally decrease penalty values. DLS algorithms have been demonstrated to achieve state-of-the-art performance for various combinatorial problems, including SAT [32]. They are conceptually related to Lagrangian methods in continuous optimisation.

19.4 Hybrid SLS Methods

While the previously discussed SLS methods provide the basis for state-of-the-art algorithms for many hard combinatorial problems, often, further performance improvements can be achieved by combining various SLS strategies into hybrid algorithms. In fact, RII can already be seen as a hybrid SLS method, since it combines two different types of search steps—random walk and iterative improvement steps. In the following, we briefly discuss several other hybrid SLS methods. In many cases, hybrid SLS methods combine constructive search steps and perturbative local search steps, or larger modifications of candidate solutions with the application of "simple" local search algorithms.

Iterated Local Search

The key idea behind this SLS method is to escape from local optima of the given evaluation function by means of a perturbation mechanism. Essentially, three components form the core of any ILS algorithm. A subsidiary local search procedure is used to efficiently find local optima; this is typically based on an iterative improvement algorithm or a "simple" SLS method. The perturbation procedure introduces a modification to a given candidate solution to allow the search process to escape from local optima. Finally, an acceptance criterion is used to decide whether the search should be continued from a newly found local optimum. Based on these components, ILS works as outlined in Figure 19.3.

```
Iterated Local Search (ILS):
  determine initial candidate solution $s$
  perform subsidiary local search on $s$
  While termination criterion is not satisfied:
    $r := s$
    perform perturbation on $s$
    perform subsidiary local search on $s$
    based on acceptance criterion, keep $s$ or revert to $s := r$
```

FIGURE 19.3 Outline of iterated local search.

When using an iterative improvement algorithm as the subsidiary local search procedure, ILS can be seen as performing a biased random walk in the space of local optima reached by this procedure. The perturbation procedure should introduce a modification that cannot be immediately reversed by the local search procedure, to achieve effective diversification of the search. The acceptance criterion determines the degree of search intensification; for example, if only improving candidate solutions are accepted, ILS performs randomised first-improvement search in the space of local optima. Together, the perturbation procedure and the acceptance criterion determine the balance between search intensification and diversification.

One of the major attractions of ILS stems from the fact that it is typically very easy to extend an existing implementation of a simple local search algorithm into a basic ILS algorithm. ILS algorithms define the current state-of-the-art for solving many hard combinatorial problems, the most prominent of which is the TSP [33]. Conceptually, there is a close relationship between ILS and some advanced forms of TS; furthermore, the previously mentioned basic and skewed variable neighbourhood search algorithms can be seen as special cases of ILS. For more details on ILS we refer to Lourenço et al. [34].

Iterated Greedy Algorithms

Greedy construction methods are at the core of many well-known approximation algorithms. They also provide the basis for iterated greedy (IG) algorithms, which can be seen as a variant of ILS in which local search and perturbation phases are replaced by construction and destruction phases. Starting from a complete candidate solution, IG alternates between phases of destructive and constructive search. During a destruction phase, some solution components are removed from the current candidate solution s (e.g., uniformly at random or heuristically, depending on their impact on the evaluation function), resulting in some partial (nonempty) candidate solution s_p. During a construction phase, solution components are added heuristically, starting from s_p, until a new complete candidate solution s' has been obtained. As in ILS, an acceptance criterion is used to decide whether to continue the search from s' or s.

Note that the initial candidate solution in IG may be generated by a construction method that may be different from the one used in subsequent construction phases. Also, a perturbative local search procedure may be used to further improve any complete candidate solutions considered during the search. In this case, IG may be seen as a variant of ILS in which a combination of a destruction and a construction phase forms the perturbation procedure. IG methods are a promising approach for solving problems for which good constructive algorithms exist. Problems for which IG algorithms reach state-of-the-art performance include set covering [35,36] and flow-shop scheduling [37].

Greedy Randomised Adaptive Search Procedures

A combination of constructive and perturbative local search forms the basis for GRASP [2,3], which works as follows: Using a randomised construction procedure, a complete candidate solution is generated, which is then improved using a perturbative local search procedure; this two-phase process is repeated until a termination criterion is satisfied.

The construction procedure in GRASP iteratively adds solution components that are chosen randomly from a *restricted candidate list*; the elements of this list are determined using a heuristic function, whose value for a given solution component may depend on the solution components already present in the current partial candidate solution (this is the “adaptive” aspect of the search process). GRASP has been applied to a broad range of combinatorial problems; for a detailed description on GRASP and various extensions we refer to Resende and Ribeiro [3].

19.5 Population-Based SLS Methods

Various SLS methods maintain a population of candidate solutions which are simultaneously manipulated in each search step. As previously noted, such population-based methods can be formulated within the unified SLS framework described in Section 19.1 by considering search positions that consist of sets of candidate solutions in combination with suitably defined neighbourhood relations as well as initialisation and step functions. The appeal of population-based SLS methods partly stems from the fact that the use of a population provides a straightforward means for achieving search diversification; however, compared with other SLS methods, this often comes at the cost of higher implementation effort and more parameters that need to be tuned to achieve competitive performance. The two widely known population-based methods described in the following are inspired by biological mechanisms; however, it should be noted that there are many other population-based SLS methods, such as population-based extensions of ILS, that are not motivated in this way.

Ant Colony Optimisation

The inspiration for ACO stems from the pheromone trail laying and following behaviour exhibited by several ant species [5]. In ACO, the (artificial) ants are randomised construction procedures that take into account (artificial) pheromone trails and heuristic information when iteratively constructing complete candidate solutions. Essentially, the pheromone trails are modelled by numerical values that are associated with solution components; these are adapted while solving a given problem instance and hence reflect the search experience of the (artificial) ant colony.

In each construction step, solution components are chosen with a probability that is proportional to their pheromone value and the heuristic information. For example, in the TSP, the first problem tackled by ACO algorithms [4], a pheromone value τ_{ij} is associated with each edge (i, j) of the given graph, and the heuristic information η_{ij} is typically defined as the inverse of the length of edge (i, j). Hence, an ant located at a vertex i would add vertex $j \in N(i)$ to its current partial tour s_p with probability

$$p_{ij} = \frac{\tau_{ij}^{\alpha} \cdot \eta_{ij}^{\beta}}{\sum_{l \in N(i)} \tau_{il}^{\alpha} \cdot \eta_{il}^{\beta}}, \tag{19.3}$$

where $N(i)$ is the feasible neighbourhood of vertex i, i.e., the set of all vertices that have not yet been visited in s_p, and α and β are parameters that control the relative influence of pheromone values and heuristic information, respectively. This probabilistic selection mechanism was used in Ant System, the first ACO algorithm [4,38]; the tour construction procedure applied by the artificial ants using this mechanism resembles a probabilistic variant of the nearest neighbour construction heuristic.

After all ants have constructed a complete candidate solution, many ACO algorithms apply a perturbative local search procedure (such as iterative improvement) to each complete candidate solution; it has been shown that in the context of solving $\mathcal{NP}$-hard problems, the overall performance of an ACO algorithm often depends crucially on this local search phase [5,39]. Then, the pheromone values are updated in two steps. In the first step (which models pheromone evaporation), all pheromone values are decreased, typically by multiplication with a constant factor. In the second step (which models pheromone deposit), the pheromone values of the solution components contained in one or more of the current candidate solutions are increased; the amount of increase often depends on the quality of the respective solutions. Cycles of construction (and subsidiary local search) phases followed by pheromone updates are repeated until a termination criterion is satisfied.

Several variants of ACO have been proposed that all share the same basic underlying ideas (see the book by Dorigo and Stützle [5] for an overview). The ACO metaheuristic [40] gives a general framework for these variants. In general, ACO is steadily gaining popularity and provides the basis for state-of-the-art algorithms for a number of hard combinatorial optimisation problems [5]. More information on ACO can be found in Chapter 26 of this book.

Evolutionary Algorithms

One of the most prominent classes of population-based SLS methods has been inspired by concepts from biological evolution. Evolutionary algorithms start with an initial set of candidate solutions (which can be generated randomly or by means of heuristic construction search methods), and iteratively modify this population by means of three types of operations: mutation, recombination, and selection.

Typical *mutation operators* introduce small perturbations to candidate solutions in a randomised fashion; the amount of perturbation applied is usually controlled by a parameter called the *mutation rate*.

Recombination operators generate one or more new candidate solutions, often called “offspring”, by combining information from two or more “parent” candidate solutions. One of the most common types of recombination is known as *crossover*; it generates offspring by assembling partial candidate solutions from two parents. *Selection operators* are used to determine which candidate solutions from the current population and from the set of new candidate solutions obtained from mutation and recombination will form the population used in the next iteration of the search process. This choice is typically based on the value of candidate solutions under the given evaluation function (which, in the context of EAs, is commonly referred to as *fitness function*), such that better candidate solutions have a higher probability to “survive” the selection process. Selection operators are also used for choosing candidate solutions from the current population to undergo mutation or recombination.

The performance of EAs depends crucially on the choice of the evolutionary operators. In general, the performance of EAs improves if knowledge about the given problem is exploited in the operators that are applied. In fact, much research in EAs has been devoted to the design of effective mutation and crossover operators; a good example for this is the TSP [41,42]. As in the case of ACO, substantial performance improvements can often be achieved by additionally optimising candidate solutions using a perturbative local search method, such as iterative improvement. The resulting hybrid algorithms are also known as memetic algorithms (MAs) [43]. For a detailed account on MAs and their performance we refer to Chapter 27 of this book. *Scatter search* and *path relinking* are SLS methods whose roots can be traced back to the mid-1970s [44] and that only recently have regained considerable attention. They can be seen as MAs that use special types of recombination and selection operators. For details on these methods, we refer to the work of Glover et al. [45] and Laguna and Martí [46].

19.6 Discussion and Research Directions

The study of SLS methods lies at the intersection of computing science, operations research, statistics, and various application areas. Their successful application requires knowledge of the various SLS techniques and their properties; despite the generic nature of many SLS methods, insights into the problem to be solved are often also crucial.

Overall, the behaviour of most high-performance SLS algorithms is not well understood, and although some theoretical results exist (e.g., for SA and ACO algorithms), these are often obtained under specific assumptions that limit their practical relevance [47,48]. Still, some theoretical properties, such as empirical approximate completeness (which guarantees that when run arbitrarily long, an algorithm finds a solution to any given, soluble problem instance with probability approaching one), have been shown to be useful in guiding the development of high-performance SLS algorithms (see, e.g., Ref. [49]).

Nevertheless, the analysis of SLS algorithms relies mostly on computational experiments, and advanced methods for the empirical analysis of SLS behaviour play an important role in the development of new algorithms. Empirical studies in this area are complicated by the fact that most SLS algorithms are heavily randomised; but using advanced empirical methods, such as the approach based on run-time distributions discussed in Chapter 14, have contributed significantly to an improved understanding of SLS behaviour as well as to the development of high-performance SLS algorithms for many hard combinatorial problems [49,50]. Yet, compared with mature empirical sciences, such as physics or biology, computing science in general, and the area of algorithmics in particular, are still in the early stages of adopting and exploiting a well-founded empirical approach.

In the past, much of the successful work on SLS algorithms and generic SLS methods has relied crucially on prior experience and good intuitions. One of the major directions in SLS research concerns the development of improved practices for developing SLS algorithms and for their application to new problems. In this context, it is likely that conceptual frameworks for the design and exploration of SLS methods, as well as implementation and experimentation environments will play an important role [51,52]. Furthermore, an improved understanding of the relationship between the features of problems and problem instances on one hand, and properties and behaviour of SLS methods on the other will likely provide the basis for more principled approaches for the design and application of SLS algorithms. Insights to be gained in this context are also of considerable scientific interest. Progress in this research direction is significantly leveraged by advanced search space analysis techniques, statistical methods, and machine learning approaches (see, e.g., Merz and Freisleben [53] or Watson et al. [54]).

The formalisation of general principles underlying the design of successful SLS algorithms remains a major challenge. One interesting question in this context concerns the role and degree of randomisation. While deterministic local search algorithms exist, most high-performance SLS algorithms are highly randomised. It is not clear to which extent it is generally possible to derandomise these algorithms without major losses in robustness or peak performance. Interestingly, there is evidence that in most cases, the quality of the random number source used by the algorithm is not critical and that the number of randomised decisions can often be significantly reduced [55]. However, in most application areas, the use of deterministic algorithms is not inherently preferable, and randomised algorithms have some general advantages, for example, with respect to straightforward and efficient parallelisation techniques. Therefore, while from a scientific point of view, the derandomisation of SLS algorithms poses interesting questions and challenges, its practical importance is somewhat unclear.

Finally, many challenges remain in the context of SLS methods to more complex combinatorial problems, including multiobjective, dynamic, and stochastic problems. Furthermore, there appears to be considerable potential in the context of SLS methods for solving continuous optimisation problems and hybrid problems with discrete and continuous components. Overall, there is no doubt that as one of the most versatile and successful approaches for solving hard combinatorial problems, SLS methods will continue to attract the attention of researchers and practitioners from many academic and application areas.

20.1 Introduction

A combinatorial optimization problem (COP) P consists of a collection of instances. An instance of P can be represented as an ordered pair (F, f), where F is the family of feasible solutions and f the objective function, which is used to compare two feasible solutions. The family F is formed by subsets of a finite set $\mathsf{E} = \{1, 2, \ldots, m\}$ called the ground set. The objective function $f : \mathsf{F} \to Q^+ \cup \{0\}$ assigns a nonnegative cost to every feasible solution S in F. The Traveling Salesman Problem (TSP) and the Minimum Spanning Tree Problem are typical examples of COPs.

Most of the COPs of practical interest are NP-hard. Local search is one of the primary solution approaches for computing an approximate solution for such hard problems. To describe a local search algorithm formally, we need the concept of a neighborhood for each feasible solution. A *neighborhood function* for an instance (F, f) of a COP P is a mapping $N_{\mathsf{F}} : \mathsf{F} \to 2^{\mathsf{F}}$. We assume that N_{F} does not depend on the objective function f. For convenience, we usually drop the subscript and simply write N. For a feasible solution S, $N(S)$ is called the neighborhood of S. We assume that$S \in N(S)$. For a minimization problem, a feasible solution $\overline{S} \in \mathsf{F}$ is said to be *locally optimal* with respect to N if $f(\overline{S}) \leq f(S)$ for all$S \in N(\overline{S})$. Then the *local search problem* is to find a locally optimal solution for a given COP.

Classic neighborhood functions studied in the combinatorial optimization literature include the 2- and 3-opt neighborhoods for the TSP [1,2], the flip neighborhood for Max Cut [3], and the swap neighborhood for Graph Partitioning [3,4]. The sizes of these neighborhoods are polynomial in the problem size. However, the class of local search algorithms that we are considering here primarily concentrates on neighborhoods of very large size, often exponential in the problem size. For the TSP, this class includes variable depth neighborhoods, ejection chain neighborhoods, pyramidal tours neighborhoods, permutation tree neighborhoods, neighborhoods induced by polynomial-time solvable special cases, etc. For partitioning problems, various multiexchange neighborhoods studied in literature have this property.

Roughly speaking, a local search algorithm starts with an initial feasible solution and then repeatedly searches the neighborhood of the "current" solution to find better solutions until it reaches a locally optimal solution. Computational studies of local search algorithms and their variations have been extensively reported in the literature for various COPs (see, e.g., Refs. [2,5] for studies of the Graph Partitioning Problem and the TSP, respectively). Empirically, local search heuristics appear to converge rather quickly, within low-order polynomial time. In general, the upper bound on the guaranteed number of improving moves is pseudopolynomial.

This chapter is organized as follows. In Section 20.2, we consider various applications of very large scale neighborhood (VLSN) search algorithms and discuss in detail how to develop such algorithms using multiexchanges for various partitioning problems. Section 20.3 deals with theoretical concepts of extended neighborhoods and linkages with domination analysis of algorithms. The results in this section reaffirm the importance of using large-scale neighborhoods in local search. In Section 20.4, we deal with performance guarantees for computing an approximation to a local minimum. This is especially relevant for VLSN search. Searching a large-scale neighborhood is sometimes NP-hard and thus approximation algorithms are used. In these cases, the algorithm may terminate at a point that is not a local minimum.

20.2 VLSN Search Applications

VLSN search algorithms have been successfully applied to solve various optimization problems of practical interest [53–62]. This includes the capacitated minimum spanning tree (CMST) problem [6–8], vehicle routing problems [9–12], the TSP [11,13–17], the weapon target assignment problem [18], the generalized assignment problem [19–21], the plant location problem [22], parallel machine scheduling problems [23], airline fleet assignment problems [24–26], the quadratic assignment problem [27], pickup and delivery problems with time windows [4,28], the multiple knapsack problem [29], manufacturing problems [30], optimization problems in IMRT treatment planning [31], school timetabling problems [32], the graph coloring problem [33], etc. The successful design of an effective VLSN search algorithm depends on the ability to identify a good neighborhood function and the ability to design an effective exact or heuristic algorithm to search the neighborhood for an improved solution. A VLSN search algorithm can be embedded within a metaheuristic framework, such as tabu search [34], genetic algorithms [35], scatter search [36], and GRASP [37] to achieve further enhances in performance. Simulated annealing may be used in principle, but is not likely to be a successful approach when the size of the neighborhood is exponentially large.

Researchers have used various techniques for developing good neighborhood functions that lead to effective VLSN search algorithms. This includes multiexchange [6,7,38,39], ejection chains [40], variable depth methods [41,42], integer programming [10], weighted matching [10,13,14,16,17], set partitioning [10], etc. A comprehensive discussion of all these techniques is outside the scope of this chapter. Applications of ejection chains in local search are discussed in other chapters of this book and hence we will not discuss it here. To illustrate the features of a VLSN search algorithm, we primarily concentrate on applications of multiexchange neighborhoods originally developed by Thompson and Orlin [43] and Thompson and Psaraftis [38]. It is one of the successful approaches for developing VLSN search algorithms for various partitioning problems [6,7,29].

20.2.1 Partitioning Problems and Multiexchange Neighborhoods

A subset B of the ground set E is said to be a *feasible subset* if it satisfies a collection of prescribed conditions called *feasibility conditions*. We assume there is a *feasibility oracle* ζ that verifies whether a subset B of E satisfies the feasibility conditions. A partition $S = \{S_1, S_2, \dots, S_p\}$ is said to be *feasible* if S_i is a feasible subset for each $i = 1, 2, \dots, p$. Let $c : 2^{\mathsf{E}} \to \mathbb{Q}$ be a prescribed cost function. The cost $C(S)$ of the

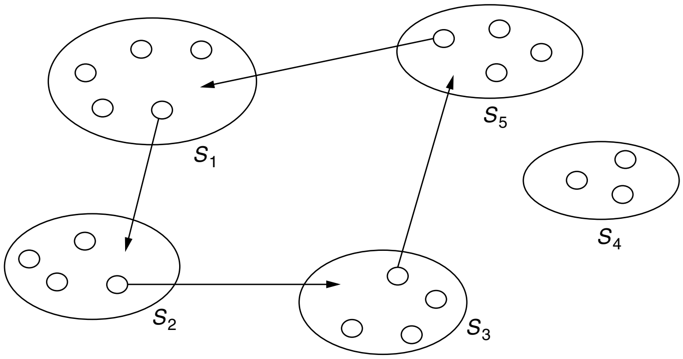

FIGURE 20.1 A cyclic exchange.

partition $S = \{S_1, S_2, \ldots, S_p\}$ is defined as $C(S) = \sum_{i=1}^{p} c(S_i)$. *Partitioning problems* are the subclass of COP, where the family of feasible solutions F is the collection of all feasible partitions of E with $C(.)$ as the objective function.

Partitioning problems are typically NP-hard even if the feasibility oracle ζ and evaluation of the cost $c(.)$ of the subsets of a partition run in polynomial time. Several well-studied COPs are special cases (or may be viewed as special cases) of partitioning problems. These include the CMST problem [6,7,44], the generalized assignment problem [19–21], vehicle routing problems [10,23], graph partitioning problems [4,42], the k-constrained multiple knapsack problem [29], etc. We will discuss some of these problems in detail later. Next, we develop a VLSN search algorithm for the general partitioning problem.

The first step in the design of a VLSN search algorithm is to develop a suitable neighborhood function.

Let $S = \{S_1, S_2, \ldots, S_p\}$ be a feasible partition. A *cyclic exchange* of S selects a collection $\{S_{\pi_1}, S_{\pi_2}, \ldots, S_{\pi_q}\}$ of subsets from S and moves an element say b_i from subset S_{π_i} to subset $S_{\pi_{i+1}}$ for i =1, 2, …, q, where $q + 1 = 1$ (see Figure 20.1). Let S^* be the resulting partition. If S^* is a feasible partition, then we call the exchange a *feasible cyclic exchange.* It can be verified that

$$C(S^*) = C(S) + \sum_{i=1}^{q} (c(\{b_{i-1}\} \cup S_{\pi_i} \backslash \{b_i\}) - c(S_{\pi_i})) \tag{20.1}$$

where b_0 is defined to be b_q. If $q = 2$, the cyclic exchange reduces to a 2-exchange, an operation well studied for various partitioning problems [5,15,45]. In a (feasible) cyclic exchange, if we omit the move from S_{π_q} to $S_{\pi_{q+1}} (= S_{\pi_1})$, the resulting exchange is called *a (feasible)path exchange.* For $q = 2$, a path exchange reduces to the shift operation, again well studied for various partitioning problems [45].

The cyclic and path exchanges discussed above were introduced by Thompson and Orlin [43] and Thompson and Psaraftis [38] and subsequently used by several researchers in the context of various partitioning problems.

Given a feasible partition S, let Z(S) be the collection of all feasible partitions of E that can be obtained by cyclic exchanges from S. Similarly, let P(S) be the collection of feasible partitions of E that can be obtained by a path exchange from S. We call Z(S) the *cyclic exchange neighborhood* of S, and we call P(S) the *path exchange neighborhood* of S. The union Z(S)∪P(S) is called the *multiexchange neighborhood* of S. The cardinality of the neighborhoods Z(S) and P(S) is often exponential. A precise estimate of this cardinality depends on various parameters including the nature of the feasibility oracle ζ. Thus Z(S) and P(S) qualify as very large-scale neighborhoods that can be used in the design of a VLSN search algorithm.

Besides the size of the neighborhood, the power of a VLSN search algorithm also depends on our ability to obtain an improved solution in the neighborhood. Given a feasible solution S, the problem of finding an improved solution in a given neighborhood is called a *local augmentation problem* [46]. We next discuss how to solve the local augmentation problem for Z(S). This is achieved by (approximately) solving an optimization problem on an associated structure called the *improvement graph.*

The improvement graph associated with a feasible partition is denoted by $G(S)$. Its node set is E, which is also the ground set. Given a partition S, for each element i of E let $\theta(i)$ denote the index of the subset in which it belongs in the partition S. That is, for $i \in S_r$, $\theta(i) = r$. The arc set $A = A(G(S))$ of $G(S)$ is constructed as follows. An arc $(i, j) \in A$ signifies that element i leaves subset $S_{\theta(i)}$ and enters subset $S_{\theta(j)}$ while element j leaves $S_{\theta(j)}$. So,

$$A = \left\{(i, j) : \ i, j \in E, \ \theta(i) \neq \theta(j) \ \text{ and } \ \{i\} \cup S_{\theta(j)} \backslash \{j\} \text{ is a feasible subset}\right\}$$

The cost α_{ij} of arc $(i, j) \in A$ is given by

$$\alpha_{ij} = c(\{i\} \cup S_{\theta(j)} \backslash \{j\}) - c(S_{\theta(j)}) \tag{20.2}$$

A directed cycle $\langle i_1 - i_2 - \cdots - i_r - i_1 \rangle$ in the improvement graph is said to be *subset disjoint* if $\theta(i_p) \neq \theta(i_q)$ for $p \neq q$. In this definition, if we replace "cycle" by "path" we get a *subset-disjoint directed path.*

Lemma 20.1 **(Thompson and Orlin [43])**

There is a one-to-one cost-preserving correspondence between cyclic exchanges with respect to S and subset-disjoint directed cycles in G (S).

A negative cost subset-disjoint directed path (cycle) in $G(S)$ is called a *valid path* (*cycle*).

In view of Lemma 20.1, a valid cycle in $G(S)$ yields an improved partition. If $G(S)$ contains no valid cycle, then S is locally optimal with respect to $\mathsf{N}(S)$. Unfortunately, finding such a valid cycle is NP-hard [43]. Thus, the local augmentation problem for the neighborhood $\mathsf{N}(S)$ is also NP-hard.

20.2.1.1 Local Augmentation Algorithm for N(S)

Ahuja et al. [7] proposed a heuristic algorithm to compute a valid cycle by modifying the label correcting algorithm for shortest paths. An exact algorithm based on dynamic programming (implicit enumeration) to solve this problem was introduced in Ref. [6]. We briefly discuss the algorithm, and refer the reader to Ref. [6] for further details.

For any subgraph H of $G(S)$, its cost $\alpha(S)$ is given by $\alpha(S) = \sum_{ij \in P} \alpha_{ij}$, where *ij* is shorthand for (i, j). For a directed path P in $G(S)$, let *tail*(P) denote the start node, *head*(P) denote the end node, and *label*(P) denote the set $\{\theta(i) \ : \ i \in P\}$. We say that a path P_1 dominates another path P_2 in $G(S)$ if $\alpha(P_1) < \alpha(P_2)$, *tail*($P_1$)= *tail*($P_2$), *head*($P_1$)= *head*($P_2$), and *label*($P_1$)= *label*($P_2$). If P_1 dominates P_2 and P_2 is part of a valid cycle $\mathbb{C}$, then clearly $P_1 \cup \mathbb{C} \backslash P_2$ contains a valid cycle with cost no more than $\alpha(\mathbb{C})$. For each path P, we associate a triplet (*tail*(P), *head*(P), *label*(P)) called the *key value* of P. In our search for a valid cycle in $G(S)$, among paths with the same key value, we only need to consider one with the smallest cost. The following lemma further cuts down the number of paths needed to be considered.

Lemma 20.2 **(Lin and Kernighan [41])**

If $W = \langle i_1 - i_2 - \cdots - i_r - i_1 \rangle$ is a negative cost cycle, then there exists a node i_h in W such that each directed path $i_h - i_{h+1}$, $i_h - i_{h+1} - i_{h+2}, \ldots, i_h - i_{h+1} - i_{h+2} - \ \ldots \ - i_{h-1}$ (where indexes are modulo r) is a negative cost-directed path.

In view of Lemma 20.2 and the preceding discussions, we need to only consider nondominated valid paths as candidates for forming valid cycles. Let Π_k be the set of all valid nondominated paths of length k in $G(S)$. The algorithm of Ahuja et al. [6] progressively generates Π_k for larger values of k. The algorithm enumerates valid paths using a forward dynamic programming recursion. It first obtains all valid paths of length 1 and uses these paths to generate valid paths of length 2, etc. This process is repeated until we have obtained all valid paths of length R for some given length R, or until we find a valid cycle. From each valid path, candidate cycles are examined by connecting the head node with the tail node by an arc in $G(S)$ if such an arc exists. A formal description of the valid cycle detection algorithm is given below.

```
algorithm valid cycle detection
begin
    $\boldsymbol{P}_1 := \{(i, j) \in A(G(S)) : \alpha_{ij} < 0\}$;
    $k := 1$;
    $W^* := \emptyset; \alpha(W^*) = \infty$;
    while $k < R$ and $\alpha(W^*) \geq 0$ do
    begin
        while $\boldsymbol{P}_k \neq \emptyset$ do
        begin
            remove a path $P$ from $\boldsymbol{P}_k$
            let $i$:= $head(P)$ and $h$:= $tail(P)$
            if $(i, h) \in A(G(S))$ and $\alpha(P)+\alpha_{ih}<\alpha(W^*)$ then $W^*$:= $P\cup\{(i, h)\}$;
            for each $(i, j) \in A(i)$ do
                if $label(j) \notin label(P)$ and $\alpha(P)+\alpha_{ij} < 0$ then
                begin
                    add the path $P\cup\{(i, j)\}$ to $\boldsymbol{P}_{k+1}$
                    if $\boldsymbol{P}_{k+1}$ contains another path with the same key as
                    $P\cup\{(i, h)\}$ then remove the dominated path;
                endif;
            endfor
        endwhile;
        $k = k+1$;
    endwhile;
    return $W^*$;
end;
```

Although the algorithm above is not polynomial, it worked very well in practice for some partitioning problems on which the algorithm was tested [6,7,29].

Path Exchange as a Cyclic Exchange

Let us now consider how a valid path can be obtained if $G(S)$ has one. Note that by Lemma 20.2, every valid cycle of length r gives $r - 1$ valid paths. Sometimes path exchanges resulting from these valid paths may be better than the best cyclic exchange. Even in the absence of a valid cycle, it is possible that $G(S)$ may have valid paths that lead to an improved solution. Let S be a partition containing p subsets, and suppose that S^* is a partition obtained from S by a cyclic exchange. In general, S^* will also contain p subsets, and they will have the same cardinalities as the original subsets of S. These are limitations of the cyclic exchange. One approach to overcome this drawback is to periodically explore the possibility of splitting one or more subsets within a partition or merging two or more subsets within a partition. In the case of communication spanning tree problems, some cyclic exchange moves lead to such simple split operations in a natural way. Interestingly, path exchange moves have the natural property of the possibility of decreasing the number of subsets in a partition. By allowing the possibility of an empty set, an improvement graph can be constructed where a path exchange can even increase the number of subsets while moving from one partition to another. This variation of path exchange is called *enhanced path exchange.*

Interestingly, we now observe that path exchanges can be viewed as cyclic exchanges in a modified improvement graph $\tilde{G}(S) = \left(\tilde{V}, \tilde{A}\right)$, which is a supergraph of $G(S)$. Introduce p new nodes (called *pseudonodes*) $s_1, s_2, \ldots, s_p$ and another node v called the *origin node.* Thus the node set $\tilde{V}$of $\tilde{G}(S)$ is $E \cup \left\{s_1, s_2, \ldots, s_p, v\right\}$. The graph $\tilde{G}(S)$ contains all arcs of $G(S)$ along with additional arcs from the set $\{(v, j) : j \in E\} \cup \{(j, s_i) : i \neq \theta(j)$ and $S_i \cup \{j\}$ is a feasible subset$\} \cup \{(s_i, v) : i = 1, 2, \ldots, p\}$ (see Figure 20.2). The cost of these additional arcs are defined as follows: $\alpha_{vj} = c(S_{\theta(j)}\backslash\{j\}) - c(S_{\theta(j)})$ for all $j \in \mathsf{E}; \alpha_{s_i v} = 0$ for $i = 1, 2, \ldots, p$; and $\alpha_{js_i} = c(S_i\cup\{j\}) - c(S_i)$ for all $(j, s_i) \in \{(j, s_i) : i \neq \theta(j)$ and $S_i \cup \{j\}$ is a feasible subset$\}$.

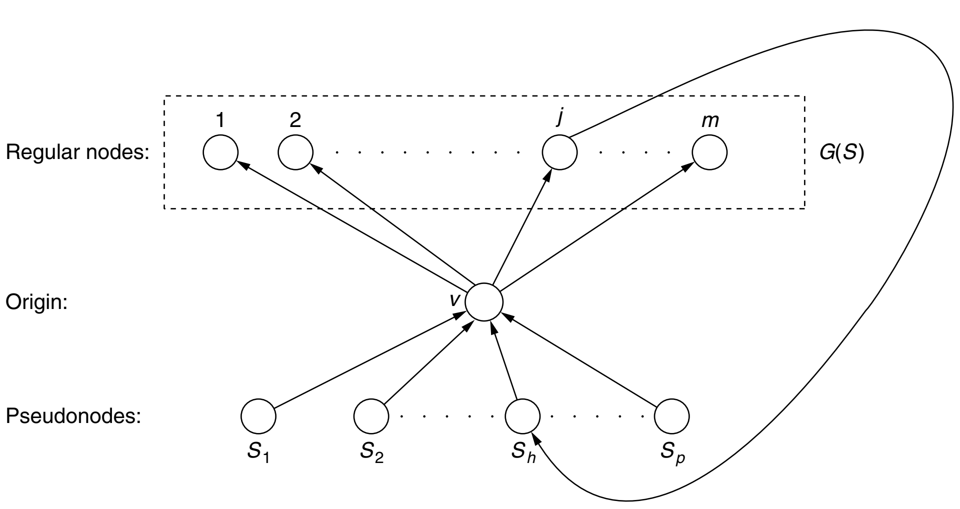

FIGURE 20.2 Construction of the improvement graph $\tilde{G}(S)$.

Note that a directed cycle $\mathbb{C}$ in $\tilde{G}(S)$ containing the node v will have exactly one pseudonode and the remaining nodes are regular. Further, these regular nodes form a path in $\mathbb{C}$ called the *regular path* associated with $\mathbb{C}$. A directed cycle $\mathbb{C}$ containing the node v in the graph $\tilde{G}(S)$ is said to be *subset disjoint* if its associated regular path is subset disjoint.

Lemma 20.3 (**Ahuja et al.** [7])

There is a one-to-one cost-preserving correspondence between path exchanges with respect to the partition S and subset-disjoint directed cycles in $\tilde{G}(S)$ containing the origin node v.

If a valid cycle in the improvement graph contains the origin node v, it corresponds to an improving path exchange. If it does not contain v, it corresponds to an improving cyclic exchange. Moreover, the improvement graph $\tilde{G}(S)$ can be further modified by adding a new node and appropriate arcs so that improving enhanced path exchanges can be identified. A VLSN search algorithm based on a multiexchange (path or cyclic) can be described as follows:

```
Algorithm Multiexchange
begin
    compute a feasible solution $S$ to the partitioning problem;
    construct the improvement graph $\tilde{G}(S)$;
    while $\tilde{G}(S)$ contains a valid cycle do
        obtain a valid cycle $W$ in $\tilde{G}(S)$;
        If $W$ contains the origin node $v$ then
            perform a path exchange using the corresponding regular path;
        else
            perform a cyclic exchange corresponding to $W$;
        endif
            update $S$ and $\tilde{G}(S)$;
    endwhile;
end.
```

Many problem-specific features can be used to simplify calculations in the VLSN search algorithm discussed above for the partitioning problem. The complexity of the construction of the improvement graph depends on that of the feasibility oracle and on the evaluation of the cost function $c(.)$. Also, problem-specific information may be used to update the improvement graph from iteration to iteration efficiently.

The Capacitated Minimum Spanning Tree Problem

Let G be a graph on the node set $V \cup \{0\}$, where $V = \{1, 2, \ldots, n\}$. Nodes in V are called *terminal nodes*, and the node 0 is called the *central node*. For each arc (i, j), a nonnegative cost c_{ij} is prescribed. Also for each node $i \in V$, a nonnegative demand $w_i$is prescribed. Let L be a given real number. For any spanning tree T of G, let $T_1, T_2, \ldots, T_{K_T}$ denote the components of T-$\{0\}$. Then the CMST problem is to

$$\begin{aligned} &\text{Minimize} \quad \sum_{ij \in T} c_{ij} \\ &\text{subject to} \\ &\qquad\qquad T \text{ is a spanning tree of } G \\ &\qquad\qquad \sum_{i \in T_j} w_i \leq L, \quad j = 1, 2, \ldots, K_T \end{aligned} \tag{20.3}$$

For any subgraph H of G, we sometimes let $V(H)$ denote its node set and let $E(H)$ denote its edge set. We also use the notation $ij \in H$ $(i \in H)$ to represent $(i, j) \in E(H)$ $(i \in V(H))$ when there is no ambiguity. It is easy to see that for an optimal spanning tree T, the component T_i must be a minimum spanning tree of the subgraph of G induced by $V(T_i)$, $i = 1, 2, \ldots, K_T$.

Thus CMST can be viewed as a partition problem where the ground E is the set V of nodes in G, the feasibility oracle is to verify the condition $\sum_{i \in S_j} w_i \leq L$. The cost $c(S_i)$ is the cost of the minimum spanning tree T_i of the subgraph of G induced by $S_i \cup \{0\}$. Without loss of generality, we assume that node 0 is a pendant node (node of degree 1) of T_i. Otherwise, we can decompose T_i into a number of subtrees equal to the degree of node 0, where 0 is a pendant node in each such subtree, yielding an alternative feasible solution.

The algorithm multiexchange can be used to find a heuristic solution for CMST. For details on implementation aspects of this heuristic specifically for the CMST problem, we refer to Ref. [6]. Instead of using the simple node exchange, Ahuja et al. [6,7] also considered subtree exchange neighborhoods and composite neighborhoods [6]. The node exchange worked well for problems where the node weights are identical (homogeneous problems). Subtree exchanges worked well for problems with different node weights (heterogeneous problems). The composite neighborhood worked well for both class of problems and produced improved solutions for several benchmark problems. Table 20.1 (taken from Ref. [6]) summarizes these results.

20.3 Extended Neighborhoods and Domination Analysis

Let us now look at some theoretical issues related to performance guarantees of VLSN search algorithms. Glover and Punnen [47] introduced the concept of domination ratio to assess the performance guarantee of a heuristic algorithm. Let α be a heuristic algorithm for a COP P. Then the domination ratio of α, denoted by $dom(\alpha)$, is

$$\mathop{Inf}_{(F,f)} |\{S \in F \ : \ f(S) \geq f(S_\alpha)\}|/|F|$$

where S_α is the solution obtained by the heuristic α on instance (F, f). Note that $0 < dom(\alpha) \leq 1$ and $dom(\alpha) = 1$ if and only if α guarantees an optimal solution.

Identifying tight deterministic bounds on domination ratio could be difficult for many algorithms. For various recent works on domination analysis of algorithms we refer to Refs.[16,30,48,49]. For VLSN search algorithms for a COP,

$$\mathop{Inf}_{(F,f)} \left\{ \frac{|N(S)|}{|F|} \ : \ S \in F \right\}$$

gives a trivial lower bound on the domination ratio, provided we can find an improving solution in $N(S)$ if exists.

We next introduce the concept of extended neighborhoods, which can be used to find improved domination ratios for a VLSN algorithm. The value of extended neighborhoods goes beyond establishing improved domination ratios. It generalizes the concept of exact neighborhoods and provides some theoretical insights on why the VLSN search algorithms work well in practice. We will address this aspect later in this section. Let us first consider some basic definitions and properties. For details of the theory of extended neighborhoods, we refer to Ref. [50].

Consider an instance $I = (\mathsf{F}, f)$ of a COP and let N be a neighborhood function defined on it. Let L_I^N denote the collection of all locally optimal solutions of I with respect to N. Two neighborhoods N^1 and N^2 are said to be LO-equivalent for a COP P if and only if $L_I^{N^1} = L_I^{N^2}$ for all instances I of P. A neighborhood function N^* of P is called an *extended neighborhood* of N if

(i) N^* and N are LO-equivalent, and
(ii) for every neighborhood function N^0that is LO-equivalent to N, $N^0(S) \subseteq N^*(S)$ for all $S \in \mathsf{F}$ and for all $I =(\mathsf{F}, f)$ of P.

Equivalently, N^* is the largest neighborhood, that is, LO-equivalent to N for P. If $N^* = \mathsf{F}$, then N is an exact neighborhood [42]. (A neighborhood is *exact* if every local optimum is a global optimum.) In this way, the concept of an extended neighborhood generalizes the concept of exact neighborhoods.

Note that the domination ratio of any local search algorithm using the neighborhood N will be at least

$$\underset{(F,f)}{Inf}\left\{\frac{|N^*(S)|}{|F|}\ :\ S \in F\right\}$$

The well-known 2-opt neighborhood for the TSP on n nodes contains $n(n-1)/2$ elements, while the extended neighborhood of 2-opt for the TSP contains at least $(n/2)!$ elements [50].

A COP is said to have linear cost if $f(x) = cx$, where $c = (c_1, c_2, \ldots, c_m)$ is the vector element costs and x the incidence vector representing a feasible solution. Note that each feasible solution S can be represented by its incidence vector $x = (x_1, x_2, \ldots, x_m)$ where

$$x_i = \begin{cases} 1 & \text{if } i \in S \\ 0 & \text{if } i \notin S \end{cases}$$

We denote by F_x the collection of all incidence vectors of elements of F. When x is the incidence vector of S, we sometimes denote $N(S)$ by $N(x)$. Let $N_F(x) = \{x^1, x^2, \ldots, x^K\}$ for some K. Then for $i = 1$ to K, let $v^i = x^i - x$. We refer to v^i as a *neighborhood vector* and let $V_F^N(x)$ be an $m \times K$ matrix whose ith column is v^i. $V_F^N(x)$ is called the matrix of neighborhood vectors at x. The following theorem characterizes extended neighborhoods for COPs with a linear cost function.

Theorem 20.4 **(Orlin and Sharma [50])**

Let P *be a COP with a linear cost function and let* N *be an associated neighborhood function. Let* F *be the collection of feasible solutions of any instance and let* $V_F^N(x)$ *be the matrix of neighborhood vectors. Then the extended neighborhood* N_F^* *of* N_F *is given by* $N_F^*(x) = \left\{\hat{x} \in F_x : \hat{x} = x + V_F^N(x)\lambda;\ \lambda \geq 0 \text{ and } \lambda \in \Re^{|N_F(x)|}\right\}$.

To illustrate the characterization of extended neighborhood in Theorem 20.4, let us construct the extended neighborhood of the 2-opt neighborhood for the TSP. In the definition of COP with a linear cost function, if E is selected as the edge set of a complete graph G and if F is selected as the family of all tours in G, we get an instance of the TSP. Let the number of nodes in G be n. A tour T in G is represented as a sequence $\langle i_1, i_2, \ldots, i_n, i_1\rangle$, where $(i_k, i_{k+1}) \in T$ for $k = 1, 2, \ldots, n-1$ and $(i_n, i_1) \in T$. Given a tour $T = \langle i_1, i_2, \ldots, i_n, i_1\rangle$, a 2-opt move can be represented as a set $\{k, l\}$, where i_k and i_l are nonadjacent in T. The move $\{k, l\}$ represents the operations of removing edges (i_k, i_{k+1}), (i_l, i_{l+1}) from T and adding edges (i_k, i_l), (i_{k+1}, i_{l+1})*to* T-$\{(i_k, i_{k+1}), (i_l, i_{l+1})\}$, where the index $n + 1 = 1$. The 2-opt neighborhood of a tour T denoted by 2-opt(T) is the collection of all tours in G that can be obtained by a 2-opt move from T. Let $T^{k,l}$ be the tour obtained from T by the 2-opt move $\{k, l\}$. The neighborhood vector corresponding to this move, denoted by $v_T^{k,l}$ is given by

$$v_T^{k,l}(e) = \begin{cases} -1 & \text{if } e = (i_k, i_{k+1}) \text{ or } e = (i_l, i_{l+1}) \\ 1 & \text{if } e = (i_k, i_l) \text{ or } e = (i_{k+1}, i_{l+1}) \\ 0 & \text{otherwise} \end{cases}$$

If x is the incidence vector of T, then $x + v_T^{k,l}$ is the incidence vector of $T^{k,l}$. Thus by Theorem 20.4, we have the extended neighborhood of 2-opt(T), denoted by 2-opt*(T) is given by

$$\left\{x' : x' \text{ is a tour in } G \text{ and } x' = x + \sum_{\{k,l\} \in 2\text{-}opt} \lambda_{kl} v_T^{k,l},\ \lambda_{kl} \geq 0\right\} \tag{20.4}$$

Theorem 20.5 **(Orlin and Sharma [50])**

(i) $|2\text{-}opt^*(T)| \geq (\lceil n/2 \rceil - 3)!(n-3)$. (ii) *Finding the best tour in 2-opt*(T) *is NP-hard.*

By definition, 2-opt and 2-opt* have the same set of local optima, but the size of 2-opt*(T) is exponentially larger than the size of 2-opt. We now show that using the same starting solution, a local search with respect to 2-opt* can terminate at a solution that cannot be reached by a local search with respect to 2-opt.

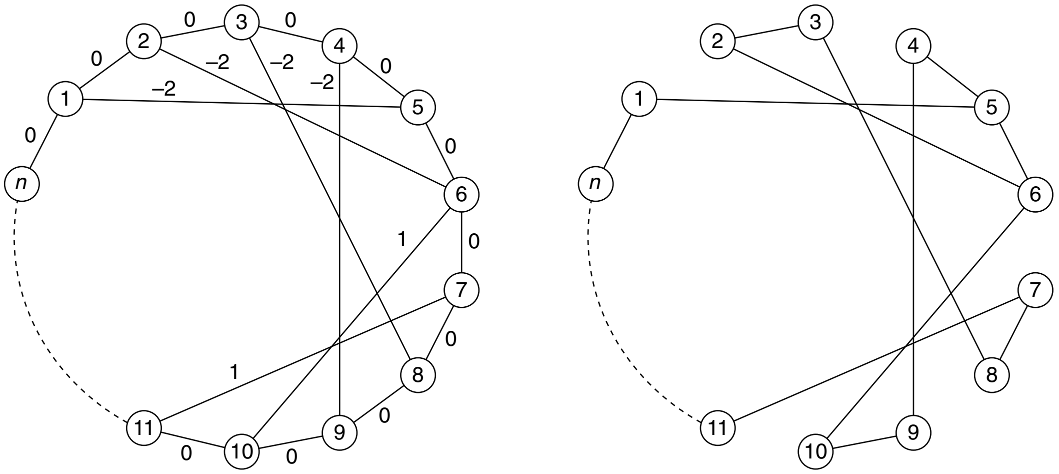

FIGURE 20.3 The graph constructed in the proof of Theorem 20.6 and tour T^*.

Theorem 20.6 (**Orlin and Sharma [50]**)

Let T be any tour with at least 11 nodes. There is a cost vector c and a tour T^* such that T^* is not reachable from T by local search with respect to 2-opt, butT^* is reachable from Tby a local search with respect to 2-opt.*

Proof

Without loss of generality assume that $T = \langle 1, 2, \ldots, n, 1\rangle$. Let all edges of T have cost 0. Introduce edges $(1, 5)$, $(2, 6)$, $(3, 8)$, and $(4, 9)$ with cost -2 and introduce edges $(6, 10)$ and $(7, 11)$ with cost 1. Complete the graph by introducing the remaining edges with a large cost (see Figure 20.3).

It can be verified that $T^* = \langle 1, 5, 4, 9, 10, 6, 2, 3, 8, 7, 11, 12, 13, \ldots, n, 1\rangle$ is an optimal tour with cost -6 . Since $T^* = T + v_T^{1,5} + v_T^{6,10} + v_T^{3,8}$, by Theorem 20.4, $T^* \in$ 2-opt*. T^*, however, is not reachable from T using improving exchanges since the moves $\{1,5\}$ and $\{3, 8\}$ lead to local optima different from T^* and $\{6, 8\}$ is not an improving move. This completes the proof.

Thus, local search with respect to extended neighborhoods fundamentally offers more possibilities than does local search using the original neighborhood. This observation further strengthens our confidence in using VLSN search algorithms to obtain good quality solutions.

20.4 Approximate Local Search

One of the most important theoretical questions in VLSN search (and local search, in general) is to find a good bound on the number of improvement steps required to reach termination. In addressing this important theoretical question, Johnson et al. [5] introduced the complexity class *PLS* [52]. A COP together with a neighborhood function belongs to class PLS if

(i) its instances are polynomial-time recognizable and an initial feasible solution is efficiently computable;
(ii) the feasibility of a proposed solution can be checked in polynomial time; and
(iii) the local optimality of a solution with respect to the neighborhood under consideration can be verified in polynomial time, and if it is not locally optimal, an improving solution can be obtained in polynomial time.

The class PLS has its own reduction scheme which leads to the class of PLS-complete problems. If a local optimum can be found in polynomial time for one of the PLS-complete problems, then a local optimum for every other PLS-complete problem can be found in polynomial time. For example, the TSP with Lin–Kernighan neighborhood [41], graph partitioning with swap neighborhood, and MAX CUT with flip neighborhood are all PLS-complete [3]. It is an outstanding open question whether there is a polynomial-time algorithm for finding a locally optimal solution for a PLS-complete problem.

In view of this open question, it is reasonable to ask whether it is possible to efficiently compute a solution "close" to a local optimum for a PLS-complete problem. This question is equally relevant for problems not in the class PLS, where the neighborhoods are searched by approximation algorithms. In this case it is interesting to see how close the solution produced is to a locally optimal solution.

A feasible solution S to an instance of a COP with neighborhood function N is said to be an *ε-local optimum* [46] if

$$\frac{f(S^*) - f(S)}{f(S)} \leq \varepsilon \text{ for all } S \in N(S)$$

where $\varepsilon > 0$. Computing an *ε-local optimum* is relatively easy [46] for problems where the cardinality of $N(S)$ is small (i.e., polynomial) for all S. Let S be a current solution and if no solution S^* exists in $N(S)$ such that $f(S^*) < f(S)/(1+\varepsilon)$ then S is an *ε-local optimum.* If such an S^* exists, then move to it and continue the search. It can be verified that the process will terminate in polynomial time (for fixed ε and integer cost function) and the resulting solution will be an *ε-local optimum.* This scheme is not applicable in many VLSN search algorithms where the neighborhood $N(S)$ is explored using heuristics.

We consider COPs with objective function f to be of the form $f(S) = \sum_{e \in S} c_e$. If there is a polynomial-time algorithm for computing an improving solution in a neighborhood, then there is a polynomial-time algorithm for computing an *ε-local optimum.* This result was originally obtained by Orlin et al. [46].

The algorithm to compute an *ε-local optimum* starts with a feasible solution S^0. Then the element costs c_e for $e \in E$ are modified using a prescribed scaling procedure to generate a modified instance. Using local search on this modified problem, we look for a solution with an objective function value (with respect to the original cost) that is half of S^0. If no such solution is found, we are at a local optimum for the modified problem and output its solution. Otherwise we replace S^0 by the solution of cost less than half and the algorithm is repeated. A formal description of the algorithm is given below. We assume that a local augmentation procedure IMPROVE$_{\mathrm{N}}$ is available, which with input of a neighborhood $N(S)$ and a cost function f computes an improved solution or declares that no improved solution exists in $N(S)$.

```
Algorithm ε-local search

Input: Objective function $f : 2^E \rightarrow \aleph$; subroutine IMPROVE$_{\mathrm{N}}$ ; initial feasible solution $S^0 \in \boldsymbol{F}$;
       accuracy $\varepsilon > 0$.
Output: Solution $S^\varepsilon \in \boldsymbol{F}$ that is an $\varepsilon$-local optimum with respect to $N$ and $f$.
Step 1: $i := 0$
Step 2: $K := f(S^i)$, $q := \frac{K\varepsilon}{2m(1+\varepsilon)}$, and $c'_e := \left\lceil \frac{c_e}{q} \right\rceil q$ for $e \in E$;
Step 3: $k := 0$ and $S^{i,k} := S^i$
Step 4: repeat
            Call IMPROVE$_{\mathrm{N}}$($S^{i,k}$, $f'$);
            {comment: $f'(S) = \sum_{e \in S} c'_e$}
            if the answer is "NO", then
                Let $S^{i,k+1} \in$ N($S^{i,k}$) such that $c'$( $S^{i,k+1}$)< $c'$( $S^{i,k}$); set $k := k + 1$;
            else $S^\varepsilon := S^{i,k}$; stop
        until $c(S^{i,k}) \leq K/2$;
Step 5: $S^{i+1}$:= $S^{i,k}$, set $i := i + 1$ and goto step 2.
```

Theorem 20.7 **(Orlin et al. [46])**

The ε-local search algorithm produces an ε-local optimum.

Proof

Let S^ε be the solution produced by the algorithm, and let S be an arbitrary solution in the neighborhood $N(S^\varepsilon)$. Let K and q denote the corresponding values from the last execution of step 2 of the algorithm. Note that

$$f(S^\varepsilon) = \sum_{e\in S^\varepsilon} c_e \le \sum_{e\in S^\varepsilon} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e\in S} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e\in S} q \left(\left\lceil \frac{c_e}{q} \right\rceil + 1 \right) \le \sum_{e\in S} c_e + mq = f(S) + mq$$

where $m = |E|$. Here, the second inequality follows from the fact that S^ε is locally optimal with respect to f'. Together with $f(S^\varepsilon) \ge K/2$, we have

$$\frac{f(S^\varepsilon) - f(S)}{f(S)} \le \frac{mq}{f(S)} \le \frac{mq}{f(S^\varepsilon) - mq} \le \frac{2mq}{K - 2mq} = \varepsilon$$

This completes the proof.

We now analyze the complexity of ε-local search algorithm as given in Ref. [46]. In each improving move within the local search in step 4 of the algorithm, the objective function value (with respect to f') is decreased by at least q units. Thus, the number of calls to IMPROVE$_{\mathrm{N}}$ between two consecutive iterations of step 2 is $O(m(1+\varepsilon)/\varepsilon) = O(m/\varepsilon)$. Step 2 is executed at most $\log f(S^0)$ times, where S^0 is the starting solution. Thus the total number of times neighborhoods searched is $O(m\varepsilon^{-1} \log f(S^0))$. Thus, whenever IMPROVE$_{\mathrm{N}}$ is a polynomial algorithm, ε-local search computes an ε-local optimum in polynomial time for fixed ε.

A strongly polynomial bound on the number of iterations was also proved in Ref. [46]. The proof makes use of the following lemma.

Lemma 20.8 (Radzik [51])

Let $d = (d_1, \ldots, d_m)$ be a real vector and let $y_1, \ldots, y_p$ be vectors on $\{0, 1\}^m$. If for all $i = 1, \ldots, p-1$, $0 \le d\, y_{i+1} \le \frac{1}{2} d y_i$ then $p = O(m \log m)$.

After each execution of step 2, K is reduced at least by half. Further, K is a linear combination of c_e for $e \in E$ with coefficients 0 or 1. Lemma 20.8 implies that step 2 of the ε-local search algorithm can be executed at most $O(m \log m)$ times. Thus IMPROVE$_{\mathrm{N}}$ at step 4 is called at most $\mathrm{O}(\varepsilon^{-1} m^2 \log m)$ times. Let $\zeta(m, \log c_{\max})$ be the complexity of IMPROVE$_{\mathrm{N}}$, $\xi(n)$ be the time needed to obtain a feasible starting solution, and $K^0 = f(S^0)$, where $c_{\max} = \max\{c_{\mathrm{e}} : e \in E\}$. Thus we have the following complexity result.

Theorem 20.9 (Orlin et al. [46])

The ε-local search algorithm correctly identifies an ε-locally optimal solution of an instance of a COP in $O(\xi(n) + \zeta(n, \log c_{max}) n\varepsilon^{-1} min\{n \log n, \log K^0\})$ time.

If the neighborhood N is exact, then ε-local search produces an ε-optimal solution [46]. Suppose that the neighborhood N is searched approximately. That is, IMPROVE$_{\mathrm{N}}$ detects an improved solution or declares that the current solution is δ-locally optimal. Even in this case an ε-local optimum can be identified in (strongly) polynomial time for any fixed ε.

20.5 Concluding Remarks

In this chapter we have discussed techniques for developing VLSN search algorithms. Empirical and theoretical indicators are provided to substantiate our belief that VLSN search algorithms are powerful tools for obtaining high-quality solutions for hard problems in reasonable amount of computational time.

Reactive Search: Machine Learning for Memory-Based Heuristics

Roberto Battiti
University of Trento

Mauro Brunato
University of Trento

21.1 Introduction: The Role of the User in Heuristics

Most state-of-the-art heuristics are characterized by a certain number of choices and free parameters, whose appropriate setting is a subject that raises issues of research methodology [1–3].

In some cases, these parameters are tuned through a feedback loop that *includes the user as a crucial learning component*: depending on preliminary algorithm tests some parameter values are changed by the user, and different options are tested until acceptable results are obtained. Therefore, the quality of results is not automatically transferred to different instances and the feedback loop can require a lengthy "trial-and-error" process every time the algorithm has to be tuned for a new application.

Parameter tuning is therefore a crucial issue both in the scientific development and in the practical use of heuristics. In some cases the role of the user as an intelligent (learning) part makes the reproducibility of heuristic results difficult and, as a consequence, the competitiveness of alternative techniques depends in a crucial way on the user's capabilities.

Reactive Search advocates the use of simple subsymbolic machine learning to automate the parameter tuning process and make it an integral (and fully documented) part of the algorithm.

If learning is performed online, task-dependent and local properties of the configuration space can be used by the algorithm to determine the appropriate balance between *diversification* (looking for better solutions in other zones of the configuration space) and *intensification* (exploring more intensively a small but promising part of the configuration space). In this way a single algorithm maintains the flexibility to deal with related problems through an internal feedback loop that considers the previous history of the search.

In the following, we shall call *reaction* the act of modifying some algorithm parameters in response to the search algorithm's behavior *during* its execution, rather than between runs. Therefore, a *reactive* *heuristic* is a technique with the ability of tuning some important parameters during execution by means of a machine learning mechanism.

It is important to notice that such heuristics are intrinsically history-dependent; thus, the practical success of this approach in some cases raises the need of a sounder theoretical foundation of non-Markovian search techniques.

21.1.1 Machine Learning for Automation and Full Documentation

Parameter tuning is a typical "learning" process where experiments are designed in a focused way, with the support of statistical estimation (parameter identification) tools.

Because of its familiarity with algorithms, the Computer Science (CS) community masters a very powerful tool for describing processes so that they can be reproduced even by a (mechanical) computer. In particular, the Machine Learning community, with significant influx from Statistics, developed in the last decades has a rich variety of "design principles" that can be used to develop machine learning methods and algorithms.

It is therefore appropriate to consider whether some of these design principles can be profitably used in the area of parameter tuning for heuristics. The long-term goal is that of completely *eliminating the human intervention* in the tuning process. This does not imply higher unemployment rates in the CS community, on the contrary, the researcher is now loaded with a heavier task: the algorithm developer must aim at transferring his expertise into the algorithm itself, a task that requires the *exhaustive description of the tuning phase* in the algorithm.

Let us note that the algorithm "complexity" will increase as a result of the process, but the price is worth paying if the two following objectives are reached:

Complete and unambiguous documentation. The algorithm (and the research paper based on the algorithm) becomes self-contained and its quality can be judged independently from the designer or specific user. This requirement is particularly important from the scientific point of view, where objective evaluations are crucial. The recent introduction of software archives (in some cases related to scientific journals) further simplifies the test and *simple reuse* of heuristic algorithms.

Automation. The time-consuming tuning phase is now substituted by an automated process. Let us note that only the final user will typically benefit from an automated tuning process. On the contrary, the algorithm designer faces a longer and harder development phase, with a possible preliminary phase of exploratory tests, followed by the above-described exhaustive documentation of the tuning process when the algorithm is presented to the scientific community.

Although formal learning frameworks do exist in the CS community, notably the Probably Approximately Correct (PAC) learning model [4,5], one should not reach the conclusion that these models can be simply adapted to the new context. On the contrary, the theoretical framework of computational learning theory and machine learning is very different from that of heuristics. For example, the definition of a "quality" function against which the learning algorithm has to be judged is complex. In addition, the abundance of negative results in computational learning should warn about excessive hopes.

Nonetheless, as a first step, some of the principles and methodologies used in machine learning can be used in an analogic fashion to develop "reactive heuristics."

21.1.2 Asymptotic Results Are Irrelevant for Optimization

Scientists, and also final users, might feel uneasy working with non-Markovian techniques because they do not benefit from the deep and wide theoretical background that covers Markovian algorithms. However, asymptotic convergence results of many Markovian search algorithms, such as Simulated Annealing (SA) [6], are often irrelevant for their application to optimization. As an example, a comparison of SA and Reactive Search has been presented in Refs. [7,8].

In any finite-time approximation, one must resort to approximations of the asymptotic convergence. In SA, for instance, the "speed of convergence" to the stationary distribution is determined by the second largest eigenvalue of the transition matrix. The number of transitions is at least *quadratic* in the size of the solution space [9], which is typically exponential in n.

When using a time-varying temperature parameter, it can happen (e.g., the Traveling Salesman Problem (TSP)) that the complete enumeration of all solutions would take less time than approximating an optimal solution with arbitrary precision by SA [9].

In addition, repeated local search [10] and even random search [11] have better asymptotic results. According to Ref. [9] "approximating the asymptotic behavior of SA arbitrarily closely requires a number of transitions that for most problems is typically larger than the size of the solution space [. . .] Thus, the SA algorithm is clearly unsuited for solving combinatorial optimization problems to optimality." Of course, practical utility of SA has been shown in many applications, in particular with fast cooling schedules, but then the asymptotic results are not directly applicable. The optimal finite-length annealing schedules obtained on specific simple problems do not always correspond to those intuitively expected from the limiting theorems [12].

21.2 Reactive Search Applied to Tabu Search

In this section, we illustrate the potential of Reactive Search by installing a reaction mechanism on the prohibition period T of a Tabu Search (TS) [13] algorithm. For the complete description of TS, the reader is referred to Chapter 23 of this handbook.

21.2.1 Prohibition-Based Diversification: Tabu Search

The TS metaheuristic is based on the use of *prohibition-based* techniques and "intelligent" schemes as a complement to basic heuristic algorithms like local search, with the purpose of guiding the basic heuristic *beyond local optimality*. It is difficult to assign a precise date of origin to these principles. For example, ideas similar to those proposed in TS can be found in the *denial* strategy of Ref. [14] (once common features are detected in many suboptimal solutions, they are forbidden) or in the opposite *reduction* strategy of Ref. [15] (in an application to the TSP, all edges that are common to a set of local optima are fixed). In very different contexts, prohibition-like strategies can be found in *cutting planes* algorithms for solving integer problems through their Linear Programming relaxation (inequalities that cut off previously obtained fractional solutions are generated) and in branch and bound algorithms (subtrees are not considered if the leaves cannot correspond to better solutions). For many examples of such techniques, see Ref. [16].

The renaissance and full blossoming of "intelligent prohibition-based heuristics" starting from the late 1980s is greatly due to the role of F. Glover in the proposal and diffusion of a rich variety of metaheuristic tools [13,17], but see also Ref. [18] for an independent seminal paper. A growing number of TS-based algorithms has been developed in the last years and applied with success to a wide selection of problems [19]. It is therefore difficult, if not impossible, to characterize a "canonical form" of TS, and classifications tend to be short-lived. Nonetheless, at least two aspects characterize many versions of TS: the fact that TS is used to complement local (neighborhood) search, and the fact that the main modifications to local search are obtained through the *prohibition* of selected moves available at the current point. TS acts to continue the search beyond the first local minimizer without wasting the work already executed, as it is the case if a new run of local search is started from a new random initial point, and to enforce appropriate amounts of diversification to avoid that the search trajectory remains confined near a given local minimizer.

In our opinion, the main competitive advantage of TS with respect to alternative heuristics based on local search like SA [6] lies in the intelligent use of the past history of the search to influence its future steps.

For a generic search space $\mathcal{X}$, let $X^{(t)} \in \mathcal{X}$ be the current configuration and $N(X^{(t)}) \subseteq \mathcal{X}$ its neighborhood. In prohibition-based search (TS) some of the neighbors can be *prohibited*, and let the subset $N_A(X^{(t)}) \subseteq N(X^{(t)})$ contain the *allowed* ones. The general way of generating the search trajectory that we consider is given by

$$X^{(t+1)} = \text{Best-Neighbor}\left(N_A\left(X^{(t)}\right)\right) \tag{21.1}$$

$$N_A(X^{(t+1)}) = \text{Allow}\left(N\left(X^{(t+1)}\right), X^{(0)}, \ldots, X^{(t+1)}\right) \tag{21.2}$$

The set-valued function ALLOW selects a subset of $N\big(X^{(t+1)}\big)$ in a manner that depends on the search trajectory $X^{(0)}, \ldots, X^{(t+1)}$.

This general framework allows several specializations. In many cases, the dependence of ALLOW on the entire search trajectory introduces too many constraints on the next move, causing the search path to avoid an otherwise promising area, or even prohibiting all neighbors. It is therefore advisable to reduce the amount of constraints by limiting the ALLOW function to the latest T configurations (where the parameter T is often called the *prohibition period*), so that Eq. (21.2) becomes

$$N_A\big(X^{(t+1)}\big) = \text{ALLOW}\left(N\big(X^{(t+1)}\big), X^{(t')}, \ldots, X^{(t+1)}\right), \quad t' = \max\{0, t - T + 1\} \qquad (21.3)$$

A practical example for Eq. (21.3) is a function ALLOW that forbids all moves that have been performed within the last T iterations. For instance, let us assume that the feasible search space $\mathcal{X}$ is the set of binary strings with a given length $L : \mathcal{X} = \{0, 1\}^L$ (this case shall be considered also in the example of Section 21.4). In this case, a practical neighborhood of configuration $X^{(t)}$ is given by the L configurations that differ from $X^{(t)}$ by a single entry. In such a case, a simple prohibition scheme may allow a move if and only if it changes an entry which has remained fixed for the previous T iterations. In other words, after an entry has been changed, it shall remain *frozen* for the following T steps.

It is apparent that the choice of the right prohibition period T is crucial to balance the amount of *intensification* (small T) and *diversification* (large T).

21.2.2 Reaction on Tabu Search Parameters

Some problems arising in TS that have been investigated in Reactive Search papers are

1. the determination of an appropriate prohibition T for the different tasks,
2. the robustness of the technique for a wide range of different problems, and
3. the adoption of minimal computational complexity algorithms for using the search history.

The three issues are briefly discussed in the following sections, together with the reaction-based methods proposed to deal with them.

21.2.2.1 Self-Adjusted Prohibition Period

In Reactive Tabu Search (RTS), i.e., Reactive Search applied to TS, the *prohibition period* T is determined through feedback (i.e., *reactive*) mechanisms during the search. At the beginning, we let $T = 1$ (the inverse of a given move is prohibited only at the next step). During the search, T increases only when there is *evidence* that diversification is needed, and it decreases when this evidence disappears. In detail: the evidence that diversification is needed is signaled by the repetition of previously visited configurations. For this purpose, all configurations found during the search are stored in memory. After a move is executed, the algorithm checks whether the current configuration has already been found and reacts accordingly (T increases if a configuration is repeated, T decreases if no repetitions occurred during a sufficiently long period).

By means of this self-adjustment algorithm, T is not fixed during the search, but it is determined in a dynamic way depending on the *local structure* of the search space. This is particularly relevant for "inhomogeneous" tasks, where the statistical properties of the search space vary widely in the different regions (in these cases a fixed T would be inappropriate).

An example of the behavior of T during the search is illustrated in Figure 21.1, for a Quadratic Assignment Problem task [20]. T increases in an exponential way when repetitions are encountered, it decreases in a gradual manner when repetitions disappear.

21.2.2.2 The Escape Mechanism

The basic tabu mechanism based on prohibitions is not sufficient to avoid long cycles. As an example, when operating on binary strings of length L, the prohibition T must be less than the length of the string, otherwise all moves are eventually prohibited; therefore, cycles longer than 2 × L are still possible. In addition, even if "limit cycles" (endless cyclic repetitions of a given set of configurations) are avoided, the

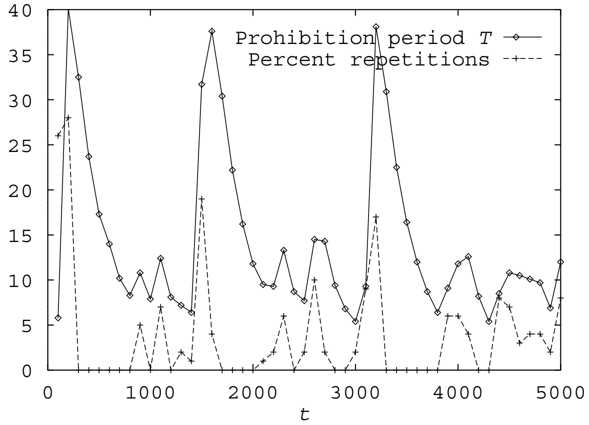

FIGURE 21.1 Dynamics of the prohibition period T on a QAP task.

first reactive mechanism is not sufficient to guarantee that the search trajectory is not confined in a limited region of the search space. A "chaotic trapping" of the trajectory in a limited portion of the search space is still possible (the analogy is with *chaotic attractors* of dynamical systems, where the trajectory is confined in a limited portion of the space, although a limit cycle is not present).

For both reasons, to increase the robustness of the algorithm a second more radical diversification step (*escape*) is needed. The *escape* phase is triggered when too many configurations are repeated too often [20]. A simple *escape* consists of a number of random steps executed starting from the current configuration (possibly with a bias toward steps that bring the trajectory away from the current search region).

With a stochastic escape, one can easily obtain the *asymptotic convergence* of RTS: in fact, in a finite search space *escape* is activated infinitely often; if the probability for a point to be reached after escaping is different from zero for all points, eventually all points will be visited—clearly including the globally optimal points. The detailed investigation of the asymptotic properties and finite-time effects of different *escape* routines to enforce long-term diversification is an open research area.

21.2.3 Implementation of History-Sensitive Techniques

The efficiency and competitiveness of history-based reaction mechanisms strongly depend on the detailed data structures used in the algorithms and on the consequent realization of the needed operations. Different data structures can possess widely different computational complexities so that attention should be spent on this subject before choosing a version of Reactive Search that is efficient on a particular problem.

Reactive-TS can be implemented through a simple list of visited configurations, or with more efficient hashing [21,20] or radix tree [20] techniques. At a finer level of detail, hashing can be realized in different ways. If the entire configuration is stored (see also Figure 21.2) an exact answer is obtained from the memory lookup operation (a repetition is reported if and only if the configuration has been visited before). On the contrary, if a "compressed" item is stored, like a hashed value of a limited length derived from the configuration, the answer will have a limited probability of *false positives* (a repetition can be reported even if the configuration is new, because the compressed items are equal by chance—an event called "collision"). Experimentally, small collision probabilities do not have statistically significant effects on the use of Reactive-TS as a heuristic tool, and hashing versions that need only a few bytes per iteration can be used.

21.2.3.1 Fast Algorithms for Using the Search History

The storage and access of the past events is executed through the well-known hashing or radix-tree techniques in a CPU time that is approximately *constant* with respect to the number of iterations. Therefore, the overhead caused by the use of the history is negligible for tasks requiring a nontrivial number of operations to evaluate the cost function in the neighborhood.

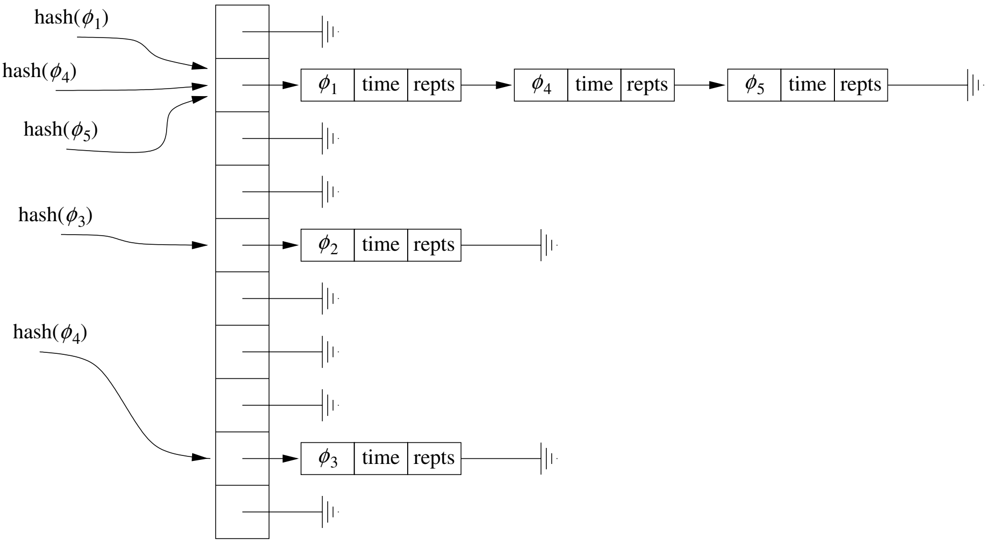

FIGURE 21.2 Open hashing scheme: items (configuration or compressed hashed value) are stored in "buckets." The index of the bucket array is calculated from the configuration.

An example of a memory configuration for the hashing scheme is shown in Figure 21.2. From the current configuration ϕ one obtains an index into a "bucket array." The items (configuration or hashed value or derived quantity, last time of visit, and total number of repetitions) are then stored in linked lists starting from the indexed array entry. Both storage and retrieval require an approximately constant amount of time if (i) the number of stored items is not much larger than the size of the bucket array and (ii) the *hashing function* scatters the items with a uniform probability over the different array indices. More precisely, given a hash table with m slots that stores n elements, a load factor $\alpha = n/m$ is defined. If collisions are resolved by chaining searches take $O(1 + \alpha)$ time, on average.

21.2.3.2 Persistent Dynamic Sets

Persistent dynamic sets are proposed to support memory-usage operations in history-sensitive heuristics in Refs. [22,23].

Ordinary data structures are *ephemeral* [24] because when a change is executed the previous version is destroyed. Now, in many contexts like computational geometry, editing, implementation of very high-level programming languages, and, last but not least, the context of history-based heuristics, multiple versions of a data structure must be maintained and accessed. In particular, in heuristics one is interested in *partially persistent* structures, where all versions can be accessed but only the newest version (the *live* nodes) can be modified. A review of ad hoc techniques for obtaining persistent data structures is given in Ref. [24] that is dedicated to a systematic study of persistence, continuing the previous work of Ref. [25].

Hashing Combined with Persistent Red-Black Trees

The basic observation is that, because TS is based on local search, configuration $X^{(t+1)}$ differs from configuration $X^{(t)}$ only because of the addition or subtraction of a single index (a single bit is changed in the string). Let us define the operations INSERT(i) and DELETE(i) for inserting and deleting a given index i from the set. As cited above, configuration X can be considered as a set of indices in $[1, L]$ with a possible realization as a balanced red-black tree (see Refs. [26,27] for two seminal papers about red-black trees). The binary string can be immediately obtained from the tree by visiting it in symmetric order, in time $O(L)$. INSERT(i) and DELETE(i) require $O(\log L)$ time, while at most a single node of the tree is allocated or deallocated at each iteration. Rebalancing the tree after insertion or deletion can be done in $O(1)$ rotations and $O(\log L)$ color changes [28]. In addition, the amortized number of color changes per update is $O(1)$ (see, e.g., Ref. [29]).

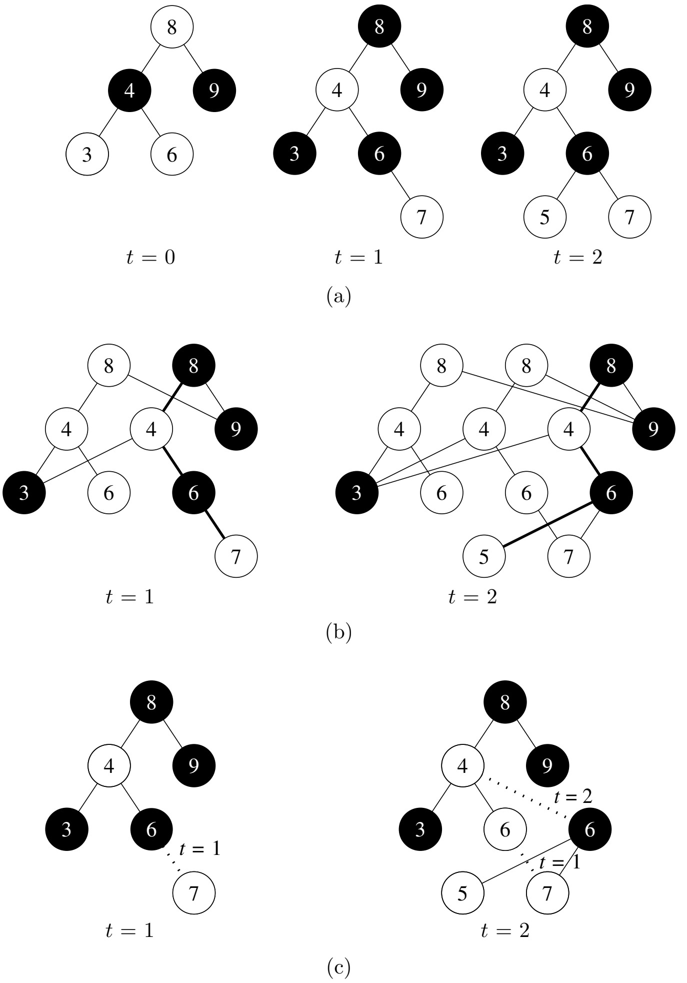

FIGURE 21.3 How to obtain (a) a partially persistent red-black tree from an ephemeral one, containing indices 3, 4, 6, 8, 9 at $t = 0$, with subsequent insertion of 7 and 5; a persistent red-black tree with path copying, with thick lines marking the copied part; (c) a persistent red-black tree with limited node copying, with broken lines denoting the "extra" pointers with time stamp.

Now, the Reverse Elimination Method [13,17,30] (a technique for the storage and analysis of the ordered list of all moves performed throughout the search) is closely reminiscent of a method studied in Ref. [25] to obtain partial persistence, in which the entire update sequence is stored and the desired version is rebuilt from scratch each time an access is performed, while a systematic study of techniques with better space–time complexities is present in Refs. [24,31]. Let us now summarize from Ref. [31] how a partially persistent red-black tree can be realized. An example of the realizations that we consider is presented in Figure 21.3.

The trivial way is that of keeping in memory all copies of the ephemeral tree (see Figure 21.3(a)), each copy requiring $O(L)$ space. A smarter realization is based on *path copying*, independently proposed by many researchers (see Ref. [31] for references). Only the path from the root to the nodes where changes are made is copied: a set of search trees is created, one per update, having different roots but *sharing* common subtrees. The time and space complexities for INSERT(i) and DELETE(i) are now of $O(\log L)$.

The method that we will use is a space-efficient scheme requiring only linear space proposed in Ref. [31]. The approach avoids copying the entire access path each time an update occurs. To this end, each node contains an additional "extra" pointer (beyond the usual left and right ones) with a time stamp.

When attempting to add a pointer to a node, if the extra pointer is available, it is used and the time of the usage is registered. If the extra pointer is already used, the node is copied, setting the initial left and right pointers of the copy to their latest values. In addition, a pointer to the copy is stored in the last parent of the copied node. If the parent has already used the extra pointer, the parent, too, is copied. Thus copying proliferates through successive ancestors until the root is copied or a node with a free extra pointer is encountered. Searching the data structure at a given time t in the past is easy: after starting from the appropriate root, if the extra pointer is used the pointer to follow from a node is determined by examining the time stamp of the extra pointer and following it iff the time stamp is not larger than t. Otherwise, if the extra pointer is not used, the normal left–right pointers are considered. Note that the pointer direction (left or right) does not have to be stored: given the search tree property it can be derived by comparing the indices of the children with that of the node. In addition, colors are needed only for the most recent (live) version of the tree. In Figure 21.3 `null` pointers are not shown, colors are correct only for the live tree (the nodes reachable from the rightmost root), extra pointers are dashed and time-stamped.

The worst-case time complexity of INSERT(i) and DELETE(i) remains of $O(\log L)$, but the important result derived in Ref. [31] is that the amortized space cost per update operation is $O(1)$. Let us recall that the total amortized space cost of a sequence of updates is an upper bound on the actual number of nodes created.

Let us now consider the context of history-based heuristics. Contrary to the popular usage of persistent dynamic sets to search past versions at a specified time t, one is interested in checking whether a configuration has already been encountered in the previous history of the search, at *any* iteration.

A convenient way of realizing a data structure supporting X-SEARCH(X) is to combine *hashing* and *partially persistent dynamic sets* (see Figure 21.4). From a given configuration X an index into a "bucket array" is obtained through a hashing function, with a possible incremental evaluation in time $O(1)$. Collisions are resolved through chaining: starting from each bucket header there is a linked list containing a pointer to the appropriate root of the persistent red-black tree and satellite data needed by the search (time of configuration, number of repetitions).

As soon as configuration $X^{(t)}$ is generated by the search dynamics, the corresponding persistent red-black tree is updated through INSERT(i) or DELETE(i). Let us now describe X-SEARCH($X^{(t)}$): the hashing value is computed from $X^{(t)}$ and the appropriate bucket searched. For each item in the linked list the

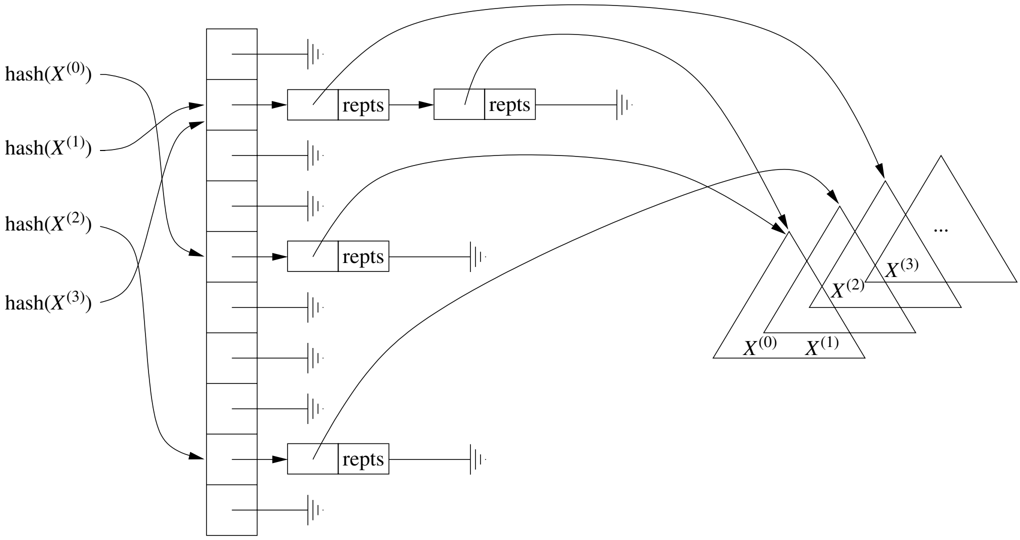

FIGURE 21.4 Open hashing scheme with persistent sets: a pointer to the appropriate root for configuration $X^{(t)}$ in the persistent search tree is stored in a linked list at a "bucket." Items on the list contain satellite data. The index of the bucket array is calculated from the configuration through a hashing function.

pointer to the root of the past version of the tree is followed and the old set is compared with $X^{(t)}$. If the sets are equal, a pointer to the item on the linked list is returned. Otherwise, after the entire list has been scanned with no success, a `null` pointer is returned.

In the last case a new item is linked in the appropriate bucket with a pointer to the root of the live version of the tree (X-INSERT(X, t)). Otherwise, the last visit time t is updated and the repetition counter is incremented.

After collecting the above cited complexity results, and assuming that the bucket array size is equal to the maximum number of iterations executed in the entire search, it is straightforward to conclude that each iteration of *reactive-TS* requires $O(L)$ average-case time and $O(1)$ amortized space for storing and retrieving the past configurations and for establishing prohibitions.

In fact, both the hash table and the persistent red-black tree require $O(1)$ space (amortized for the tree). The worst-case time complexity per iteration required to update the current $X^{(t)}$ is $O(\log L)$, the average-case time for searching and updating the hashing table is $O(1)$ (in detail, searches take time $O(1 + \alpha)$, α being the load factor, in our case upper bounded by 1). The time is therefore dominated by that required to compare the configuration $X^{(t)}$ with that obtained through X-SEARCH($X^{(t)}$), i.e., $O(L)$ in the worst case. Because $\Omega(L)$ time is needed during the neighborhood evaluation to compute the f values, the above complexity is optimal for the considered application to history-based heuristics.

21.3 Wanted: A Theory of History-Sensitive Heuristics

Randomized Markovian local search algorithms have enjoyed a long period of scientific and applicative excitement, in particular see the flourishing literature on SA [6,32]. SA generates a *Markov chain*: the successor of the current point is chosen stochastically, with a probability that does not depend on the previous history (standard SA does not learn). A consequence is that the "trapping" of the search trajectory in an attractor cannot be avoided: the system has no memory and cannot detect that the search is localized. Incidentally, the often cited asymptotic convergence results of SA are unfortunately irrelevant for the application of SA to optimization. In fact, repeated local search [10], and even random search [11] has better asymptotic results.

History-sensitive techniques in local search contain an internal *feedback loop* that uses the information derived from the past history to influence the future behavior. In the cited prohibition-based diversification techniques one can, for example, decide to increase the diversification when configurations are encountered again along the search trajectory [20,33]. It is of interest that state-of-the-art versions of SA incorporate "temporal memory" [34]. The non-Markovian property is a mixed blessing: it permits heuristic results that are much better in many cases, but makes the theoretical analysis of the algorithm difficult.

Therefore, one has an unfortunate chasm: on one side there is an abundance of mathematical results derived from the theory of Markov processes, but their relevance to optimization is dubious, on the other there is mounting evidence that simple *machine learning* or history-sensitive schemes can augment the performance of heuristics in a significant way, but the theoretical instruments to analyze history-sensitive heuristics are lacking.

The practical success of history-sensitive techniques should motivate new search streams in Mathematics and Computer Science for their theoretical foundation.

21.4 Applications of Reactive Search and the Maximum Clique Example

Reactive Search principles have been used for example for the problem of Quadratic Assignment [20], training neural nets and control problems [35], vehicle-routing problems [36–38], structural acoustic control problems [39], special-purpose VLSI realizations [40], graph partitioning [41], electric power distribution [42], maximum satisfiability [43], constraint satisfaction [44,45], optimization of continuous functions [46,47], traffic grooming in optical networks [48], maximum clique [33], real-time dispatch of trams in storage yards [49], and increasing Internet capacity [50]. Because of space limitation we consider with some detail only the application to the Maximum Clique (MC) problem.

The MC problem is NP-hard, and strong negative results have been shown about its approximability [51,52]. In particular, if P $\neq$ NP, MC is *not approximable* within $n^{1/4-\epsilon}$ for any $\epsilon > 0$, n being the number of nodes in the graph [53], and it is not approximable within $n^{1-\epsilon}$ for any $\epsilon > 0$, unless coRP = NP [54].

These theoretical results stimulated a research effort to design efficient heuristics for this problem, and computational experiments to demonstrate that optimal or close approximate values can be efficiently obtained for significant families of graphs [55,56].

In particular, a new *reactive* heuristic (Reactive Local Search (RLS)) is proposed for the MC problem in Ref. [33]. The present description is a summarized version of the cited paper.

The experimental efficacy and efficiency [33] of RLS is strengthened by an analysis of the complexity of a single iteration. It is possible to show that the worst-case cost is $O(\max\{n, m\})$, where n and m are the number of nodes and edges, respectively. In practice, the cost analysis is pessimistic and the measured number of operations tends to be a small constant times the average degree of nodes in $\overline{G}$, the complement of the original graph.

21.4.1 Reactive Local Search for Max Clique

The RLS algorithm for the MC problem takes into account the particular neighborhood structure of MC. This is reflected in the following two facts: a single reactive mechanism is used to determine the prohibition parameter T, and an explicit restart scheme is added so that all possible configurations will eventually be visited, even if the search space is not connected by using the basic local search moves. Both building blocks of RLS use the past history of the search (set of visited configurations) to influence the choice.

The admissible search space $\mathcal{X}$ is the set of all cliques in a graph G defined over a vertex set V. Let us recall that a clique is a subset X of V such that all pairs of nodes in X are connected by an edge. The function to be maximized is the clique size $f(X) = |X|$, X being the current clique, and the neighborhood $M(X)$ consists of all cliques that can be obtained from X by adding or dropping a single vertex (*add* or *drop* moves).

At a given iteration, the neighborhood set $M(X)$ is partitioned into the set of *prohibited* neighbors and the set of *allowed* ones. As soon as a vertex is moved (added or removed from the current clique), changing its status is prohibited for the next T iterations; it is allowed otherwise. With a slight abuse of terminology, the terms *allowed* and *prohibited* shall also be applied to vertices.

The top-level description of RLS is shown in Figure 21.5. First (lines 2–5) the relevant variables and structures are initialized: they are the iteration counter t, the prohibition period T, the time t_T of the last

Global variables and data structures	
t	Time (iteration counter)
t_T	Time of last period change
S	Nodes in $V \backslash X$ adjacent to all nodes in X
deltaS[j]	Nodes in $V \backslash S$ adjacent to all nodes in $X \setminus \{j\}$
k_b	Cardinality of best configuration
lastMoved[v]	Time of last movement concerning node v

Local variables	
T	Prohibition period
t_R	Time of last restart
X	Current configuration
I_b	Best configuration
t_b	Time of best configuration

```
 1. procedure Reactive-Local-Search

```

FIGURE 21.5 RLS algorithm: pseudocode description.

change of T, the last restart time t_R, the current clique X, the largest clique I_b found so far with its size k_b, and the iteration t_b at which it is found. The set S shall be used by function BEST-NEIGHBOR and contains the set of eligible nodes to improve the current clique (initially, the current clique is empty, and no node is prohibited, so all nodes in V are eligible); the role of array *deltaS* shall be explained in Section 21.4.1.1. Then the loop (lines 6–15) continues to be executed until a satisfactory solution is found or a limiting number of iterations is reached.

The function HISTORY-REACTION searches for the current clique X in memory, inserts it if it is a new one, and adjusts the prohibition T through feedback from the previous history of the search.

Then the best neighbor is selected and the current clique updated (line 8). The iteration counter is incremented. If a better solution is found, the new solution, its size, and the time of the last improvement are saved (lines 10–11). A restart is activated after a suitable number of iterations are executed from the last improvement and from the last restart (lines 12–13).

The prohibition period T is equal to one at the beginning, because in this manner one avoids coming back to the just abandoned clique. Nonetheless, let us note that RLS behaves exactly as local search in the first phase, as long as only new vertices are added to the current clique X, and therefore prohibitions do not have any effect. The difference starts when a maximal clique with respect to set inclusion is reached and the first vertex is dropped.

21.4.1.1 Choice of the Best Neighbor

The function BEST-NEIGHBOR is described in Figure 21.6. Given a current clique X, let us define S as the vertex set of possible additions, i.e., the vertices that are adjacent to all nodes of X. Let $G(S)$ be the subgraph induced by S. Finally, if $j \in X$, *deltaS*$[j]$ is the number of vertices adjacent to all nodes of X but j. A vertex v is *prohibited* at iteration t iff it satisfies *lastMoved*$[v] \geq (t - T^{(t)})$, where *lastMoved*$[v]$ is the last iteration at which it has been added to or dropped from the current clique. Vector *lastMoved* is used to determine the allowed vertices (see lines 3 and 11).

The best neighbor is chosen in stages with this overall scheme: first an allowed vertex that can be added to the current clique is searched for (lines 3–7). If none is found, an allowed vertex to drop is searched for (lines 10–13). Finally, if no allowed moves are available, a random vertex in X is dropped if X is not empty (line 15), a random vertex in V is added in the opposite case (lines 16–18).

Parameters	
X	Configuration to be changed

Local variables	
type	Type of move (addMove or dropMove)
v	Node to be added or removed

```
1.  function BEST-NEIGHBOR ($X$)
2.      $type \leftarrow$ notFound
3.      if {allowed nodes $\in S\} \neq \emptyset$
4.          $type \leftarrow$ addMove
5.          $maxDegAllowed \leftarrow$ maximum degree in $G(S)$
6.          $v \leftarrow$ random allowed $w \in S$
7.              with $\deg_{G(S)}(w) = maxDegAllowed$
8.      if $type =$ notFound and $X \neq \emptyset$
9.          $type \leftarrow$ dropMove
10.         if {allowed $v \in X\} \neq \emptyset$
11.             $maxDeltaS \leftarrow \max_{\text{allowed} j \in X} deltaS[j]$
12.             $v \leftarrow$ random allowed $w \in X$
13.                 with $deltaS[w] = maxDeltaS$
14.         else
15.             $v \leftarrow$ random $w \in X$
16.     if $type =$ notFound
17.         $type \leftarrow$ addMove
18.         $v \leftarrow$ random $w \in V$
19.     INCREMENTAL-UPDATE ($v$, $type$)
20.     if $type =$ addMove return $X \cup \{v\}$
21.         else return $X \setminus \{v\}$
```

FIGURE 21.6 RLS algorithm: the function BEST-NEIGHBOR.

Local variables	
Z	Hash item (or pointer)
$lastVisit[Z]$	Time of last visit of item Z
R	Time since last visit

```
1.  function HISTORY-REACTION ($X$, $T$)
2.      $Z \leftarrow$ HASH-SEARCH ($X$)
3.      if $Z \neq$ null
4.          $R \leftarrow t$ - $lastVisit[Z]$
5.          $lastVisit[Z] \leftarrow t$
6.          if $R < 2(n\text{-}1)$
7.              $t_T \leftarrow t$
8.              return INCREASE($T$)
9.      else
10.         HASH-INSERT($X$, $t$)
11.     if $t$ - $t_T > 10\ k_b$
12.         $t_T \leftarrow t$
13.         return DECREASE($T$)
14.     return $T$
```

FIGURE 21.7 RLS algorithm: routine HISTORY-REACTION.

Ties among *allowed* vertices that can be added are broken by preferring the ones with the largest degree in $G(S)$ (line 7); a random selection is executed among vertices with equal degree in $G(S)$.

Ties among *allowed* vertices that can be dropped are broken by preferring those causing the largest increase $|S^{(t+1)}| - |S^{(t)}|$ where, $S^{(t)}$ is the set S at iteration t (line 13). Again, a random selection is then executed if this criterion selects more that one winner.

21.4.1.2 Reaction and Periodic Restart

The function HISTORY-REACTION is illustrated in Figure 21.7. The prohibition T is minimal at the beginning ($T = 1$), and is then determined by two competing processes: T increases when the current clique comes back to one already found, it decreases when no cliques are repeated in a suitable period. In detail: the current clique X is searched in memory by utilizing hashing techniques (line 1). If X is found, a reference Z is returned to a data structure containing the last visit time (line 2). If the repetition interval R is sufficiently short, cycles are discouraged by increasing T (lines 5–7). If X is not found, it is stored in memory with the time t when it was encountered (line 9). If T remained constant for a number of iterations greater than $10k_b$, and therefore no clique is repeated during this interval, it is decreased (lines 10–12). Increases and decreases, with a minimal change of one unit plus upper and lower bounds, are realized by the two following functions:

$$\text{INCREASE}(T) = \min\{\max\{T \cdot 1.1,\ T + 1\},\ n - 2\}$$
$$\text{DECREASE}(T) = \max\{\min\{T \cdot 0.9,\ T - 1\},\ 1\}$$

The routine RESTART is similar to that in Ref. [57]. If there are vertices that have never been part of the current clique during the search, i.e., that have never been moved since the beginning of the run, one of them with maximal degree in V is randomly selected (lines 3–5 in Figure 21.8). If all vertices have already

Local variables	
L	Nodes in V not moved yet

```
1.  procedure RESTART
2.      $T \leftarrow 1$ ; $t_T \leftarrow t$
3.      if $\exists v \in V(lastMoved[v] = -\infty)$
4.          $L \leftarrow \{w \in V\text{: } lastMoved[w] = -\infty\}$
5.          $v \leftarrow$ random vertex with maximum $\deg_{G(V)}(v)$ in $L$
6.      else
7.          $v \leftarrow$ random vertex $\in V$
8.      relevant data structures are reinitialized
9.      INCREMENTAL-UPDATE ($v$, addMove)
10.     X $\leftarrow \{v\}$
```

FIGURE 21.8 RLS algorithm: routine RESTART.

been members of X in the past, a random vertex in V is selected (line 7). Data structures are updated to reflect the situation of $X = \emptyset$, then the incremental update is applied and the vertex v is added.

21.4.2 Complexity per Iteration

The computational complexity of each iteration of RLS is the sum of a term caused by the usage and updating of reaction-related structures and a term caused by the local search part: neighborhood evaluation and generation of the next clique.

Let us first consider the reaction-related part. The overhead per iteration incurred to determine the prohibitions is $O(|M(X)|)$, $M(X)$ being the neighborhood, that for updating the last usage time of the chosen move is $O(1)$, that to check for repetitions and to update and store the new *hashing value* of the current configuration has an average complexity of $O(1)$, if an incremental *hashing* calculation is applied.

In our case the single-iteration RLS complexity is dominated by the neighborhood evaluation. This evaluation requires an efficient update of the sets S and SMINUS plus the computation of the degrees of the vertices in the induced subgraph $G(S)$ (used in function BEST-NEIGHBOR, Figure 21.6, line 6). It is therefore crucial to consider incremental algorithms, in an effort to reduce the complexity. In our algorithm, the sets S and SMINUS are maintained by the routine INCREMENTAL-UPDATE that is used in the function BEST-NEIGHBOR and in the procedure RESTART. The limited space of this extended abstract force us to omit the detailed description of INCREMENTAL-UPDATE and of the related data structures. The following theorem is proved in the full paper:

Theorem 21.1

The incremental algorithm for updating X, S, and SMINUS *during each iteration of RLS has a worst-case complexity of $O(n)$. In particular, if vertex v is added to or deleted from S, the required operations are $O(\deg_{\overline{G}}(v))$.*

Let us note that the actual multiplicative constant is very small and that the algorithm tends to be faster for dense graphs, where the average degree $\deg_{\overline{G}}(v)$ in the complement graph can be much smaller than n.

Finally, the computation of the vertex degrees in the induced subgraph $G(S)$ costs at most $O(m)$ by the following trivial algorithm. All the edges are inspected, if both endpoints are in S, the corresponding degrees are incremented by 1. In practice the degree is not computed from scratch but it is updated incrementally with a much lesser computational effort; in fact, the maximum number of nodes that enter or leave S at a given iteration is at most $\deg_{\overline{G}}(v)$, v being the just moved vertex. Therefore, the number of operations performed is at most $O(\deg_{\overline{G}}(v) \cdot |S^{(t+1)}|)$. Because the search aims at maximizing the clique X, the set S tends to be very small (at some steps empty!) after a first transient period, and the dominant factor is the same $O(\deg_{\overline{G}}(v))$ factor that appears in the above theorem.

Putting together all the complexity considerations the following corollary is immediately implied:

Corollary 21.1

The worst-case complexity of a single iteration is $O(\max\{n, m\})$.

Experimental results of RLS on the benchmark suite for the MC problem by the organizers of the Second DIMACS Implementation Challenge [55] are analyzed in Ref. [33].

21.5 Related Reactive Approaches

Because Reactive Search is rooted in the automation of the algorithm tuning process by embodying the typical experimental cycle followed by heuristic algorithm designers, it is not surprising to see related ideas and principles arising in various areas. For space limitation we list in this section a limited selection of interesting related papers.

Probabilistic methods that explicitly maintain statistics about the search space by creating models of the good solutions found so far are considered, for example, in Refs. [58,59].

Implicit models of the configuration space are built by a population of searchers in Genetic Algorithms, where learning comes in the form of "survival of the fittest" and generation of new sampling points depends on the previous evolution (see, e.g., Ref. [60]). The issue of controlling parameters of an evolutionary algorithm, including adaptive and "self-adaptive" techniques is considered in Ref. [61], while fitness landscape analysis for the choice of appropriate operators in "memetic" algorithms (combining genetic algorithms with local search) is considered in Ref. [62].

In the area of stochastic optimization, which considers noise in the evaluation process, memory-based schemes for validation and tuning of function approximators are used in Refs. [63,64].

Guided local search aims at exploiting the problem and search-related information to effectively guide local search heuristics [65]. Evaluation functions for global optimization and Boolean satisfiability are learnt in Ref. [66].

Learning mechanisms with biological motivations are used in Ant Colony Optimization based on feedback, distributed computation, and the use of a constructive greedy heuristic. For example, "pheromone trail" information to perform modifications on solutions for the quadratic assignment problem is considered in Refs. [67,68].

Dynamic local search, which increases penalties of some solution components to move the tentative solution away from a given local minimum can also be considered as a form of learning based on the previous history of the search. An example is the dynamic local search algorithm on the MAXSAT problem in Ref. [69], see also Ref. [70] for additional references about stochastic local search methods including adaptive versions.

In the area of computer systems management, "autonomic" systems are based on self-regulating biological systems (http://www.research.ibm.com/autonomic/), which have many points of contact with Reactive Search.

22.1 Introduction

Artificial neural networks have been proposed as a tool for machine learning (see, e.g., Refs. [1–4]) and many results have been obtained regarding their application to practical problems in robotics control, vision, pattern recognition, grammatical inferences, and other areas (see, e.g., Refs. [5–8]). In these roles, a neural network is trained to recognize complex associations between inputs and outputs that were presented during a *supervised* training cycle. These associations are incorporated into the weights of the network, which encode a distributed representation of the information that were contained in the input patterns. Once trained, the network will compute an input/output mapping which, if the training data were representative enough, will closely match the unknown rule which produced the original data. Massive parallelism of computation, as well as noise and fault tolerance, are often offered as justifications for the use of neural nets as learning paradigms.

Traditionally, especially in the structural complexity literature (see, e.g., Ref. [4]), feedforward circuits composed of AND, OR, NOT, or threshold gates have been thoroughly studied. However, in practice, when designing a neural net, continuous activation functions such as the *standard sigmoid* are more commonly used. This is because usual learning algorithms such as the backpropagation algorithm assumes a continuous activation function. As a result, neural nets are distinguished from those conventional circuits because they perform real-valued computation and admit efficient learning procedures. The last three decades have seen a resurgence of theoretical techniques to design and analyze the performances of neural nets (see, e.g., the survey in Ref. [9]) as well as novel application of neural nets to various applied areas (see, e.g., Ref. [6] and some of the references there). Theoretical researches in computational capabilities of neural nets have given valuable insights into the mechanisms of these models.

In subsequent discussions, we distinguish between two types of neural networks, commonly known as the "feedforward" neural nets and the "recurrent" neural nets. A feedforward net consists of a number of processors ("nodes" or "neurons") each of which computes a function of the type $y = \sigma(\sum_{i=1}^{k} a_i u_i + b)$ of its inputs $u_1, \ldots, u_k$. These inputs are either external (input data are fed through them) or they represent the outputs y of other nodes. No cycles are allowed in the connection graph and the output of one designated node is understood to provide the output value produced by the entire network for a given

[*] B. DasGupta was supported in part by NSF grants CCR-0206795, CCR-0208749, and IIS-0346973.

vector of input values. The possible coefficients a_i and b appearing in the different nodes are the *weights* of the network, and the functions σ appearing in the various nodes are the *node*, *activation*, or *gate* functions. An *architecture* specifies the interconnection structure and the σs, but not the actual numerical values of the weights. A recurrent neural net, however, allows cycles in the connection graph, thereby allowing the model to have substantially more computational capabilities (see Section 22.3.2).

In this chapter we survey research works dealing with basic questions regarding *computational capabilities* and *learning* of neural models. There are various types of such questions that one may ask, most of them closely related and complementary to each other. We next describe a few of them *informally*.

One direction of research deals with the *representational capabilities* of neural nets, assuming *unlimited* number of neurons are available (see, e.g., Refs. [10–16]). The origin of this type of research can be traced back to the work of the famous mathematician Kolmogorov [17], who essentially proved the first existential result on the representation capabilities of depth 2 neural nets. This type of research ignores the training question itself, asking instead if it is *at all* possible to compute or approximate arbitrary functions (e.g., Refs. [11–17]) or if the net can simulate, say, Turing machines (e.g., Refs. [15,16]). Many of the results and proofs in this direction are nonconstructive.

Another perspective to learnability questions of neural nets takes a *numerical analysis or approximation theoretic* point of view. There one asks questions such as *how many* hidden units are necessary to well approximate, that is to say, approximate with a small overall error, an unknown function. This type of research also ignores the training question, asking instead what is the best one could do, in this sense of overall error, if the best possible network with a given architecture were to be eventually found. Some papers along these lines are Refs. [18,19], which dealt with single hidden layer nets and Ref. [20], which dealt with multiple hidden layers.

Another possible line of research deals with the *sample complexity* questions, that is, the quantification of the amount of information (number of samples) needed to characterize a given unknown mapping. Some recent references to such work, establishing sample complexity results, and hence "weak learnability" in the Valiant model, for neural nets, are the papers in Refs. [21–25]; the first of these references deals with networks that employ hard threshold activations, the third and fourth cover continuous activation functions of a type (piecewise polynomial), and the last one provides results for networks employing the standard sigmoid activation function.

Yet another direction in which to approach theoretical questions regarding learning by neural networks originates with the work of Judd (see, e.g., Refs. [26,27] as well as the related work [28,29]). Judd was motivated by the observation that the "backpropagation" algorithm often runs very slowly, especially for high-dimensional data. Recall that this algorithm is used to find a network (i.e., find the weights, assuming a fixed architecture) that reproduces the observed data. Of course, many modifications of the vanilla "backprop" approach are possible, using more sophisticated techniques such as high-order (Newton), conjugate gradient, or sequential quadratic programming methods. However, the "curse of dimensionality" seems to arise as a computational obstruction to all these training techniques as well, when attempting to learn arbitrary data using a standard feedforward network. For the simpler case of linearly separable data, the perceptron algorithm and linear programming techniques help to find a network—with no "hidden units"—relatively fast. Thus one may ask if there exists a *fundamental barrier* to training by general feedforward networks, a barrier that is insurmountable no matter which particular algorithm one uses. (Those techniques which *adapt* the architecture to the data, such as cascade correlation or incremental techniques, would not be subject to such a barrier.)

22.2 Feedforward Neural Networks

As mentioned earlier, a feedforward neural net is one in which the underlying connection graph contains *no* directed cycles. More precisely, a feedforward neural net (or, in our terminology, a Γ net) can be defined as follows.

Let Γ be a class of real-valued functions, where each function is defined on some subset of $\mathbb{R}$. A Γ net C is an unbounded fan-in circuit whose edges and vertices are labeled by real numbers. The real number

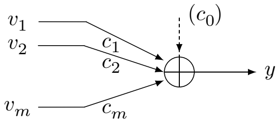

FIGURE 22.1 Classical perceptrons.

assigned to an edge (resp. vertex) is called its *weight* (resp. its *threshold*). Moreover, to each vertex v a *gate* (or *activation)* function $\gamma_v \in \Gamma$ is assigned.

The circuit C *computes* a function $f_C : \mathbb{R}^m \to \mathbb{R}$ as follows. The components of the input vector $x = (x_1, \ldots, x_m) \in \mathbb{R}^m$ are assigned to the sources of C. Let $v_1, \ldots, v_n$ be the immediate predecessors of a vertex v. The input for v is then $s_v(x) = \sum_{i=1}^{n} w_i y_i - t_v$, where w_i is the weight of the edge (v_i, v), t_v the *threshold* of v, and y_i the value assigned to v_i. If v is not a sink, then we assign the value $\gamma_v(s_v(x))$ to v. Otherwise we assign $s_v(x)$ to v.

Without any loss of generality, one can assume that C has a single sink t. Then $f_C = s_t$ is the function computed by C.

The function class Γ, quite popular in the structural-complexity literature (see, e.g., Refs. [30–32]), is the *binary threshold function* $\mathcal{H}$ defined by

$$\mathcal{H}(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ 1 & \text{if } x > 0 \end{cases}$$

However, in practice this function is not so popular because the function is discrete, and hence using this gate function may pose problems in most commonly used learning algorithms like the backpropagation algorithms [3] or their variants. Also, from biological perspectives, real neurons have continuous input–output relations [33]. In practice, various continuous (or, at least locally smooth) gate functions have been used, for example, *the cosine squasher, the standard sigmoid, radial basis functions, generalized radial basis functions, piecewise linear, polynomials, and trigonometric polynomial* functions. In particular, the standard sigmoid function $\sigma(x) = 1/(1 + \mathbf{e}^{-x})$ is very popular.

The simplest type of feedforward neural net is the classical *perceptron.* This consists of a single neuron computing a threshold function (see Figure 22.1). In other words, the perceptron P is characterized by a vector (of "weights") $\vec{c} \in \mathbb{R}^m$, and computes the inner product $\vec{c} \cdot v + c_0 = c_1 v_1 + \cdots + c_m v_m + c_0$. Such a model has been well studied and efficient learning algorithms for it exists (e.g., Ref. [34], see also Ref. [35]). In this chapter we will be, however, more interested in more complex *multilayered neural nets* (see Figure 22.2).

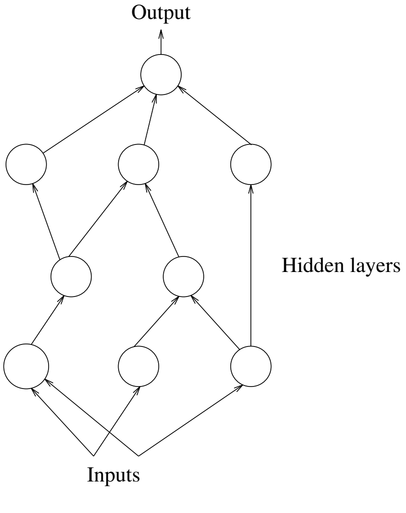

FIGURE 22.2 A feedforward neural net with three hidden layers and two inputs.

22.2.1 Approximation Properties

It is known that neural nets of only depth 2 and with arbitrarily large number of nodes can approximate any real-valued function up to any desired accuracy, using a continuous activation function such as the sigmoidal function (see e.g., Refs. [11,17]). However, these proofs are mostly nonconstructive and, from a practical point of view, one is more interested in designing *efficient* neural nets (i.e., roughly speaking, neural nets with small size and depth) to exactly or approximately compute different functions. It is also important, from a practical point of view, to understand the *size–depth trade-off* of the complexity of feedforward nets while computing functions, since generally neural nets with more layers are more costly to simulate or implement.

Threshold circuits, i.e., feedforward nets with threshold activation functions, have been quite well studied, and upper/lower bounds for them have been obtained while computing various Boolean functions (see, e.g., Refs. [30–32,36–38] among many other works). Functions of special interest have been the parity function, computing the multiplication and division of binary numbers, and so forth.

However, as mentioned earlier, it is more common in practice to use a continuous activation function, such as the standard sigmoid function. Refs. [39,40], among others, considered efficient computation or approximation of various functions by feedforward circuits with continuous activation functions and also studied size–depth trade-offs. In particular, Ref. [39] showed that any polynomial of degree n with polynomially bounded coefficients can be approximated with exponential accuracy by depth 2 feedforward sigmoidal neural nets with a polynomial number of nodes. Refs. [39,40] also show how to simulate threshold circuits by sigmoidal circuits with a polynomial increase in size and a constant factor increase in depth. Thus, in effect, functions computed by threshold circuits can also be computed by sigmoidal circuits with not too much increase in size and depth. Maass [23] shows how to simulate nets with piecewise-linear activation functions with bounded depth, arbitrary real weights, and for Boolean inputs and outputs by a threshold net of somewhat larger size and depth with weights from $\{-1, 0, 1\}$. Refs. [39,40] showed that circuits composed of sufficiently smooth gate functions are capable of efficiently approximating polynomials within any degree of accuracy. Complementing these results, Ref. [39] also provided nontrivial lower bounds on the size of *bounded-depth* sigmoidal nets with polynomially large weights when computing oscillatory functions. In essence, one can prove results of the following types.

Definition 22.1 **(DasGupta and Schnitger [39])**[1]

Let $\gamma : \mathbb{R} \to \mathbb{R}$ be a function. We call γ nontrivially smooth with parameter k if and only if there exists rational numbers α, $\beta (\alpha > 0)$, and an integer k such that α and β have logarithmic size at most k and

- *(a) γ can be represented by the power series $\sum_{i=0}^{\infty} a_i (x-\beta)^i$ for all $x \in [\beta-\alpha, \beta+\alpha]$. For each $i > 1$, a_i is a rational number of logarithmic size at most i^k.*
- *(b) For each $i > 1$ there exists j with $i \le j \le i^k$ and $a_j \neq 0$.*
- *(c) For each $i > 1$, $||\gamma^{(i)}||_{[-\alpha,\alpha]} \le 2^{i^k}$.*

Theorem 22.1 **(DasGupta and Schnitger [39])**[2]

Assume that γ is nontrivially smooth with parameter k. Let $p(x)$ be a degree n polynomial whose coefficients are rational numbers of logarithmic size at most max. Then $p(x)$ can be ε approximated (over the domain $[-D, D]$ with $[\beta-\alpha, \beta+\alpha] \subseteq [-D, D]$) by a $\{\gamma\}$-circuit C_p. C_p has depth 2 and size $O(n^{2k})$. The Lipschitz-bound[3] of C_p (over $[-D, D]^n$) is at most $c_\gamma \cdot \left(2^{max} \cdot (2+D) \cdot \frac{1}{\varepsilon}\right)^{poly(n)}$, where the constant c_γ depends only on γ and not on p.

[1] The notation $\gamma^{(i)}$ denotes the ith derivative of γ.

[2] $poly(n)$ denotes a polynomial in n.

[3] The Lipschitz bound of the net is a measure of the numerical stability of the circuit. Informally speaking, a net has a Lipschitz bound of L if all its weights and thresholds are bounded in absolute value by L.

Theorem 22.2 **(DasGupta and Schnitger [39])**

Let $f : [-1, 1] \to \mathbb{R}$ be a function that ε oscillates t times[4] *and let C be a Γ circuit of depth d, size s, and Lipschitz-bound 2^s over $[-1, 1]$. If C approximates f with error at most $\frac{\varepsilon}{4}$, then $s \geq t^{\Omega(1/d)}$.*

Note that the standard sigmoid is nontrivially smooth with a constant k, and so is the case for most of the other continuous activation functions mentioned in Section 22.1. However, the simulation in Theorem 22.1 needs quadratically many nodes to simulate a polynomial by sigmoidal nets with exponential accuracy. Unfortunately, the proof of Theorem 22.2 relies on efficient simulation of a sigmoidal circuit by a spline circuit and hence cannot be extended to the case of arbitrary weights (i.e., the Lipschitz-bound condition cannot be dropped).

22.2.2 Backpropagation Algorithms

Basic backpropagation [41] is currently the most popular supervised learning method that is used to train multilayer feedforward neural networks with differentiable transfer functions. It is a gradient descent algorithm in which the network weights are moved along the negative of the gradient of the performance function.

The basic backpropagation algorithm performs the following steps:

1. *Forward pass.* Inputs are presented and the outputs of each layer are computed.
2. *Backward pass.* Errors between the target and the output are computed. Then, these errors are "backpropagated" from the output to each layer until the first layer. Finally, the weights are adjusted according to the gradient descent algorithm with the derivatives obtained by backpropagation.

We will discuss in more detail a generalized version of this approach for recurrent networks, termed as the "real-time backpropagation through time," (BPTT) in Section 22.3.1. The key point of basic backpropagation is that the weights are adjusted in response to the derivatives of performance function with respect to weights, which only depend on the current pattern; the weights can be adjusted sequentially or in batch mode. More details about the basic backpropagation can be found in Ref. [41]. The asymptotic convergence rates of backpropagation is proved in Ref. [42]. Traditionally, the parity function has been used as an important benchmark for testing the efficiency of a learning algorithm. Empirical studies in Ref. [43] show that the training time of a feedforward net using backpropagation while learning the parity function grows exponentially with the number of inputs, thereby rendering the learning algorithm to be very time consuming. Unfortunately, a satisfactory theoretical justification for this behavior is yet to be shown. Also, it is well known that the backpropagation algorithm may get stuck in local minima, and in fact, in general, gradient descent algorithms may fail to classify correctly data that even simple perceptrons can classify correctly (see, e.g., Refs. [44–46]). Strategies of avoiding local minima include local perturbation and simulated-annealing techniques, whereas the later problem (in absence of a local minima) can be avoided using, say, threshold LMS procedures.

22.2.3 Learning Theoretic Results

Approximation results discussed in Section 22.2.1 do not necessarily translate into good learning algorithms. For example, even though a sigmoidal net has great computational power, we still need to investigate how to learn the weights of such a network from a set of examples. Learning is a very important aspect of designing efficient neural models from a practical point of view. There are a few possible approaches to tackle this issue; we describe one of those approaches next.

[4] f ε oscillates t times if and only if there are real numbers $-1 \leq x_1 < \cdots < x_{t+1} \leq 1$ such that (a) $f(x_1) = f(x_2) = \cdots = f(x_{t+1})$, (b) $|x_{i+1} - x_i| \geq \varepsilon$ for all i, and (c) there are real numbers $y_1, \ldots, y_t$ such that $x_i \leq y_i \leq x_{i+1}$ and $|f(x_i) - f(y_i)| \geq \varepsilon$ for all i.

22.2.3.1 VC-Dimension Approach

Vapnik–Chervonenkis (VC) dimensions (and, their suitable extensions to real-valued computations) provide *information-theoretic bounds* to the sample complexities for learning problems in neural nets. We very briefly (also, somewhat informally) review some (by now standard) notions regarding sample complexity which deals with the calculation of VC dimensions as applicable for neural nets (for more details, see Refs. [9,47–49].

In the general classification problem, an input space $\mathbb{X}$ as well as a collection $\mathcal{F}$ of maps $\mathbb{X} \to \{-1, 1\}$ are assumed to have been given. (The set $\mathbb{X}$ is assumed to be either countable or an Euclidean space, and the maps in $\mathcal{F}$, the set of functions computable by the specific neural nets under consideration, are assumed to be measurable. In addition, mild regularity assumptions are made which ensure that all sets appearing below are measurable, but details are omitted since in the context of neural nets these assumptions are almost always satisfied.) Let W be the set of all sequences

$$w = (u_1, \psi(u_1)), \ldots, (u_s, \psi(u_s))$$

over all $s \geq 1$, $(u_1, \ldots, u_s) \in \mathbb{X}^s$, and $\psi \in \mathcal{F}$. An *identifier* is a map $\varphi : W \to \mathcal{F}$. The value of φ on a sequence w as above will be denoted as φ_w. The *error* of φ with respect to a probability measure P on $\mathbb{X}$, a $\psi \in \mathcal{F}$, and a sequence $(u_1, \ldots, u_s) \in \mathbb{X}^s$, is

$$\text{Err}_\varphi(P, \psi, u_1, \ldots, u_s) := \text{Prob}\,[\varphi_w(u) \neq \psi(u)]$$

(where the probability is being understood with respect to P).

The class $\mathcal{F}$ of functions is said to be (uniformly) *learnable* if there is some identifier φ with the following property: For each $\varepsilon, \delta > 0$ there is some s so that, for every probability P and every $\psi \in \mathcal{F}$,

$$\text{Prob}\,[\text{Err}_\varphi(P, \psi, u_1, \ldots, u_s) > \varepsilon] < \delta$$

(where the probability is being understood with respect to P^s on $\mathbb{X}^s$).

In the learnable case, the function $s(\varepsilon, \delta)$ which provides, for any given ε and δ, the smallest possible s as above, is called the *sample complexity* of the class $\mathcal{F}$. It can be proved that learnability is equivalent to finiteness of a combinatorial quantity called *VC dimension* ν of the class $\mathcal{F}$ in the following sense (cf. Refs. [49,50]):

$$s(\varepsilon, \delta) \;\leq\; \max\left\{ \frac{8\nu}{\varepsilon} \log\left(\frac{13}{\varepsilon}\right), \frac{4}{\varepsilon} \log\left(\frac{2}{\delta}\right) \right\}$$

Moreover, lower bounds on $s(\varepsilon, \delta)$ are also known, in the following sense (cf. Ref. [49]): for $0 < \varepsilon < \frac{1}{2}$, and assuming that the collection $\mathcal{F}$ is not trivial (i.e., $\mathcal{F}$ does not consist of just one mapping or a collection of two disjoint mappings, see Ref. [49] for details), we must have

$$s(\varepsilon, \delta) \;\geq\; \max\left\{ \frac{1-\varepsilon}{\varepsilon} \ln\left(\frac{1}{\delta}\right), \nu(1 - 2(\varepsilon(1-\delta) + \delta)) \right\}$$

The above bounds motivate studies dealing with estimating VC dimensions of neural nets. When there is an algorithm that allows computing an identifier φ in time polynomial on the sample size, the class is said to be learnable in the PAC ("probably approximately correct") sense of Valiant (cf. Ref. [51]). Generalizations to the learning of real-valued (as opposed to Boolean) functions computed by, say, sigmoidal neural nets, by evaluation of the "pseudodimension," are also possible; see the discussion in Ref. [9].

It is well known that a simple perceptron with n inputs has a VC dimension of $n + 1$ [49]. However, the VC dimension of a threshold network with w programmable parameters is $\Theta(w \log w)$ [21,23,52,53]. Maass [23] and Goldberg and Jerrum [24], among others, investigated VC dimensions of neural nets with continuous activations and showed polynomial bounds on neural nets with piecewise-polynomial activation functions. Even finiteness of the VC dimension of sigmoidal neural nets was unknown for a long time, until it was showed to be finite [25]. Subsequently, an $O(w^2 n^2)$ bound on the VC dimension of sigmoidal neural nets, where w is the number of programmable parameters and n the number of nodes, was established [54]. Ref. [55] gives a $\Omega(w^2)$ lower bound for sigmoidal nets.

22.2.3.2 The Loading (Consistency) Problem

The VC dimensions provide information-theoretic bounds on sample complexities for learning. To design an *efficient* learning algorithm, the learner should be able to design a neural net consistent with the (polynomially many) samples it receives. This is known as the *consistency* or the *loading* problem. In other words, now we consider the *tractability* of the training problem, that is, of the question (essentially quoting Judd [27]): "Given a network architecture (interconnection graph as well as choice of activation function) and a set of training examples, does there exist a set of weights so that the network produces the correct output for all examples?"

The simplest neural network, that is, the perceptron, consists of one threshold neuron only. It is easily verified that the computational time of the loading problem in this case is polynomial in the size of the training set irrespective of whether the input takes continuous or discrete values. This can be achieved via a linear programming technique. Blum and Rivest [28] showed that this problem is NP-hard for a simple three-node threshold neural net. Refs. [56,57] extended this result to show NP-hardness of a three-node neural net where the activation function is a simple, saturated piecewise linear activation function, the extension was nontrivial due to the continuous part of the activation function. It was also observed in Ref. [57] that the loading problem is polynomial time if the input dimension is constant. However, the complexity of the loading problem for sigmoidal neural nets still remains an open problem, though some partial results when the net is somewhat restricted appeared in Ref. [58]. Any NP-hardness results of the loading problems also prove hardness in the PAC learning model, due to the result in Ref. [59].

Another possibility to design efficient learning algorithms is to assume that the inputs are drawn according to some particular distributions. For example, see Ref. [60] for efficient learning a depth 2 threshold net with a fixed number of hidden nodes and with the output gate being an AND gate, assuming that the inputs are drawn uniformly from a n-dimensional unit ball.

22.3 Recurrent Neural Networks

As stated in the introduction, a recurrent neural net allows cycles in the connection graph. A sample recurrent neural network is illustrated in Figure 22.3.

22.3.1 Learning Recurrent Networks: Backpropagation through Time

Backpropagation through time is an approach to solve temporal differentiable optimization problems with continuous variables [61] and used most often as a training method for recurrent neural networks. In this section, we describe the method in more detail.

22.3.1.1 Network Definition and Performance Measure

We will use the general expression of Werbos [41] to describe the network dynamics. Symbol y denotes node inputs and outputs, while symbol s denotes the weighted sum of node inputs. An ordered set of i, j, l, k on the weights denotes a connection from node j of layer i to node k of layer l; $w_{0,j,l,k}$ denotes connections from outside the network. The node activation function is denoted by $f(\cdot)$. The last layer of the network is denoted by M. The number of nodes in a layer l is denoted by n_l. The bias inputs to each node are handled homogeneously using the connection weights for zeroth input, where inputs $y_0^{\text{ext}}(t)$ and $y_{l-1,0}(t)$ are fixed at unity for this purpose.

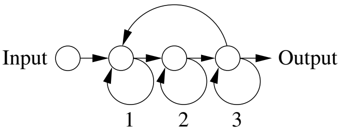

FIGURE 22.3 A simple recurrent network.

All the algorithms presented in the following part of the chapter are based on the following network dynamics expressed in *pseudocode* format:

```
f or k = 1 to n_1{
        $s_{1,k}(t) = \sum_{j=0}^{n^{\text{ext}}} w_{0,j,1,k}(t) y_j^{\text{ext}}(t) + \sum_{j=1}^{n_M} w_{M,j,1,k}(t) y_{M,j}(t-1) + \sum_{j=1}^{n_1} w_{1,j,1,k}(t) y_{1,j}(t-1)$    (22.1)
        $y_{1,k} = f(s_{1,k}(t))$    (22.2)
}

for l = 2 to M{
    for k = 1 to n_l {
        $s_{l,k}(t) = \sum_{j=0}^{n_{l-1}} w_{l-1,j,l,k}(t) y_{l-1,j}(t) + \sum_{j=1}^{n_l} w_{l,j,l,k}(t) y_{l,j}(t-1)$    (22.3)
        $y_{1,k} = f(s_{1,k}(t))$    (22.4)
    }
}
```

Note that the input line is not the first layer. Assume that the task to be performed by the network is sequential supervised learning task, meaning that certain of units' output values are to match specified target values at each time step. Define a time-varying $e_j(t)$:

$$e_j(t) = \begin{cases} d_j(t) - y_j(t) & \text{if } j \in \text{layer } M \\ 0 & \text{otherwise} \end{cases} \tag{22.5}$$

where $d_j(t)$ is the target of the output of the jth unit at time t and define the two performance measure functions:

$$J(t) = \frac{1}{2} \sum_{k \in M} [e_k(t)]^2 \tag{22.6}$$

$$J^{\text{total}}(t_0, t) = \sum_{\tau = t_0}^{t} J(\tau) \tag{22.7}$$

22.3.1.2 Unrolling a Network

In essence, BPTT is the algorithm that calculates derivatives of performance measure with respect to weights for a feedforward neural network, which is obtained by *unrolling* the network in time. Let $\mathcal{N}$ denote the network, which is to be trained to perform a desired sequential behavior. Assume that $\mathcal{N}$ has n units and that it is to run from time t_0 up through some time t. As described by Rumelhart et al. [64], we may "unroll" this network in time to obtain a feedforward network $\mathcal{N}^*$, which has a layer for each time step in $[t_0, t]$ and n units in each layer. Each unit in $\mathcal{N}$ has a copy in each layer of $\mathcal{N}^*$, and each connection from unit j to unit i in $\mathcal{N}$ has a copy connecting unit j in layer τ to unit i in layer $\tau + 1$, for each $\tau \in [t_0, t)$. An example of this unrolling mapping is given in Figure 2 in Ref. [62]. The key value of this conceptualization is that it allows one to regard the problem of training a recurrent network as the corresponding problem of training a feedforward neural network with certain constraints imposed on its weights. The central result driving the BPTT approach is that to compute $\partial J(t_0, t)/\partial w_{ij}$ in $\mathcal{N}$ one simply computes the partial derivatives of $\partial J(t_0, t)$ with respect to each of the τ weights in $\mathcal{N}^*$ corresponding to w_{ij} and adds them up.

Straightforward application of this idea leads to two different algorithms, depending on whether an epochwise or continual operation approach is sought. One is real-time BPTT and the other is epochwise BPTT. We only describe the real-time BPTT because of space limitations.

22.3.1.3 Derivation of BPTT Formulation

Suppose that a differentiable function F expressed in terms of $\{y_{l,j}(\tau)|t_0 \leq \tau \leq t\}$, the outputs of the network over time interval $[t_0, t]$ is given. Note while F may have an *explicit* dependence on $y_{l,j}(\tau)$, it may also have an *implicit* dependence on this same value through later output values. To avoid the ambiguity in interpreting partial derivatives such as $\frac{\partial F}{\partial y_{l,j}(\tau)}$, we introduce variable $y^*_{l,j}(\tau)$ such that $y^*_{l,j}(\tau) = y_{M,j}(\tau)$ for all $l = M$. Define the following:

$$\epsilon_{l,j}(\tau) = \frac{\partial F}{\partial y_{l,j}(\tau)} \tag{22.8}$$

$$\delta_{l,j}(\tau) = \frac{\partial F}{\partial s_{l,j}(\tau)} \tag{22.9}$$

Since F depends on $y_{l,j}(\tau)$, $s_{l,k}(\tau + 1)$, and $s_{l+1,m}(\tau)$, we have

$$\frac{\partial F}{\partial y_{l,j}(\tau)} = \frac{\partial F}{\partial y^*_{l,j}(\tau)} + \sum_{k=1}^{n_l} \frac{\partial F}{\partial s_{l,k}(\tau+1)} \frac{\partial s_{l,k}(\tau+1)}{\partial y_{l,j}(\tau)} + \sum_{m=1}^{n_{l+1}} \frac{\partial F}{\partial s_{l+1,m}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \tag{22.10}$$

from which we derive the following:

1. $\tau = t$. For this case,

$$\epsilon_{M,j}(\tau) = \frac{\partial F}{\partial y^*_{M,j}(\tau)} = -e_j(\tau) \tag{22.11}$$

where M means the output layer of the network and $j \in \{1, 2, \ldots, n_M\}$ and

$$\begin{aligned}\epsilon_{l,j}(\tau) = \frac{\partial F}{\partial y_{l,j}(\tau)} &= \sum_{m=1}^{n_{l+1}} \frac{\partial F}{\partial s_{l+1,m}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \\ &= \sum_{m=1}^{n_{l+1}} \frac{\partial F}{\partial y_{l+1,m}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \\ &= \sum_{m=1}^{n_{l+1}} \epsilon_{l+1,m}(\tau) f^{'}(s_{l+1,m}(\tau)) w_{l,j,l+1,m}\end{aligned} \tag{22.12}$$

where $l = 1, 2, \ldots, M - 1$ and $j = 1, 2, \ldots, n_l$, and

$$\delta_{l,j}(\tau) = \frac{\partial F}{\partial s_{l,j}(\tau)} = \frac{\partial F}{\partial y_{l,j}(\tau)} \frac{\partial y_{l,j}(\tau)}{\partial s_{l,j}(\tau)} = \epsilon_{l,j}(\tau) f^{'}(s_{l,j}(\tau)) \tag{22.13}$$

where $l = 1, 2, \ldots, M$ and $j = 1, 2, \ldots, n_l$.

2. $\tau = t - 1, \ldots, t_0$. In this case,

$$\begin{aligned}\epsilon_{M,j}(\tau) &= \frac{\partial F}{\partial y_{M,j}(\tau)} \\ &= \frac{\partial F}{\partial y^*_{M,j}(\tau)} + \sum_{k=1}^{n_1} \frac{\partial F}{\partial s_{1,k}(\tau+1)} \frac{\partial s_{1,k}(\tau+1)}{\partial y_{M,j}(\tau)} + \sum_{k=1}^{n_M} \frac{\partial F}{\partial s_{M,k}(\tau+1)} \frac{\partial s_{M,k}(\tau+1)}{\partial y_{M,j}(\tau)} \\ &= -e_j(\tau) + \sum_{k=1}^{n_1} \delta_{1,k}(\tau+1) w_{M,j,1,k} + \sum_{k=1}^{n_M} \delta_{M,k}(\tau+1) w_{M,j,M,k}\end{aligned} \tag{22.14}$$

where M means the output layer M of network and $j \in \{1, 2, \ldots, n_M\}$,

$$\begin{aligned}
\epsilon_{l,j}(\tau) = \frac{\partial F}{\partial y_{l,j}(\tau)} &= \sum_{k=1}^{n_l} \frac{\partial F}{\partial s_{l,k}(\tau+1)} \frac{\partial s_{l,k}(\tau+1)}{\partial y_{l,j}(\tau)} + \sum_{m=1}^{n_{l+1}} \frac{\partial F}{\partial s_{l+1,m}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \\
&= \sum_{k=1}^{n_l} \delta_{l,k}(\tau+1) w_{l,j,l,k} + \sum_{m=1}^{n_{l+1}} \frac{\partial F}{\partial y_{l+1,m}(\tau)} \frac{\partial y_{l+1,m}(\tau)}{\partial s_{l+1,m}(\tau)} \frac{\partial s_{l+1,m}(\tau)}{\partial y_{l,j}(\tau)} \\
&= \sum_{m=1}^{n_l} \delta_{l,k}(\tau+1) w_{l,j,l,k} + \sum_{m=1}^{n_{l+1}} \epsilon_{l+1,m}(\tau) f'(s_{l+1,m}(\tau)) w_{l,j,l+1,m} \qquad (22.15)
\end{aligned}$$

where $l = 1, 2, \ldots, M-1$ and $j = 1, 2, \ldots, n_l$ and

$$\delta_{l,j}(\tau) = \frac{\partial F}{\partial s_{l,j}(\tau)} = \frac{\partial F}{\partial y_{l,j}(\tau)} \frac{\partial y_{l,j}(\tau)}{\partial s_{l,j}(\tau)} = \epsilon_{l,j}(\tau) f'(s_{l,j}(\tau)) \qquad (22.16)$$

where $l = 1, 2, \ldots, M$ and $j = 1, 2, \ldots, n_l$.

In addition, for any appropriate i and j

$$\frac{\partial F}{\partial w_{i,j,l,k}} = \sum_{\tau=t_0}^{t} \frac{\partial F}{\partial w_{i,j,l,k}(\tau)} \qquad (22.17)$$

and for any τ

$$\frac{\partial F}{\partial w_{i,j,l,k}(\tau)} = \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{i,j,l,k}(\tau)} = \delta_{l,k}(\tau) y_{i,j}(\tau) \ or\ \delta_{l,k}(\tau) y_{i,j}(\tau-1) \qquad (22.18)$$

Combining these last two equations yields

$$\frac{\partial F}{\partial w_{i,j,l,k}} = \sum_{\tau=t_0}^{t} \delta_{l,k}(\tau) y_{i,j}(\tau) \ or\ \delta_{l,k}(\tau) y_{i,j}(\tau-1) \qquad (22.19)$$

Eqs. (22.11)–(22.16) and (22.19) represent the BPTT computation of $\partial F/\partial w_{i,j,l,k}$ for differentiable function F expressed in terms of the outputs of individual units in the network.

22.3.1.4 Real-Time Backpropagation through Time

In real-time BPTT, the performance measure is $J(t)$ at each time. To compute the gradient of $J(t)$ at time t, we proceed as follows. First, consider t fixed for the moment. This allows us the notational convenience of suppressing any reference to t in the following. Compute $\epsilon_{l,j}(\tau)$ and $\delta_{l,k}(\tau)$ for $\tau \in [t_0, t]$ by means of Eqs. (22.11)–(22.13). Eq. (22.14) needs a little change since with $F = J(t)$, $e_j(\tau) = 0$; thus, for $\tau < t$,

$$\begin{aligned}
\epsilon_{M,j}(\tau) = \frac{\partial F}{\partial y_{M,j}(\tau)} &= \frac{\partial F}{\partial y^*_{M,j}(\tau)} + \sum_{k=1}^{n_1} \frac{\partial F}{\partial s_{1,k}(\tau+1)} \frac{\partial s_{1,k}(\tau+1)}{\partial y_{M,j}(\tau)} + \sum_{k=1}^{n_1} \frac{\partial F}{\partial s_{M,k}(\tau+1)} \frac{\partial s_{M,k}(\tau+1)}{\partial y_{M,j}(\tau)} \\
&= \sum_{k=1}^{n_1} \frac{\partial F}{\partial s_{1,k}(\tau+1)} \frac{\partial s_{1,k}(\tau+1)}{\partial y_{M,j}(\tau)} + \sum_{k=1}^{n_1} \frac{\partial F}{\partial s_{M,k}(\tau+1)} \frac{\partial s_{M,k}(\tau+1)}{\partial y_{M,j}(\tau)} \\
&= \sum_{k=1}^{n_1} \delta_{1,k}(\tau+1) w_{M,j,1,k} + \sum_{k=1}^{n_M} \delta_{M,k}(\tau+1) w_{M,j,M,k} \qquad (22.20)
\end{aligned}$$

Thus, Eqs. (22.11)–(22.16), (22.19) and (22.20) represent the real-time BPTT. The process begins by using Eq. (22.11) to determine $\epsilon_{M,j}(t)$. This step is called *injecting error*, or to be more precise, *injecting* $e(t)$ at time t. Then δ and ϵ are obtained for successively earlier time steps through the repeated use of the Eqs. (22.15), (22.16), and (22.20). Here $\epsilon_{l,j}(\tau)$ represents the sensitivity of the *instantaneous performance* measure $J(t)$ to small perturbations in the output of the jth unit at layer l at time τ, while $\delta_{l,j}(\tau)$ represents the corresponding sensitivity to small perturbations to that unit's net input at that time. Once the backpropagation computation has been performed down to time t_0, the desired gradient of instantaneous performance is computed by the following pseudocode:

```
for $\tau = t$ to $t_0$ {
  for $l = 2$ to $M$ {
    for $k = 1$ to $n_l$ {
for $j = 0$ to $n_{l-1}$ {
      $\frac{\partial F}{\partial w_{l-1,j,l,k}} += \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{l-1,j,l,k}} = \delta_{l,k}(\tau) y_{l-1,j}(\tau)$    (22.21)
}
for $j = 1$ to $n_l$ {
      $\frac{\partial F}{\partial w_{l,j,l,k}} += \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{l,j,l,k}} = \delta_{l,k}(\tau) y_{l,j}(\tau - 1)$    (22.22)
}
} /*k loop*/ } /*l loop*/
for $k = 1$ to $n_1$ {
for $j = 1$ to $n^{ext}$ {
      $\frac{\partial F}{\partial w_{0,j,1,k}} += \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{0,j,1,k}} = \delta_{1,k}(\tau) y_j^{ext}(\tau)$    (22.23)
}
for $j = 1$ to $n_M$ {
      $\frac{\partial F}{\partial w_{M,j,1,k}} += \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{M,j,1,k}} = \delta_{1,k}(\tau) y_{M,j}(\tau - 1)$    (22.24)
}
for $j = 1$ to $n_1$ {
      $\frac{\partial F}{\partial w_{1,j,1,k}} += \frac{\partial F}{\partial s_{l,k}(\tau)} \frac{\partial s_{l,k}(\tau)}{\partial w_{1,j,1,k}} = \delta_{1,k}(\tau) y_{1,j}(\tau - 1)$    (22.25)
}
} /*k loop*/
} /*τ loop*/
```

where the notation "$+ =$" is to indicate that the quantity on the right-hand side of an expression is added to the previous value (time) on the left-hand side. Thus, the sum of $\frac{\partial F}{\partial w_{i,j,l,k}}$ from t_0 to t is computed. Because this algorithm makes use of potentially unbounded history storage, it is also sometimes called BPTT(∞).

22.3.2 Computational Capabilities of Discrete and Continuous Recurrent Networks

The computational power of recurrent nets is investigated in Refs. [15,16]; see also Ref. [63] for a thorough discussion of recurrent nets and analog computation in general. Recurrent nets include feedforward nets and thus the results of feedforward nets apply to recurrent nets as well. But recurrent nets gain considerably more computational power with increasing computation time. In the following, for the sake of concreteness, we assume that the piecewise-linear function

$$\pi(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ x & \text{if } 0 \leq x \leq 1 \\ 1 & \text{if } x \geq 1 \end{cases}$$

is chosen as activation function. We concentrate on binary input and assume that the input is provided one bit at a time.

First of all, if weights and thresholds are integers, then each node computes a bit. Recurrent net with integer weights thus turn out to be equivalent to finite automata and they recognize exactly the class of regular language over the binary alphabet {0, 1}.

The computational power increases considerably for rational weights and thresholds. For instance, a "rational" recurrent net is, up to a polynomial-time computation, equivalent to a Turing machine. In particular, a network that simulates a universal Turing machine does exist and one could refer to such a network as "universal" in the Turing sense. It is important to note that the number of nodes in the simulating recurrent net is fixed (i.e., *does not grow* with increasing input length).

Irrational weights provide a further boost in computation power. If the net is allowed exponential computation time, then arbitrary Boolean functions (including noncomputable functions) are recognizable. However, if only polynomial computation time is allowed, then nets have less power and recognize exactly the languages computable by polynomial-size Boolean circuits.

23.1 Introduction

Tabu search (TS) is a metaheuristic that guides a local heuristic search procedure to explore the solution space beyond local optimality. The term *tabu search* was coined in the same paper that introduced the term *metaheuristic* [1]. Tabu search is based on the premise that problem solving, to qualify as intelligent, must incorporate *adaptive memory* and *responsive exploration*. The adaptive memory feature of TS allows the implementation of procedures that are capable of searching the solution space economically and effectively. Since local choices are guided by information collected during the search, TS contrasts with memoryless designs that heavily rely on semirandom processes that implement a form of sampling. The emphasis on responsive exploration (and hence purpose) in TS, whether in a deterministic or probabilistic implementation, derives from the supposition that a bad strategic choice can often yield more information than a good random choice. Over a wide range of problem settings, strategic use of memory can make dramatic differences in the ability to solve problems.

Tabu search can be directly applied to virtually any kind of optimization problem. We can state most of these problems in the following form, where "optimize" means to minimize or maximize:

$$\begin{array}{ll} \text{Optimize} & f(x) \\ \text{subject to} & x \in \mathrm{X} \end{array}$$

The function $f(x)$ may be linear, nonlinear, or even stochastic, and the set $\mathbf{X}$ summarizes constraints on the vector of decision variables x. The constraints may similarly include linear, nonlinear, or stochastic inequalities, and may compel all or some components of x to receive discrete values.

While this representation is useful for discussing a number of problem-solving considerations, we emphasize that in many applications of combinatorial optimization, the problem of interest may not be easily formulated as an objective function subject to a set of constraints. The requirement $x \in \mathbf{X}$, for example, may specify logical conditions or interconnections that would be cumbersome to formulate mathematically, but may be better left as verbal stipulations that can be then coded as rules.

The TS technique is rapidly becoming the method of choice for designing solution procedures for hard combinatorial optimization problems. A comprehensive examination of this methodology can be found in the book by Glover and Laguna [2]. Widespread successes in practical applications of optimization have spurred a rapid growth of the method as a means of identifying extremely high-quality solutions

TABLE 23.1 Illustrative Tabu Search Applications

Scheduling	**Telecommunications**
Flow-time cell manufacturing	Call routing
Heterogeneous processor scheduling	Bandwidth packing
Workforce planning	Hub facility location
Rostering	Path assignment
Machine scheduling	Network design for services
Flow shop scheduling	Customer discount planning
Job shop scheduling	Failure immune architecture
Sequencing and batching	Synchronous optical networks
Design	**Production, Inventory, and Investment**
Computer-aided design	Supply chain management
Fault tolerant networks	Flexible manufacturing
Transport network design	Just-in-time production
Architectural space planning	Capacitated MRP
Diagram coherency	Part selection
Fixed charge network design	Multiitem inventory planning
Irregular cutting problems	Volume discount acquisition
Layout planning	Project portfolio optimization
Logic and Artificial Intelligence	**Routing**
Maximum satisfiability	Vehicle routing
Probabilistic logic	Capacitated routing
Pattern recognition/classification	Time window routing
Data mining	Multimode routing
Clustering	Mixed fleet routing
Statistical discrimination	Traveling salesman
Neural network training	Traveling purchaser
Neural network design	Convoy scheduling
Location and Allocation	**Graph Optimization**
Multicommodity location/allocation	Graph partitioning
Quadratic assignment	Graph coloring
Quadratic semiassignment	Clique partitioning
Multilevel generalized assignment	Maximum clique problems
Large-scale GAP problems	Maximum planner graphs
Technology	**General Combinational Optimization**
Seismic inversion	Zero–one programming
Electrical power distribution	Fixed charge optimization
Engineering structural design	Nonconvex nonlinear programming
Minimum volume ellipsoids	All-or-none networks
Space station construction	Bilevel programming
Circuit cell placement	Multiobjective discrete optimization
OffShore oil exploration	General mixed integer optimization

efficiently. Tabu search methods have also been used to create hybrid procedures with other heuristic and algorithmic methods, to provide improved solutions to problems in production planning and scheduling, resource allocation, network design, routing, financial analysis, telecommunications, portfolio planning, supply chain management, agent-based modeling, business process design, forecasting, machine learning, data mining, biocomputation, molecular design, forest management and resource planning, and many other areas. Some of the diversity of TS applications is shown in Table 23.1.

The TS emphasis on adaptive memory makes it possible to exploit the types of strategies that underlie the best of human problem-solving, instead of being confined to mimicking the processes found in lower orders of natural phenomena and behavior. The basic elements of TS have several important features, summarized in Table 23.2. Tabu search is concerned with finding new and more effective ways of taking advantage of the concepts embodied in Table 23.2, and with identifying associated principles that can expand the foundations of intelligent search.

TABLE 23.2 Principal Tabu Search Features

Adaptive Memory
Selectivity (including strategic forgetting)
Abstraction and decomposition (through explicit and attributive memory)
Timing Recency of events Frequency of events Differentiation between short term and long term
Quality and impact Relative attractiveness of alternative choices Magnitude of changes in structure or constraining Relationships
Context Regional interdependence Structural interdependence Sequential interdependence
Responsive Exploration
Strategically imposed restraints and inducements (*tabu conditions* and *aspiration levels*)
Concentrated focus on good regions and good solution features (*intensification processes*)
Characterizing and exploring promising new regions (*diversification processes*)
Nonmonotonic search patterns (*strategic oscillation*)
Integrating and extending solutions (*path relinking*)

In this chapter we will describe some key aspects of this methodology, as the use of memory structures and search strategies, and illustrate them in an implementation to solve the linear ordering problem (LOP).

23.2 Memory Structures

Tabu search begins in the same way as ordinary local or neighborhood search, proceeding iteratively from one point (solution) to another until a chosen termination criterion is satisfied. Each solution x has an associated neighborhood $N(x) \subset X$, and each solution $x' \in N(x)$ is reached from x by an operation called a *move*.

We may contrast TS with a simple descent method where the goal is to minimize $f(x)$. Such a method only permits moves to neighbor solutions that improve the current objective function value and ends when no improving solutions can be found. The final x obtained by a descent method is called a local optimum, since it is at least as good as or better than all solutions in its neighborhood. The evident shortcoming of a descent method is that such a local optimum in most cases will not be a global optimum, that is, it usually will not minimize $f(x)$ over all $x \in \mathbf{X}$.

Tabu search permits moves that deteriorate the current objective function value but the moves are chosen from a modified neighborhood $N^*(x)$. Short- and long-term memory structures are responsible for the specific composition of $N^*(x)$. In other words, the modified neighborhood is the result of maintaining a selective history of the states encountered during the search. In the TS strategies based on short-term considerations, $N^*(x)$ characteristically is a subset of $N(x)$, and the tabu classification serves to identify elements of $N(x)$ excluded from $N^*(x)$. In TS strategies that include longer term considerations, $N^*(x)$ may also be expanded to include solutions not ordinarily found in $N(x)$, such as

TABLE 23.3 Examples of Recency-Based Memory

Context	Attributes	To Record the Last Time ...
Binary problems	Variable index (i)	Variable i changed its value from 0 to 1 or 1 to 0 (depending on its current value)
Job sequencing	Job index (j) Job index (j) and position (p) Pair of job indexes (i, j)	Job j changed positions Job j occupied position p Job i exchange positions with job j
Graphs	Arc index (i)	Arc i was added to the current solution Arc i was dropped from the current solution

solutions found and evaluated in past search, or identified as high-quality neighbors of these past solutions. Characterized in this way, TS may be viewed as a dynamic neighborhood method. This means that the neighborhood of x is not a static set, but rather a set that can change according to the history of the search.

The structure of a neighborhood in TS differs from that used in local search in an additional manner, by embracing the types of moves used in constructive and destructive processes (where the foundations for such moves are accordingly called *constructive neighborhoods* and *destructive neighborhoods*). Such expanded uses of the neighborhood concept reinforce a fundamental perspective of TS, which is to define neighborhoods in dynamic ways that can include serial or simultaneous consideration of multiple types of moves.

Tabu search uses attributive memory for guiding purposes (i.e., to compute $N^*(x)$). Instead of recording full solutions, attributive memory structures are based on recording attributes. This type of memory records information about solution properties (attributes) that change in moving from one solution to another. The most common attributive memory approaches are recency- and frequency-based memory. Recency, as its name suggests, keeps track of solutions attributes that have changed during the recent past. Frequency typically consists of ratios about the number of iterations a certain attribute has changed or not (depending whether it is a transition or a residence frequency). Some examples of recency- and frequency-based memory are shown in Table 23.3 and Table 23.4 respectively.

Characteristically, a TS process based strictly on short-term strategies may allow a solution x to be visited more than once, but it is likely that the corresponding reduced neighborhood $N^*(x)$ will be different each time. With the inclusion of longer term considerations, the likelihood of duplicating a previous neighborhood upon revisiting a solution, and more generally of making choices that repeatedly visit only a limited subset of X, is all but nonexistent.

Recency-based memory is the most common memory structure used in TS implementations. As its name suggests, this memory structure keeps track of solutions attributes that have changed during the recent past. To exploit this memory, selected attributes that occur in solutions recently visited are labeled

TABLE 23.4 Examples of Frequency-Based Memory

Context	Residence Measure	Transition Measure
Binary problems	Number of times variable i has been assigned the value of 1	Number of times variable i has changed values
Job sequencing	Number of times job j has occupied position p Average objective function value when job j occupies position p	Number of times job i has exchanged positions with job j Number of times job j has been moved to an earlier position in the sequence
Graphs	Number of times arc i has been part of the current solution Average objective function value when arc i is part of the solution	Number of times arc i has been deleted from the current solution when arc j has been added Number of times arc i has been added during improving moves

tabu-active, and solutions that contain tabu-active elements, or particular combinations of these attributes, are those that become tabu. This prevents certain solutions from the recent past from belonging to $N^*(x)$ and hence from being revisited. Other solutions that share such tabu-active attributes are also similarly prevented from being visited. Note that while the tabu classification strictly refers to solutions that are forbidden to be visited, by virtue of containing tabu-active attributes (or more generally by violating certain restriction based on these attributes), moves that lead to such solutions are also often referred to as being tabu.

Frequency-based memory provides a type of information that complements the information provided by recency-based memory, broadening the foundation for selecting preferred moves. Like recency, frequency often is weighted or decomposed into subclasses. Also, frequency can be integrated with recency to provide a composite structure for creating penalties and inducements that modify move evaluations.

Frequencies typically consist of ratios, whose numerators represent counts expressed in two different measures: a *transition measure*—the number of iterations where an attribute changes (enters or leaves) the solutions visited on a particular trajectory, and a *residence measure*—the number of iterations where an attribute belongs to solutions visited on a particular trajectory, or the number of instances where an attribute belongs to solutions from a particular subset. The denominators generally represent one of three types of quantities: (1) the total number of occurrences of all events represented by the numerators (such as the total number of associated iterations); (2) the sum (or average) of the numerators; and (3) the maximum numerator value. In cases where the numerators represent weighted counts, some of which may be negative, denominator (3) is expressed as an absolute value and denominator (2) is expressed as a sum of absolute values (possibly shifted by a small constant to avoid a zero denominator). The ratios produce *transition frequencies* that keep track of how often attributes change, and *residence frequencies* that keep track of how often attributes are members of solutions generated. In addition to referring to such frequencies, thresholds based on the numerators alone can be useful for indicating when phases of greater diversification are appropriate.

23.3 Search Strategies

The use of recency and frequency memory in TS generally fulfills the function of preventing searching processes from *cycling*, that is, from endlessly executing the same sequence of moves (or more generally, from endlessly and exclusively revisiting the same set of solutions). More broadly, however, the various manifestations of these types of memory are designed to impart additional robustness or vigor to the search.

A key element of the adaptive memory framework of TS is to create a balance between search intensification and diversification. Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. Diversification strategies, however, seek to incorporate new attributes and attribute combinations that were not included within solutions generated previously. In one form, these strategies undertake to drive the search into regions dissimilar to those already examined. It is important to keep in mind that intensification and diversification are not mutually opposing, but are rather mutually reinforcing.

Most types of intensification strategies require a means for identifying a set of elite solutions as basis for incorporating good attributes into newly created solutions. Membership in the elite set is often determined by setting a threshold that is connected to the objective function value of the best solution found during the search. A simple instance of the intensification strategy is shown in Figure 23.1. Two simple variants for elite solution selection have proved quite successful. One introduces a diversification measure to assure the solutions recorded differ from each other by a desired degree, and then erases all short-term memory before resuming from the best of the recorded solutions. The other keeps a bounded length sequential list that adds a new solution at the end only if it is better than any previously seen, and the short-term memory that accompanied this solution is also saved.

```
Apply TS short-term memory
Apply an elite selection strategy.
do {
        Choose one of the elite solutions.
        Resume short-term memory TS from chosen solution.
        Add new solutions to elite list when applicable.
} while (iterations < limit and list not empty)
```

FIGURE 23.1 Simple TS intensification approach.

Diversification is automatically created in TS (to some extent) by short-term memory functions, but is particularly reinforced by certain forms of longer term memory. TS diversification strategies are often based on modifying choice rules to bring attributes into the solution that are infrequently used. Alternatively, they may introduce such attributes by periodically applying methods that assemble subsets of these attributes into candidate solutions for continuing the search, or by partially or fully restarting the solution process. Diversification strategies are particularly helpful when better solutions can be reached only by crossing barriers or "humps" in the solution space topology.

The incorporation of modified choice rules can be moderated by using the following penalty function:

$$MoveValue' = MoveValue + d * Penalty$$

This type of penalty approach is commonly used in TS, where the *Penalty* value is often a function of frequency measures such as those indicated in Table 23.2, and *d* is an adjustable diversification parameter. Larger *d* values correspond to a desire for more diversification.

23.4 Advanced Designs: Strategic Oscillation and Path Relinking

There are many forms in which a simple TS implementation can be improved by adding long-term elements. In this paper we restrict our attention to two of the most used methods, namely strategic oscillation and path relinking (PR), which constitute the core of many adaptive memory programming algorithms.

Strategic oscillation operates by orienting moves in relation to a critical level, as identified by a stage of construction or a chosen interval of functional values. Such a critical level or *oscillation boundary* often represents a point where the method would normally stop. Instead of stopping when this boundary is reached, however, the rules for selecting moves are modified, to permit the region defined by the critical level to be crossed. The approach then proceeds for a specified depth beyond the oscillation boundary, and turns around. The oscillation boundary again is approached and crossed, this time from the opposite direction, and the method proceeds to a new turning point (see Figure 23.2).

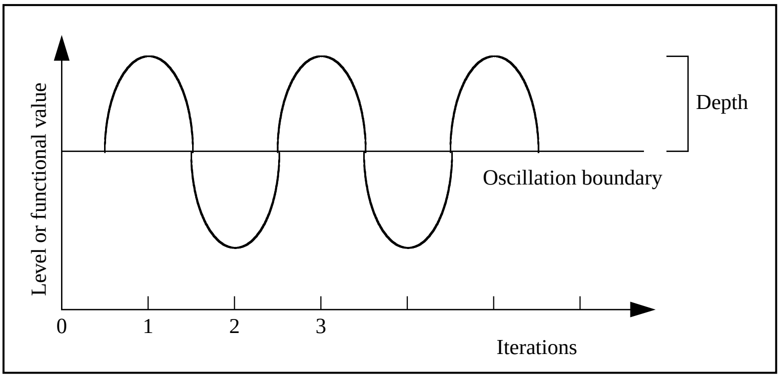

FIGURE 23.2 Strategic oscillation.

The process of repeatedly approaching and crossing the critical level from different directions creates an oscillatory behavior, which gives the method its name. Control over this behavior is established by generating modified evaluations and rules of movement, depending on the region navigated and the direction of search. The possibility of retracing a prior trajectory is avoided by standard TS mechanisms, like those established by the recency-based and frequency-based memory functions.

When the level or functional values in Figure 23.2 refer to degrees of feasibility and infeasibility, a vector-valued function associated with a set of problem constraints can be used to control the oscillation. In this case, controlling the search by bounding this function can be viewed as manipulating a parameterization of the selected constraint set. A preferred alternative is often to make the function a Lagrangean or surrogate constraint penalty function, avoiding vector-valued functions and allowing tradeoffs between degrees of violation of different component constraints.

Path relinking, as a strategy of creating trajectories of moves passing through high-quality solutions was first proposed in connection with TS by Glover [3]. The approach was then elaborated in greater detail as a means of integrating TS intensification and diversification strategies, and given the name PR by Glover and Laguna [4]. Path relinking generally operates by starting from an *initiating solution*, selected from a subset of high-quality solutions, and generating a path in the neighbourhood space that leads toward the other solutions in the subset, which are called *guiding solutions.* This is accomplished by selecting moves that introduce attributes contained in the guiding solutions.

Path relinking can be considered an extension of the combination method of scatter search [4,5]. Instead of directly producing a new solution when combining two or more original solutions, PR generates paths between and beyond the selected solutions in the neighborhood space. The character of such paths is easily specified by reference to solution attributes that are added, dropped, or otherwise modified by the moves executed. Examples of such attributes include edges and nodes of a graph, sequence positions in a schedule, vectors contained in linear programming basic solutions, and values of variables and functions of variables.

The approach may be viewed as an extreme (highly focused) instance of a strategy that seeks to incorporate attributes of high-quality solutions, by creating inducements to favor these attributes in the moves selected. However, instead of using an inducement that merely encourages the inclusion of such attributes, the PR approach subordinates other considerations to the goal of choosing moves that introduce the attributes of the guiding solutions, to create a "good attribute composition" in the current solution. The composition at each step is determined by choosing the best move, using customary choice criteria, from a restricted set—the set of those moves currently available that incorporate a maximum number (or a maximum-weighted value) of the attributes of the guiding solutions. (Exceptions are provided by aspiration criteria, as subsequently noted.) The approach is called PR either by virtue of generating a new path between solutions previously linked by a series of moves executed during a search, or by generating a path between solutions previously linked to other solutions but not to each other.

To generate the desired paths, it is only necessary to select moves that perform the following role: upon starting from an *initiating solution,* the moves must progressively introduce attributes contributed by a *guiding solution* (or reduce the distance between attributes of the initiating and guiding solutions). The roles of the initiating and guiding solutions are interchangeable; each solution can also be induced to move simultaneously toward the other as a way of generating combinations. First, consider the creation of paths that join two selected solutions x' and x'', restricting attention to the part of the path that lies "between" the solutions, producing a solution sequence $x' = x(1), x(2), \ldots, x(r) = x''$. To reduce the number of options to be considered, the solution $x(i+1)$ may be created from $x(i)$ at each step by choosing a move that minimizes the number of moves remaining to reach x''. The relinked path may encounter solutions that may not be better than the initiating or guiding solution, but that provide fertile "points of access" for reaching other, somewhat better, solutions. For this reason it is valuable to examine neighboring solutions along a relinked path, and keep track of those of high quality that may provide a starting point for launching additional searches.

As described by Martí et al. [6], we can apply different PR elements to perform more elaborated designs. Some examples are simultaneous relinking, tunneling strategy, extrapolated relinking, multiple guiding solutions, constructive neighborhoods, or vocabulary building.

23.5 The Linear-Ordering Problem

Given a matrix of weights $E = \{e_{ij}\}_{m\times m}$, the LOP consists of finding a permutation p of the columns (and rows) to maximize the sum of the weights in the upper triangle. In mathematical terms, we seek to maximize

$$C_E(p) = \sum_{i=1}^{m-1} \sum_{j=i+1}^{m} e_{p_i p_j}$$

where p_i is the index of the column (and row) in position i in the permutation. Note that in the LOP, the permutation p provides the ordering of both the columns and the rows. Solution methods for this NP-hard problem have been proposed since 1958, when Chenery and Watanabe outlined some ideas on how to obtain solutions for this problem [7]. In this section we describe a TS implementation by Laguna et al. [8] for the LOP.

The LOP has a wide range of applications in several fields. Perhaps, the best known application occurs in the field of economics. In this application, the economy (regional or national) is first subdivided into sectors. Then, an input/output matrix is created, in which the entry (i, j) represents the flow of money from sector i to sector j. Economists are often interested in ordering the sectors so that suppliers tend to come first followed by consumers. This is achieved by permuting the rows and columns of the matrix so that the sum of entries above the diagonal is maximized, which is the objective of the LOP.

Insertions are used as the primary mechanism to move from one solution to another in Laguna et al.'s method for the LOP. *INSERT_MOVE*(p_j, i) consist of deleting p_j from its current position j to be inserted in position i (i.e., between the current sectors p_{i-1} and p_i). This operation results in the ordering p', as follows:

$$p' = \begin{cases} (p_1, \ldots, p_{i-1}, p_j, p_i, \ldots, p_{j-1}, p_{j+1}, \ldots, p_m) & \text{for } i < j \\ (p_1, \ldots, p_{j-1}, p_{j+1}, \ldots, p_{i-1}, p_j, p_i, \ldots, p_m) & \text{for } i > j \end{cases}$$

The neighborhood N consists of all permutations resulting from executing general insertion moves as

$$N = \{p' : \mathit{INSERT\_MOVE}(p_j, i), \mathit{for}\, j = 1, \ldots, m\, \mathit{and}\, i = 1, 2, \ldots, j-1, j+1, \ldots, m\},$$

and N is partitioned into m neighborhoods, N^j, associated with each sector p_j, for $j = 1, \ldots, m$:

$$N^j = \{p' : \mathit{INSERT\_MOVE}(p_j, i), i = 1, 2, \ldots, j-1, j+1, \ldots, m\}$$

Starting from a randomly generated permutation p, the basic TS procedure alternates between an intensification and a diversification phase. An iteration of the *intensification phase* begins by randomly selecting a sector. The probability of selecting sector j is proportional to its weight w_j according to

$$w_j = \sum_{i\neq j} (e_{ij} + e_{ji})$$

The move INSERT_MOVE$(p_j, i) \in N^j$ with the largest move value is selected. (Note that this rule may result in the selection of a nonimproving move.) The move is executed even when the move value is not positive, resulting in a deterioration of the current objective function value. The moved sector becomes tabu-active for *TabuTenure* iterations, and therefore it cannot be selected for insertions during this time.

The number of times that sector j has been chosen to be moved is accumulated in the value *freq*(j). This frequency information is used for diversification purposes. The intensification phase terminates after *MaxInt* consecutive iterations without improvement. Before abandoning this phase, a local search procedure based in the same neighborhood is applied to the best solution found (during the current intensification). We denote this solution as $p^{\#}$, in contrast to p^* (the best solution found over the entire search). By applying this greedy procedure (without tabu restrictions), a local optimum is guaranteed as the output of the intensification phase.

The *diversification phase* is performed for *MaxDiv* iterations. At each iteration, a sector is randomly selected, where the probability of selecting sector j is inversely proportional to the frequency count *freq*(j). The chosen sector is placed in the best position, as determined by the move values associated with the insert moves in N^j. The procedure stops when *MaxGlo* global iterations are performed without improving $C_E(p^*)$. A global iteration is an application of the intensification phase followed by the application of the diversification phase.

An additional intensification is introduced by implementing a long-term PR phase. Specifically, the best solution found at the end of an intensification phase $p^{\#}$ (which does not necessarily represent p^*, the best solution overall) is subjected to a relinking process. The process consists of making moves starting from $p^{\#}$ (the initiating solution) in the direction of a set of elite solutions (also referred to as guiding solutions). The set of elite solutions consists of the *EltSol* best solutions found during the entire search. The insertions used to move the initiating solution closer to the guiding solutions can be described as follows. For each sector p_j in the current solution:

(1) Find the position i for which the absolute value of $(j\text{-}i)$ is minimized, where i is the position that p_j occupies in at least one of the guiding solutions.
(2) Perform *INSERT_MOVE*(p_j, i).

A long-term diversification phase is also implemented to complement the diversification phase in the basic procedure. The long-term diversification is applied after *MaxLong* global iterations have elapsed without improving $C_E(p^*)$. For each sector p_j, a rounded average position $\alpha(p_j)$ is calculated using the positions occupied by this sector in the set of elite solutions and the solutions visited during the last intensification phase. Then, m diversification steps are performed which insert each sector p_j in its complementary position $m\text{-}\alpha(p_j)$, that is, *INSERT_MOVE*(p_j, $m\text{-}\alpha(p_j)$) is executed for $j = 1, \ldots, m$.

After preliminary experimentation, the search parameters are set to *MaxGlo* $= 100$, *MaxLong* $= 50$, *EltSol* $= 4$, *TabuTenure* $= 2\sqrt{m}$, *MaxInt* $= m$, and *MaxDiv* $= 0.5m$ and *EltSol* $= 4$. In the 49 instances of the public domain library of linear ordering problems (LOLIB [15]), the method obtains the optimal solution within 1 s of computer time run on a Pentium IV at 3 GHz. The method is also compared with a previous procedure due to Chanas and Kobylanski [9] and a greedy procedure based on the N local search. The methods were run in a way that the best solution found was reported every 0.5 s. These data points were used to generate the performance graph in Figure 23.3. The superior performance of TS_LOP is made evident by Figure 23.3.

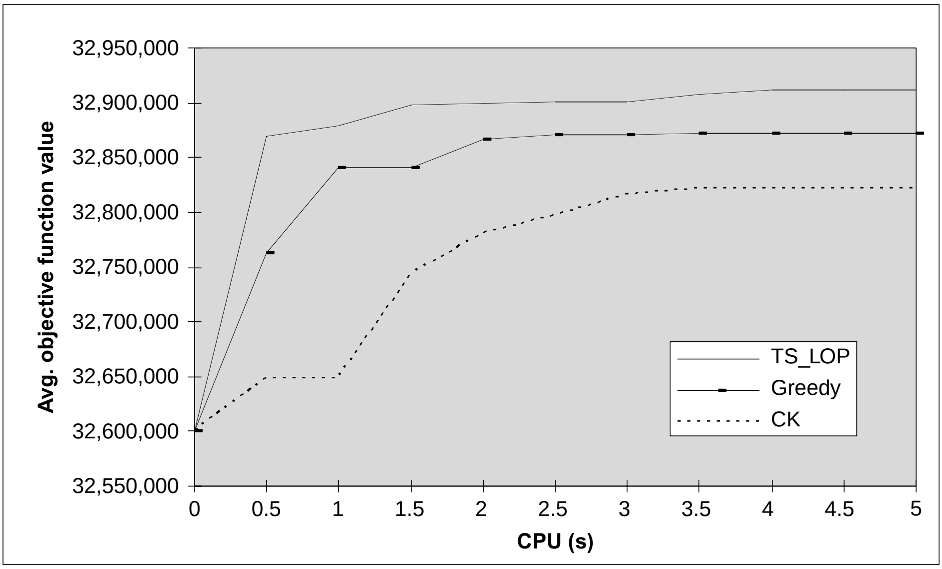

FIGURE 23.3 Performance graph.

23.6 The Tabu Cycle and Conditional Probability Methods

In this section, we describe the implementation and testing of the tabu cycle method and two variants of the conditional probability method [10]. These methods were originally described by Glover [11] and again in a book by Glover and Laguna [2], but have been largely ignored in the TS literature. The *tabu cycle method* is a short-term memory mechanism that is based on partitioning the elements (i.e., move attributes) of a tabu list. The methodology is general and capable of accommodating multiattribute TS memory, as described by Glover and Laguna [2]. In its most basic form, the tabu cycle method divides the short-term memory list into *TabuGroups* groups, where group k consists of elements that were added to the list between a specified range of iterations ago. While in some variants of TS (e.g., probabilistic TS) it is common to progressively relax the tabu status of elements as they become older, the tabu cycle method, by contrast, allows the elements of some groups to fully escape their tabu status according to certain frequencies that increase with the age of the groups. The method is based on the use of iteration intervals called *tabu cycles*, which are made smaller for older groups than for younger groups (with the exception of a small buffer group). Specifically, if group k has a tabu cycle of $TC(k)$ iterations, then at each occurrence of this number of iterations, on average, the elements of group k escape their tabu status and are free to be chosen. In other words, on average, group k is designated as FREE every $TC(k)$ iterations. Mechanisms and data structures that are useful for achieving this are described in Ref. [10].

The *conditional probability method* is a variant of the tabu cycle method that chooses elements by establishing the probability that a group will be FREE on a given iteration. The probability assigned to group k may be viewed conceptually as the inverse of the tabu cycle value. That is, $P(k) = 1/TC(k)$. Analogous to the tabu cycle method, group k is FREE if all older groups likewise are FREE. The method employs a *conditional probability*, $CP(k)$, as a means of determining whether a particular group k can be designated as FREE. The conditional probability values are fixed and the status of a group is determined by a probabilistic process that is not affected by previous choices. Consequently, the approach ignores the possibility that actual tabu cycle values may be far from their targets for some groups. This may happen, for example, when for a number of iterations no elements are chosen from a particular set of FREE groups. The conditional probability method also makes use of a buffer group, for which no element is allowed to escape its tabu status.

A variant of the conditional probability method uses substitute probability values to keep the expected number of elements per iteration chosen from groups no older than any given group k close to $P(k)$. The substitute probabilities replace the original $P(k)$ values in the determination of the conditional probabilities. These substitute probabilities make use of cycle counts, which are also used in connection with the tabu cycle method.

Laguna [10] uses a single machine scheduling problem to test the merit of implementations of the tabu cycle method and both variants of the conditional probability method. The problem consists of minimizing the sum of the setup costs and linear delay penalties when n jobs, arriving at time zero, are to be scheduled for sequential processing on a continuously available machine. Several variants of TS for this problem have been reported in the literature [12–14]. Experiments with more than 300 problem instances with up to 200 jobs were performed to compare a simple static and dynamic short-term memory schemes with a tabu cycle implementation (Cycle), a conditional probability implementation (C-Prob) and an implementation of the conditional probability method with substitute probabilities (S-Prob). The static short-term memory assigns a constant to the tabu tenure to all attributes during the search. The dynamic short-term memory randomly selects from a specified range a tabu tenure. Therefore, the tabu tenure assigned to an attribute in a given iteration may not be the same as the tabu tenure assigned to another attribute in a different iteration. Table 23.5 shows the number of best solutions found by each method in each set of 100 problems.

The results in Table 23.5 show the merit of the tabu cycle and the conditional probability variants as the problem size increases. In addition to these results, the S-Prob is able to find 17 new best solutions to 20 problems used for experimentation by Glover and Laguna [13]. For problems with up to 60 jobs,

TABLE 23.5 Number of Best Solutions (Out of 100) Found by Each Method

Problem Set	Static	Dynamic	Cycle	C-Prob	S-Prob
$n = 50$	2	50	9	31	65
$n = 100$	0	10	28	17	47
$n = 200$	0	8	37	26	29

for which a lower bound can be computed, S-Prob produces a maximum gap of 3.56% in relation to this optimistic bound.

These results confirm that a TS procedure based solely on a static tabu list is not a robust method, because it is incapable of maintaining an acceptable level of diversity during the search. The dynamic short-term memory continues to be an appealing alternative, because it is easy to implement and provides a good balance between diversification and intensification. The results also show that improved outcomes are possible with the additional effort required to implement the tabu cycle or conditional probability methods.

Additional strategies identified by Glover and Laguna [2] can be valuable for exploiting other aspects of intensification and diversification, but this example demonstrates the importance of handling short-term memory in a strategic way, especially when faced with larger and more difficult problems.

23.7 Conclusions

The focus and emphasis of TS have a number of implications for the goal of designing improved optimization procedures. These research opportunities carry with them an emphasis on producing systematic and strategically designed rules, rather than following the policy of relegating decisions to random choices, as often is fashionable in evolutionary methods. The highly attractive results provided by the adaptive memory structures underlying TS are producing an evident impact on the design of metaheuristic methods in general, and are motivating the emergence of new hybrids of TS with other procedures.

24.1 Introduction

This chapter aims to give a summary of evolutionary computation (EC) techniques. The summary includes a general description of the main families of algorithms belonging to the EC field as well as their main components. Also, we describe their evolution through the last years including latest advances in constraint-handling methods, parallel models and algorithms, methods for dynamic environments and multiobjective optimization, etc. Also included are some observations about the relationship between EC techniques and other methods for optimization, in particular metaheuristics. Finally, we describe some new trends and give a glimpse of the numerous applications of EC techniques.

Optimization problems are of high importance in industry and science. Examples of practical optimization problems include train scheduling, time tabling, shape optimization, or telecommunication network design. An optimization problem $\mathcal{P}$ can be described as a triple $(\mathcal{S}, \Omega, f)$, where

1. $\mathcal{S}$ is the search space defined over a finite set of decision variables X_i, $i = 1, \ldots, n$. In case these variables have discrete domains we deal with discrete optimization (or combinatorial optimization), and in case of continuous domains $\mathcal{P}$ is called a continuous optimization problem. Mixed variable problems also exist. Ω is a set of constraints among the variables.
2. $f : \mathcal{S} \rightarrow I\!R^+$ is the objective function that assigns a positive cost value to each element (or solution) of $\mathcal{S}$.

The goal is to find a solution $s \in \mathcal{S}$ such that $f(s) \leq f(s'), \forall s' \in \mathcal{S}$ (in case we want to minimize the objective function), or $f(s) \geq f(s'), \forall s' \in \mathcal{S}$ (in case the objective function must be maximized). In real-life problems the goal is often to optimize several objective functions at the same time. This form of optimization is labelled as multiobjective optimization.

Due to the practical importance of optimization problems, many algorithms to tackle them have been developed. These algorithms can be classified as either *complete* or *approximate* algorithms. Complete algorithms are guaranteed to find for every finite size instance of an optimization problem an optimal solution in bounded time (see Refs. [1,2]). Yet, many practically relevant optimization problems are—because of their size or their structure—very hard to be solved to optimality. Therefore, complete methods might need a computation time too high for practical purposes. Thus, the development of approximate methods—in which we sacrifice the guarantee of finding optimal solutions for the sake of getting good solutions in a significantly reduced amount of time—has received more and more attention in the last 30 years.

A very successful strand of approximate optimization algorithms originates from a field known as EC. EC can be regarded as a metaphor for building, applying, and studying algorithms based on Darwinian principles of natural selection. The instances of algorithms that are based on evolutionary principles are called evolutionary algorithms (EAs) [3]. Evolutionary algorithms can be characterized as computational models of evolutionary processes. They are inspired by nature's capability to evolve living beings well adapted to their environment. At the core of each EA is a population of individuals. At each algorithm iteration a number of *reproduction* operators is applied to the individuals of the current population to generate the individuals of the population of the next generation. Evolutionary algorithms might use operators called *recombination* or *crossover* to recombine two or more individuals to produce new individuals. They also might use *mutation* or *modification* operators that cause a self-adaptation of individuals. The driving force in EAs is the *selection* of individuals based on their *fitness* (which might be based on the objective function, the result of a simulation experiment, or some other kind of quality measure). Individuals with a higher fitness have a higher probability to be chosen as members of the population of the next generation (or as parents for the generation of new individuals). This corresponds to the principle of *survival of the fittest* in natural evolution. It is the capability of nature to adapt itself to a changing environment, which gave the inspiration for EAs.

There has been a variety of slightly different EAs proposed over the years. Three different strands of EAs were developed independently of each other over time. These are evolutionary programming (EP) as introduced by Fogel [4] and Fogel et al. [5], evolutionary strategies (ES) proposed by Rechenberg [6] and genetic algorithms (GAs) initiated by Holland [7] (see Refs. [8–11] for further references). Evolutionary programming arose from the desire to generate machine intelligence. While EP originally was proposed to operate on discrete representations of finite-state machines, most of the present variants are used for continuous optimization problems. The latter also holds for most present variants of ES, whereas GAs are mainly applied to solve discrete problems. More recently, other members of the EA family such as, for example, genetic programming (GP) and scatter search (SS) were developed. Despite this division into different strands, EAs can be understood from a unified point of view with respect to their main components and the way they explore the search space. Over the years there have been quite a few overviews and surveys about EC methods. Among those are the ones by Bäck [12], Fogel et al. [13], Hertz and Kobler [14], Spears et al. [15], and Michalewicz and Michalewicz [16]. In Ref. [17] a taxonomy of EAs is proposed.

The structure of this chapter is as follows. Section 24.2 gives an introduction to EAs and covers shortly important aspects such as the solution representations and search operators. Section 24.3 analyzes the evolution of EAs emphasizing some of the important recent research advances. Section 24.4 discusses and highlights the connections between EAs and other stochastic search methods, namely metaheuristics. We conclude in Section 24.5 with an overview on EAs applications and an outline of new research trends.

24.2 Evolutionary Algorithms

The algorithm in Figure 24.1 shows the basic structure of EAs. In this algorithm, P denotes the population of individuals. These individuals are not necessarily solutions to the considered problem. They may be partial solutions, or sets of solutions, or any object which can be transformed into one or more solutions in a structured way. The set of all possible individuals is generally called the *genotype space* denoted by $\mathcal{G}$, whereas the search space of the tackled optimization problem is called the *phenotype space* denoted by $\mathcal{S}$. Hereby, the structure of the individuals is called the *solution representation, or solution encoding.* $\mathcal{G}$ and $\mathcal{S}$, respectively, constitute the domain and codomain of a function g known as the *growth* (or *expression*) function. In some cases $\mathcal{G}$ and $\mathcal{S}$ are actually equivalent, g being a trivial identity function. However, this is not the general situation. As a matter of fact, the only requirement posed on g is surjectivity, that is, for each $s \in \mathcal{S}$ there must be an individual $i \in \mathcal{G}$ such that $g(i) = s$ (see Figure 24.2). Furthermore, g might be undefined for some elements in $\mathcal{G}$ or even might not be injective at all (a redundant representation).

At the start of an EA, an initial population of individuals is generated by applying a function ι to the genotype space $\mathcal{G}$. Function ι might represent a random procedure that generates individuals at random,

```
Evolutionary algorithm:
  1. $P \leftarrow$ apply $\iota$ on $\mathcal{G}$ to generate $\mu$ individuals (the initial population);
  2. while termination criteria not met do
       (a) $P' \leftarrow$ apply $\sigma$ on $P$; /* selection */
       (b) $P'' \leftarrow$ apply $\omega_r$ on $P'$; $r \in \{1, \ldots, \#operators\}$; /* reproduction */
       (c) $P \leftarrow$ apply $\psi$ on $P$ and $P''$; /* replacement */
     endwhile
```

FIGURE 24.1 Pseudocode of an evolutionary algorithm.

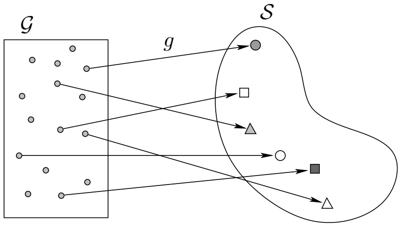

FIGURE 24.2 Mapping from the genotype space to the phenotype space.

or it might represent a heuristic seeding procedure. Then, at each iteration (also called generation) of the algorithm, the following three major operations are performed. First, a set of individuals P' are selected from the current population P by applying a function σ to P. The selection process is based on the individuals' *fitness* value, which is a measure of how good the solution represented by an individual is for the problem being considered. The fitness value is in general tightly coupled to the objective function. It is the main source for guiding the search process. Second, a population P'' of offspring is generated from P' by the application of *reproduction* operators, that is, the application of a function ω_r to P'. Finally, the replacement function ψ is applied to the current population P and the set of offspring individuals P'' to generate the population for the next generation. To choose the individuals for the next population exclusively from the offspring is called *generational replacement*. In some schemes, such as *elitist strategies*, successive generations overlap to some degree, that is, some portion of the previous generation is retained in the new population. The fraction of new individuals at each generation is called the *generational gap* [18]. In *steady-state* selection, only a few individuals are replaced in each iteration: usually a small number of the least fit individuals are replaced by offspring.

The process described above is repeated until certain termination criteria (usually reaching a maximum number of iterations, or reaching a time limit) are satisfied. Most EAs deal with populations of constant size. However, it is also possible to have a variable population size. In case of a continuously shrinking population size, the situation in which only one individual is left in the population (or no crossover partners can be found for any member of the population) might also be one of the stopping conditions of the algorithm. For a graphical presentation of an algorithm iteration see Figure 24.3.

Every possible instantiation of this general framework gives rise to different EAs. In fact, it is possible to distinguish among different EA families by considering some guidelines on how to perform this instantiation. However, before we outline the main EA families, we first deal in more detail with some important aspects that have to be taken into account when applying EAs. Figure 24.4 shows a typical line of decisions with which a practitioner is faced when applying an EA.[1] The first step consists in finding an appropriate *problem formulation*, that is, a concise and manageable description of the problem to be

[1] Note that this is similar when applying an approximate optimization technique other than EC.

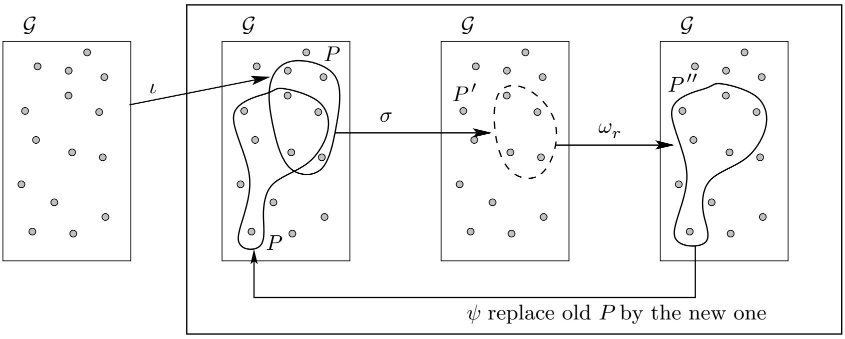

FIGURE 24.3 Illustration of the evolutionary process from the perspective of the genotype space $\mathcal{G}$.

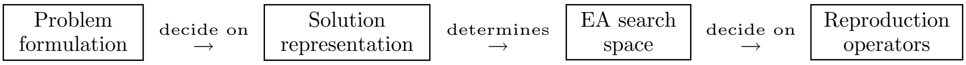

FIGURE 24.4 The different steps in the process of applying an EA to an optimization problem.

tackled (e.g., a sentence, a mathematical formula, or a mathematical program). Having decided on the problem formulation, the choice of the solution representation (which defines the EA search space), and the development of the reproduction operators are crucial for the success of the algorithm.

Solution Representation (i.e., the Individuals)

Most commonly used in EAs is the representation of solutions as bit strings or as permutations of n integer numbers. However, also real-value encodings, tree structures or other complex structures are possible. See Figure 24.5 for some examples. In GAs, an individual usually consists of one or more so-called chromosomes. Chromosomes are strings of smaller units termed genes. The different values a gene can take are called the alleles for that gene. Holland's schema analysis [7] and Radcliffe's generalization to formae [19] are examples of how theory can help to guide representation choices.

Reproduction Operators

The chosen solution encoding determines the complexity and size of the EA search space. To explore this search space it is mandatory to design a set of reproduction operators (the number and type of these operators will depend on the solution encoding and the particular EA instance). In general, we distinguish between *recombination* operators (i.e., N-ary operators) and *mutation* operators (i.e., unary operators). In most cases it is possible to recombine all individuals with each other. However, sometimes this is not the case. In general, a neighborhood function $\mathcal{N}_{\mathcal{EC}} : \mathcal{G} \rightarrow 2^{\mathcal{G}}$ assigns to each individual $i \in \mathcal{G}$ a set of individuals $\mathcal{N}_{\mathcal{EC}}(i) \subseteq \mathcal{G}$ whose members are permitted to act as recombination partners for i to create offspring. If an individual can be recombined with any other individual (as, e.g., in the simple GA [11]) we talk about *unstructured* populations, otherwise we talk about *structured* populations. An example of an EA that works on structured populations is the parallel genetic algorithm (PGA) proposed by Mühlenbein [20] (see Section 24.2.1 for more information on parallel models and algorithms).

The most common form of a recombination operator is two-parent crossover, in which one or two offspring are produced from two parents. But there are also recombination operators that operate on more than two individuals to create new individuals (multiparent crossover), (see Ref. [21,22]). More recent developments even use population statistics for generating the individuals of the next generation. Examples are the recombination operators called gene pool recombination [23] and bit-simulated crossover [24], which make use of a probability distribution over the search space given by the current population to generate the next population. The simplest form of a mutation operator just performs a small random perturbation of an individual, introducing a kind of *noise*. More complex mutation

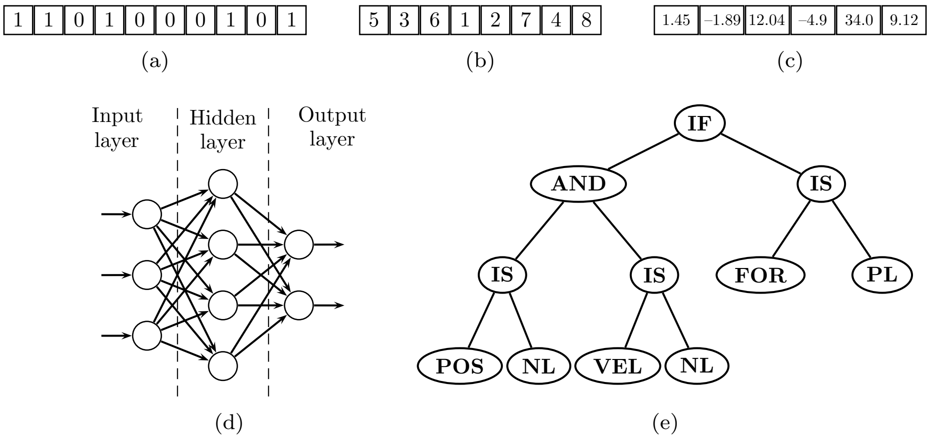

FIGURE 24.5 Five examples for solution representations. (a) Binary strings representation. They are popular, for example, to encode solutions to subset problems such as the knapsack problem. (b) Permutation representation. It is often used for permutation problems such as the traveling salesman problem. (c) The gray value (or real vector) representation. It is used, for example, for continuous optimization. (d) Graphs or trees representing a neural network. They are often represented by edge sets. (e) Trees representing a fuzzy rule. They are often used as encoding for logical rules.

operators include, for example, random moves or more goal-directed moves in a neighborhood of the individual.

It is important to remark that each possible operator will define its own characteristic neighborhood structure, i.e., the set of individuals that might be the outcome of the operators' application. Figure 24.6 and Figure 24.7 show a general view of the neighborhood sizes with respect to the whole EA search space $\mathcal{G}$. In Figure 24.6 we can observe two different neighborhoods for the same individual. For example, consider $\mathcal{G}$ to consist of all binary strings of length n. A mutation operator might be allowed to flip maximally $n/2$ bits of each individual, or, for example, only $n/10$ bits. In the first case the neighborhood of the operator is much bigger than in the second case. Therefore, different mutation operator will define neighborhoods of different sizes and complexities.

Figure 24.7 shows the neighborhood of a hypothetical (binary) recombination operator. As the distance between two individuals gets smaller (from (a) over (b) to (c)) the size of the respective neighborhood for the same operator also diminishes. The neighbor size generally depends on the operator characteristics in addition to the distance between the parent individuals. The sequence from left to right can also be

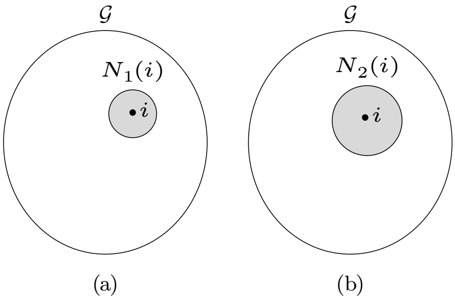

FIGURE 24.6 Graphical representation of the neighborhood $N(i)$ of a mutation operator around an individual i. The neighborhood size depends on the operator characteristics. (a) shows the example of a mutation operator with a smaller neighborhood than the one shown in (b).

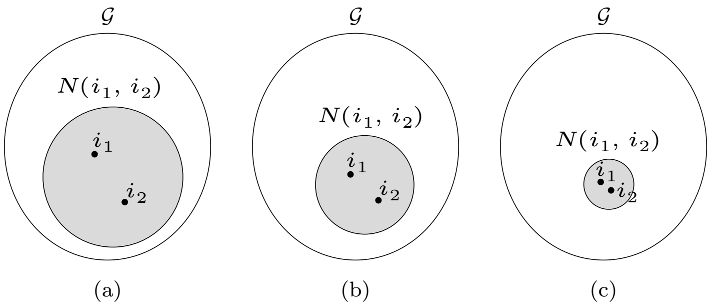

FIGURE 24.7 Graphical representation of the neighborhood $N(i_1, i_2)$ of a binary recombination operator when applied to two individuals i_1 and i_2. From (a) over (b) to (c) the distance between the two individuals changes, and therefore also the neighborhood size.

seen as the changing exploration capacity of the operator as the population tends to converge, that is, the individuals from the population are getting closer, which means that the EA converges.

Finally, in Table 24.1, we provide some commonly used reproduction operators for popular solution representations.

Exploitation versus Exploration

Of great importance for the success of an EA is the right balance between *exploitation* and *exploration*. The term exploitation refers to the use of the accumulated search experience, whereas the term exploration generally refers to the search for areas in the search space that were not visited yet. In terms of exploitation, it proved in many EA applications quite beneficial to use improvement mechanisms to increase the fitness of individuals. While the use of a population ensures an exploration of the search space, the use of local search techniques helps to quickly identify "good" areas in the search space. Another exploitation strategy is the use of recombination operators that explicitly try to combine "good" parts of individuals (rather than, e.g., a simple one-point crossover for bit strings). This may guide the search performed by EAs to areas of individuals with certain "good" properties. Techniques of this kind are sometimes called *linkage learning* or *building block learning* (see, e.g., Refs. [25–28]). Furthermore, generalized recombination operators which incorporate the notion of "neighborhood search" into EC have been proposed in the literature. An example can be found in Ref. [29].

One of the major difficulties of EAs (especially when applying local search) is the premature convergence toward suboptimal solutions. The simplest mechanism to increase exploration is the use of a mutation operator. The simplest form of a mutation operator just performs a small random perturbation of an individual, introducing a kind of *noise*. To avoid premature convergence there are also a number of other ways of maintaining the population diversity. Probably the oldest strategies are *crowding* [18] and its close relative, *preselection* [30]. Newer strategies are *fitness sharing* [31], (respectively *niching* [32]), which is a

TABLE 24.1 Some Representative Solution Encodings together with Commonly Used Reproduction Operators

Solution Representation	**Reproduction Operators**
Binary strings	One-point crossover, uniform crossover, flip mutation, etc.
Permutations	Partially matched crossover (PMX), order crossover (OX), SWAP mutation, etc.
Gray value encoding (i.e., real vectors)	Arithmetic crossover, *k*-point crossover, Gauss mutation, etc.
Integer vectors	*k*-point crossover, little and big creep mutation, random mutation, etc.
S-expressions	Subree exchange, node function alteration, etc.

collective name, whereby the reproductive fitness allocated to an individual in a population is reduced proportionally to the number of other individuals that share the same region of the search space.

24.2.1 Families of Evolutionary Algorithms

Evolutionary algorithms, as we know them today, were first introduced during the late 1960s and early 1970s. In these years, scientists from different places in the world almost simultaneously began to transfer nature's optimization capabilities into algorithms for search and problem solving. The existence of these different primordial sources resulted in the rise of three different EA models. These classical families are:

- *Evolutionary programming*. This EA family originated from the work of Fogel et al. [5]. EP focuses on the adaption of individuals rather than on the evolution of their genetic information. This implies a much more abstract view of the evolutionary process, in which the behavior of individuals is directly modified (as opposed to manipulating its genes). This behavior is typically modeled by using complex data structures such as finite automata or graphs (see, e.g., Figure 24.5 [d]). Traditionally, EP uses asexual reproduction (i.e., mutation) by introducing slight changes in an existing solution, and selection techniques based on direct competition among individuals.
- *Evolutionary strategies*. These techniques were initially developed by Rechenberg [6]. Their original goal was to create a tool for solving engineering problems. With this goal in mind, these techniques are characterized by manipulating arrays of floating-point numbers (see, e.g., Figure 24.5 [c]). Nowadays also exist versions of ES for discrete problems, but still their application to continuous optimization problems is predominant. As in EP, mutation is often the unique reproductive operator used in ES; however, sometimes also recombination operators are used within ES. A very important feature of ES is the utilization of self-adaptive mechanisms for controlling the application of mutation. These mechanisms are aimed at optimizing the progress of the search by evolving not only the individuals, but also some parameters for mutating these individuals (in a typical situation, an ES individual is a pair $(i, \vec{\sigma})$, where $\vec{\sigma}$ is a vector of standard deviations used to control the Gaussian mutation exerted on the individual i).
- *Genetic algorithms*. These are possibly the most widespread variant of EAs. They were first introduced by Holland [7]. Holland's work had a great influence on the developments in the field, to the point that some aspects of his work nearly achieved dogma status (e.g., the ubiquitous use of binary strings as solution representation, as shown, for example, in Figure 24.5 [a]). Later, the seminal book of Goldberg [8] resulted in a widespread use of GAs for discrete optimization. The main feature of GAs is the use of a recombination (or *crossover*) operator as the primary search tool. The rationale is the assumption that different parts of the optimal solution can be independently discovered, and be later combined to create better solutions. Additionally, mutation is used, but is generally considered a secondary background operator whose purpose is merely "to keep the pot boiling" by introducing new information in the population. However, this classical interpretation is no longer considered valid nowadays.

The three EA families described above have not developed in complete isolation from each other. On the contrary, numerous researchers have built bridges among them, and cross-fertilization was and is common. As a result of this interaction, the borders of these classical families tend to be fuzzy (the reader may consult [12] for a unified presentation of EA families), and new variants have emerged of which we cite the following ones:

- *Evolution programs*. This term owes to Michalewicz [33], and comprises those techniques that, while using the fundamental principles of GAs, evolve complex data structures, as in EP. Nowadays, it is accepted to use the acronym GA—or more generally EA—to refer to such an algorithm, leaving the term "traditional GA" to denote classical bit-string-based GAs.
- *Genetic programming*. The roots of GP can be traced back to the work of Cramer [34]. However, nowadays this technique is mostly associated with Koza, who promoted GP to its current status [35].

Essentially, GP could be viewed as an evolution program in which the structures evolved represent computer programs. Such programs are typically encoded by trees (see, e.g., Figure 24.5 [e]). The ultimate goal of GP is the automatic design of a program for performing a certain task, formulated as a collection of (input, output) examples.

- *Memetic algorithms (MA).* These techniques owe their name to Moscato and Cotta [36]. Some widespread misconception equates MAs to EAs augmented with local search; although such an augmented EA could be indeed considered an MA, there are additional properties that define MAs (e.g., restarting procedures). In general, an MA is a problem-aware EA. This problem awareness is typically acquired by combining the EA with existing algorithms such as hill climbing, branch and bound, etc.
- *Scatter search.* The original ideas for SS go back to Glover [37] and originated from strategies for creating composite decision rules and surrogate constraints [38]. The generation of new solutions is achieved by systematically following unifying principles for joining solutions based on generalized path constructions in Euclidean spaces. The terminology in SS is slightly different to the rest of the EAs. For example, the main population of individuals is called the *reference set.* This reference set is manipulated by the application of the following five methods: (1) diversification generation, (2) improvement, (3) reference set update, (4) subset generation, and (5) solution combination.

24.3 Advanced EA Research Topics

Due to their success in practice, EAs have received an evergrowing amount of attention during the last two decades. Nowadays, the diversity of research on EAs is impressive. Besides the improvement of their theoretical understanding, the main aims of this research concern their efficiency and the discovery of new problem domains to which they can be applied. More and more advanced versions of EAs for increasingly complex problems were developed. In the following we will shortly deal with the following examples: EAs for constrained optimization problems (COPs), for dynamic optimization problems (DOPs), and for multiobjective optimization problems (MOPs). Figure 24.8 shows a time line which—in addition to the main EA families—indicates the start of the research activities in these areas. Furthermore, we will shortly present parallel EAs (PEAs) whose aim is to exploit the implicit parallelism that is based on the fact that EAs are population-based techniques.

Constrained Problems

So far we have assumed that the outcome of a reproduction operator consists always of one ore more feasible individuals. However, sometimes reproduction operators are applied that do not guarantee that. This is the case in particular when real-world problems are concerned that often include constraints in their formulation. However, early applications of EAs were designed to solve mainly unconstrained

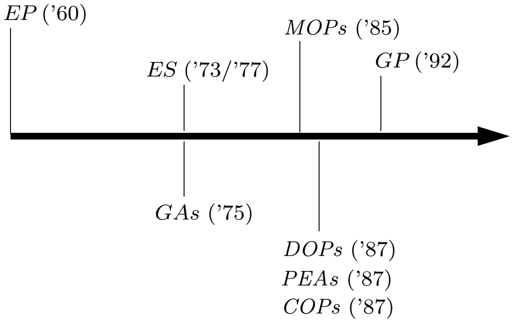

FIGURE 24.8 Time line of EA research including the main EA families and some new developments. The dates indicate the beginning of the respective research activity.

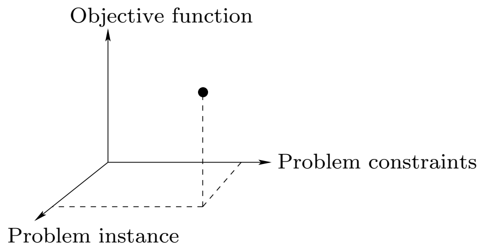

FIGURE 24.9 Dynamic environments seen as a three-dimensional field.

combinatorial and continuous optimization problems. As soon as the research community began to explore the application of EAs to more realistic problems, several constraint handling techniques were accordingly developed. The simplest method is to *reject* infeasible individuals. Nevertheless, for some highly constrained problems (e.g., for timetabling problems) it might be very difficult to find feasible individuals. A very popular method is the incorporation of constraints into the fitness function through a penalty factor. However, this technique experiences many drawbacks due to the need of finding appropriate penalty factors. Therefore, other proposals were designed to automatically adapt the penalty factors during the evolutionary process. In addition, plenty of works have been devoted in the last years to develop improved and alternative constraint-handling techniques including advanced penalty approaches, repair of infeasible individuals, design of special representations and operators, and several versions of hybrid methods. For a comprehensive survey of constraint-handling techniques see Ref. [39].

Dynamic Problems

One of the most recent applications of EAs is the application to DOPs. These are problems that exhibit changes in the problem formulation during the algorithms' execution. These changes might concern different parts of the problem formulation. For example, Morrison [40] exclusively dealt with changes of the objective function. These problems are also called problems with a *dynamic fitness landscape*. A different example is the work of Branke [41], who adopts a more general point of view in which the problem might change either in the objective function, in the problem instance, or in terms of the problem constraints (see Figure 24.9). A general definition of DOPs does not exist so far. However, Branke gives a categorization of dynamic environments with respect to the frequency, severity, predictability, and cycle of the changes [41]. The central aspects of EAs that are specially designed for dynamic optimization are the introduction and maintainance of diversity in the population, and the use of implicitly or explicitly stored search history. These adaptive EAs must find a trade-off between the quality, robustness, and flexibility of the found solutions.

Multiobjective Problems

Multiobjective optimization is another important research field in which EAs have been successfully applied [42]. As a population-based technique, EAs seem to be particularly suitable to face this class of problems. In contrast to other traditional techniques, EAs provide an entire set of Pareto optimal solutions in a single run. During the last years a number of different EA-based approaches have been proposed to deal with multiobjective optimization. Some of the most popular ones are (according to Coello [42]): the aggregation of the objective functions (combinations of all objectives into a single one), VEGA[2] (an extended version of Grefenstette's GENESIS that implements an alternative selection operator), MOGA (is a scheme in which the population is ranked on the basis of nondominance; this rank is used to accordingly calculate each individuals' fitness value), NSGA (bases its behavior on successive classification and manipulation of nondominated individuals; this allows to search and quickly converge to nondominated regions), and

[2] VEGA was probably the first approach proposed by Schaffer [43] explicitly aimed at solving MOPs.

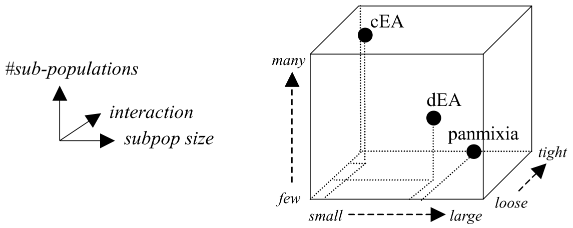

FIGURE 24.10 The structured-population genetic algorithm cube.

NPGA (implements an extended version of tournament selection in which the competitors compete against a certain number of other individuals). Of course, each of these approaches has strengths and weakness. However, they offer a clear evidence of the intrinsic flexibility and robustness of EAs which makes them suitable for tackling MOPs.

Parallel Models and Algorithms

Even though the use of populations in EAs has many advantages, EAs often suffer from the disadvantage of being highly computation time consuming. This is especially the case when the application of the fitness function is costly, or when the population size is required to be large. However, EAs are naturally prone to parallelism since the most usual operations on the individuals are mostly independent from each other. Besides that, the whole population (also called panmixia) can be geographically structured in separate subpopulations, often leading to better algorithms. The geographical structuring of a population is a form of decentralization. Decentralizing an EA by structuring the population has many advantages, but using structured algorithms may have some disadvantages too, as for example, the higher complexity of implementation and analysis, added to the fact that decentralizing the algorithm is not always better. Research on EAs that exploit these aspects, called PEAs [44], give often evidence of higher efficiency, larger diversity maintenance, higher availability of memory and CPU resources, and multisolution capabilities of these algorithms. In the following, we shortly describe two important models of PEAs.

- In coarse-grained or distributed EAs (dEAs) the population is partitioned into several subpopulations (islands). Each island is treated independently, and there are exchanges of information among them.
- In fine-grained or cellular evolutionary algorithms (cEAs) the individuals are placed on a toroidal N-dimensional grid (where $N = 1, 2, 3$ is used in practice), with one individual per grid location (this location is often referred to as a cell, the fine-grained approach being also known as cellular). Every individual has a neighborhood and can only be recombined with individuals from this neighborhood. The main difference of a cEA with respect to a panmistic EA is its decentralized selection, since the reproductive loop is performed inside each of the numerous pools. Hereby, each individual has its own pool composed of neighboring individuals, and at the same time, this individual belongs to many other pools. Usually, a two-dimensional structure with overlapped neighborhoods is used to provide a smooth diffusion of good solutions along the grid.

The relation between dEAs and cEAs is graphically represented in Figure 24.10. Structured EAs usually outperform standard EAs (i.e., unstructured EAs) numerically. A way for further improving PEAs lies in parallelized implementations and further decentralization.

24.4 EAs in the Context of Metaheuristics

In a wider context, EAs belong to the class of metaheuristic algorithms, which are search algorithms for approximate optimization. The term *metaheuristic*, first introduced in Ref. [45], derives from the composition of two Greek words. *Heuristic* is derived from the verb *heuriskein* ($\epsilon\upsilon\rho\iota\sigma\kappa\epsilon\iota\nu$) which means "to find", while the suffix *meta* means "beyond, in an upper level." Before this term was widely adopted, metaheuristics were often called *modern heuristics* [46]. Except for EAs, this class of algorithms includes[3]—but is not restricted to—ant colony optimization (ACO), iterated local search (ILS), simulated annealing (SA), and tabu search (TS).

Metaheuristics can be characterized as high-level strategies for exploring search spaces by defining general rules that are later customized to the problem at hands. Of great importance hereby is that a dynamic balance is achieved between *diversification* and *intensification*. The term diversification generally refers to the exploration of the search space, whereas the term intensification refers to the exploitation of the accumulated search experience. These terms stem from the TS field [47] and it is important to clarify that the terms *exploration* and *exploitation* are used instead in EC [48] (as outlined before). The balance between diversification and intensification is important, on one side to quickly identify regions in the search space with high-quality solutions, and on the other side not to waste too much time in regions of the search space which are either already explored or which do not provide high-quality solutions. Blum and Roli [49] elaborated on the importance of the two concepts in their survey on metaheuristics.

The search strategies of different metaheuristics are highly dependent on the philosophy of the metaheuristic itself. There are several different philosophies apparent in the existing metaheuristics. Some of them can be seen as "intelligent" extensions of local search algorithms. The goal of this kind of metaheuristic is to escape from local minima to proceed in the exploration of the search space and to move on to find other hopefully better local minima. This is, for example, the case in TS, ILS, VNS, and SA. These metaheuristics (also called trajectory methods) work on one or several neighborhood structure(s) imposed on the search space. We can find a different philosophy in algorithms such as ACO and EAs. They incorporate a learning component in the sense that they implicitly or explicitly try to learn correlations between decision variables to identify high-quality areas in the search space. This kind of metaheuristic performs, in a sense, a biased sampling of the search space. For instance, in EAs this is achieved by recombination of solutions and in ACO by sampling the search space at each iteration according to a probability distribution.

An important research direction is the hybridization of EAs with other techniques for optimization, and in particular with other metaheuristics. One of the most popular ways of hybridization concerns the use of trajectory methods in EAs. Many of the successful applications of EC make use of this feature. The reason for that becomes apparent when analyzing the respective strengths of trajectory methods and EAs. The power of EAs is certainly based on the concept of recombining solutions to obtain new ones. This allows to make guided steps in the search space which are usually "larger" than the steps done by trajectory methods. In other words, a solution resulting from a recombination in EAs is usually more "different" from the parents than, say, a predecessor solution to a successor solution (obtained by applying a move) in TS. We also have "large" steps in trajectory methods such as ILS and VNS, but in these methods the steps are usually not guided (these steps are rather called "kick move" or "perturbation" indicating the lack of guidance). It is interesting to note that in population-based methods there are mechanisms in which elite solutions from the search history influence the search process in the hope of finding better solutions in-between those elite solutions and the current solutions. In EAs this is often obtained by keeping the best (or a number of the best) solution(s) found since the beginning of the respective run of the algorithm in the population. This is called a *steady state* evolution process. Scatter search performs a steady-state process by definition. In contrast, the strength of trajectory methods is rather to be found in the more structured way in which they explore a promising region in the search space. In this way the danger of being close to good solutions but "missing" them is not as high as in population-based methods such as EAs.

In summary, population-based methods are better in identifying promising areas in the search space, whereas trajectory methods are better in exploring promising areas in the search space. Thus, EA hybrids that in some way manage to combine the advantage of population-based methods with the strength of trajectory methods are often very successful.

[3] In alphabetical order.

24.5 Applications and New Trends

Evolutionary algorithms have been applied to most optimization problems (discrete, continuous, as well as multiobjective). In the classical area of combinatorial optimization, for example, EAs have been applied to NP-hard problems such as the traveling salesman problem, the multiple knapsack problem, number partitioning, max independent set, and graph coloring, among others. Other nonclassical–yet important–COPs to which EAs have been applied are scheduling (in many variants), timetabling, vehicle routing, quadratic assignment, placement problems, and transportation problems. Telecommunications is also a field that has witnessed successful applications of EAs. For example, EAs have been applied to the placement of antennas and converters, frequency assignment, digital data network design, predicting bandwidth demands in ATM networks, error code design, etc. Evolutionary algorithms have been actively used in electronics and engineering as well. For example, work has been done in structure optimization, aeronautic design, power planning, circuit design, computer-aided design, analogue network synthesis, and service restoration, among other areas. For an extensive collection of references to EC applications we refer to Ref. [3].

In addition to the above mentioned areas of applications there is an increasing interest in new areas for which EAs seems to be a good choice. Recent successes were obtained, for example, in the rapidly growing bioinformatics area (see, e.g., Refs. [50–52]), software engineering [53], the banking sector [54,55], computer imagery [56], drug design [57], clustering [58], cryptology [59], games [60,61], elevator groups [62], and evolvable hardware [63].

The research field of EC is vast, indeed, and continuously under development. This is indicated by a significant number of international conferences such as

- the *International Congress on Evolutionary Computation (CEC)*;
- the *Genetic and Evolutionary Computation Conference (GECCO)*;
- the *European Conference on Evolutionary Computation in Combinatorial Optimization (EvoCOP)*;
- the *Metaheuristics International Conference (MIC)*; and
- the *International Conference on Parallel Problems Solving in Nature (PPSN)*, among others.

Futhermore exist a number of periodical journals such as *Evolutionary Computation, and IEEE Transactions on Evolutionary Computation,* etc., which are devoted specifically to this area. The interested reader may also want to query any bibliographical database or web search engine for "evolutionary algorithm application" to get an idea of the vast number of problems that have been tackled with EAs.

24.6 Conclusions

In this chapter we gave an introduction into the working of EAs. We presented an overview of the main families of EAs as well as a description of their main components from a unifying perspective. Furthermore we dealt with advanced research directions in EC such as parallel models and algorithms, and the application of EAS to constrained, dynamic, and multiobjective problems. We have put EAs into perspective by describing them as a member of the class of metaheuristic algorithms, highlighting hereby the strengths of EAs in contrast to the strengths of other metaheuristics. Finally, we briefly dealt with typical as well as with more recent EA applications. The rich diversity of EA applications gives a flavor of the popularity and the generality of these techniques.

25.1 Introduction

In the early 1980s, Kirkpatrick et al. [1] and, independently, Černý [2] introduced simulated annealing as a randomized local search algorithm to solve combinatorial optimization problems. In a combinatorial optimization problem we are given a finite or countably infinite set of solutions S and a cost function f that assigns a cost to each solution. The problem is to find a solution $i^* \in S$ for which $f(i^*)$ is either minimal or maximal, depending on whether the problem is a minimization or a maximization problem. Such a solution i^* is called a (globally) optimal solution. Without loss of generality, we restrict ourselves in this chapter to minimization problems.

Simulated annealing is a local search algorithm, which means that it starts with an initial solution and then searches through the solution space by iteratively generating a new solution that is "near" to the current solution. A neighborhood function $N: S \to 2^S$ defines for any given solution $s \in S$, the set $N(s) \subseteq S$ of solutions that are near to it. The set $N(s)$ is called the neighborhood of solution s, and each $s' \in N(s)$ is called a neighbor of s. The process of searching through the solution space can be modeled as a walk through a directed graph $G = (V, E)$, where node set V is given by the solution space S and arc set E contains arc (i, j) if and only if $j \in N(i)$. This graph G is called the neighborhood graph.

The solution space of combinatorial optimization problems can typically be formulated in terms of discrete structures, such as sequences, permutations, graphs, and partitions. Local search uses these representations by defining neighborhood functions in terms of local rearrangements, such as moving, swapping, and replacing items, that can be applied to a representation to obtain a neighboring solution.

The simplest form of local search is iterative improvement. An iterative improvement algorithm continuously explores neighborhoods for a solution with lower cost. If such a solution is found, then the current solution is replaced by this better solution. The procedure is repeated until no better solutions can be found in the neighborhood of the current solution. By definition, iterative improvement terminates in a local optimum, which is a solution having a cost at least as good as all of its neighbors.

A disadvantage of using iterative improvement is that it easily gets trapped in poor local optima. To avoid this disadvantage, simulated annealing accepts in a limited way neighboring solutions with a cost that is worse than the cost of the current solution.

25.2 Basic Simulated Annealing

Originally, the use of simulated annealing in combinatorial optimization was heavily inspired by an analogy between the physical annealing process of solids and the problem of solving large combinatorial optimization problems. Since this analogy is quite appealing we use it here as a background for introducing simulated annealing.

In condensed matter physics, annealing is known as a thermal process for obtaining low-energy states of a solid in a heat bath. The process consists of the following two steps [1]:

- Increase the temperature of the heat bath to a maximum value at which the solid melts.
- Decrease carefully the temperature of the heat bath until the particles arrange themselves in the ground state of the solid.

In the liquid phase all particles arrange themselves randomly, whereas in the ground state of the solid, the particles are arranged in a highly structured lattice, for which the corresponding energy is minimal. The ground state of the solid is obtained only if the maximum value of the temperature is sufficiently high and the cooling is done sufficiently slow. Otherwise the solid will be frozen into a metastable state rather than into the true ground state.

It is known that, if the lowering of the temperature is done sufficiently slow, the solid can reach thermal equilibrium at each temperature. Already in 1953, Metropolis et al. [28] introduced a simple algorithm for simulating the evolution of a solid in a heat bath to thermal equilibrium. Their algorithm is based on Monte Carlo techniques [3], and generates a sequence of states of the solid in the following way. Given a current state i of the solid with energy E_i, a subsequent state j is generated by applying a perturbation mechanism that transforms the current state into a next state by a small distortion, for instance, by a displacement of a single particle. The energy of the next state is E_j. If the energy difference, $E_j - E_i$, is less than or equal to 0, the state j is accepted as the current state. If the energy difference is greater than 0, then state j is accepted with a probability given by

$$\exp\left(\frac{E_i - E_j}{k_B T}\right)$$

where T denotes the temperature of the heat bath and k_B a physical constant known as the Boltzmann constant. The acceptance rule described above is known as the Metropolis criterion and the algorithm that goes with it is known as the Metropolis algorithm. In the Metropolis algorithm thermal equilibrium is achieved by generating a large number of transitions at a given temperature value. Thermal equilibrium is characterized by the Boltzmann distribution, which gives the probability of the solid to be in a state i with energy E_i at temperature T, and is given by

$$\mathbb{P}_T\{\mathbf{X} = i\} = \frac{\exp(-E_i/k_B T)}{\sum\limits_j \exp(-E_j/k_B T)} \tag{25.1}$$

where $\mathbf{X}$ is a random variable denoting the current state of the solid and the summation extends over all possible states. As we show below, the Boltzmann distribution plays an essential role in the analysis of the convergence of simulated annealing.

Returning to simulated annealing, the Metropolis algorithm can be used to generate a sequence of solutions of a combinatorial optimization problem by assuming the following equivalences between a physical many-particle system and a combinatorial optimization problem:

- Solutions in the combinatorial optimization problem are equivalent to states of the physical system.
- The cost of a solution is equivalent to the energy of a state.

Simulated annealing can be viewed as a sequence of Metropolis algorithms, evaluated at decreasing values of the temperature.

```
procedure SIMULATED_ANNEALING
begin
    $i$ := initial solution
    $c$ := initial value
    repeat
        for $l := 1$ to $L$ do
        begin
            probabilistically generate neighbor $j$ of $i$
            if $f(j) \leq f(i)$ then accept $j$
            else accept $j$ with probability
                $\exp\left(\frac{f(i)-f(j)}{c}\right)$
        end
        update $L$
        decrease $c$
    until stopcriterion
end;

FIGURE 25.1 The simulated annealing algorithm in pseudo-code.

We now formulate simulated annealing in terms of a local search algorithm. For an instance (S, f) of a combinatorial optimization problem and a neighborhood function N, Figure 25.1 describes simulated annealing in pseudocode.

The algorithm generates neighbors randomly. If the cost of a neighbor j is at most the cost of the current solution i, then j is always accepted. If neighbor j has higher cost than i, then j is still accepted with a positive probability of

$$\exp\left(\frac{f(i) - f(j)}{c}\right)$$

where c is a control parameter that plays the role of the temperature. The probability of accepting a deterioration in cost depends on the value of the control parameter c: the higher the value of the control parameter, the higher the probability of accepting the deterioration.

The value of the control parameter is decreased during the execution of the algorithm. In Figure 25.1 the value L specifies the number of iterations that the control parameter is kept constant before it is decreased. The values of c and L and the stop criterion are specified by the "cooling schedule."

Initially, at large values of c, large deteriorations will be accepted; as c decreases, only smaller deteriorations will be accepted and, finally, as the value of c approaches 0, no deteriorations will be accepted at all. Note that there is no limitation on the size of deterioration with respect to its acceptance. In simulated annealing, arbitrarily large deteriorations are accepted with positive probability; for these deteriorations the acceptance probability is small, however. This feature means that simulated annealing, in contrast to iterative improvement, can escape from local minima while it still exhibits the favorable features of iterative improvement, namely simplicity and general applicability. The speed of convergence of simulated annealing is determined by the cooling schedule. In Section 25.4, we will indicate that under certain mild conditions on the choice of the cooling schedule simulated annealing converges asymptotically to the set of globally optimal solutions.

Comparing simulated annealing with iterative improvement it is evident that simulated annealing can be viewed as a generalization. Simulated annealing becomes identical to iterative improvement in the case where the value of the control parameter is taken equal to 0. With respect to a comparison between the performances of both algorithms we mention that for most problems simulated annealing performs better than iterative improvement, in the case that we give iterative improvement the same amount of time by repeating it for a number of different initial solutions.

The remainder of this chapter is organized as follows. Section 25.3 is devoted to practical cooling schedules. The asymptotic convergence of simulated annealing is discussed in Section 25.4. As an intermediate result, we mention in Section 25.4 that if the value of the control parameter is kept constant, then the probability distribution of the solutions converges to a unique stationary distribution. In Section 25.5 we derive some characteristic features for simulated annealing in the case that this stationary distribution is attained. We conclude Section 25.6 with some final remarks.

25.3 Practical Implementations

To implement simulated annealing we have to specify the cooling schedule that governs the convergence of the algorithm. A cooling schedule specifies a finite sequence of values of the control parameter and the number of iterations that are executed at each value of the control parameter. More precisely, it is specified by

- an initial value of the control parameter c_0,
- a decrement function for lowering the value of the control parameter,
- a final value of the control parameter specified by a stop criterion, and
- for each value of the control parameter a finite number that specifies the number of iterations that are made with this value of the control parameter.

The search for adequate cooling schedules has been the subject of many studies. Reviews are given by Van Laarhoven and Aarts [4], Collins et al. [5], and Romeo and Sangiovanni-Vincentelli [6]. A more recent empirical study on several cooling schedules is given by Triki et al. [7]. Below we discuss some results.

Most of the existing work on cooling schedules presented in the literature deals with heuristic schedules. We distinguish between two broad classes: static and dynamic schedules. In a static cooling schedule the parameters are fixed; they cannot be changed during execution of the algorithm. In a dynamic cooling schedule the parameters are adaptively changed during execution of the algorithm. Below we illustrate both types of cooling schedules.

25.3.1 Static Cooling Schedules

The following simple schedule is known as the geometric schedule. It originates from the early work on cooling schedules by Kirkpatrick et al. [1], and is still used in many practical situations.

Initial value of the control parameter. To ensure that initially a sufficiently large number of solutions is accepted, one may choose $c_0 = \Delta f_{\max}$, where $\Delta f_{\max}$ is the maximal difference in cost between any two neighboring solutions. Exact calculation of $\Delta f_{\max}$ is quite time-consuming in many cases. However, one often can give simple estimates of its value.

Lowering the control parameter value. The decrement function is given by

$$c_{k+1} = \alpha \cdot c_k, \quad k = 0, 1, \ldots$$

where α is a positive constant smaller than but close to 1. Typical values lie between 0.8 and 0.99.

Final value of the control parameter. The final value is fixed at some small value, which may be related to the smallest possible difference in cost between two neighboring solutions.

Number of iterations that the control parameter is kept constant. This number is fixed and may be related to the size of the neighborhoods in the problem instance at hand.

25.3.2 Dynamic Cooling Schedules

There exist many extensions of the simple static schedule presented above that lead to a dynamic schedule. For instance, a sufficiently large value of c_0 may be obtained by starting off at a small positive value of c_0 and multiplying it with a constant factor, larger than 1, until the fraction $\omega(c_0)$ of accepted solutions is close to 1. Typical values of $\omega(c_0)$ lie between 0.9 and 0.99. An adaptive calculation of the final value of the control parameter may be obtained by terminating the execution of the algorithm if the best solution cost obtained at value c of the control parameter remains unchanged for a number of consecutive values of c. Clearly such a value exists for each local minimum that is found. The number of iterations that the control parameter is kept constant may be determined by requiring that at each value c of the control parameter, a minimum number of solutions is accepted. However, since solutions are accepted with decreasing probability, one would obtain $L \to \infty$ for $c \downarrow 0$. Therefore, L is usually bounded by some constant $L_{\max}$ to avoid that c is kept constant for an extremely large number of iterations.

In addition to this basic dynamic schedule the literature presents a number of more elaborate schedules. Most of these schedules are based on a statistical analysis of simulated annealing using the equilibrium statistics of Section 25.5.

25.4 Asymptotic Convergence

Simulated annealing can be mathematically modeled by means of Markov chains. For details on Markov chain theory we refer to Feller [8], Isaacson and Madsen [9], and Seneta [10]. In this model, we view simulated annealing as a Markov chain that consists of a sequence of trials, where the outcome of the kth trial corresponds to the solution that simulated annealing visits in the kth iteration.

Let (S, f) be a problem instance, N a neighborhood function, $\mathbf{X}(k)$ a random variable denoting the outcome of the kth trial, and c_k the value of the control parameter at the kth trial. Then the transition probability at the kth trial for each pair $i, j \in S$ of outcomes is defined as

$$P_{ij}(k) = \mathbb{P}\{\mathbf{X}(k) = j | \mathbf{X}(k-1) = i\}$$

$$= \begin{cases} G_{ij}(c_k)A_{ij}(c_k) & \text{if } i \neq j \\ 1 - \sum\limits_{l \in S, l \neq i} G_{il}(c_k)A_{il}(c_k) & \text{if } i = j \end{cases} \tag{25.2}$$

where $G_{ij}(c_k)$ denotes the generation probability, that is, the probability of generating a solution j when being at solution i, and $A_{ij}(c_k)$ denotes the acceptance probability, that is, the probability of accepting solution j once it is generated from solution i. The most frequently used choices for these probabilities are the following [11]:

$$G_{ij}(c_k) = \begin{cases} |N(i)|^{-1} & \text{if } j \in N(i) \\ 0 & \text{if } j \notin N(i) \end{cases} \tag{25.3}$$

and

$$A_{ij}(c_k) = \begin{cases} 1 & \text{if } f(j) \leq f(i) \\ \exp((f(i) - f(j))/c_k) & \text{if } f(j) > f(i) \end{cases} \tag{25.4}$$

Instead of one long Markov chain, we can also view simulated annealing as a process in which a sequence of Markov chains is generated, one for each value of the control parameter. In this case, the transition probabilities of each Markov chain are independent of k, in which case the resulting Markov chain is called time-independent or homogeneous. We now focus on this homogeneous model.

Using the theory of Markov chains it is fairly straightforward to show that, under the condition that the neighborhood graph is strongly connected and finite and not all solutions are optimal—in which case the Markov chain is irreducible and aperiodic—there exist a unique stationary distribution of the outcomes to which the Markov chain converges. Under the additional condition that the generation matrix satisfies $G_{ij} = G_{ji}$ for all solutions $i, j \in S$, this distribution assumes the following form [11], where S^* denotes the set of globally optimal solutions.

Theorem 25.1

Let (S, f) be an instance of a combinatorial optimization problem with $S^* \neq S$ and S finite. Furthermore, let N be a neighborhood function that induces a strongly connected neighborhood graph. If the generation matrix *satisfies $G_{ij} = G_{ji}$ for all $i,\ j \in S$, then, after a sufficiently large number of transitions at a fixed value c of the control parameter, applying the transition probabilities of (25.2), (25.3), and (25.4), simulated annealing will find a solution $i \in S$ with a probability given by*

$$\mathbb{P}_c\{\mathbf{X} = i\} \overset{def}{=} q_i(c) = \frac{1}{N_0(c)} \exp\left(-\frac{f(i)}{c}\right) \tag{25.5}$$

where $\mathbf{X}$ is a stochastic variable denoting the current solution obtained by simulated annealing and

$$N_0(c) = \sum_{j \in S} \exp\left(-\frac{f(j)}{c}\right)$$

denotes a normalization constant.

A proof of this theorem is considered beyond the scope of this chapter. For those interested we refer to Aarts and Korst [11]. The probability distribution of (25.5), which besides stationary distribution is also called equilibrium distribution, is the equivalent of the Boltzmann distribution of (25.1). We can now formulate the following important result.

Theorem 25.2

Let the components of distribution $q(c)$ be given by (25.5). Then

$$\lim_{c \downarrow 0} q_i(c) \overset{def}{=} q_i^* = \frac{1}{|S^*|} \chi_{(S^*)}(i)$$

where for any two sets A and $A' \subseteq A$ the characteristic function χ is defined such that $\chi_{(A')}(a) = 1$ if $a \in A'$ and $\chi_{(A')}(a) = 0$ if $a \in A \setminus A'$.

Proof

Using the fact that for all $a \leq 0$, $\lim_{x \downarrow 0} e^{\frac{a}{x}} = 1$ if $a = 0$, and 0 otherwise, we obtain

$$\begin{aligned}
\lim_{c \downarrow 0} q_i(c) &= \lim_{c \downarrow 0} \frac{\exp\left(-\frac{f(i)}{c}\right)}{\sum_{j \in S} \exp\left(-\frac{f(j)}{c}\right)} \\
&= \lim_{c \downarrow 0} \frac{\exp\left(\frac{f^* - f(i)}{c}\right)}{\sum_{j \in S} \exp\left(\frac{f^* - f(j)}{c}\right)} \\
&= \lim_{c \downarrow 0} \frac{1}{\sum_{j \in S} \exp\left(\frac{f^* - f(j)}{c}\right)} \chi_{(S^*)}(i) \\
&\quad + \lim_{c \downarrow 0} \frac{\exp\left(\frac{f^* - f(i)}{c}\right)}{\sum_{j \in S} \exp\left(\frac{f^* - f(j)}{c}\right)} \chi_{(S \setminus S^*)}(i) \\
&= \frac{1}{|S^*|} \chi_{(S^*)}(i) + \frac{0}{|S^*|} \chi_{(S \setminus S^*)}(i),
\end{aligned}$$

which completes the proof. □

The results of Theorems 25.1 and 25.2 are quite interesting since they guarantee asymptotic convergence of the simulated annealing algorithm to the set of globally optimal solutions under the condition that the stationary distribution of (25.5) is attained at each value of c. More specifically, it implies that asymptotically optimal solutions are obtained. This can be expressed as

$$\lim_{c \downarrow 0} \lim_{k \to \infty} \mathbb{P}_c\{\mathbf{X}(k) \in S^*\} = 1$$

We note that it can be proved that this convergence result still holds if we replace the constraint that the neighborhood function satisfies $|N(i)| = |N(j)|$ for all $i,\ j \in S$ by the constraint that the neighborhood graph has to be symmetric [12,29].

Of course, it is not possible to implement simulated annealing such that it consists of a sequence of infinitely long Markov chains. However, we now indicate that simulated annealing also converges in a more realistic inhomogeneous model in which simulated annealing is modeled by a single inhomogeneous Markov chain, where the value of the control parameter may be changed after each iteration. Necessary and sufficient conditions for asymptotic convergence in this case have been derived by Hajek [13]. To discuss this result we need the following definitions.

For any two solutions $i,\ j \in S,\ j$ is reachable at height h from i if there exists a sequence of solutions $i = l_0, l_1, \ldots, l_p = j \in S$ with $G_{l_k,l_{k+1}}(c) > 0$ for $k = 0, \ldots, p-1$ and $f(l_k) \leq h$ for all $k = 0, \ldots, p$.

The depth $d(\hat{\imath})$ of a local optimum $\hat{\imath}$ is the smallest positive number x, such that there is a solution $j \in S$ with $f(j) < f(\hat{\imath})$ that is reachable at height $f(\hat{\imath}) + x$ from $\hat{\imath}$. By definition, for an optimal solution i^*, $d(i^*) = \infty$.

We now can formulate Hajek's result.

Theorem 25.3

Given are an instance $(S,\ f)$ of a combinatorial optimization problem with S finite and a suitable neighborhood function. Furthermore, let $\{c_k\}_{k=1}^{\infty}$ be a sequence of values of the control parameter satisfying

$$c_k = \frac{\Gamma}{\log(k+1)}, \quad k = 0, 1, \ldots$$

for some constant Γ. Then asymptotic convergence of simulated annealing to the set of globally optimal solutions, using the transition probabilities of (25.2), (25.3), and (25.4), is guaranteed if and only if

- *the neighborhood graph is strongly connected,*
- *i is reachable from j at height h if and only if j is reachable from i at height h, for arbitrary $i,\ j \in S$ and h, and*
- *the constant Γ satisfies $\Gamma \geq D$, where D is the depth of the deepest local, nonglobal minimum.*

Kern [14] has addressed the problem of calculating the value of D. In particular, he showed for a number of problems that it is unlikely that D can be calculated in polynomial time for arbitrary instances. Kern also presents bounds on the value of D for several combinatorial optimization problems.

Several authors have addressed the convergence of simulated annealing for more general forms of the generation and acceptance probabilities than the probabilities of (25.3) and (25.4). Especially the use of more general forms of the acceptance probability has been studied extensively with the aim to find probabilities different from the exponential form of the Metropolis criterion that exhibit a similar asymptotic convergence behavior. However, this has not resulted in practical acceptance probabilities that are essentially different from the ones used above.

Summarizing, simulated annealing can find optimal solutions with probability 1 if it is allowed an infinite number of transitions. This result is mainly of theoretical interest. The real strength of simulated annealing lies in the good practical results that can be obtained by applying more efficient finite-time implementations, which we discussed in Section 25.3. Several papers derive theoretical results for finite-time implementations of simulated annealing [15–27]. These results are mainly concerned with the application of simulated annealing to a particular combinatorial optimization problem and not with the algorithm as a whole as is the case for the convergence result discussed.

25.5 Equilibrium Statistics

To enhance our understanding of the simulated annealing algorithm, we discuss in this section some characteristic features of the algorithm in the case that we are at equilibrium. We will assume that all conditions of Theorem 25.1 are satisfied. This means that the equilibrium is given by the stationary distribution defined by (25.5), that is, at any value c of the control parameter, the probability of being in solution $i \in S$ is given by $q_i(c) = \frac{1}{N_0(c)} \exp(-\frac{f(i)}{c})$, where $N_0(c) = \sum_{j \in S} \exp(-\frac{f(j)}{c})$. We can write the expected cost $\langle f \rangle_c$ and the variance σ_c^2 of the cost as

$$\langle f \rangle_c = \sum_{i \in S} f(i) q_i(c) \tag{25.6}$$

and

$$\sigma_c^2 = \sum_{i \in S} (f(i) - \langle f \rangle_c)^2 \, q_i(c) \tag{25.7}$$

respectively. Note that because $S \neq S^*$ by one of the conditions of Theorem 25.1 and because $q_i(c) > 0$ for all $c > 0$, we have $\sigma_c^2 > 0$. Using this observation and the following theorem yields that if the control parameter decreases, then the expected cost at equilibrium also decreases.

Theorem 25.4

Let $\langle f \rangle_c$ and σ_c^2 be defined by (25.6) and (25.7), respectively. Then, we have

$$\frac{\partial}{\partial c} \langle f \rangle_c = \frac{\sigma_c^2}{c^2}$$

Proof

Using the definition of $\langle f \rangle_c$ gives

$$\frac{\partial}{\partial c} \langle f \rangle_c = \sum_{i \in S} f(i) \frac{\partial}{\partial c} q_i(c) \tag{25.8}$$

Furthermore, simple calculus yields

$$\frac{\partial}{\partial c} N_0(c) = \sum_{j \in S} \frac{f(j)}{c^2} \exp\left(\frac{-f(j)}{c}\right)$$

and thus, by using $\frac{\partial}{\partial c}(g(c) \cdot h(c)) = g(c)\frac{\partial}{\partial c}h(c) + h(c)\frac{\partial}{\partial c}g(c)$ with $g(c) = 1/N_0(c)$ and $h(c) = \exp\left(\frac{-f(i)}{c}\right)$,

$$\begin{aligned}
\frac{\partial}{\partial c} q_i(c) &= \frac{\partial}{\partial c} \frac{\exp\left(\frac{-f(i)}{c}\right)}{N_0(c)} \\
&= \frac{f(i)}{c^2} \frac{\exp\left(\frac{-f(i)}{c}\right)}{N_0(c)} - \frac{\exp\left(\frac{-f(i)}{c}\right)}{N_0^2(c)} \frac{\partial}{\partial c} N_0(c) \\
&= \frac{q_i(c)}{c^2} f(i) - \frac{q_i(c)}{c^2} \frac{\sum_{j \in S} f(j) \exp\left(\frac{-f(j)}{c}\right)}{N_0(c)} \\
&= \frac{q_i(c)}{c^2} (f(i) - \langle f \rangle_c)
\end{aligned}$$

Substituting this for $\frac{\partial}{\partial c} q_i(c)$ in (25.8) now gives

$$\begin{aligned}
\frac{\partial}{\partial c} \langle f \rangle_c &= \frac{1}{c^2} \sum_{i \in S} q_i(c) \left(f^2(i) - f(i) \langle f \rangle_c \right) \\
&= \frac{1}{c^2} \left(-\langle f \rangle_c^2 + \sum_{i \in S} f^2(i) q_i(c) \right)
\end{aligned}$$

By definition, we have $\langle f\rangle_c = \sum_{i\in S} f(i)q_i(c)$. Furthermore, because $\sum_{i\in S} q_i(c) = 1$ we also have $\langle f\rangle_c = \sum_{i\in S}\langle f\rangle_c q_i(c)$. Using these observations we obtain

$$\begin{aligned}\frac{\partial}{\partial c}\langle f\rangle_c &= \frac{1}{c^2}\left(-2\langle f\rangle_c^2 + \langle f\rangle_c^2 + \sum_{i\in S} f^2(i)q_i(c)\right)\\ &= \frac{1}{c^2}\sum_{i\in S}\left(f^2(i) - 2f(i)\langle f\rangle_c + \langle f\rangle_c^2\right)q_i(c)\\ &= \frac{1}{c^2}\sum_{i\in S}(f(i) - \langle f\rangle_c)^2 q_i(c)\\ &= \frac{\sigma_c^2}{c^2}\end{aligned}$$

□

By using the following theorem, we can strengthen the observation that the expected cost at equilibrium decreases if the control parameter decreases. It implies that the expected cost at equilibrium decreases from some value that is at most the average cost to the optimal cost.

Theorem 25.5

Let $\langle f\rangle_c$ and σ_c^2 be defined by (25.6) and (25.7), respectively. Furthermore, let $\langle f\rangle_\infty = \frac{1}{|S|}\sum_{i\in S} f(i)$ denote the average cost and let f^* denote the optimal cost. Then, we have

$$\begin{aligned}\lim_{c\to\infty}\langle f\rangle_c &= \langle f\rangle_\infty\\ \lim_{c\downarrow 0}\langle f\rangle_c &= f^*\\ \lim_{c\to\infty}\sigma_c^2 &= \frac{1}{|S|}\sum_{i\in S}(f(i) - \langle f\rangle_\infty)^2\\ \lim_{c\downarrow 0}\sigma_c^2 &= 0\end{aligned}$$

Proof

The theorem can be proved by using the definitions of $\langle f\rangle_c$, σ_c^2, and $q(c)$. □

In the above two theorems, we studied the solutions space as a whole. For an individual solution $i \in S$, we can derive the following result. For decreasing c, the probability of being in solution i at equilibrium increases if i is optimal and it decreases if i has a cost that is at least the average cost. Otherwise, a turning point c_i exists, such that the probability of being in solution i increases if $c > c_i$ and it decreases if $c < c_i$.

Theorem 25.6

Let $\langle f\rangle_\infty = \frac{1}{|S|}\sum_{i\in S} f(i)$ denote the average cost, and let f^* denote the optimal cost. Furthermore, let the components of distribution $q(c)$ of S be given by (25.5). If $S \neq S^*$, then we have for any $i \in S$

$$\frac{\partial}{\partial c}q_i(c) < 0$$

if $f(i) = f^*$,

$$\frac{\partial}{\partial c}q_i(c) > 0$$

if $f(i) \geq \langle f\rangle_\infty$, and

$$\frac{\partial}{\partial c}q_i(c)\begin{cases} < 0 & \text{if } c > c_i\\ = 0 & \text{if } c = c_i\\ > 0 & \text{if } c < c_i\end{cases}$$

for some $c_i > 0$ if $f^* < f(i) < \langle f\rangle_\infty$.

Proof
In Theorem 25.4 we proved

$$\frac{\partial}{\partial c} q_i(c) = \frac{q_i(c)}{c^2}(f(i) - \langle f \rangle_c)$$

As $\frac{q_i(c)}{c^2} > 0$, this implies that the sign of $\frac{\partial}{\partial c} q_i(c)$ is determined by the sign of $f(i) - \langle f \rangle_c$. As we concluded from Theorems 25.4 and 25.5, $\langle f \rangle_c$ increases from f^* to $\langle f \rangle_\infty$ when c increases. The theorem now follows easily. □

25.6 Conclusion

Simulated annealing is a local search algorithm that uses randomization to escape from local optima. Since its introduction in 1983 simulated annealing has been applied to a large amount of different problems in many different areas. More than 20 years of experience had led to the following general observations:

- High-quality solutions can be obtained but sometimes at the cost of large amounts of computation time.
- In many practical situations, where no tailored algorithms are available, simulated annealing is a valuable algorithm due to its general applicability and its ease of implementation.

Free University of Brussels

26.1 Introduction

This chapter presents an overview of ant colony optimization (ACO)—a metaheuristic inspired by the behavior of real ants. Ant colony optimization was proposed by Dorigo and colleagues [1–3] as a method for solving hard combinatorial optimization problems (COPs).

Ant colony optimization algorithms are part of *swarm intelligence*, that is, the research field that studies algorithms inspired by the observation of the behavior of *swarms*. Swarm intelligence algorithms are made up of simple individuals that cooperate through self-organization, that is, without any form of central control over the swarm members. A detailed overview of the self-organization principles exploited by these algorithms, as well as examples from biology, can be found in Ref. [4]. Many swarm intelligence algorithms have been proposed in the literature. For an overview of the field of swarm intelligence, we refer the interested reader to Ref. [5].

This chapter, which is dedicated to present a concise overview of ACO, is organized as follows. Section 26.2 presents the biological phenomenon that provided the original inspiration. Section 26.3 presents a formal description of the ACO metaheuristic. Section 26.4 overviews the most popular variants of ACO and gives examples of their application. Section 26.5 shows current research directions, and Section 26.6 summarizes and concludes the chapter.

26.2 From Biology to Algorithms

Ant colony optimization was inspired by the observation of the behavior of real ants. In this section, we present a number of observations made in experiments with real ants, and then we show how these observations inspired the design of the ACO metaheuristic.

26.2.1 Ants

One of the first researchers to investigate the social behavior of insects was the French entomologist Pierre-Paul Grassé. In the 1940s and 1950s, he was observing the behavior of termites—in particular, the *Bellicositermes natalensis* and *Cubitermes* species. He discovered [6] that these insects are capable to react to what he called "significant stimuli," signals that activate a genetically encoded reaction. He observed [7] that the effects of these reactions can act as new significant stimuli for both the insect that produced them and for the other insects in the colony. Grassé used the term *stigmergy* [7] to describe this particular type of indirect communication in which "the workers are stimulated by the performance they have achieved."

The two main characteristics of stigmergy that differentiate it from other means of communication are:

- the physical, nonsymbolic nature of the information released by the communicating insects, which corresponds to a modification of physical environmental states visited by the insects; and
- the local nature of the released information, which can only be accessed by those insects that visit the place where it was released (or its immediate neighborhood).

Examples of stigmergy can be observed in colonies of ants. In many ant species, ants walking to—and from—a food source, deposit on the ground a substance called *pheromone*. Other ants are able to smell this pheromone, and its presence influences the choice of their path, that is, they tend to follow strong pheromone concentrations. The pheromone deposited on the ground forms a *pheromone trail*, which allows the ants to find good sources of food that have been previously identified by other ants.

Some researchers investigated experimentally this pheromone laying and following behavior to better understand it and to be able to quantify it. Deneubourg et al. [8] set up an experiment called a "binary bridge experiment." They used *Linepithema humile* ants (also known as Argentine ants). The ants' nest was connected to a food source by two bridges of equal length. The ants could freely choose which bridge to use when searching for food and bringing it back to the nest. Their behavior was then observed over a period of time.

In this experiment, initially there is no pheromone on the two bridges. The ants start exploring the surroundings of the nest and eventually cross one of the bridges and reach the food source. When walking to the food source and back, the ants deposit pheromone on the bridge they use. Initially, each ant randomly chooses one of the bridges. However, because of random fluctuations, after some time there will be more pheromone deposited on one of the bridges than on the other. Because ants tend to prefer in probability to follow a stronger pheromone trail, the bridge that has more pheromone will attract more ants. This in turn makes the pheromone trail grow stronger, until the colony of ants converges toward the use of a same bridge.[1]

This colony level behavior, based on autocatalysis, that is, on the exploitation of positive feedback, can be exploited by ants to find the shortest path between a food source and their nest. This was demonstrated in another experiment conducted by Goss et al. [9], in which the two bridges were not of the same length: one was significantly longer than the other. In this case, the stochastic fluctuations in the initial choice of a bridge were much reduced as a second mechanism played an important role: those ants choosing by chance the shorter bridge were also the first to reach the nest, and when returning to the nest, they chose the shorter bridge with higher probability as it had a stronger pheromone trail. Therefore, the ants—thanks to the pheromone following and depositing mechanism—quickly converged to the use of the shorter bridge.

In the next section we explain how these experiments and findings were used to develop optimization algorithms.

[1] Deneubourg et al. [8] conducted several experiments, and results show that each of the two bridges was used in about 50% of the cases.

26.2.2 Algorithms

Stimulated by the interesting results of the experiments described in the previous section, Goss et al. [9] developed a model to explain the behavior observed in the binary bridge experiment. Assuming that after t time units since the start of the experiment, m_1 ants had used the first bridge and m_2 the second one, the probability p_1 for the $(m+1)$th ant to choose the first bridge can be given by

$$p_{1(m+1)} = \frac{(m_1+k)^h}{(m_1+k)^h + (m_2+k)^h} \tag{26.1}$$

where parameters k and h are needed to fit the model to the experimental data. The probability that the same $(m+1)$th ant chooses the second bridge is $p_{2(m+1)} = 1 - p_{1(m+1)}$. Monte Carlo simulations, run to test whether the model corresponds to the real data [10], showed very good fit for $k \approx 20$ and $h \approx 2$.

This basic model, which explains the behavior of real ants, may be used as an inspiration to design artificial ants that solve optimization problems defined in a similar way. In the above described *ant foraging behavior* example, stigmergic communication happens via the pheromone that ants deposit on the ground. Analogously, artificial ants may simulate pheromone laying by modifying appropriate pheromone variables associated with problem states they visit while building solutions to the optimization problem. Also, according to the stigmergic communication model, the artificial ants would have only local access to these pheromone variables.

Therefore, the main characteristics of stigmergy mentioned in the previous section can be extended to artificial agents by

- associating state variables with different problem states; and
- giving the agents only local access to these variables.

Another important aspect of real ants' foraging behavior that may be exploited by artificial ants is the coupling between the autocatalytic mechanism and the *implicit evaluation* of solutions. By implicit solution evaluation, we mean the fact that shorter paths (which correspond to lower cost solutions in the case of artificial ants) are completed earlier than longer ones, and therefore they receive pheromone reinforcement quicker. Implicit solution evaluation coupled with autocatalysis can be very effective: the shorter the path, the sooner the pheromone is deposited, and the more ants use the shorter path. If appropriately used, it can be a powerful mechanism in population-based optimization algorithms (e.g., in evolutionary algorithms [11,12] autocatalysis is implemented by the selection/reproduction mechanism).

Stigmergy, together with implicit solution evaluation and autocatalytic behavior, gave rise to ACO. The basic idea of ACO follows very closely the biological inspiration. Therefore, there are many similarities between real and artificial ants. Both real and artificial ant colonies are composed of a population of individuals that work together to achieve a certain goal. A colony is a population of simple, independent, asynchronous agents that cooperate to find a good *solution* to the problem at hand. In the case of real ants, the problem is to find the food, while in the case of artificial ants, it is to find a good solution to a given optimization problem. A single ant (either a real or an artificial one) is able to find a solution to its problem, but only cooperation among many individuals through stigmergy enables them to find *good* solutions.

In the case of real ants, they deposit and react to a chemical substance called *pheromone*. Real ants simply deposit it on the ground while walking. Artificial ants live in a *virtual* world, hence they only modify numeric values (called for analogy *artificial pheromones*) associated with different problem states. A sequence of pheromone values associated with problem states is called *artificial pheromone trail*. In ACO, the artificial pheromone trails are the sole means of communication among the ants. A mechanism analogous to the evaporation of the physical pheromone in real ant colonies allows the artificial ants to *forget* the history and focus on new promising search directions.

Just like real ants, artificial ants create their solutions sequentially by moving from one problem state to another. Real ants simply walk, choosing a direction based on local pheromone concentrations and a stochastic decision policy. Artificial ants also create solutions step by step, moving through available problem states and making stochastic decisions at each step.

There are however some important differences between real and artificial ants:

- Artificial ants live in a discrete world—they move sequentially through a finite set of problem states.
- The pheromone update (i.e., pheromone depositing and evaporation) is not accomplished in exactly the same way by artificial ants as by real ones. Sometimes the pheromone update is done only by some of the artificial ants, and often *only after* a solution has been constructed.
- Some implementations of artificial ants use additional mechanisms that do not exist in the case of real ants. Examples include look-ahead, local search, backtracking, etc.

26.3 The Ant Colony Optimization Metaheuristic

Ant colony optimization has been formalized into a combinatorial optimization metaheuristic by Dorigo et al. [13,14] and has since been used to tackle many combinatorial optimization problems (COPS).

Given a COP, the first step for the application of ACO to its solution consists in defining an adequate model. This is then used to define the central component of ACO: the pheromone model. The model of a COP may be defined as follows:

Definition 26.1

A model $P = (\mathbf{S}, \mathbf{\Omega}, f)$ *of a COP consists of*

- *a search space* $\mathbf{S}$ *defined over a finite set of discrete decision variables and a set* $\mathbf{\Omega}$ *of constraints among the variables;*
- *an objective function* $f : \mathbf{S} \to \mathbb{R}_0^+$ *to be minimized.*[2]

The search space $\mathbf{S}$ *is defined as follows: Given is a set of discrete variables* X_i, $i = 1, \dots, n$, *with values* $v_i^j \in \mathbf{D}_i = \{v_i^1, \dots, v_i^{|\mathbf{D}_i|}\}$. *A variable instantiation, that is, the assignment of a value* v_i^j *to a variable* X_i, *is denoted by* $X_i \leftarrow v_i^j$. *A solution* $s \in \mathbf{S}$, *that is, a complete assignment in which each decision variable has a value assigned that satisfies all the constraints in the set* $\mathbf{\Omega}$, *is a feasible solution of the given COP. If the set* $\mathbf{\Omega}$ *is empty,* P *is called an unconstrained problem model, otherwise it is said to be constrained. A solution* $s^* \in \mathbf{S}$ *is called a global optimum if and only if* $f(s^*) \leq f(s)\ \forall s \in \mathbf{S}$. *The set of all globally optimal solutions is denoted by* $\mathbf{S}^* \subseteq \mathbf{S}$. *Solving a COP requires finding at least one* $s^* \in \mathbf{S}^*$.

The model of a COP is used to derive the pheromone model used by ACO. First, an instantiated decision variable $X_i = v_i^j$ (i.e., a variable X_i with a value v_i^j assigned from its domain $\mathbf{D}_i$) is called a *solution component* and denoted by c_{ij}. The set of all possible solution components is denoted by $\mathbf{C}$. A pheromone trail parameter T_{ij} is then associated with each component c_{ij}. The set of all pheromone trail parameters is denoted by $\mathbf{T}$. The value of a pheromone trail parameter T_{ij} is denoted by τ_{ij} (and called pheromone value).[3] This pheromone value is then used and updated by the ACO algorithm during the search. It allows modeling the probability distribution of different components of the solution.

In ACO, artificial ants build a solution to a COP by traversing the so-called *construction graph*, $G_C(\mathbf{V}, \mathbf{E})$. The fully connected construction graph consists of a set of vertices $\mathbf{V}$ and a set of edges $\mathbf{E}$. The set of components $\mathbf{C}$ may be associated either with the set of vertices $\mathbf{V}$ of the graph G_C, or with the set of its edges $\mathbf{E}$. The ants move from vertex to vertex along the edges of the graph, incrementally building a *partial solution.* Additionally, the ants deposit a certain amount of pheromone on the components, that is, either on the vertices or on the edges that they traverse. The amount $\Delta\tau$ of pheromone deposited may depend

[2] Note that minimizing over an objective function f is the same as maximizing over $-f$. Therefore, every COP can be described as a minimization problem.

[3] Note that pheromone values are in general a function of the algorithm's iteration $t : \tau_{ij} = \tau_{ij}(t)$.

on the quality of the solution found. Subsequent ants utilize the pheromone information as a guide toward more promising regions of the search space.

The ACO metaheuristic is shown in Algorithm 26.1. It consists of an initialization step and a loop over three algorithmic components. A single iteration of the loop consists of constructing solutions by all ants, their (optional) improvement with the use of a local search algorithm, and an update of the pheromones. In the following, we explain these three algorithmic components in more detail.

Algorithm 26.1 Ant colony optimization metaheuristic

```
Set parameters, initialize pheromone trails
while termination conditions not met do
  ConstructAntSolutions
  ApplyLocalSearch        {optional}
  UpdatePheromones
end while
```

ConstructAntSolutions

A set of m artificial ants construct solutions from elements of a finite set of available solution components $\mathbf{C} = \{c_{ij}\}$, $i = 1, \ldots, n$, $j = 1, \ldots, |\mathbf{D}_i|$. A solution construction starts with an empty partial solution $s^p = \emptyset$. Then, at each construction step, the current partial solution s^p is extended by adding a feasible solution component from the set of feasible neighbors $\mathbf{N}(s^p) \subseteq \mathbf{C}$. The process of constructing solutions can be regarded as a path on the construction graph $G_C = (\mathbf{V}, \mathbf{E})$. The allowed paths in G_C are implicitly defined by the solution construction mechanism that defines the set $\mathbf{N}(s^p)$ with respect to a partial solution s^p.

The choice of a solution component from $\mathbf{N}(s^p)$ is done probabilistically at each construction step. The exact rules for the probabilistic choice of solution components vary across different ACO variants. The best known rule is the one of ant system (AS) [3]:

$$p(c_{ij}|s^p) = \frac{\tau_{ij}^{\alpha} \cdot \eta(c_{ij})^{\beta}}{\sum_{c_{il} \in \mathbf{N}(s^p)} \tau_{il}^{\alpha} \cdot \eta(c_{il})^{\beta}}, \quad \forall c_{ij} \in \mathbf{N}(s^p) \tag{26.2}$$

where τ_{ij} is the pheromone value associated with the component c_{ij}, and $\eta(\cdot)$ is a function that assigns at each construction step a heuristic value to each feasible solution component $c_{ij} \in \mathbf{N}(s^p)$. The values that are returned by this function are commonly called *heuristic information.* Furthermore, α and β are positive parameters, whose values determine the relative importance of pheromone versus heuristic information. Eq. (26.2) is a generalization of Eq. (26.1) presented in Section 26.2: ACO formalization follows closely the biological inspiration.

ApplyLocalSearch

Once solutions have been constructed, and before updating pheromones, often some optional actions may be required. These are often called *daemon actions*, and can be used to implement problem specific and/or centralized actions, which cannot be performed by single ants. The most used daemon action consists in the application of local search to the constructed solutions: the locally optimized solutions are then used to decide which pheromones to update.

UpdatePheromones

The aim of the pheromone update is to increase the pheromone values associated with good or promising solutions, and to decrease those that are associated with bad ones. Usually, this is achieved (i) by decreasing all the pheromone values through *pheromone evaporation*, and (ii) by increasing the pheromone levels associated with a chosen set of good solutions $\mathbf{S}_{upd}$:

$$\tau_{ij} \leftarrow (1-\rho)\tau_{ij} + \rho \sum_{s \in \mathbf{S}_{upd} | c_{ij} \in s} F(s) \tag{26.3}$$

where $\mathbf{S}_{upd}$ is the set of solutions that are used for the update, $\rho \in (0, 1]$ is a parameter called evaporation rate, and $F : \mathbf{S} \to \mathbb{R}_0^+$ a function such that $f(s) < f(s') \Rightarrow F(s) \geq F(s'), \forall s \neq s' \in \mathbf{S}$. $F(\cdot)$ is commonly called the *fitness function*.

Pheromone evaporation is needed to avoid a too rapid convergence of the algorithm. It implements a useful form of *forgetting*, favoring the exploration of new areas in the search space. Different ACO algorithms, for example, Ant Colony System (ACS) [15] or $\mathcal{MAX}$-$\mathcal{MIN}$ Ant System ($\mathcal{MM}$AS) [16] differ in the way they update the pheromone.

Instantiations of the update rule presented in Eq. (26.3) are obtained by different specifications of $\mathbf{S}_{upd}$, which in many cases is a subset of $\mathbf{S}_{iter} \cup \{s_{bs}\}$, where $\mathbf{S}_{iter}$ is the set of solutions that were constructed in the current iteration, and s_{bs} the *best-so-far* solution, that is, the best solution found since the first algorithm iteration. A well-known example is the AS-update rule, that is, the update rule of AS [3], where

$$\mathbf{S}_{upd} \leftarrow \mathbf{S}_{iter} \tag{26.4}$$

An example of a pheromone update rule that is more often used in practice is the IB-update rule (where IB stands for *iteration best*):

$$\mathbf{S}_{upd} \leftarrow \arg\max_{s \in \mathbf{S}_{iter}} F(s) \tag{26.5}$$

The IB-update rule introduces a much stronger bias toward the good solutions found than the AS-update rule. Although this increases the speed with which good solutions are found, it also increases the probability of premature convergence. An even stronger bias is introduced by the BS-update rule, where BS refers to the use of the best-so-far solution s_{bs}. In this case, $\mathbf{S}_{upd}$ is set to $\{s_{sb}\}$. In practice, ACO algorithms that use variants of the IB or the BS-update rules and that additionally include mechanisms to avoid premature convergence achieve better results than those that use the AS-update rule.

26.3.1 Example: The Traveling Salesman Problem

One of the most popular ways to illustrate how the ACO metaheuristic works, is via its application to the traveling salesman problem (TSP). The TSP consists of a set of locations (cities) and a traveling salesman that has to visit all the locations once and only once. The distances between the locations are given and the task is to find a Hamiltonian tour of minimal length. The problem has been proven to be NP-hard [17].

The application of ACO to the TSP is straightforward. The moves between the locations become the solution components, that is, the move from city i to city j becomes a solution component $c_{ij} \equiv c_{ji}$. The construction graph $G_C = (\mathbf{V}, \mathbf{E})$ is defined by associating the set of locations with the set $\mathbf{V}$ of vertices of the graph. Since, in principle, it is possible to move from any city to any other one, the construction graph is fully connected and the number of vertices is equal to the number of locations defined by the problem instance. Furthermore, the lengths of the edges between the vertices are proportional to the distances between the locations represented by these vertices. The pheromone is associated with the set $\mathbf{E}$ of edges of the graph. An example of the resulting construction graph G_C is presented in Figure 26.1(a).

The ants construct the solutions as follows. Each ant starts from a randomly selected location (vertex of the graph G_C). Then, at each construction step it moves along the edges of the graph. Each ant keeps a memory of its path through the graph, and in subsequent steps it chooses among the edges that do not lead to vertices that it has already visited. An ant has constructed a solution once it has visited all the vertices of the graph. At each construction step an ant chooses probabilistically the edge to follow among the available ones (those that lead to yet unvisited vertices). The exact rule depends on the implementation, an example being Eq. (26.2). Once all the ants have completed their tour, the pheromone on the edges is updated according to one of the possible implementations of Eq. (26.3). Ant colony optimization has been shown to perform quite well on the TSP [18].

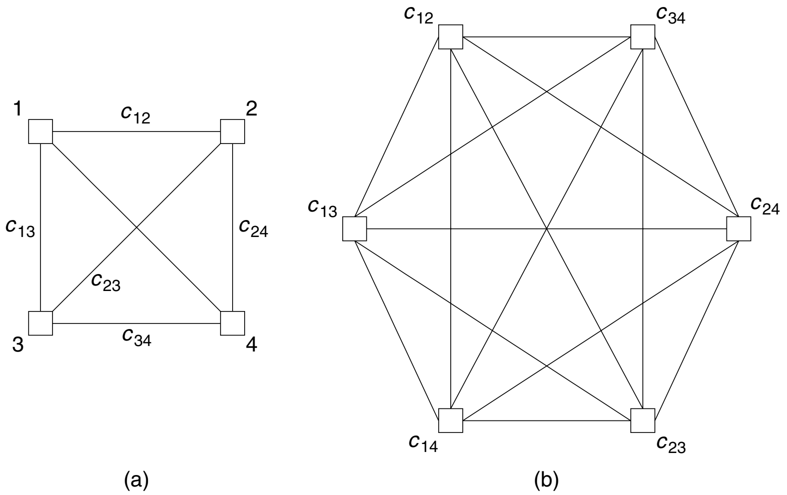

FIGURE 26.1 Example construction graphs for a four-city TSP when (a) components are associated with the edges of the graph, and when (b) components are associated with the vertices of the graph. Note that $c_{ij} \equiv c_{ji}$.

It is worth noticing that it is also possible to associate the set of solution components of the TSP (or any other COP) with the set of vertices **V** rather than the set of edges **E** of the construction graph G_C. For the TSP, this would mean associating the moves between locations with the set **V** of vertices of the construction graph, and the locations with the set **E** of its edges. The corresponding example construction graph for a four-city TSP is presented in Figure 26.1(b). When using this approach, the ants' solution construction process has to be also properly modified: the ants would have to move from vertex to vertex of the construction graph choosing thereby the *connections between the cities*.

It is important to note that both ways of defining the construction graph are correct and both may be used in practice. Although for the TSP the first way seems more intuitive and was in fact used in all the applications of ACO to the TSP that we are aware of, in other cases the second way might be better suited. For example, it was the selected choice in the case of the university course timetabling problem (UCTP) [19].

26.4 Main Variants of ACO

Several variants of ACO have been proposed in the literature. Here we present the three most successful ones, Ant System (AS)—the first implementation of an ACO algorithm—followed by $\mathcal{MAX}$-$\mathcal{MIN}$ Ant System ($\mathcal{MM}$AS) and Ant Colony System (ACS), together with a short list of their applications.

To illustrate the differences between them clearly, we use the example of the TSP, as described in Section 26.3.1.

26.4.1 Ant System

Ant System was the first ACO algorithm to be proposed in the literature [1–3]. Its main characteristic is that the pheromone values are updated by *all* the ants that have completed the tour. The pheromone update for τ_{ij}, that is, for edge joining cities i and j, is performed as follows:

$$\tau_{ij} \leftarrow (1-\rho)\cdot\tau_{ij} + \sum_{k=1}^{m} \Delta\tau_{ij}^{k} \tag{26.6}$$

where ρ is the evaporation rate, m is the number of ants, and $\Delta\tau_{ij}^{k}$ is the quantity of pheromone per unit length laid on edge $(i,\ j)$ by the kth ant:

$$\Delta\tau_{ij}^{k} = \begin{cases} \frac{Q}{L_k} & \text{if ant } k \text{ used edge } (i,\ j) \text{ in its tour} \\ 0 & \text{otherwise} \end{cases} \tag{26.7}$$

where Q is a constant and L_k is the tour length of the kth ant.

When constructing the solutions, the ants in AS traverse a construction graph and make a probabilistic decision at each vertex. The transition probability p_{ij}^{k} of the kth ant moving from city i to city j is given by

$$p_{ij}^{k} = \begin{cases} \frac{\tau_{ij}^{\alpha}\cdot\eta_{ij}^{\beta}}{\sum_{l\in \text{ allowed}_k}\tau_{il}^{\alpha}\cdot\eta_{il}^{\beta}} & \text{if } j \in \text{allowed}_k \\ 0 & \text{otherwise} \end{cases} \tag{26.8}$$

where allowed$_k$ is the list of cities not yet visited by the kth ant, and α and β are the parameters that control the relative importance of the pheromone versus the heuristic information η_{ij} given by

$$\eta_{ij} = \frac{1}{d_{ij}} \tag{26.9}$$

where d_{ij} is the length of edge $(i,\ j)$.

Several implementations of the AS algorithm have been applied to different COPs. The first and best known is the application to the TSP [1–3]. However, AS was also used successfully to tackle other combinatorial problems. The AS–QAP [20,21] algorithm was used for solving the quadratic assignment problem (QAP), AS–JSP [22] for the job-shop scheduling problem (JSP), AS–VRP [23,24] for the vehicle routing problem (VRP), and AS–SCS [25,26] for the shortest common supersequence (SCS) problem.

26.4.2 $\mathcal{MAX}$-$\mathcal{MIN}$ Ant System

$\mathcal{MAX}$-$\mathcal{MIN}$ Ant System is an improvement over the original AS idea. $\mathcal{MM}$AS was proposed by Stützle and Hoos [16], who introduced a number of changes of which the most important are the following:

- only the best ant can update the pheromone trails, and
- the minimum and maximum values of the pheromone are limited.

Eq. (26.6) takes the following new form:

$$\tau_{ij} \leftarrow (1-\rho)\cdot\tau_{ij} + \Delta\tau_{ij}^{\text{best}} \tag{26.10}$$

where $\Delta\tau_{ij}^{\text{best}}$ is the pheromone update value defined by

$$\Delta\tau_{ij}^{\text{best}} = \begin{cases} \frac{1}{L_{\text{best}}} & \text{if the best ant used edge } (i,\ j) \text{ in its tour} \\ 0 & \text{otherwise} \end{cases} \tag{26.11}$$

L_{best} is the length of the tour of the best ant. This may be (subject to the algorithm designer decision) either the best tour found in the current iteration—*iteration best*, L_{ib}—or the best solution found since the start of the algorithm—*best-so-far*, L_{bs}—or a combination of both.

Concerning the limits on the minimal and maximal pheromone values allowed, respectively τ_{min} and τ_{max}, Stützle and Hoos suggest that they should be chosen experimentally based on the problem at hand. The maximum value τ_{max} may be calculated analytically provided that the optimum ant tour length is known. In the case of the TSP, τ_{max} is given by

$$\tau_{max} = \frac{1}{\rho}\cdot\frac{1}{L^{*}} \tag{26.12}$$

where L^{*} is the length of the optimal tour. If L^{*} is not known, it can be approximated by L_{bs}. The minimum pheromone value τ_{min} should be chosen with caution as it has a rather strong influence on the algorithm performance. Stützle and Hoos present an analytical approach to finding this value based on the probability p_{best} that an ant constructs the best tour found so far. This is done as follows. First, it is assumed that at each construction step an ant has a constant number k of options available. Therefore, the probability that an ant makes the *right* decision (i.e., the decision that belongs to the sequence of decisions leading to the construction of the best tour found so far) at each of n steps is given by $p_{\text{dec}} = \sqrt[n-1]{p_{\text{best}}}$. The analytical formula they suggest for finding τ_{min} is

$$\tau_{min} = \frac{\tau_{max} \cdot (1 - p_{dec})}{k \cdot p_{dec}} \tag{26.13}$$

For more details on how to choose τ_{max} and τ_{min}, we refer to Ref. [16]. It is important to mention here that it has also been shown [19] that for some problems the choice of an appropriate τ_{min} value is more easily done experimentally than analytically.

The process of pheromone update in $\mathcal{MM}$AS is concluded by verifying that all pheromone values are within the imposed limits:

$$\tau_{ij} = \begin{cases} \tau_{min} & \text{if } \tau_{ij} < \tau_{min} \\ \tau_{ij} & \text{if } \tau_{min} \leq \tau_{ij} \leq \tau_{max} \\ \tau_{max} & \text{if } \tau_{ij} > \tau_{max} \end{cases} \tag{26.14}$$

$\mathcal{MAX}$-$\mathcal{MIN}$ Ant System provided a significant improvement over the basic AS performance. While the first implementations focused on the TSP [16], it has been later applied to many other COPs such as the QAP [27], the UCTP [19], the generalized assignment problem (GAP) [28], and the set-covering problem (SCP) [29].

26.4.3 Ant Colony System

Another improvement over the original AS was Ant Colony System (ACS), introduced by Gambardella and Dorigo [15,30]. The most interesting contribution of ACS is the introduction of a *local pheromone update* in addition to the pheromone update performed at the end of the construction process (called here *offline* pheromone update).

The local pheromone update is performed by all the ants after each construction step. Each ant applies it only to the last edge traversed:

$$\tau_{ij} = (1 - \varphi) \cdot \tau_{ij} + \varphi \cdot \tau_0 \tag{26.15}$$

where $\varphi \in (0, 1)$ is the pheromone decay coefficient, and τ_0 is the initial value of the pheromone.

The main goal of the local update is to diversify the search performed by subsequent ants during one iteration. In fact, decreasing the pheromone concentration on the edges as they are traversed during one iteration encourages subsequent ants to choose other edges and hence to produce different solutions. This makes less likely that several ants produce identical solutions during one iteration.

The offline pheromone update, similarly to $\mathcal{MM}$AS, is applied at the end of each iteration by only one ant (either the one that found the best solution in the iteration or the best-so-far). However, the update formula is slightly different:

$$\tau_{ij} \leftarrow \begin{cases} (1 - \rho) \cdot \tau_{ij} + \rho \cdot \Delta\tau_{ij} & \text{if edge } (i,\ j) \text{ belongs to the tour of the best ant} \\ \tau_{ij} & \text{otherwise} \end{cases} \tag{26.16}$$

and in case of the TSP, $\Delta\tau_{ij} = \frac{1}{L_{\text{best}}}$ (as in $\mathcal{MM}$AS, L_{best} can be set to either L_{ib} or L_{bs}.)

Another important difference between AS and ACS is in the decision rule used by the ants during the construction process. Ants in ACS use the so-called *pseudorandom proportional* rule: the probability for an ant to move from city i to city j depends on a random variable q uniformly distributed over $[0, 1]$, and a parameter q_0; if $q \leq q_0$, then $j = \text{argmax}_{l \in N(s^p)}\{\tau_{il}\eta_{il}^{\beta}\}$, otherwise Eq. (26.8) is used.

Ant Colony System has been initially developed for the TSP [15,30], but it was later used to tackle various COPs, including vehicle routing [31], sequential ordering [32], and timetabling [33].

26.5 Current Research Directions

Research in ACO is very active. It includes the application of ACO algorithms to new real-world optimization problems or new types of problems, such as dynamic optimization [34], multiobjective optimization [35], stochastic problems [36], or continuous and mixed-variable optimization [37,42]. Also, with an increasing popularity of parallel hardware architectures (multicore processors and the grid technology), a lot of research is being done on creating parallel implementations of ACO that will be able to take advantage of the available hardware. In this section we briefly present current research in these new areas.

26.5.1 Other Types of Problems

One of the new areas of application of ACO is dynamic optimization. This type of problems is characterized by the fact that the search space dynamically changes. While an algorithm searches for good solutions, the conditions of the search as well as the quality of the solutions already found may change. This poses a whole new set of issues for designing successful algorithms that can deal with such situations. It becomes crucial for an algorithm to be able to adjust the search direction, following the changes of the problem being solved. Initial attempts to apply ACO to dynamic optimization problems have been quite successful [34,38,39].

Multiobjective optimization is another area of application for metaheuristics that has received increasing attention over the past years. A multiobjective optimization problem involves solving simultaneously several optimization problems with potentially conflicting objectives. For each of the objectives, a different objective function is used to assess the quality of the solutions found. Algorithms usually aim at finding the so-called *Pareto set*, that is, a set of nondominated solutions, based on the defined objective functions. In the Pareto set, no solution is worse than any other in the set, when evaluated over all the objective functions. Some ACO algorithms designed to tackle multiobjective problems have been proposed in the literature [35,40,41].

Finally, recently researchers attempted to apply ACO algorithms to continuous optimization problems. When an algorithm designed for combinatorial optimization is used to tackle a continuous problem, the simplest approach is to divide the domain of each variable into a set of intervals. The set of intervals is finite and may be handled by the original discrete optimization algorithm. However, when the domain of the variables is large, and the required accuracy is high, this approach runs into problems. The problem size (i.e., the number of intervals) grows, and combinatorial optimization algorithms become less efficient. Also, this approach requires setting the number of intervals *a priori*—before the algorithm is run. In case of real-world problems, this is not always a sensible thing to do.

Due to these reasons, optimization algorithms able to handle continuous parameters natively have been developed. Recently, Socha and Dorigo [37,42] have extended ACO to continuous (and mixed-variable—continuous and discrete) problems. Research in this respect is ongoing and should result in new, efficient ACO implementations for continuous and mixed-variable problems.

26.5.2 Parallel ACO Implementations

Parallelization of algorithms becomes more and more an interesting and practical option for algorithm designers. Ant colony optimization is particularly well suited for parallel implementations, thanks to ants operating in an independent and asynchronous way. There have already been many attempts to propose parallel ACO algorithms. They are usually classified by their *parallel grain*, that is, the relationship between computation and communication. We can then distinguish between *coarse-* and *fine-grained* models. While the formers are characterized by many ants using the same CPU and rare communication between the CPUs, in the latters only few ants use each CPU and there is a lot of communication going on. An overview of the trends and strategies in designing parallel metaheuristics may be found in Refs. [43,44].

Randall and Lewis [45] proposed a first reasonably complete classification of parallel ACO implementations. Although many parallel ACO implementations have been proposed in the literature [46–51], the results are fragmented and difficult to compare. Experiments are usually of limited scale and concern different optimization problems. Also, not all parallel implementations proposed are compared with their sequential counterparts, which is an essential measure of their usefulness [51]. All this implies that more research is necessary in the area of parallelization of the ACO metaheuristic (for some recent work in this direction see Ref. [52]).

26.6 Conclusions

We have presented an introduction to ACO—a metaheuristic inspired by the foraging behavior of real ants. The central component of ACO is the pheromone model based on the underlying model of the problem being solved. The basic idea of ACO, which has been formalized into a metaheuristic framework, leaves many options and choices to the algorithm designer. Several variants of ACO have been already proposed, the most successful being $\mathcal{MM}$AS and ACS.

Ant colony optimization is a relatively young metaheuristic, when compared to others such as evolutionary computation, tabu search, or simulated annealing. Yet, it has proven to be quite efficient and flexible. Ant colony optimization algorithms are currently state-of-the-art for solving many COPs including the sequential ordering problem [32], the resource constraint project scheduling problem [53], and the open-shop scheduling problem [54]. For an in-depth overview of ACO, including theory and applications, the interested reader should refer to Ref. [55].

Carlos Cotta
University of Málaga

27.1 Introduction

The term *memetic algorithms* [1] (MAs) was introduced in the late 1980s to denote a family of metaheuristics that have as central theme the hybridization of different algorithmic approaches for a given problem. Special emphasis was given to the use of a population-based approach in which a set of cooperating and competing agents was engaged in periods of individual improvement of the solutions while they interact sporadically. Another main objective theme was to introduce *problem and instance-dependent knowledge* as a way of speedingup the search process. Initially, hybridizations included Evolutionary Algorithms (EAs) [2–5], Simulated Annealing and its variants [6,7], and Tabu Search [8,9]. Today, a number of hybridizations include other metaheuristics [10] as well as exact algorithms, in *complete anytime* memetic algorithms [11]. These methods not only prove optimality, but can also deliver high-quality solutions early on in the process.

The adjective "memetic" comes from the term "meme," coined by R. Dawkins [12], to denote a term analogous to the *gene* in the context of cultural evolution. It was first proposed as a means of conveying the message that, although inspiring for many, biological evolution should not constrain the imagination to develop population-based methods. Other forms of evolution may be faster, with cultural evolution being one of those less-restrictive examples.

Due to the fact that MAs aimed at drawing the attention from two communities of researchers with different agendas, focusing at hybridizations of their methods, this metaheuristic had to suffer tough initial times. Today they are becoming increasingly popular due to their impressive success record and the high sophistication of the hybridizations proposed. As a consequence of its evolution, it is not unusual to find MAs disguised in the literature under different names such as "hybrid EAs" or "Lamarckian EAs." Furthermore, many of the underlying ideas of MAs can also be found in other metaheuristics that evolved in relative isolation from MAs. Scatter search [13] is a good example of a metaheuristic sharing much of its functioning philosophy with MAs. In Ref. [14], the authors cite a paper by S. Kase, in which a "game" between a set of hierarchical agents (players and referees) is proposed to hybridize heuristic approaches for a layout problem [15]. What makes this interesting is that this is an approach that does not rely on computers for optimization and helps the employees to become engaged in these issues. Anticipating further definitions, we can say that an MA is a search strategy in which a population of optimizing agents synergistically cooperate and compete [16]. A more detailed description of the algorithm as well as a functional template will be given in Section 27.2.

As mentioned before, MAs are a hot topic nowadays, mainly due to their success in solving many hard optimization problems, attracting experienced researchers to work on the challenges of this field. A particular feature of MAs accounts for this: unlike traditional EAs, MAs are intrinsically concerned with exploiting *all available knowledge* about the problem under study. The advantages of this approach were notably neglected in EAs for a long time despite some contrary voices, most notably Davis' who also advocated for hybridization in his book [17]. The formulation of the so-called *No-Free-Lunch Theorem* (NFL) by Wolpert and Macready [18] made it definitely clear that a search algorithm strictly performs in accordance with the amount and quality of the problem knowledge they incorporate, thus backing up one of the *leiv motivs* of MAs.

MAs exploit problem knowledge by incorporating preexisting heuristics, preprocessing data reduction rules, approximation and fixed-parameter tractable algorithms, local search techniques, specialized recombination operators, truncated exact methods, and so on. Also, an important factor is the use of adequate representations of the problem being tackled. This results in highly efficient optimization tools. We provide a brief abstracted overview of MA applications in combinatorial optimization in Section 27.3. We will finish with a brief summary of the current research trends in MAs, with special mention to those which we believe will play a major role in the near future.

27.2 Dissecting a Basic Memetic Algorithm

As mentioned in the previous section, MAs blend different search strategies in a combined algorithmic approach. Like EAs, MAs are population-based metaheuristics. This means that in MAs we maintain a *population* of solutions for the problem at hand. We are using the term "solutions" rather loosely here, as we can have either feasible or protosolutions (structures that can be extended/modified to produce feasible solutions) or even unfeasible solutions (which can be "repaired" to restore feasibility). It is also assumed that both repairing and extension processes can be done quite fast, as to justify including them in the population. Each of these solutions will be termed *individual* as in the EA jargon, mainly to simplify the discussion. In the context of MAs, the denomination *agent* represents a processing unit that can hold multiple solutions and has problem-domain methods that help to improve them if required [1]. Each individual/agent represents a tentative solution/method for the problem under consideration. When the agents adapt their methods we call the resulting strategy an *adaptive memetic algorithm*. Adaptation may include a modification of the data as in Ref. [10].

Due to the agent's interactions, solutions are subject to processes of competition and mutual cooperation. The general structure of MAs is shown in Figure 27.1, aiming to highlight similarities with other population-based metaheuristics such as EAs. Relevant differences are nevertheless evident when we inspect the innards of the high-level blocks depicted in Figure 27.1. First of all, notice the existence of an

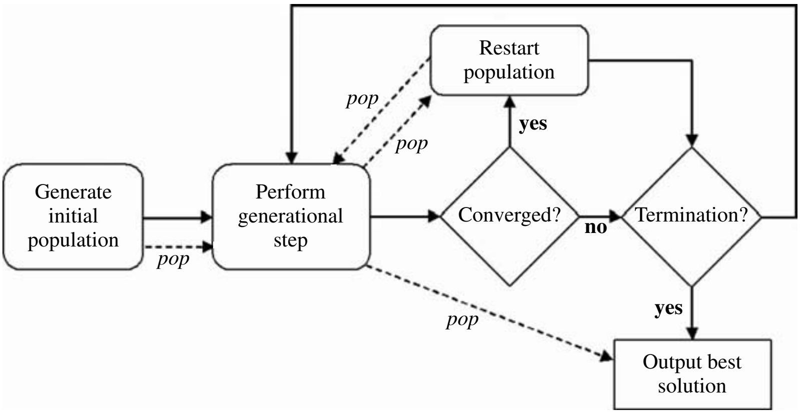

FIGURE 27.1 The general structure of MAs. Solid arrows indicate the control flow, whereas broken arrows indicate the data flow.

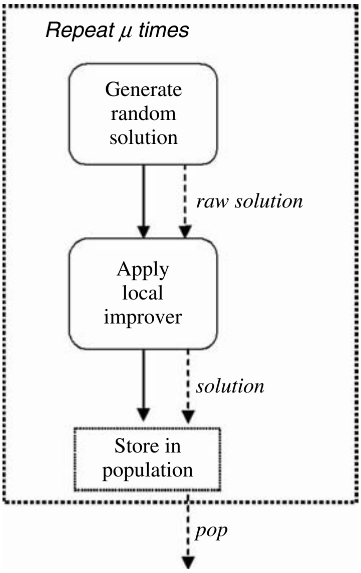

FIGURE 27.2 Generation of the initial population. A local improver can be used to enhance the quality of starting solutions.

initialization block. Standard EAs would simply generate $\mu = |pop|$ random solutions. This can be also done in MAs, but more sophisticated mechanisms are typically used as they are more useful. For example, some constructive heuristic can be utilized to produce high-quality solutions [19,20]. Another possibility refers to the use of a local improvement method, as illustrated in Figure 27.2.

There is another interesting element in the flow chart shown in Figure 27.1: the *Re-start Population* process. This component is sometimes present in some EAs, but it is essential in MAs. Consider that the population may reach a state in which the generation of a new improved solution might be very unlikely. This could be the case when all solutions in the population are very similar to each other. In this situation of population convergence, it is better to refresh the population, rather than keeping the population constrained to a small region of the search space, probably expending most of the time resampling the same solutions [21]. This is specifically important in MAs since the inclusion of several knowledge-augmented components contributes to accelerate the convergence of the population. Typical criteria for determining population convergence are measuring the diversity of solutions—via Shannon's entropy [22] for instance—and Bayesian decision making [23]. In either case, and whenever the population is considered to have converged, restarting can be done in different ways. One of these is shown in Figure 27.3: top individuals of the population are kept (a certain fraction p of the population; this value should not be very high since otherwise the population would obviously converge again in a very short time afterwards), and the remaining solutions are created from scratch, as it is done in the initialization phase.

The main functional block in the MA template is the *generational step* process. This is actually the part of the algorithm in which evolution of solutions takes place. Its internal structure is depicted in Figure 27.4. As can be seen, there are three main components in this generational step: selection, reproduction, and update. Selection and update are responsible for the competition aspects of individuals in the population. Using the information provided by a problem-dependent guiding function (termed *fitness* function in the EA terminology), the goodness of individuals in pop is evaluated, and a sample of individuals is selected according to this goodness measure to help create new solutions. Essentially, this selection can be done using fitness-proportionate methods (the probability of selecting an individual is proportional to its fitness) and nonproportionate methods (selection is done on the basis of qualitative comparisons

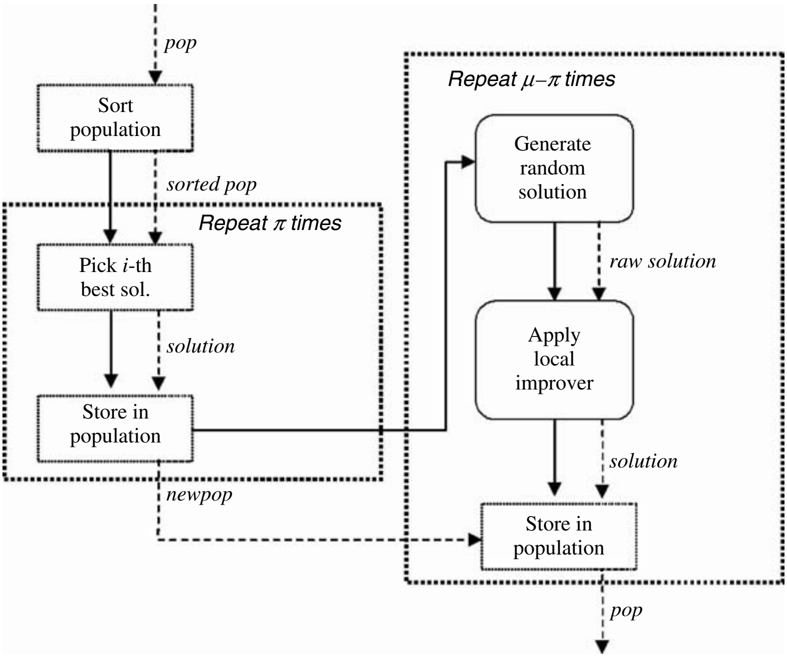

FIGURE 27.3 A possible restarting procedure for the population. The top $\pi = p\mu$ agents in the population are kept, and the remaining μ–π are generated from scratch.

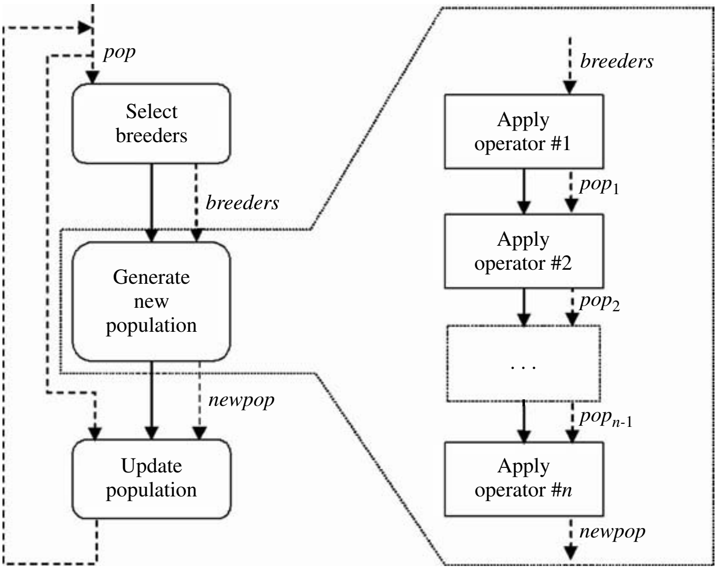

FIGURE 27.4 The basic generational step. Notice the use of a pipeline of reproductive operators for creating new solutions.

among individuals). The latter are being increasingly used, since they avoid some problems of the former (assumption of maximization, need of transformation for dealing with minimization, scaling problems, etc.). Among these, we can cite rank- (the top in the rank of an individual, the higher are its chances for being selected) and tournament-based methods (individuals are selected on the basis of a direct competition within small subgroups of individuals).

As to update, this component takes care of maintaining the population at a constant size, or more properly, at a manageable size, since variable-size populations are not rare [24]. This is done by substituting some preexisting individuals in *pop* by some of the new ones from *newpop*, using some specific criteria. Two major strategies are possible: the *plus* strategy in which the best μ individuals from $pop \cup newpop$ are kept and the *comma* strategy in which the best μ from *newpop* are kept. In the latter case, if $|pop| = |newpop|$ then the update is termed *generational*; if $|newpop|$ is small (say $|newpop| = 1$) then we have a *steady-state* replacement (the worst $|newpop|$ solutions from *pop* are substituted). Other intermediate *generational gaps* are possible by selecting higher values of $|newpop|$.

We finally arrive at the reproduction stage, where new individuals (or agents) are created using the information existing in the population. More precisely, several reproductive *operators* (i.e., transformation functions) are used in a pipelined fashion, as illustrated in Figure 27.4. Reproductive operators are algorithms that can be classified into two classes: unary operators and n-ary ($n > 1$) operators. Beginning with the former, two further types of operators are typically used, namely *mutation* operators and *individual-improvement* operators (in many cases based on some form of local search). The latter were already mentioned before, for example, in the initialization phase. As indicated by their name, their purpose is to improve the quality of a certain solution. In general, this is implemented via an iterative process whereby small modifications are introduced in a solution and kept if they result in an effective quality improvement. This process is repeated until it can be determined that no further improvement is possible, until the amount of quality improvement is considered good enough, or—most typically—until a maximum number of improving attempts are performed. Hence, the process need not stop at an optimum for the individual improver, and therefore characterizations of MAs as *"EAs working in the space of local-optima [with respect to a certain fitness landscape]"* are clearly restricting even the methods that originated the denomination [1,25] and should be avoided. As to mutation, it is intended to generate new solutions by partly modifying existing solutions. This modification can be random—as it is typically the case in EAs—or can be endowed with problem-dependent information so as to bias the search to probably good regions of the search space.

Nonunary operators are usually termed recombination operators. These operators constitute a distinctive added-value possibility of population-based search and encapsulate the mutual cooperation among several individuals (typically two of them, but a higher number is possible). They generate new individuals using the information contained in a number of selected solutions called *parents.* If the resulting individuals (the *offspring*) are entirely composed of information taken from the parents, then the recombination is said to be *transmitting* [26]. This property can be difficult to achieve for certain problem domains (the *Traveling Salesman Problem* (TSP) is a typical example). In those situations, it is possible to consider other properties of interest such as *respect* or *assortment.* The former refers to the fact that the recombination operator generates descendants carrying all *features* (i.e., basic properties of solutions with relevance for the problem attacked) common to all parents; thus, this property can be seen as a part of the *exploitative* side of the search. In contrast, *assortment* represents the exploratory side of recombination. A recombination operator is said to be *assorting* if, and only if, it can generate descendants carrying any combination of compatible features taken from the parents. In either case, similar to mutation, performing the combination of information in a problem-oriented way (rather than blindly) is crucial for the performance of the algorithm (see, e.g., Refs. [27,28]).

This description of recombination has introduced a crucial concept, namely, *relevant features.* By relevant features we mean the information pieces that can be extracted from solutions, exerting a direct influence on the quality of these. Consider that a certain solution can contain a high number of *atomic* information units, but only some of them are directly linked with quality. For example, a permutation π can be interpreted as a collection of positional information units, that is, position i has value π_i. It also can be interpreted as a collection of adjacency information units, that is, values a and b occur in adjacent positions of the permutation. It turns out that if the permutation is taken as a solution to the TRAVELING SALESMAN PROBLEM, the latter are indeed the relevant features, while for the FLOWSHOP SCHEDULING PROBLEM positional information is much more important [29]. The definition of operators manipulating the relevant features is one of the key aspects in the design of MAs.

There have been several attempts for quantifying how good a certain set of information units is for representing solutions for a specific problems. We can cite a few of them.

- *Minimizing epistasis.* Epistasis can be defined as the nonadditive influence on the guiding function of combining several information units (see, e.g., Ref. [30]). Clearly, the higher this nonadditive influence, the lower the absolute relevance of individual information units. Since the algorithm will be processing such individual units (or small groups of them), the guiding function turns out to be low informative, and prone to misguide the search.
- *Minimizing fitness variance.* [26]. This criterion is strongly related to the previous one. The fitness variance for a certain information unit is the variance of the values returned by the guiding function, measured across a representative subset of solutions carrying this information unit. By minimizing this fitness variance, the information provided by the guiding function is less *noisy*, with the subsequent advantages for the guidance of the algorithm.
- *Maximizing fitness correlation.* In this case a certain reproductive operator is assumed, and the correlation in the values of the guiding function for parents and offspring is measured. If the fitness correlation is high, good solutions are likely to produce good solutions too, and thus the search will gradually shift toward the most promising regions of the search space. Again, there is a clear relationship with the previous approaches; for instance, if epistasis (or fitness variance) is low, then solutions carrying specific features will have similar values for the guiding function; since the reproductive operators will create new solutions by manipulating these features, the offspring is likely to have a similar guiding value as well.

Obviously, the description of these approaches may appear somewhat idealized, but the underlying philosophy is well illustrated. For further advice on the design of MAs, the reader is referred to Refs. [31,32].

27.3 MAs and Combinatorial Optimization

MAs constitute a extremely powerful tool for tackling combinatorial optimization problems. Indeed, MAs are state-of-the-art approaches for many such problems. Traditional NP optimization problems constitute one of the most typical battlefields of MAs, and a remarkable history of successes has been reported with respect to the application of MAs to such problems. Combinatorial optimization problems (both single- and multiobjective [33–35]) arising in scheduling, manufacturing, telecommunications, and bioinformatics among other fields have been also satisfactorily tackled with MAs. Some of these applications are summarized in Table 27.1.

This list of applications is by no means complete since its purpose is simply to document the wide applicability of the approach for combinatorial optimization. Indeed, MAs have been successfully applied to other domains. Other such application areas of MAs include machine learning, robotics, engineering, electronics, bioinformatics, and oceanography. For further information about MA applications we suggest checking Refs. [31,32], or querying bibliographical databases or web browsers for the keywords "*memetic algorithms*" and "*hybrid genetic algorithm*."

27.4 Conclusions and Future Directions

We believe that MAs have very favorable perspectives for their development and widespread application. We ground our belief for several reasons: first, MAs are showing a great record of efficient implementations, providing very good results in practical problems (cf. previous section). We also have reasons to believe that we are near some major leaps forward in our theoretical understanding of these techniques, including, for example, the computational complexity analysis of recombination procedures. In contrast, the inherent asynchronous parallelism of MAs adapts very well to the increasing availability of distributed systems.

TABLE 27.1 Some Applications of Memetic Algorithms in Combinatorial Optimization

Graph Partitioning	[40,41]	Min Number Partitioning	[9,42]
Max Independent Set	[43–45]	Bin-Packing	[46]
Min Graph Coloring	[47,48]	Set Covering	[49]
Min Generalized Assignment	[50]	Multidimensional Knapsack	[51–53]
Quadratic Assignment	[54,55]	Quadratic Programming	[56]
Set Partitioning	[57]	Gate Matrix Layout	[58,59]
Traveling Salesman Problem	[10,60,61,63–65]	Min Weighted k-Cardinality Tree	[62]
Uncapacitated Hub Location	[67]	Min k-Cut Problem	[66]
Vehicle Routing	[71–73]	Placement Problems	[68–70]
Prize-Collecting Steiner Tree	[75]	Task Allocation	[74]
Vertex-Biconnectivity Augmentation	[79]	Network Design	[76–78]
		Error Correcting Codes	[80]
OSPF Routing	[81]	Maintenance Scheduling	[82]
Open Shop Scheduling	[83]	Flowshop Scheduling	[84–86]
Single Machine Scheduling	[87–89]	Parallel Machine Scheduling	[90]
Project Scheduling	[91]	Production Planning	[92]
Timetabling	[93,94]	Rostering	[95]
Sport Games Scheduling	[96,97]	Airport Gate Scheduling	[98,99]
Multistage Capacitated Lot-Sizing	[100]	Graph Isomorphism Problem	[101]
Protein Structure Prediction	[36,102,103]	Clustering	[104–106]

We also see as a healthy sign the systematic development of other particular optimization strategies. If a simpler, nonpopulation-based, metaheuristic performs the same as a more complex method (GAs, MAs, Ant Colonies, and so on), Ockham's razor should prevail and we must resort either to the simpler method or to the one that has less free parameters, or to the one that is easier to implement. Such a fact should defy us to adapt the complex methodology to beat a simpler heuristic, or to check if that is possible at all. An unhealthy sign of current research, however, is the attempt to encapsulate metaheuristics on stretched confinements. The evolutionary computing community had to endure a difficult time in the past, until the artificial boundaries among the different EA families were overcome. It would be unwise to repeat the same mistakes in the wider context of metaheuristics.

There are many open lines of research in MAs. One of them is multilevel evolution. It was anticipated in Ref. [11] that future MAs could simultaneously evolve solutions (in a short timescale), as well as representations and methods (in a longer timescale). In this sense, Krasnogor and collaborators have recently introduced techniques to adaptively change the neighborhood definition [36], and used these adaptive memetic algorithms for the difficult problem of *protein structure prediction* [37]. Smith [38,39] also presents a recent study on these issues.

Multiparent recombination is another promising area in which further work has to be done. Recall that recombination is precisely one of the additional search possibilities contributed by population-based algorithms, and that its augmentation with problem knowledge results in notably enhanced optimization capabilities. It seems natural to generalize these ideas to multiple-solution recombination. Not only can one have a wider pool of information for building the offspring, but additional hints can be obtained with respect to, for example, negative knowledge, that is, what pieces of information should be avoided in the offspring. This is definitely one of the most challenging issues for future development in MAs.

28.1 Introduction

In classical combinatorial optimization, the quality of a solution is often measured with a single objective function while, in practice, a decision is rarely made with only one criterion. Then, several conflicting criteria are necessary to measure the quality of a solution. This is the case in a number of areas including transportation, communication, biology, finance, and also computer science [1]. Multiobjective combinatorial optimization (MCO) arises in situations where at least two objective functions are simultaneously taken into account. This framework offers more freedom, and models coming from MCO better fit to real situations than those being from classical combinatorial optimization. Of course, this higher freedom has a price which often turns out to be a higher degree in complexity.

In monocriterion optimization, the notion of optimality is clear while it is not the case when multiple objectives are considered. Conflicts between the competing criteria lead to a frequent situation where no feasible solution meet optimality for all objectives. Instead of a unique and ideal solution, a set of incomparable alternatives *dominating* all the others acts as an optimum. Many years before the emergence of computer science, Vilfredo Pareto gave a characterization of these dominating solutions known today as *Pareto optima* or *Pareto set*. The Pareto set captures the notion of trade-off and its computation is problematic for mainly two reasons:

- it is typically exponential in size; and
- computing one of these *Pareto optima* is often **NP**-hard.

Some problems, known to be polynomially solvable in the monocriterion optimization framework, become **NP**-hard when two (or more) objectives are simultaneously taken into account. Consequently, approximation in multiobjective optimization seems unavoidable.

Since Pareto's pioneering work on optimality, different approaches to tackle a multiobjective problem were proposed. One can divide them into three classes:

- turning a multiobjective problem into a monocriterion one;
- optimize each objective separately; and
- preserve the multidimensional nature of the quality of a solution.

According to this classification of the various attempts, we aim at giving some results that are representative of the MCO area. Before presenting these results, we propose an introduction to MCO which mainly deals with optimality and complexity.

28.2 Multiobjective Combinatorial Optimization Problems

This section first introduces an general definition of an MCO problem. Afterwards, the notion of optimality in multiobjective optimization is addressed. The end of the section is devoted to computational complexity in the MCO area.

28.2.1 General Definition

An MCO problem gathers the following ingredients:

- a finite set $\mathcal{S}$ of feasible solutions;
- a vector $\vec{f} = (f_1, \ldots, f_k)$ of k objective functions; and
- a vector $\vec{g} = (g_1, \ldots, g_k)$ of k goals so that $g_i = min$ (respectively, $g_i = max$) means f_i has to be minimized (respectively, maximized).

The *image* of a solution $s \in \mathcal{S}$ under $\vec{f}$ is a k-dimensional vector $\vec{f}(s)$. The image of $\mathcal{S}$ under $\vec{f}$ is denoted by $\mathcal{I}$. Then, $\mathcal{S}$ and $\mathcal{I}$ respectively define the *decision space* and the *objective space*. The difference between an objective function and a criterion is blurred and then the words *multicriteria* and *multiobjective* are both used to refer to the same framework.

28.2.2 Notions of Optimality

Unless the criteria are not in conflict with each other, it is difficult to define an appropriate notion of optimality and, given this notion, find an optimum.

28.2.2.1 Optimality of Pareto

The optimality of Pareto is based on the notion of *dominance*. Roughly speaking, a solution s dominates another solution s' if it is at least as "good" as s' on every criteria and strictly "better" for at least one criterion. If we suppose that all objective functions of $\vec{f}$ must be minimized, a solution s dominates a solution s', denoted by $s < s'$, if

- $f_i(s) \leq f_i(s')$ for each component f_i of $\vec{f}$; and
- there exists one objective function f_{i^*} of $\vec{f}$ such that $f_{i^*}(s) < f_{i^*}(s')$.

A solution $s \in \mathcal{S}$ is called *Pareto optimal* if there is no $s' \in \mathcal{S}$ such that $s' < s$. The image $\vec{f}(s)$ of a Pareto optimal solution s is called *efficient*. The subset of all Pareto optimal solutions in $\mathcal{S}$, called the *Pareto set*, is denoted by $\mathcal{S}_{Par}$ while $\mathcal{I}_{Eff}$, also called the *Pareto curve*, is its image under $\vec{f}$.

Typically, computing the whole Pareto set is not required and a subset of it having the same image is often sufficient [2].

28.2.2.2 Other Notions of Optimality

Hierarchical Optimality

A ranking between all objective functions is sometimes assumed. A solution s is preferred to s', denoted by $s <_{hier} s'$, iff $f_j(s) < f_j(s')$, where j is the smallest index in the ranking such that $f_i(s) \neq f_i(s')$.

Min Max *Optimality*

A solution is sometimes said to be optimal if it minimizes the largest coordinate of its image. Then, we try to find a solution s such that $\max\{f_1(s), \ldots, f_k(s)\} = \min_{s' \in \mathcal{S}} \max\{f_1(s'), \ldots, f_k(s')\}$.

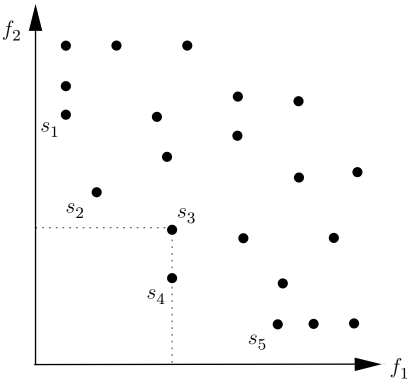

FIGURE 28.1 s_4 dominates s_3. $\{s_1, s_2, s_4, s_5\}$ are Pareto optimal while $\{\vec{f}(s_1), \vec{f}(s_2), \vec{f}(s_4), \vec{f}(s_5)\}$ defines the Pareto curve. s_1 and s_5 are hierarchically optimal. s_3 and s_4 are optimal for the *min max* optimality.

One can remark that the hierarchical optimality is a special case of the Pareto optimality while the *min max* optimality is less demanding than the Pareto optimality since a *min max* optimum is not necessarily Pareto optimal.

Figure 28.1 gives an illustration of the notions given in this subsection.

28.2.3 Hardness

Modeling a problem with more than one objective function offers more freedom but it also brings complications.

28.2.3.1 NP-Completeness

Proving **NP**-completeness for some MCO problems is sometimes easy since it directly follows from **NP**-completeness of an underlying problem with less objectives. For example, this is the case for a multiobjective *traveling salesman problem* (TSP), where the distance between two cities is a vector of distances instead of a scalar. However, some polynomially solvable problems become **NP**-complete when two (or more) criteria are simultaneously taken into account.

As an example, we consider an extension of the well-known *minimal spanning tree problem* called BMST for *bicriteria minimal spanning tree.* We are given a simple graph $G = (V, E)$, where each edge $e \in E$ has a weight w_e and a length l_e. A solution to this problem is a tree t spanning all the vertices of V, having a total weight $W(t) = \sum_{e \in t} w_e$ and a total length $L(t) = \sum_{e \in t} l_e$.

It is well known that the minimal spanning tree problem can be solved in polynomial time [3]. However, we have the following theorem:

Theorem 28.1 (Camerini et al. [4])

BMST *is* **NP**-*complete.*

Proof

Suppose that we have a set A of n integers $\{a_1, \ldots, a_n\}$. Given an integer b, the SUBSET SUM problem asks whether a subset $A' \subseteq A$ such that $\sum_{a_i \in A'} a_i = b$ exists. This decision problem is **NP**-complete [5]. Now consider the following decision problem: Given W_0 and L_0, does there exist a spanning tree t that satisfies $W(t) \leq W_0$ and $L(t) \leq L_0$? Set $W_0 = b$, $L_0 = \sum_{i=1}^{n} a_i - b$ and consider the instance G given in Figure 28.2. We only consider spanning trees containing the edge $[v_{n+1}, v_{n+2}]$ since those which do not cannot be preferred. A tree t satisfying $W(t) \leq W_0$ and $L(t) \leq L_0$ yields a subset A' verifying $\sum_{a_i \in A'} a_i = b$ if $a_i \in A' \Leftrightarrow [v_i, v_{n+1}] \in t$. Indeed, $\sum_{e \in t} w_e \leq b \Leftrightarrow \sum_{a_i \in A'} a_i \leq b$ and $\sum_{e \in t} l_e \leq \sum_{i=1}^{n} a_i - b \Leftrightarrow \sum_{a_i \in A'} a_i \geq b$. □

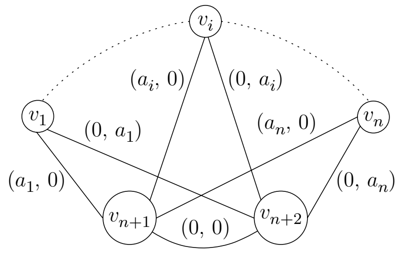

FIGURE 28.2 G has $n+2$ vertices $\{v_1, \ldots, v_{n+2}\}$ and each edge e has a couple (w_e, l_e). Does G admit a spanning tree t such that $W(t) \leq W_0$ and $L(t) \leq L_0$?

Thus, several MCO problems generalizing some polynomially solvable ones are **NP**-complete. For example, this is also the case for SHORTEST PATH or ASSIGNMENT [6]. Sometimes, the complexity relies on the notion of optimality. Finding a hierarchical optimum for the BMST problem can be easily done with a slightly modified version of Kruskal's algorithm where the edges are sorted lexicographically [3]. However, finding a *min max* optimum for the BMST problem is hard because of PARTITION (see the instance in Figure 28.2 and set $W_0 = L_0 = \frac{1}{2}\sum_{i=1}^{n} a_i$).

28.2.3.2 Intractability

Besides the complexity of generating one Pareto optimal solution, computing the Pareto set is problematic since it is often exponential in size and thus, there is no chance to compute it in an efficient manner. In the following, an MCO problem is said *intractable* if $|\mathcal{I}_{Eff}|$ can be exponential in the size of an instance.

We consider an extension of a classical problem called BSP for *bicriteria shortest path.* We are given a graph $G = (V, A)$, where each arc $a \in A$ has a cost c_a and a delay d_a. Given two vertices s and t of the vertex set V, a feasible solution p is a path from s to t whose total cost and total delay are, respectively, $C(p) = \sum_{a \in p} c_a$ and $D(p) = \sum_{a \in p} d_a$.

Theorem 28.2 (**Hansen et al.** [7])

BSP *is intractable.*

Proof

Consider the instance given in Figure 28.3. There are two arcs between two consecutive nodes v_i and v_{i+1}, one with cost–delay vector $(2^i, 0)$ and another with cost–delay vector $(0, 2^i)$. Each path p between s and t satisfies $\sum_{a \in p}(c_a + d_a) = 2^{n+1} - 1$. Moreover, for every positive integer $z \leq 2^{n+1} - 1$ we can build a path p_z such that $C(p_z) = z$. Then, $|\mathcal{I}_{Eff}| = 2^{n+1}$ and BSP is intractable. A similar result on nonoriented graphs can be derived. □

A proof of intractability for BMST can be found in Ref. [8] and the bicriteria ASSIGNMENT problem is addressed in Ref. [9].

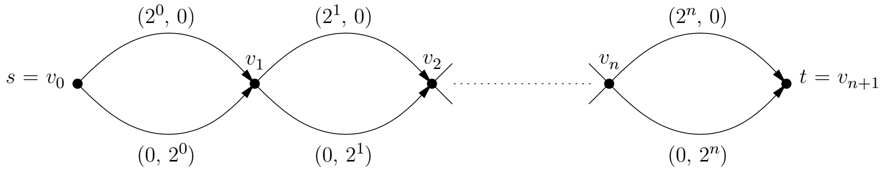

FIGURE 28.3 Each arc a has a cost–delay vector (c_a, d_a). Two different $s-t$ paths in G cannot have the same total cost and total delay.

28.3 Multiobjective Approximation

Three main classes of approaches exist in MCO. Two approaches of the first class are presented in subsections 28.3.1 and 28.3.2. Subsections 28.3.3 and 28.3.4 are, respectively, devoted to the second and third class. Short examples from the literature illustrate the approaches.

28.3.1 Aggregation Approach

One of the most natural ways to address a multiobjective problem is to turn it into a monocriterion one. Instead of dealing with k objective functions, we can aggregate them and get a single function $\tilde{f}$ defined as follows:

$$\tilde{f} = \sum_{i=1}^{k} \lambda_i f_i, \quad \text{where } \lambda_i \in I\!R^+ \text{ and } \sum_{i=1}^{k} \lambda_i = 1$$

Then, considering different values for λ_i allows us to explore different regions of the objective space. This technique consists in searching the objective space with a hyperplane (see Figure 28.4 for an illustration on a biobjective problem).

Interestingly, this *aggregation approach* gives the opportunity to generate some Pareto optimal solutions with an exact monocriterion algorithm. Indeed, any solution s which minimizes $\tilde{f}$, where $\lambda_i > 0$ for all i is Pareto optimal since no other solution s' such that $s' < s$ and $\tilde{f}(s') \geq \tilde{f}(s)$ can exist. By definition, $s' < s$ means $f_i(s') \leq f_i(s)$ for all i and there is a criterion i^* such that $f_{i^*}(s') < f_{i^*}(s)$. Hence, $s' < s$ and $\lambda_i > 0$ imply $\tilde{f}(s') < \tilde{f}(s)$ and contradicts the fact that s minimizes $\tilde{f}$.

The fact that the objective space can be nonconvex implies that only a subset of the Pareto set can be generated with this approach. Then, Pareto optimal solutions are often partitioned into two sets, the *supported* ones which can be computed with the aggregation approach and the *nonsupported* ones (see the encircled dots in Figure 28.4). In early articles addressing MCO, nonsupported solutions were often ignored.

28.3.1.1 A Biobjective Scheduling Problem

We address the problem of scheduling n jobs on a single machine without preemption. Each job $j \in \{1, \ldots, n\}$ has a processing time p_j, a cost c_j, and a weight w_j. We assume that p_j, c_j, and w_j are positive integers. All jobs are available at time $t = 0$ and no precedence constraints are taken into account. Only schedules without idle times are considered and then a feasible solution is a permutation π of the jobs. If a job j is at the ith position in π (i.e., $\pi(i) = j$) then its *completion time* C_j^π is equal to $\sum_{q=1}^{i} p_{\pi(q)}$. A permutation π has a *total cost* $c(\pi) = \sum_{j=1}^{n} c_j C_j^\pi$ and a *total weight* $w(\pi) = \sum_{j=1}^{n} w_j C_j^\pi$. These two possibly conflicting objectives have to be minimized. This biobjective scheduling problem is **NP**-complete [10] and

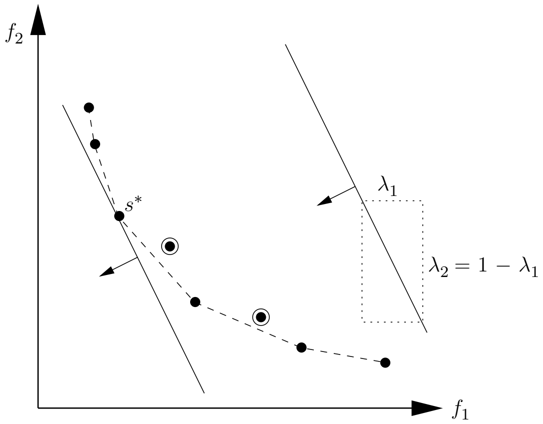

FIGURE 28.4 $\tilde{f} = \lambda_1 f_1 + \lambda_2 f_2$ finds its minimum for s^* which is supported. Nonsupported solutions are encircled.

intractable [11]. We consider a convex combination of the objectives $\tilde{f}_\lambda(\pi) = \lambda c(\pi) + (1-\lambda)w(\pi)$ and we try to compute a set of permutations P such that for any λ between 0 and 1, there is a permutation $\pi \in P$ that minimizes $\tilde{f}_\lambda$. This set is called a *minimal set of supported solutions.*

Each objective can be separately optimized with the rule of Smith [12], since a permutation π that minimizes the total cost (respectively, the total weight) can be computed in time $\mathcal{O}(n \log n)$ if the jobs are sorted by their nondecreasing ratios p_j/c_j (respectively, p_j/w_j). Therefore, an optimal permutation for $\tilde{f}_\lambda$ can be found efficiently if the jobs are sorted by their nondecreasing ratios $r(\lambda, j) = p_j/(\lambda c_j + (1-\lambda)w_j)$. Given a pair of distinct jobs j and j' such that $p_j/c_j \le p_{j'}/c_{j'}$, their ordering in an optimal permutation for $\tilde{f}_\lambda$ does not depend on λ when $p_j/w_j \le p_{j'}/w_{j'}$ (the criteria are not in conflict) but depends on λ when $p_j/w_j > p_{j'}/w_{j'}$ (the criteria are conflicting). Then, one can calculate $\lambda_{jj'}$ such that $r(\lambda_{jj'}, j) = r(\lambda_{jj'}, j')$ for each pair of jobs in conflict and state that the ordering between j and j' in any permutation minimizing $\tilde{f}_\lambda$ depends on the position of λ compared to $\lambda_{jj'}$ [11].

Algorithm (*MSUP*)
returns a minimal set of supported solutions

```
let $\Lambda$ be an ordered list of distinct reals, set $\Lambda = \{0, 1\}$, set $P = \emptyset$
for each pair $j\ j'$ of conflicting jobs
    find $\lambda_{j\,j'}$ such that $0 < \lambda_{j\,j'} < 1$ and $r(\lambda_{j\,j'}, j) = r(\lambda_{j\,j'}, j')$, insert $\lambda_{j\,j'}$ into $\Lambda$
let $\Lambda(i)$ be the $i$th element of $\Lambda$
for $i = 1$ to $|\Lambda| - 1$
    take arbitrarily a $\lambda$ such that $\Lambda(i) < \lambda < \Lambda(i+1)$
    sort the jobs by their nondecreasing ratios $r(\lambda, j)$ and put the permutation in $P$
return $P$
```

Finally, P contains exactly $|\Lambda| - 1$ permutations while $|\Lambda| \le \frac{n(n-1)}{2} + 2$. Thus, *MSUP* runs in $\mathcal{O}(n^3 \log n)$.

28.3.2 Budget Approach

This approach consists in turning a k objective problem into a monocriterion one subject to $k-1$ budget constraints. It is like viewing KNAPSACK as a problem with two objectives: utility and size. More generally (the minimization of each objective is assumed), we are given a $(k-1)$-dimensional vector $(B_2, \ldots, B_k)$ and one tries to minimize $f_1(s)$ such that $s \in \mathcal{S}$, $f_2(s) \le B_2, \ldots, f_k(s) \le B_k$. Let $B_1 = \min_{s \in \mathcal{S}}\{f_1(s) \mid f_i(s) \le B_i, i = 2, \ldots, k\}$; a solution s is called ϵ-approximate if $f_1(s) \le (1+\epsilon)B_1$ and $f_i(s) \le B_i$, $i = 2, \ldots, k$.

28.3.2.1 The Bicriteria Shortest Path Problem on Acyclic Graphs

We consider the BSP problem on acyclic digraphs with a budget approach. Namely, one tries to compute a path p between two nodes s and t such that $D(p) \le D_0$ and $C(p)$ is minimized (D_0 is an entry of the instance). An s–t path with total delay at most D_0 is also called a D_0-path in the following. The material presented in this subsection comes from the articles [13–16].

There is a pseudopolynomial dynamic programming-like procedure to solve the problem. Let $\delta_j(z)$ be the minimal delay for an s–j path of total cost at most z.

Algorithm (*EXACT*(*c*,*d*))
returns a minimal cost D_0-path

```
for all $z \ge 0$, set $\delta_s(z) = 0$
for all $j \ne s$, set $\delta_j(z) = \infty$
for $z = 1, 2, \ldots$
    for all $j \ne s$, set $\delta_j(z) = \min_{ij:\, c_{ij} \le z}\{\delta_j(z-1), \min\{\delta_i(z - c_{ij}) + d_{ij}\}\}$
    if $\delta_t(z) \le D_0$ then output $OPT = z$ and its corresponding path, exit
```

The running time of *EXACT* is $\mathcal{O}(m\ OPT)$, where $m = |A|$ and *OPT* is the minimal cost for a D_0-path. Using a *rounding-and-scaling* technique, one can design a fully polynomial time approximation scheme (FPTAS) for the problem. This technique consists in replacing c (the function that maps a cost to each arc) by a scaled down function $\tilde{c}$ so that *EXACT* $(\tilde{c}, d)$ runs in polynomial time and an optimum for the scaled down instance is an approximation with bounded error of the original optimum.

Suppose that we have two bounds *LB* and *UB* satisfying $LB \leq OPT \leq UB$ and there is a constant $\theta > 1$ such that $UB \leq \theta LB$. Given an ϵ and $n = |V|$, the costs on the original instance are scaled down as follows: $\tilde{c}_a = \lfloor n\, c_a/(\epsilon\, LB)\rfloor$, $\forall a \in A$. Since $\lfloor x \rfloor$ is between $x - 1$ and x, any path p satisfies

$$\sum_{a\in p}\left(\frac{nc_a}{\epsilon\, LB} - 1\right) \leq \sum_{a\in p}\tilde{c}_a \leq \sum_{a\in p}\frac{nc_a}{\epsilon LB}$$

Suppose that p' is an optimal solution for the scaled down instance while p^* is optimal for the original one.

$$\begin{aligned}
\sum_{a\in p'}\tilde{c}_a &\leq \sum_{a\in p^*}\tilde{c}_a\\
\sum_{a\in p'}\left(\frac{n\, c_a}{\epsilon\, LB} - 1\right) &\leq \sum_{a\in p^*}\frac{n\, c_a}{\epsilon\, LB}\\
\sum_{a\in p'}\left(c_a - \frac{\epsilon\, LB}{n}\right) &\leq \sum_{a\in p^*} c_a = OPT\\
C(p') - \epsilon\, LB &\leq OPT\\
C(p') &\leq (1+\epsilon)OPT
\end{aligned}$$

Thus, running *EXACT*$(\tilde{c}, d)$ for $z = 1, 2, \ldots, \lfloor\theta\ n/\epsilon\rfloor$, we get an ϵ-approximate D_0-path in time $\mathcal{O}(nm/\epsilon)$. The remaining part of the result concerns efficient ways to get *LB* and *UB*. Let $c_1 < c_2 < \cdots < c_l$ be the distinct costs of the arcs in A. We clearly have $l \leq m$. Let $A_i = \{a \in A \mid c_a \leq c_i\}$ for $1 \leq i \leq l$, $A_0 = \emptyset$, and $G_i = (V, A_i)$. Therefore, there must be an index j such that G_j admits a D_0-path while G_{j-1} does not. Given this j, one can claim that *OPT* is in the range $[c_j, nc_j]$ since G_{j-1} has no D_0-path means that any D_0-path in G uses at least one arc a such that $c_a \geq c_j$, and *OPT* is upper-bounded by the minimal cost of a D_0-path in G_j which is itself upper-bounded by nc_j. The following algorithm called *INDEX* finds j in $\mathcal{O}(\log\ m)$ steps.

Algorithm (*INDEX*)
returns the minimal j such that G_j admits a D_0-path

```
set $low = 1$ and $high = l$
while $low < high - 1$
    set $j = \lfloor (high + low)/2 \rfloor$
    find an $s - t$ path $p$ in $G_j$ with minimal total delay
    if $p$ exists and $D(p) < D_0$ then $high = j$ else $low = j$
return $high$
```

Thus, *INDEX* helps to get a lower and an upper bound which are within a factor n. Starting with these bounds, one can narrow the range so that $UB/LB \leq 2$. The idea is to iteratively use a procedure which, given $K \in [LB, UB]$ and $\gamma \leq n$, tests if $OPT > K$ or $OPT \leq K(1+\gamma)$:

Algorithm (*TEST*(K, γ))
checks if $OPT > K$ or $OPT \leq K(1+\gamma)$

```
for all $a \in A$, set $\tilde{c}_a = \lfloor (n\tilde{c}_a)/(K\gamma) \rfloor$
for all $z \geq 0$, set $\delta_s(z) = 0$
for all $j \neq s$, set $\delta_j(z) = \infty$
for $z = 1, 2, \ldots, \lfloor n/\gamma \rfloor$
    for all $j \neq s$, set $\delta_j(z) = \min_{ij:\tilde{c}_{ij}\leq z}\{\delta_j(z-1), \min\{\delta_i(z - \tilde{c}_{ij}) + d_{ij}\}\}$
        if $\delta_t(z) \leq D_0$ then output $OPT \leq K(1+\gamma)$ and exit
output $OPT > K$
```

TEST(K, γ) runs in $\mathcal{O}(mn/\gamma)$ time for $\gamma \le n$. Now, we can present the FPTAS for BSP called *ADAPT*.

Algorithm (*ADAPT*(ϵ))
returns an ϵ-approximate D_0-path

```
use $INDEX$ to initialize $UB$ and $LB$ such that $UB \le nLB$
while $UB > 2LB$
    set $\gamma = \sqrt{UB/LB} - 1$ and $K = \sqrt{UB\,LB/(1+\gamma)}$
    if $TEST(K, \gamma)$ outputs $OPT > K$ then set $LB = K$ else set $UB = (1+\gamma)K$
invoke $EXACT(\lfloor nc/(LB\epsilon) \rfloor, d)$ and output its result
```

Theorem 28.3 (Ergun et al. [13])
ADAPT has running time $\mathcal{O}(mn/\epsilon)$.

Proof
Let UB_i, LB_i, K_i, and γ_i be the parameters used in the ith application of *TEST*. The ratio UB_{i+1}/LB_{i+1} is sometimes equal to UB_i/K_i and sometimes equal to $K_i(1+\gamma_i)/LB_i$ but we always have

$$UB_{i+1}/LB_{i+1} = (UB_i/LB_i)^{3/4} \tag{28.1}$$

Let q be the number of applications of *TEST* in *ADAPT*. The total time required to have $UB \le 2LB$ is $\sum_{i=1}^{q} \mathcal{O}(mn/\gamma_i)$ and it therefore suffices to show that $\sum_{i=1}^{q} 1/\gamma_i = \mathcal{O}(1)$. The definition of γ_i implies $1/\gamma_i = 1/(\sqrt{UB_i/LB_i} - 1)$. Since $UB_i > 2LB_i$ for $i \le q$, we have $\sqrt{LB_i/UB_i} \le 1/\gamma_i \le (2+\sqrt{2})\sqrt{LB_i/UB_i}$. Hence, $\sum_{i=1}^{q} 1/\gamma_i = \mathcal{O}\big(\sum_{i=1}^{q} \sqrt{LB_i/UB_i}\big)$. We also have

$$\begin{aligned}\sum_{i=1}^{q} \sqrt{LB_i/UB_i} &= \sum_{j=1}^{q} (LB_q/UB_q)^{(1/2)(4/3)^j} \le \sum_{j=1}^{q} 2^{-(1/2)(3/4)^j} \le 2^{(-1/2)} \sum_{i=j}^{q} (2^{-1/6})^j \\ &\le \frac{2^{-1/2}}{1-2^{-1/6}} \le 6.5\end{aligned}$$

The first equality follows from repeatedly applying Eq. (28.1). The first inequality follows from $UB_q > 2LB_q$. The second inequality holds since $2^{-(1/2)(4/3)^{j+1}} \le (2^{-1/6})2^{-(1/2)(4/3)^j}$ for $j \ge 0$. □

The same approach was successfully used for the BMST problem [17,18].

28.3.3 Simultaneous Approach

No ideal solution meeting optimality for all objectives is likely to exist if the criteria are in conflict. However, the image of this solution, called the *ideal point*, can act as a reference to measure the quality of a compromise solution. The *simultaneous approach* or *ideal point approach* consists in giving a feasible solution whose image approximates the ideal point with a performance guarantee on each objective.

Given a k-criteria optimization problem, the ideal point is a vector $\vec{\mu} = (\mu_1, \ldots, \mu_k)$ such that

$$\mu_i = g_i\{f_i(s) \mid s \in \mathcal{S}\}, \quad i = 1, \ldots, k$$

A solution s is $\vec{\epsilon}$-approximate if for all i between 1 and k we have $f_i(s) \le (1+\epsilon_i)\mu_i$ in case $g_i = min$ or $\mu_i \le (1+\epsilon_i) f_i(s)$ in case $g_i = max$.

28.3.3.1 The Bicriteria MAX-CUT Problem

Given an undirected graph $G = (V, E)$ with nonnegative edge weights w_{ij}, the objective of the classical maximal-cut problem (MAX-CUT) is to find a partition of the vertex set V into two subsets S and $\overline{S}$, such that the sum of the weights of the edges having endpoints in different subsets is maximal. Denoted by $W(S, \overline{S})$, the *total weight* of the cut $(S, \overline{S})$ is $\sum_{i \in S,\ j \in \overline{S}} w_{ij}$. Finding a cut of maximal total weight is **NP**-hard [19].

A biobjective version of this problem is considered. In addition to the weight, the edges have a nonnegative length l_{ij}. The *total length* of a cut, denoted by $L(S, \overline{S})$ is equal to $\sum_{i \in S,\ j \in \overline{S}} l_{ij}$. In the following, the ideal point is denoted by (*OPTW, OPTL*).

We are given an instance of the biobjective problem and two cuts $(S_1, \overline{S_1})$ and $(S_2, \overline{S_2})$ which are, respectively, α-approximate for the total weight (i.e., $OPTW \le (1+\alpha)W(S_1, \overline{S_1})$) and α-approximate for the total length (i.e., $OPTL \le (1+\alpha)L(S_2, \overline{S_2})$). These two cuts are supposed to be computed with a deterministic monocriterion α-approximation algorithm AL. One can build a feasible $(1+2\alpha, 1+2\alpha)$-approximate cut with the following algorithm:

Algorithm (*BIAPPROX*(S_1, S_2))
returns a feasible $(1+2\alpha, 1+2\alpha)$-approximate cut

```
if $L(S_1, \overline{S_1}) \ge L(S_2, \overline{S_2})/2$ then return $(S_1, \overline{S_1})$ and exit
if $W(S_2, \overline{S_2}) \ge W(S_1, \overline{S_1})/2$ then return $(S_2, \overline{S_2})$ and exit
return $\big((S_1 \cap S_2) \cup (\overline{S_1} \cap \overline{S_2}), (\overline{S_1} \cap S_2) \cup (S_1 \cap \overline{S_2})\big)$
```

Theorem 28.4 (Angel et al. [20])

BIAPPROX returns a feasible $(1+2\alpha, 1+2\alpha)$*-approximate cut.*

Proof

The vertex set V can be partitioned into four subsets: $X = S_1 \cap S_2$, $Y = \overline{S_1} \cap S_2$, $Z = S_1 \cap \overline{S_2}$, and $T = \overline{S_1} \cap \overline{S_2}$ (see Figure 28.5). *BIAPPROX* potentially returns the cuts $(S_1, \overline{S_1})$, $(S_2, \overline{S_2})$ or $(X \cup T, Y \cup Z)$. If $L(S_1, \overline{S_1}) \ge L(S_2, \overline{S_2})/2$ then $2(1+\alpha)L(S_1, \overline{S_1}) \ge (1+\alpha)L(S_2, \overline{S_2}) \ge OPTL$. So, $(S_1, \overline{S_1})$ is $(\alpha, 1+2\alpha)$-approximate and thus $(1+2\alpha, 1+2\alpha)$-approximate. If $W(S_2, \overline{S_2}) \ge W(S_1, \overline{S_1})/2$ then $2(1+\alpha)W(S_2, \overline{S_2}) \ge (1+\alpha)W(S_1, \overline{S_1}) \ge OPTW$. So, $(S_2, \overline{S_2})$ is $(1+2\alpha, \alpha)$-approximate and thus $(1+2\alpha, 1+2\alpha)$-approximate. If $L(S_1, \overline{S_1}) < L(S_2, \overline{S_2})/2$ and $W(S_2, \overline{S_2}) < W(S_1, \overline{S_1})/2$ then $W(X, Y) + W(Z, T) \ge W(S_1, \overline{S_1})/2 \ge OPTW/(2(1+\alpha))$ and $L(X, Z) + L(Y, T) \ge L(S_2, \overline{S_2})/2 \ge OPTL/(2(1+\alpha))$. As a consequence $(X \cup T, Y \cup Z)$ is $(1+2\alpha, 1+2\alpha)$-approximate. □

Suppose that AL is an exact (0-approximation) algorithm, then *BIAPPROX* provides a constructive proof on the existence of a feasible (1, 1)-approximate cut. Now suppose that AL is the derandomized version of the 0.13821-approximation algorithm of Goemans and Williamson [21] ($0.13821 = 0.87856^{-1} - 1$), *BIAPPROX* returns a feasible (1.276, 1.276)-approximate cut in polynomial time. In contrast to these positive results, one can remark that no (ϵ_1, ϵ_2)-approximation algorithm can be designed for the biobjective MAX CUT when ϵ_1 and ϵ_2 are both strictly inferior to 1. Indeed, the instance depicted in Figure 28.6 shows that no such cut exists.

The same approach was successfully used for a scheduling problem [22].

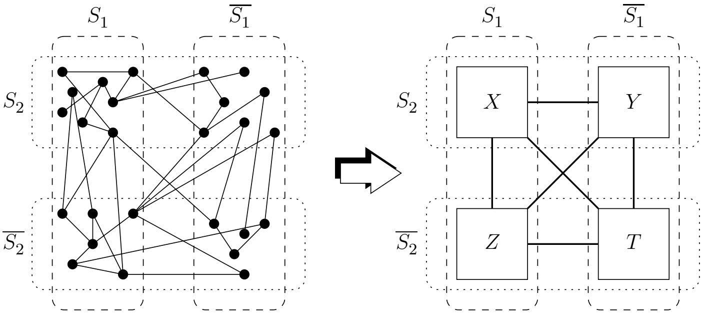

FIGURE 28.5 S_1, $\overline{S_1}$, S_2, and $\overline{S_2}$ define a partition of V into four sets called X, Y, Z, and T.

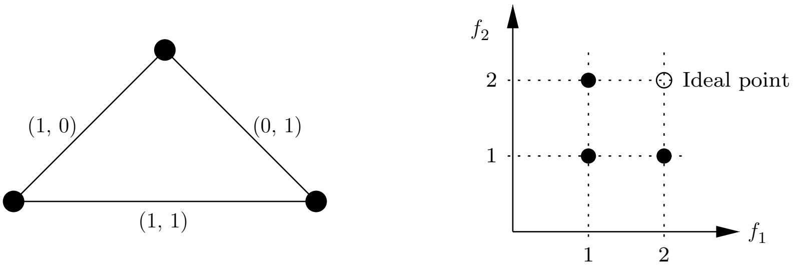

FIGURE 28.6 Each edge e of this graph has a couple (w_e, l_e). The ideal point is (2, 2) while no feasible cut $(S, \overline{S})$ such that $W(S, \overline{S}) > 1$ and $L(S, \overline{S}) > 1$ exists.

28.3.4 Pareto Set Approach

Providing the whole set of Pareto optimal solutions or a subset having the same image under $\vec{f}$ is the best answer one could give to a multiobjective problem. Despite the hardness of computing such a set, one can try to generate in polynomial time an approximation of it. Hence, a succinct set of incomparable solutions which approximately dominate all the others is of great interest.

Given a vector $\vec{\epsilon} = (\epsilon_1, \ldots, \epsilon_k)$, we say that s $\vec{\epsilon}$-dominates s' if $f_i(s) \leq (1 + \epsilon_i) f_i(s')$, $i = 1, \ldots, k$ (the minimization of every objective function is assumed). Hence, an *$\vec{\epsilon}$-approximate Pareto set* $\mathcal{S}_{\vec{\epsilon}}$ is a set of feasible solutions such that for every solution $s' \in \mathcal{S}$ there exists an $s \in \mathcal{S}_{\vec{\epsilon}}$ which $\vec{\epsilon}$-dominates s'. The image of $\mathcal{S}_{\vec{\epsilon}}$ under $\vec{f}$ is called an *$\vec{\epsilon}$-approximate Pareto curve.*

Theorem 28.5 (Papadimitriou and Yannakakis [2])

For any multiobjective optimization problem and any ϵ there is an $\vec{\epsilon}$-approximate Pareto set consisting of a number of solutions that is polynomial in the size of the instance and $1/\epsilon$ but exponential in the number of criteria.

Proof

Given an instance x of a k-criteria problem and a solution $s \in \mathcal{S}$, we assume that $f_i(s)$ is between $2^{-p(|x|)}$ and $2^{p(|x|)}$ for some polynomial p. Consider the objective space and subdivide it into hyperrectangles, such that, in each dimension, the ratio of the larger to the smaller coordinate is $1 + \epsilon$ (see Figure 28.7). There are $\mathcal{O}\left(\frac{(2p(|x|))^k}{\epsilon^k}\right)$ such subdivisions. Define $\mathcal{S}_{\vec{\epsilon}}$ by choosing one solution of $\mathcal{S}_{Par}$ in each hyperrectangle that contains such a solution. □

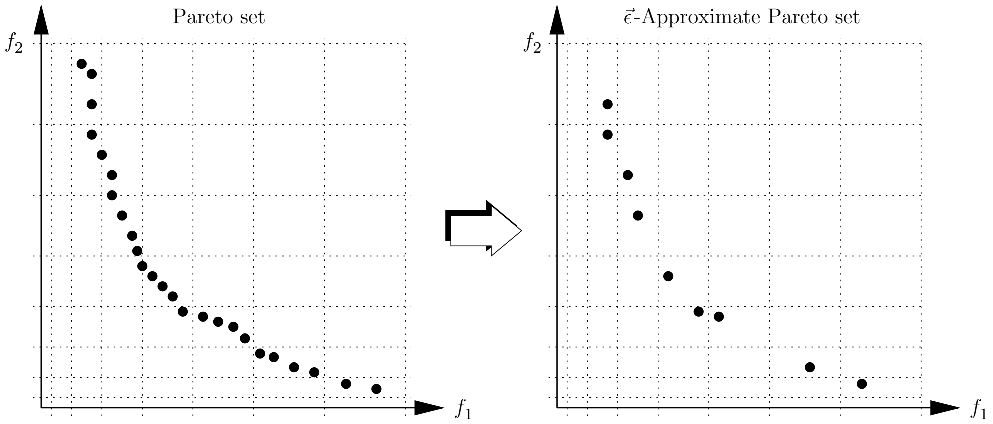

FIGURE 28.7 The geometric grid ensures that the image of two solutions in the same box are within a factor $1 + \epsilon$ on every coordinate. Keeping one solution per box leads to an $\vec{\epsilon}$-approximate Pareto set.

28.3.4.1 An Approximate Pareto Set with a Simultaneous Approach

Let s^* be a Pareto optimal solution for a multiobjective problem. Given $\vec{\mu}$ as the ideal point, we have $f_i(s^*) \geq \mu_i$ when $g_i = min$ and $f_i(s^*) \leq \mu_i$ when $g_i = max$. Let s be an $\vec{\epsilon}$-approximate solution with respect to the simultaneous approach. We have $f_i(s) \leq (1+\epsilon_i)\mu_i$ when $g_i = min$ and $\mu_i \leq (1+\epsilon_i) f_i(s)$ when $g_i = max$. Hence, s $\vec{\epsilon}$-dominates s^* since $f_i(s) \leq (1+\epsilon_i)\mu_i \leq (1+\epsilon_i) f_i(s^*)$ when $g_i = min$ and $f_i(s^*) \leq \mu_i \leq (1+\epsilon_i) f_i(s^*)$ when $g_i = max$. Therefore, $\{s\}$ constitutes an $\vec{\epsilon}$-approximate Pareto set.

28.3.4.2 An Approximate Pareto Set with a Budget Approach

We first address a problem with two objectives f_1 and f_2 in which both have to be minimized. We make the assumption that every solution $s \in \mathcal{S}$ satisfies $LB \leq f_2(s) \leq LB(1+\epsilon)^Q$, where $LB > 0$, $\epsilon > 0$, and Q is a positive integer. Now suppose that we have an ϵ'-approximation algorithm AL with respect to the budget approach. Namely, $AL(B_2)$ returns a solution s such that $f_1(s) \leq (1+\epsilon')B_1$ and $f_2(s) \leq B_2$, where $B_1 = \min_{s' \in \mathcal{S}}\{f_1(s') \mid f_2(s') \leq B_2\}$.

Algorithm ($MULTIBUDGET(LB, \epsilon, AL)$)
returns a (ϵ', ϵ)-approximate Pareto set

```
1: set $P = \emptyset$
2: for $q = 1, \ldots, Q$
3:     set $P = P \cup \{AL(LB(1+\epsilon)^q)\}$
4: output $P$
```

Theorem 28.6

MULTIBUDGET returns an (ϵ', ϵ)*-approximate Pareto set.*

Proof

Take any Pareto optimal solution $s^* \in \mathcal{S}_{Par}$. By the assumption, we know that there exists a q^* such that $1 \leq q^* \leq Q$ and $LB(1+\epsilon)^{q^*-1} \leq f_2(s^*) \leq LB(1+\epsilon)^{q^*}$. Let s' be such that $f_1(s') = \min_{s \in \mathcal{S}}\{f_1(s) \mid f_2(s) \leq LB(1+\epsilon)^{q^*}\}$. We have $f_1(s') \leq f_1(s^*)$. Let $s \in P$ be the solution returned by $AL(LB(1+\epsilon)^{q^*})$. We have $f_1(s) \leq (1+\epsilon') f_1(s')$ and $f_2(s) \leq LB(1+\epsilon)^{q^*}$. Thus, we get $f_1(s) \leq (1+\epsilon') f_1(s^*)$ and $f_2(s) \leq (1+\epsilon) f_2(s^*)$ meaning that s (ϵ', ϵ)-dominates s^*. □

Therefore, an algorithm which outputs an $\vec{\epsilon}$-approximate Pareto set for the BSP problem can be designed if we combine *MULTIBUDGET* and *ADAPT*. This approach acts as a general technique which can be directly adapted for problems with more than two criteria. The minimization of each criterion is assumed in the following theorem:

Theorem 28.7 (Papadimitriou and Yannakakis [2]**)**

There is an algorithm for constructing an $\vec{\epsilon}$-approximate Pareto set, polynomial in the size of the instance and $1/\epsilon$, if the following problem (called GAP*) can be so solved: Given the instance and a k-vector $(B_1, \ldots, B_k)$, either return a solution s with $f_i(s) \leq (1+\epsilon)B_i$ for all i, or answer that there is no solution s′ with $f_i(s') \leq B_i$.*

Proof

Define $\epsilon' = \sqrt{1+\epsilon} - 1 \approx \epsilon/2$ and subdivide the objective space as in the proof of Theorem 28.5, using ϵ'. Call the GAP problem for each corner (see Figure 28.8 for an illustration). Keep (an undominated subset of) all solutions returned and then we get an $\vec{\epsilon}$-approximate Pareto set. □

This approach was successfully used for a scheduling problem [23]. The following subsection addresses a problem where the general technique cannot be used.

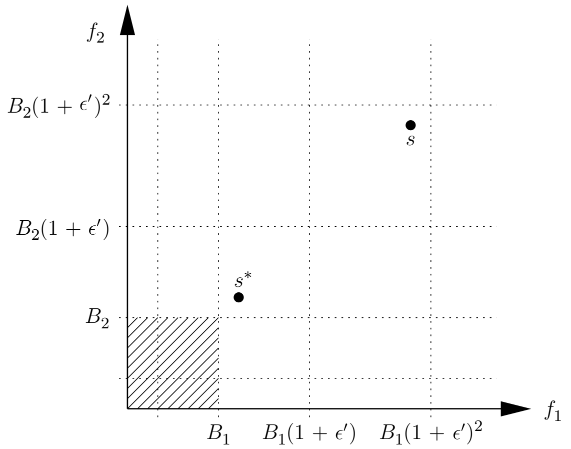

FIGURE 28.8 Suppose that s^* is Pareto optimal. Call GAP for (B_1, B_2) and suppose that no solution s' satisfies $f_i(s') \leq B_i$. Call GAP for $(B_1(1+\epsilon'), B_2(1+\epsilon'))$ and suppose that it returns a solution s with $f_i(s) \leq B_i(1+\epsilon')^2$. Then, we get $f_i(s) \leq (1+\epsilon')^2 f_i(s^*) = (1+\epsilon) f_i(s^*)$.

28.3.4.3 The Bicriteria TSP (1, 2)

Given a complete graph $G = (V, E)$ and a function d that maps a nonnegative distance to each edge $e \in E$, the TSP consists in finding a tour (a Hamiltonian cycle) whose total distance is minimum. Papadimitriou and Yannakakis [24] addressed a restricted, but still **NP**-hard, version of the TSP where distances can be one or two (denoted by TSP(1, 2) in the following). They proposed a polynomial-time 1/6-approximation algorithm, while Engebretsen and Karpinski [25] provided a lower bound of 1/740 on this ratio (for polynomial-time approximation).

We consider a bicriteria version of the TSP(1, 2) where all distance vectors belong to $\{1, 2\}^2$. A tour t has total distance vector $\vec{D}(t)$ such that $n \leq D_k(t) \leq 2n$, $n = |V|$, and $1 \leq k \leq 2$. For any instance of this biobjective problem, one can compute in polynomial time a set P' of two tours such that the image of P' under $\vec{D}$ is a $(\frac{1}{2}, \frac{1}{2})$-approximation of $\mathcal{I}_{Eff}$. Each of these two tours is computed with an extended version of the old *nearest neighbor* heuristic. Starting from a single node, this greedy procedure consists in iteratively adding the "lightest" edge connecting the last inserted node with a noninserted one. A tour is simply built by linking the extremities of the path that was computed. If distances are scalars then the word "lightest" means "minimal distance." In case distances are vectors then a definition of "lightness" must be given since some distance vectors cannot be objectively compared.

Suppose that we are given a permutation σ of the criteria. One can derive a lexicographic order between the distance vectors as follows: According to σ, $\vec{d}(e)$ is lighter than $\vec{d}(e')$, denoted by $\vec{d}(e) <_\sigma \vec{d}(e')$, if $d_{\sigma(j)}(e) < d_{\sigma(j)}(e')$ and j is the smallest index satisfying $d_{\sigma(j)}(e) \neq d_{\sigma(j)}(e')$.

The following algorithm takes a permutation σ as an entry and returns an approximate tour t_σ (t_σ is viewed as a permutation of the nodes so that $t_\sigma(i)$ denotes the ith visited node):

Algorithm (*BINN*(σ))
returns an approximate tour t_σ

```
choose arbitrarily one node $v \in V$
set $t_\sigma(1) = v$ and $VISITED = \{v\}$
for $i = 1, \ldots, n-1$
    find $v' \in V \setminus VISITED$ the nearest neighbor of $t_\sigma(i)$
    set $t_\sigma(i+1) = v'$ and $VISITED = VISITED \cup \{v'\}$
return $t_\sigma$
```

Theorem 28.8 **(Angel et al. [26])**

BINN(σ) returns a tour t_σ which $(\frac{1}{2}, \frac{1}{2})$-dominates any tour t' satisfying $D_{\sigma(1)}(t') \le D_{\sigma(2)}(t')$.

Proof

Given $\vec{a} \in \{1,2\}^2$, let $x_{\vec{a}}$ (respectively, $x'_{\vec{a}}$) be the number of edges in t_σ (respectively, t') having a distance vector equal to $\vec{a}$. For $k = 1$ or $k = 2$, we have $D_k(t_\sigma) = \sum_{\vec{a}:a_k=1} x_{\vec{a}} + 2\sum_{\vec{a}:a_k=2} x_{\vec{a}}$ and $D_k(t') = \sum_{\vec{a}:a_k=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_k=2} x'_{\vec{a}}$. Since t_σ and t' are two tours with n edges, we have

$$n = \sum_{\vec{a}:a_k=1} x_{\vec{a}} + \sum_{\vec{a}:a_k=2} x_{\vec{a}} = \sum_{\vec{a}:a_k=1} x'_{\vec{a}} + \sum_{\vec{a}:a_k=2} x'_{\vec{a}}, \quad k = 1, 2$$

Thus, $D_k(t_\sigma) = 2n - \sum_{\vec{a}:a_k=1} x_{\vec{a}}$ and $D_k(t') = 2n - \sum_{\vec{a}:a_k=1} x'_{\vec{a}}$. The hypothesis $D_{\sigma(1)}(t') \le D_{\sigma(2)}(t')$ gives

$$\sum_{\vec{a}:a_{\sigma(1)}=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_{\sigma(1)}=2} x'_{\vec{a}} \le \sum_{\vec{a}:a_{\sigma(2)}=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_{\sigma(2)}=2} x'_{\vec{a}} \Leftrightarrow \sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} \le \sum_{\vec{a}:a_{\sigma(1)}=1\wedge a_{\sigma(2)}=2} x'_{\vec{a}} \tag{28.2}$$

Let Ω be a subset of $\{1,2\}^2$ such that no couple of vectors $\vec{a}, \vec{b}$ satisfies $\vec{a} \in \{1,2\}^2\backslash\Omega$, $\vec{b} \in \Omega$ and $\vec{a} \prec_\sigma \vec{b}$. For example, Ω can be $\{(1,1),(1,2)\}$ or $\{(1,1)\}$ if σ is the identity permutation. Let X_Ω (respectively, X'_Ω) be the set of edges in t_σ (respectively, t') which have a distance vector in Ω. Let $map : X'_\Omega \to X_\Omega$ be a function such that $map(e) = e$ if $e \in X'_\Omega \cap X_\Omega$; otherwise $map(e) = e'$, where $e = [t_{\sigma(i)}, t_{\sigma(j)}]$, $e' = [t_{\sigma(i)}, t_{\sigma(i+1)}]$, and $1 \le i < j \le n$. Remark that e' must belong to X_Ω because $t_{\sigma(i+1)}$ is the nearest neighbor of $t_{\sigma(i)}$, i.e., $\vec{d}(e) \not\prec_\sigma \vec{d}(e')$ and $\vec{d}(e') \in \Omega$. Since in a tour, exactly two edges are incident to a vertex, we have $2|X_\Omega| \ge |X'_\Omega|$. Then, taking $\Omega = \{\vec{a} \mid a_{\sigma(1)} = 1\}$ and $\Omega = \{\vec{a} \mid a_{\sigma(1)} = a_{\sigma(2)} = 1\}$, we get

$$2\sum_{\vec{a}:a_{\sigma(1)}=1} x_{\vec{a}} \ge \sum_{\vec{a}:a_{\sigma(1)}=1} x'_{\vec{a}} \tag{28.3}$$

$$2\sum_{\vec{a}:a_{\sigma(1)}=a_{\sigma(2)}=1} x_{\vec{a}} \ge \sum_{\vec{a}:a_{\sigma(1)}=a_{\sigma(2)}=1} x'_{\vec{a}} \tag{28.4}$$

Proving that t_σ $(\frac{1}{2}, \frac{1}{2})$-dominates t' is equivalent to $D_{\sigma(k)}(t_\sigma) \le (1 + \frac{1}{2})D_{\sigma(k)}(t')$ for $k = 1, 2$.

$$\begin{aligned} D_{\sigma(k)}(t_\sigma) \le \left(1 + \frac{1}{2}\right) D_{\sigma(k)}(t') &\Leftrightarrow 2n - \sum_{\vec{a}:a_{\sigma(k)}=1} x_{\vec{a}} \le \frac{3}{2}\Big(2n - \sum_{\vec{a}:a_{\sigma(k)}=1} x'_{\vec{a}}\Big) \\ &\Leftrightarrow -2\sum_{\vec{a}:a_{\sigma(k)}=1} x_{\vec{a}} \le 2n - 3\sum_{\vec{a}:a_{\sigma(k)}=1} x'_{\vec{a}} \\ &\Leftrightarrow -2\sum_{\vec{a}:a_{\sigma(k)}=1} x_{\vec{a}} \le 2\sum_{\vec{a}:a_{\sigma(k)}=2} x'_{\vec{a}} - \sum_{\vec{a}:a_{\sigma(k)}=1} x'_{\vec{a}} \qquad (28.5) \end{aligned}$$

Since $x'_{\vec{a}} \ge 0$ for any vector $\vec{a} \in \{1,2\}^2$, inequality (28.5) when $k = 1$ follows from Eq. (28.3) and $0 \le 2\sum_{\vec{a}:a_{\sigma(1)}=2} x'_{\vec{a}}$.

Starting from Eq. (28.2) we get

$$2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} \le 2\sum_{\vec{a}:a_{\sigma(1)}=1\wedge a_{\sigma(2)}=2} x'_{\vec{a}}$$

$$2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=2} x'_{\vec{a}} \le 2\sum_{\vec{a}:a_{\sigma(2)}=2} x'_{\vec{a}}$$

$$2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=2} x'_{\vec{a}} - \sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} \le 2\sum_{\vec{a}:a_{\sigma(2)}=2} x'_{\vec{a}} - \sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}}$$

$$\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} + 2\sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=2} x'_{\vec{a}} \le 2\sum_{\vec{a}:a_{\sigma(2)}=2} x'_{\vec{a}} - \sum_{\vec{a}:a_{\sigma(1)}=2\wedge a_{\sigma(2)}=1} x'_{\vec{a}} \tag{28.6}$$

Since $x'_{\vec{a}} \geq 0$ and $x_{\vec{a}} \geq 0$ for any vector $\vec{a} \in \{1, 2\}^2$, we have

$$-2 \sum_{\vec{a}:a_{\sigma(1)}=2 \wedge a_{\sigma(2)}=1} x_{\vec{a}} \leq \sum_{\vec{a}:a_{\sigma(1)}=2 \wedge a_{\sigma(2)}=1} x'_{\vec{a}} + 2 \sum_{\vec{a}:a_{\sigma(1)}=2 \wedge a_{\sigma(2)}=2} x'_{\vec{a}}$$

This inequality and Eq. (28.6) give

$$-2 \sum_{\vec{a}:a_{\sigma(1)}=2 \wedge a_{\sigma(2)}=1} x_{\vec{a}} \leq 2 \sum_{\vec{a}:a_{\sigma(2)}=2} x'_{\vec{a}} - \sum_{\vec{a}:a_{\sigma(1)}=2 \wedge a_{\sigma(2)}=1} x'_{\vec{a}} \tag{28.7}$$

Finally, one can add Eq. (28.4) to Eq. (28.7) and get inequality (28.5) when $k = 2$. □

Running *BINN* with the two possible permutations σ, one can build a set P' of two tours which $(\frac{1}{2}, \frac{1}{2})$-dominates any feasible tour. Hence, P' is a $(\frac{1}{2}, \frac{1}{2})$-approximate Pareto set for the bicriteria TSP(1, 2).

28.4 Conclusion

Practical situations without any clearly established optimum are often met. Indeed, considering several conflicting criteria is sometimes necessary or simply relevant. Instead of a well-identified optimum, one faces a set of trade-off solutions whose computation is highly problematic. Thus, approximation seems reasonable in multiobjective optimization.

There are various approaches or techniques for the study of a multiobjective problem:

- aggregate the objective functions and get a single criterion which has to be optimized;
- optimize only one objective function while the others are turned into constraints;
- get a trade-off by combining solutions which are good for each separate objective function; and
- compute a set of solutions which approximately dominates all the others.

Stochastic Local Search Algorithms for Multiobjective Combinatorial Optimization: A Review

29.1 Introduction

Multiobjective Combinatorial Optimization Problems (MCOPs) are combinatorial problems that involve the optimization of several, typically conflicting objectives. An MCOP arises, for example, when planning a holiday trip from a city A to some city B. Besides the minimization of the overall distance between the two sites, one may also be interested in minimizing the cost, the overall travel time, etc. An unequivocal solution to such problems is the one which is *optimal* with respect to all objectives. But is there such a solution? The shortest tour is not necessarily the fastest nor the fastest needs to be the cheapest one—just consider tolled highways.

Which is then the optimal solution to such a multiobjective problem? It depends on the notion of *optimality*. In this chapter, we focus on the notion of Pareto optimality, which arises when the decision maker is not able to express his preferences a priori, simply because he is not present in the process or not able to give an a priori formula or ranking of the objectives. In this case, one is interested in obtaining a set of solutions that represents the *optimal trade-off* between the objectives, i.e., solutions which are not worse than any other and strictly better in at least one of the objectives.

The set of available algorithms for computing high-quality approximations to the Pareto optimal set has grown enormously over the recent years as witnessed by a large number of papers at international conferences and workshops [1–4], special issues of scientific journals [5–7] and numerous regular papers at multiple criteria decision making as well as at algorithms conferences. The majority of these approaches are based on stochastic local search (SLS) algorithms (see Chapter 19 for more details on SLS), a trend that reflects the enormous success of these algorithms for single-objective problems.

Here, we review the main developments in the application of SLS algorithms to MCOPs. Stochastic local search techniques range from simple constructive algorithms and iterative improvement algorithms to general algorithm frameworks that can be adapted to a specific problem under consideration. These latter general-purpose SLS methods (also often called metaheuristics) include simulated annealing, tabu search, evolutionary algorithms, ant colony optimization (ACO), and many others. While these techniques can result in rather complex algorithms already for single-objective problems, when applied to MCOPs they become even more complicated because they need to return a set of solutions instead of a single one.

For tackling MCOPs with SLS algorithms, two fundamentally different approaches can be distinguished. The first is to base the search on the component-wise ordering of the objective value vectors of solutions (or some *ranking* derived from these orderings). We will say that SLS algorithms that mainly focus on this approach follow the *component-wise acceptance criterion* (CWAC) *search model.* The second approach is based on the usage of parameterized scalarization methods by aggregating the objectives; the SLS algorithms following such lines use the *scalarized acceptance criterion* (SAC) *search model.* These two choices somehow define the two main *schools* for the design of SLS algorithms for MCOPs. Different choices for the remaining components of an SLS algorithm for MCOPs crucially depend on the choice taken for the search model.

In the following sections, we review available SLS algorithms in dependence of these two choices, which also makes this review different from several earlier ones [8–13]. In addition, some proposals combine these two search models. We will review these latter *hybrid* approaches separately from the others. Despite the view taken here, it is inevitable to further discuss the proposed algorithms in dependence of the analogy to known SLS methods for the single-objective problems. However, since we are more interested in the differences between the main search strategies, we do not consider specific problem-dependent implementation choices in detail and also try to avoid the highly specialized jargon found in the context of various SLS methods.

29.2 Basics

The main goal of solving MCOPs in terms of Pareto optimality is to find solutions which are not worse than any other solution and strictly better in at least one of the objectives. Let Q be the number of objectives and $\mathcal{S}$ be the set of all candidate solutions; then the objective function for a solution $s \in \mathcal{S}$ to MCOPs can be defined as a mapping $\vec{f} : s \mapsto \mathbb{R}^Q$. The following orders hold for objective function vectors in $\mathbb{R}^Q$. Let $\vec{u}$ and $\vec{v}$ be vectors in $\mathbb{R}^Q$; we define the (i) *weak component-wise order* as $\vec{u} \leq \vec{v}$, *i.e.*, $u_i \leq v_i,\ i = 1, \ldots, Q$; and (ii) the *component-wise order* as $\vec{u} \prec \vec{v}$, *i.e.*, $\vec{u} \neq \vec{v}$ and $u_i \leq v_i, i = 1, \ldots, Q$. In the context of optimization, we denote the relation between objective function value vectors of two feasible solutions s and s' as follows: (i) if $\vec{f}(s) \prec \vec{f}(s')$, we say that $\vec{f}(s)$ *dominates* $\vec{f}(s')$; and (ii) if $\vec{f}(s) \leq \vec{f}(s')$, then $\vec{f}(s)$ *weakly dominates* $\vec{f}(s')$. In addition, we say that $\vec{f}(s)$ and $\vec{f}(s')$ are *nondominated* if $\vec{f}(s) \nprec \vec{f}(s')$ and $\vec{f}(s') \nprec \vec{f}(s)$, and they are *nonweakly dominated* if $\vec{f}(s) \nleq \vec{f}(s')$ and $\vec{f}(s') \nleq \vec{f}(s)$. Note that the latter implies that $\vec{f}(s) \neq \vec{f}(s')$. For simplification purposes, we shall use the same notation among solutions when the above relations hold between their objective function value vectors.

Since the notion of optimal solution clearly differs from the single-objective counterpart, we need to define the notion of a *Pareto global optimum solution* and a *Pareto global optimum set*: A solution $s \in \mathcal{S}$ is a Pareto global optimum if and only if there is no $s' \in \mathcal{S}$ such that $\vec{f}(s') \prec \vec{f}(s)$; we say that $\mathcal{S}' \subseteq \mathcal{S}$ is a Pareto global optimum set if and only if it contains *only* and *all* Pareto global optimum solutions. We call the image of the Pareto global optimum set in the objective space *the efficient set*. In most cases, solving an MCOP in terms of Pareto optimality would correspond to finding solutions that are representative of the efficient set.

When solving an MCOP in terms of scalarized optimality, it is assumed that the decision maker is able to *weigh* the importance of each objective; the objective function vector is then *scalarized* according to some weight vector $\vec{\lambda} = (\lambda_1, \ldots, \lambda_Q)$. We will denote the scalarized objective function value by $f_{\lambda}(s)$.

We then say that a solution $s \in \mathcal{S}$ is a scalarized global optimum solution if and only if there is no $s' \in \mathcal{S}$ such that $f_{\lambda}(s) < f_{\lambda}(s')$ with respect to a given $\vec{\lambda}$. The weight vector $\vec{\lambda}$ is usually normalized such that $\sum_{q=1}^{Q} \lambda_q = 1$. Thus, $\vec{\lambda}$ is an element from the set of normalized weight vectors Λ given by

$$\Lambda = \{\vec{\lambda} \in R^Q : \lambda_q > 0, \sum_{q=1}^{Q} \lambda_q = 1, q = 1, \ldots, Q\} \tag{29.1}$$

In the case of different ranges of values between objectives, a normalization by range equalization factors must be considered [14]. The scalarization of the objective function vector is usually based on the family of weighted L_p-metrics as

$$f_{\lambda}(s) = \left[\sum_{i=1}^{Q} \left(\lambda_i | f_i(s) - y_i | \right)^p \right]^{1/p} \tag{29.2}$$

where $s \in \mathcal{S}$, $p > 0$, and $\vec{y} = y_1, \ldots, y_Q$ is the *ideal* vector, where we have $y_i = \min f_i$, $i = 1, \ldots, Q$. Settings of $p = 1$ or $p = \infty$ are most often used. When $p = 1$, we have the well-known *weighted sum* formulation given by

$$f_{\lambda}(s) = \sum_{i=1}^{Q} \lambda_i f_i(s) \tag{29.3}$$

It is well known that a scalarized global optimum solution for Eq. (29.3) with $p \neq \infty$ is also a Pareto global optimum solution, either if it is a unique solution or if the components of the weight vectors are all positive [14]. Obviously, the great advantage of using a weighted sum formulation is that the same SLS algorithm for solving the single-objective problem can be used for tackling the multiobjective version. When using such formulations, the available algorithms typically change the weight vectors to generate solutions that are of high quality for different weights. A disadvantage is that, when finding optimal solutions with respect to the weighted sum formulation, only *supported solutions*, that is, solutions on the convex hull of the efficient set, are obtained.

Finally, let us mention that (with a few exceptions) common to all SLS algorithms for MCOPs is that they return a set of nondominated solutions. Therefore, most of these algorithms include an additional data structure that maintains a set of solutions during the search process that we call *archive* and that is returned when the algorithm is terminated at an arbitrarily chosen time. In our review, we consider that the best nondominated solutions found during the algorithm's run are maintained in the archive, if not expressed otherwise. During the search process, the algorithm needs to *update* the archive and, if nothing else is said, we assume that this update consists of (i) adding new nondominated solutions and (ii) removing dominated ones.

Many of the available SLS algorithms make use of two further techniques. The first is *archive bounding*; it is used because the archive may grow very strongly and the operations for manipulating the archive become increasingly time consuming. The second are techniques for maintaining the solutions in the archive spread in the objective space, since it is assumed that clusters of solutions are not informative for the decision maker.

29.3 Component-Wise Acceptance Criterion

We first give an overview of SLS algorithms that make direct or indirect use of the component-wise ordering when deciding about the acceptance of new candidate solutions. By *direct* we mean that this decision is exclusively based on the component-wise ordering introduced in Section 29.2; by *indirect* we understand that from this component-wise ordering some *ranking* of candidate solutions is derived that is then finally used for deciding on which solutions to accept or choose for further manipulation. The algorithms that fall into this latter category are mainly evolutionary algorithms.

29.3.1 Direct Use of the Component-Wise Ordering

When designing an SLS algorithm for single-objective problems, one typically starts by implementing some form of an iterative improvement algorithm. In fact, it is relatively straightforward to apply iterative improvement algorithms also to multiobjective problems by modifying the acceptance criterion, making use of the component-wise ordering of solutions, and the use of an archive of nondominated solutions found so far. With such modifications, iterative improvement algorithms under the CWAC search model can iteratively improve the current set of candidate solutions in the archive by adding nondominated neighboring solutions to it [15]. Such an algorithm can be seeded either by one single solution that may be generated randomly, or by a set of candidate solutions generated by, for example, an exact algorithm. Despite their widespread use for single-objective problems, iterative improvement algorithms for MCOPs were proposed only recently; nevertheless, almost all SLS algorithms that make direct usage of the component-wise ordering are such iterative improvement algorithms or extensions thereof.

Iterative Improvement Algorithms

Among the first such approaches is Pareto local search (PLS) by Paquete et al. [16–18]. Pareto local search applies iteratively the two following steps. First, it selects randomly one candidate solution s from the archive that has not been visited and examines all neighbors of s. Second, it adds all neighbors of s that are nonweakly dominated with respect to the archive. It stops when the neighborhood of all candidate solutions has been examined. Independent of PLS, Angel et al. [19] proposed a similar approach called bicriteria local search (BLS). The main difference between PLS and BLS is that the latter examines the neighborhood of all candidate solutions in the archive, while PLS chooses only one and updates the archive immediately after examining a candidate solution's neighborhood. Angel et al. also proposed an extension of BLS by using an archive bounding technique that only accepts neighboring solutions whose objective function value vectors do not lie in a same partition of the objective space; in addition, also a restart version of BLS was presented. A similar idea was also proposed by Laumanns et al. [20] for a simple evolutionary multiobjective optimizer (SEMO) that examines only one randomly chosen solution in the neighborhood. A variant of SEMO [20], called fair evolutionary multiobjective optimizer (FEMO), selects the candidate solution of the archive whose neighborhood was examined least often.

An iterative improvement algorithm with a more complex acceptance criterion, called Pareto archived evolution strategy (PAES), was proposed by Knowles and Corne [21], which induces explicitly some dispersion among the solutions of a bounded-size archive. The acceptance criterion of PAES works as follows: A neighboring candidate solution s' is chosen randomly from the neighborhood of a current candidate solution s of the archive; if s' is dominated by any of the candidate solutions in the archive it is discarded, while if s' dominates candidate solutions in the archive, s' is added and the dominated candidate solutions are removed. If s' is nondominated with respect to s and to the archived candidate solutions, one of the two following possibilities is applied: (i) if the archive is not full, s' is added to the archive; (ii) if the archive is already full, s' is only added if there exists another solution s^* lying in a partition of the objective space that contains more solutions. In that case, s^* is removed from the archive. A more complex version of PAES, called M-PAES, is proposed in Ref. [22].

Extensions of Tabu Search

An obvious further extension of the iterative improvement algorithms described above is to incorporate features of other general-purpose SLS methods. Few approaches in that direction have been proposed so far and the ones we are aware of are based on multiobjective tabu search. The central idea is to examine the neighborhood of a set of solutions, extract nondominated solutions and accept among those only some nontabu ones for inclusion into an archive. Examples of such an approach have been presented by Baykasoglu et al. [23,24] and by Armetano and Arroyo [25]. In the latter approach, a bounded-size archive is used and special bounding and dispersion techniques are used that are based on the location of centroids of clusters of solutions in the objective space.

29.3.2 Indirect Use of the Component-Wise Ordering

Many current population-based SLS algorithms rely on a mapping of the objective function value vector of each candidate solution in the archive into a single value, a *rank*, where the lower a candidate solution's rank is, the higher are its chances of being chosen. This indirect use of the component-wise ordering is mainly made by a number of *multiobjective evolutionary algorithms* (MEAs). Here, we describe the most relevant of these MEAs with particular emphasis on the ranking procedure. All these approaches consider an archive of bounded size. An illustration of the ranking procedure used in the algorithms presented next is given in Figure 29.1; the brighter the color of an objective function value vector the better is the solution considered by the ranking procedure. Note that, as said before, we do not discuss details of these approaches such as crossover or mutation operators, since these are problem specific.

- Fonseca and Fleming [26] proposed the multiple objective genetic algorithm (MOGA), which scores each solution with the number of solutions that weakly dominate it in the archive. Then, solutions are ranked according to those values, where ties result in ranks being averaged. A sampling algorithm chooses the next set of solutions to remain in the archive, even if some of them are dominated. The top-left plot in Figure 29.1 shows this ranking procedure, before averaging tied ranks.
- Srinivas and Deb [27] proposed the nondominated sorting genetic algorithm (NSGA), which extended a ranking procedure initially proposed (but not tested) by Goldberg [28]: the lowest rank is assigned to the set of candidate solutions in the archive that are nondominated. These solutions are then removed and the nondominated solutions among the remaining candidate solutions are assigned the next rank level. This procedure is iterated until no candidate solution remains to be assigned a rank. Next, a sampling procedure is used for choosing the next set of solutions according

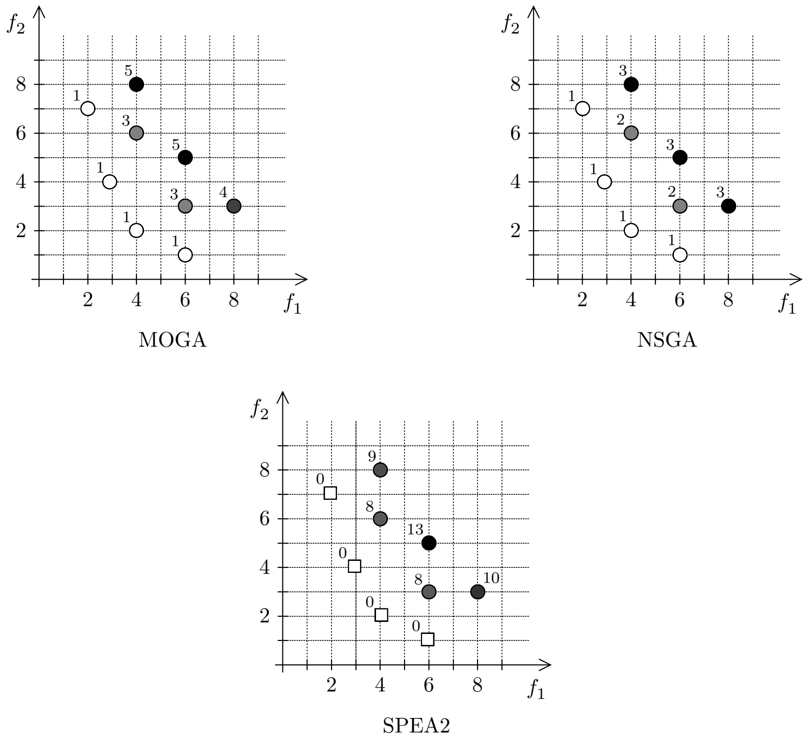

FIGURE 29.1 Graphical illustration of several ranking procedures in MEAs where the numbers at the points indicate the respective rank values (See text for more details).

to the ranking. Similarly to MOGA, also dominated solutions could be chosen. The top-right plot in Figure 29.1 illustrates this ranking procedure. Some further improvements are found in NSGA-II [29]; these include a faster computation of the ranks and a strategy for maintaining a dispersed set of solutions called *crowding*.

- Zitzler et al. [30] proposed strength Pareto evolutionary algorithm 2 (SPEA2) that maintains two sets of solutions, one being the archive of the best nondominated solutions found so far and the second being the set of current candidate solutions that play the usual role of the population in evolutionary algorithms. Some of the solutions from the archive might be removed by a clustering algorithm if their number exceeds the maximum allowable size. The ranking procedure of SPEA2 works as follows:
  1. To each solution in the archive and in the set of current solutions is assigned the number of current solutions that are dominated by it.
  2. For each solution in both sets, its rank is given by the sum of the values computed for the solutions from both sets that weakly dominate it.

  Solutions, whose ranks are less than one, are added to the archive. The size of the archive is maintained fixed at some value j in two ways: if the number of solutions becomes larger than j, solutions which are clustered in the objective space are removed (except those that are the best to each objective); if the archive is not full, the best current solutions are added to it until the total number of solutions reaches j. The bottom plot in Figure 29.1 illustrates this ranking procedure, where circles correspond to the set of current solutions and squares correspond to the solutions in the archive. The ranking procedure used by SPEA2 corrects the previous version called SPEA [31], in which a solution that is dominated by another one could be assigned a lower rank.

Since these approaches typically use an archive of fixed size, it is desirable that the existing solutions are dispersed in the objective space. Therefore, this aspect also affects how solutions are going to be chosen. Both MOGA and NSGA use a *fitness sharing* strategy, which decreases a solution's rank depending on how large is the number of solution in the archive within a certain radius in the objective space. NSGA-II applies a *crowding* strategy, which modifies a solution's rank based on an average distance from the nearest nondominated solutions in the objective space. A similar approach is also used in SPEA2, where to each solution rank the inverse of the distance from the kth nearest neighbor solution in the objective space is added (k is a parameter).

Recently, some MEAs have been proposed that add a further exploration step by making direct use of the component-wise ordering. For instance, Talbi [32] proposed an algorithm that starts with an MEA, whose final set of solutions is used afterward as starting solutions for an iterative improvement similar to PLS; similar approaches are found also in Brizuela et al. [33] and Basseur et al. [34]. In Jozefowiez et al. [35], the further step after the termination of an MEA consists of a tabu search algorithm, with similar principles to Ref. [23], that is run several times for different regions of the objective space. Finally, Morita et al. [36] proposed a more complex combination by maintaining two sets of solutions such as SPEA2. At each iteration, some solutions are chosen from each set and are recombined and mutated; the resulting solutions are then added to the current set of solutions and to the archive. Then, the CWAC step consists of the examination of the solutions neighboring to one chosen from the archive. Finally, the archive is updated and some solutions from the current set of solutions are removed to maintain a given cardinality at the end of each iteration.

29.4 Scalarized Acceptance Criterion

The main principle underlying the SAC search model is to use the value returned by the scalarization of the objective function vector with respect to some weight vector to distinguish between *better* and *worse* solutions. Obviously, using only one weight vector is not enough for obtaining a reasonable approximation to the efficient set. Hence, most approaches consider to change the components of the weight vector while running the algorithm to attain different regions of the objective space.

In the following, we divide the approaches in *nonproprietary* and *proprietary* ones. In nonproprietary approaches, an SLS algorithm is embedded into a general framework that mainly says how an underlying SLS algorithm is applied to tackle an MCOP. In the proprietary approaches, some specific, general-purpose SLS method is enhanced by additional features or specific search strategies that make it adapted for tackling MCOPs. Several examples of such proprietary approaches are therefore discussed in dependence of the underlying general-purpose SLS method.

29.4.1 Nonproprietary Approaches

In the simplest case, a single-objective SLS algorithm could be run several, say k, times using k different weight vectors and one could for each scalarization return the best solution found by the SLS algorithm. Then, the set of objective value vectors of the k returned final solutions forms an approximation to the efficient set. To output a set of nondominated solutions, the dominated solutions from the final set are removed.

Surprisingly, such a very basic approach is very rarely used, not even for a comparison to more complex algorithms. Exceptions are found in Borges and Hansen [37] and Knowles and Corne [38], who used the set of solutions returned by such an approach to get insight into certain instance features. In the following, we describe some approaches that further extend these ideas:

- Borges [39] proposed a general framework, called changing horizon efficient set search (CHESS), whose acceptance criterion is based on a function of the distance between a new solution and an archive; in particular, the neighboring solution that is accepted to the archive is the one that maximizes the minimum difference between each component of the objective function value vector to any solution in the archive. However, this distance does not take into account any weight vector. This general rule for the acceptance criterion can be applied to SLS methods such as simulated annealing or tabu search.
- Paquete and Stützle [40] proposed two-phase local search (TPLS), which works as follows: in a first phase, a high-quality solution for one objective is obtained by some high-performance SLS algorithm. Then, in the second phase, a sequence of scalarizations is solved; the initial solution of each scalarized problem is the one returned by the previous scalarization; the starting solution for the first scalarization is the one returned from the first phase. The weight vectors that define the scalarizations in the second phase are modified according to some strategy. This strategy could consist of a random sequence of weight vectors, or of a sequence such that a small change is incurred between components of successive weight vectors. This latter strategy is the most applied one so far. For a detailed description of this algorithm see Refs. [18,40,41].

29.4.2 Proprietary Approaches

Proprietary Simulated Annealing

Differently from the CWAC model, many algorithms that follow the SAC model use simulated annealing principles. Here, we describe some of the most relevant ones:

- Serafini [42] proposed several ways of modifying the usual probabilistic acceptance criterion of simulated annealing for tackling multiobjective problems. Given the current solution s and a neighboring solution s', he gives guidelines that should be applied to the computation of the probability p of accepting s': if $\vec{f}(s') \prec \vec{f}(s)$, then $p = 1$; if $\vec{f}(s) \prec \vec{f}(s')$, then $p < 1$; otherwise, p depends on the value returned from a function of a parameter called "temperature" and the weighted distance between $\vec{f}(s')$ and $\vec{f}(s)$ (or between $\vec{f}(s')$ and the ideal vector). To attain more solutions, Serafini proposed to use small random variations on the components of the weight vector during the run.
- Ulungu [43] proposed Multi-Objective Simulated Annealing (MOSA), where a set of weight vectors is defined a priori and for each scalarization one run of a simulated annealing algorithm is done. The

probabilistic acceptance criterion in MOSA follows similar principles to those proposed by Serafini [42]. Each time a neighboring solution is accepted, an archive A_λ of nondominated solutions for the current weight vector λ is updated; the final set of solutions returned by the algorithm is obtained after removing the dominated solutions from the union of the resulting sets A_λ.

Proprietary Tabu Search

Hansen [44] proposed Multi-Objective Tabu Search (MOTS) that uses an archive, which is improved during the search process. In MOTS, only neighboring solutions that are nontabu and the best with respect to a given scalarization can be added to the archive. To obtain a final set of solutions that is dispersed in the objective space, the current weight vector is updated such that neighboring solutions that are isolated in the objective space are preferably chosen. This update is done as follows: given a solution s from the archive, the ith weight vector component increases by a fixed amount for each solution in the archive that is worse in the ith objective; then, a *nontabu* neighbor of s that has the best scalarized objective function value with respect to the new weight vector is chosen and added to the archive if it is nondominated with respect to all solutions in the archive and, in that case, the tabu list is updated. Further features of MOTS are described in Ref. [44].

Proprietary Memetic Algorithms

Several memetic algorithms for MCOPs have been proposed in analogy to principles of the single-objective case. Usually, these algorithms consist of a sequence of runs of an SLS algorithm using a scalarized objective function, each one seeded by solutions that are generated by recombination and mutation procedures applied to elements of the current set of solutions. We describe the following main approaches:

- Ishibuchi and Murata [45] proposed Multi-Objective Genetic Local Search (MOGLS), which is a straightforward extension of MEAs to memetic algorithms. At each iteration, two solutions are selected from the archive by a sampling procedure that takes into account the ranking of all solutions based on a scalarization of the objective function vector with respect to a randomly generated weight vector. These two solutions are then recombined, generating a new one, which is then further improved by a local search algorithm that uses the current weight vector. In the first proposal only one randomly chosen solution from the neighborhood is examined at each iteration of the local search, but more recently also analyses on the influence of the strength of the local search on the overall performance have been done [46].
- Jaszkiewicz [47] proposed another memetic algorithm also called MOGLS. This algorithm maintains two sets of solutions as SPEA2, where one set holds the current solutions while a second one corresponds to the archive of the best solutions found. At each iteration, two solutions are taken from a subset of the best current solutions with respect to a certain randomly chosen weight vector and then recombined. Next, a local search algorithm starts from this new solution using the scalarized objective function defined by the generated weight vector. The solution returned by the local search algorithm is then added to the two sets of solutions according to some acceptance rules.

29.5 Combination of Search Models

Several recently proposed algorithms combine the SAC and the CWAC search model, giving place to hybrid algorithms. Two main trends can be identified. Either the overall SLS algorithm applies two clearly distinct phases based on the two search models in sequence (sequential combination), or the SLS algorithm combines components of the two search models and iteratively changes between those in the overall search process (iterative combination).

29.5.1 Sequential Combination

All the sequential combinations we are aware of first apply algorithms based on the SAC search model. The reason for this choice may be due to the fact that optimal solutions with respect to scalarizations of the objective function vector can identify only supported solutions, possibly leaving large gaps in the final set of solutions returned; in addition, the number of solutions returned by some methods following the SAC model is limited to the number of scalarizations. Algorithms that follow the CWAC search model can easily be applied after the SAC step with the aim of filling these gaps and increasing the number of returned solutions. Note that in the SAC step of such a combination, not necessarily SLS algorithms are required. In fact, if the scalarized problem is polynomially solvable, it is more useful to use an exact algorithm; this is also the case in the first two combinations described below.

- Hamacher and Ruhe [48] and Andersen et al. [49] proposed an algorithm that combines the two search models for tackling the multiobjective minimum spanning tree problem. In their approaches, the SAC step consists of obtaining several supported solutions for different scalarizations (note that a minimum spanning tree can be computed in polynomial time) and in the CWAC step, candidate solutions in the neighborhood of the supported ones are added to the archive if they are nondominated by any other candidate solution.
- Gandibleux et al. [50] proposed an algorithm to search for nondominated solutions with respect to a set of supported solutions that was previously obtained in the SAC step. (As in Refs. [48,49], an efficient algorithm is known to the single-objective version of the MCOP tackled in that paper, the multiobjective assignment problem.) The CWAC step follows principles from evolutionary algorithms: several pairs of solutions are chosen randomly from the archive and are recombined to generate a new set of solutions; the recombination operator used here takes into account some information about the components of the supported solutions. The so obtained solutions are then changed by a mutation procedure and, if the mutated solutions are not dominated by some previously calculated bounds, their neighborhood is explored and the nondominated neighbors are added to the archive. This step is repeated for a given number of iterations.
- Paquete and Stützle [40] proposed a Pareto double two-phase local search (PDTPLS) as a further extension of the TPLS approach (see Section 29.4.1). For each scalarization, a solution s is returned and a CWAC step examines all neighboring solutions of s; all nondominated solutions found in this way are returned once all scalarizations have been examined.

29.5.2 Iterative Combination

Iterative combinations of the SAC and CWAC search models could be conceived in various ways and, hence, it is probably not surprising that the approaches in this category are more varied than when only sequential combinations are considered. In the following we restrict ourselves to give some examples of such combinations that range from local search algorithms like tabu search and simulated annealing to population-based algorithms like memetic algorithms or ACO algorithms. These examples illustrate the range of possibilities that are opened by such iterative combinations.

- Gandibleux et al. [51] use tabu search principles in an algorithm called MOTS. This algorithm iteratively changes between the neighborhood exploration based on an SAC search model and CWAC search model. In the SAC step, a nontabu solution that minimizes the distance from a *local* utopian point[1] or a tabu but aspired solution replaces the current one. Once a new solution in the neighborhood of the current one, s, is accepted, a CWAC step adds nondominated neighbors of s to the archive. To favor more isolated regions of the objective space, the weight vector is updated periodically; to maintain the diversity of the search process, weight vectors are declared tabu for a given number of iterations.
- Abdelaziz and Krichen [52] developed an algorithm that was also called MOTS. Given some solution s, the SAC step works as follows: A constructive algorithm is run several times for several scalarizations to generate a set T of solutions; for each run of the constructive algorithm, the weight

[1] An utopian point dominates the ideal point. In MOTS, a local utopian point dominates all neighbors of the current solution.

vector takes into account the two worst components of the objective function value vector of s multiplied by some random values. The neighboring solutions to s are added to T, from which then the dominated solutions are removed and the resulting set T' is used to update the archive. Then, a CWAC step that follows similar principles as in Ref. [23] (see also Section 29.3.1) is applied for a given number of iterations. The iterative combination of the SAC and CWAC steps is repeated until no solution can be added to the archive during some iterations. A further extension, using an MEA, has been proposed in Ref. [53].

- Czyzak and Jaszkiewicz [54] proposed an algorithm which further extends the simulated annealing principles for tackling MCOPs. First, a set of solutions T is generated randomly and each solution from this set is assigned a weight and added to the archive. For each candidate solution s from T, a neighboring solution s' is added to the archive if it is not dominated by s (CWAC step). The SAC step is then applied for determining s' as the new current solution according to probabilistic rules similar to the ones proposed by Serafini; the weight vector is changed automatically during the search process to favor the acceptance of neighboring solutions that are more *isolated* in the objective space. This iterative process is repeated for all solutions in T.
- López-Ibáñez et al. [55] proposed a combination of SPEA2 with SLS algorithm, which combines a CWAC step, as executed by SPEA2, with a SAC step used for defining the search direction for the SLS algorithm. In that proposal, the SLS algorithm is applied to every new solution obtained from a recombination of solutions in the archive using randomly generated weights.

Recently, there has been some interest in applying ACO algorithms [56] to MCOPs. Ant colony optimization algorithms are based on the repeated, construction of solutions that is stochastically biased by artificial *pheromone* trails (pheromone trails are essentially some numerical information attached to solution components that are used in the solution construction) and heuristic information on the problem under being solved. The pheromone trails are updated during the algorithm's run in dependence of the search experience. Interestingly, all applications of ACO algorithms to MCOPs that are solved under the notion of Pareto optimality combine the two search models: The solution construction is typically based on an SAC step, where weights are defined to join various types of pheromone information with respect to the various objectives, while the artificial ants (representing the generated solutions) that update the pheromone information are typically chosen based on a CWAC step. Some approaches are described as follows:

- Iredi et al. [57] proposed several extensions of ACO algorithms where the pheromone and heuristic information are associated to different weight vectors, defined according to subintervals within the range [0, 1]. Thus, different weight vectors direct the constructive steps toward different regions of the objective space. The artificial pheromones are then updated with the nondominated solutions found. Extensions of these algorithms were also proposed by López-Ibáñez et al. [55,58], where an SLS algorithm based on a scalarization of the objective function vector is applied after each new constructed solution.
- Doerner et al. [59] describe an ACO algorithm that uses one pheromone matrix for each objective but only one same type of heuristic information. Each solution is constructed based on the heuristic information and on the weighted aggregation of the pheromone matrices according to a randomly chosen weight vector. Some of the best nondominated solutions found are then used for updating the pheromones.

29.6 Conclusions

We have reviewed the research on SLS algorithms for tackling MCOPs with respect to the notion of Pareto optimality. The existing approaches were classified according to whether they use the SAC and CWAC search models or some combinations thereof. For each of the resulting main classes of algorithms we have shortly described some main representatives without the intention of providing a fully comprehensive enumeration of all the existing proposals, which would be almost impossible, given their large number and the limited amount of space. While we described here only the main features of available approaches, several other interesting details can be found in the original papers.

Among the possible approaches for tackling MCOPs, a recent and interesting one is to use an acceptance criterion based on solution quality indicators. Such an algorithm has been proposed by Knowles et al. [60]; it applies at each step the hypervolume indicator [31] to decide which solutions are added to the archive. A similar approach has also been followed in Ref. [61], where binary performance indicators are used, that is, quality indicators that return a pair of values for each nondominated set. We remark that the performance of these algorithms strongly depends on the performance of the underlying algorithm for computing the quality indicators and we expect further development on ways of computing these more efficiently.

There are a few important areas related to SLS algorithms for MCOPs that were not covered here. One of the most important is the empirical assessment of the performance of these algorithms. This is far from being a trivial issue since, as shown by Zitzler et al. [62], frequently used quality indicators for comparing nondominated sets obtained by SLS algorithms have severe problems. A recognized exception is the use of attainment functions. Initially proposed in Ref. [63], the attainment function characterizes the performance of the SLS algorithms by describing the distribution of the outcomes. This function has shown to be a first-order moment measure of these outcomes and it can be seen as generalization of the multivariate empirical distribution function [64]. This allows the use of statistical inference and experimental design techniques to *infer* conclusions on the performance of SLS algorithms [65,66]. Some further extension of attainment functions for second-order moments can be found in Ref. [67].

Finally, we remark that little is known on the dependence between the performance of SLS algorithms and certain features of the MCOPs. Exceptions can be found in Mote et al. [68] and Müller-Hannemann and Weihe [69] who identified several features of the Multiobjective Shortest Path problem and variations that translate in a tractable number of Pareto optimal solutions, which contrasts with the known worst case for the same problem; see also Ref. [70]. In Refs. [17,37], it is conjectured that most efficient solutions and approximations thereof are strongly clustered in the solution space for the multiobjective traveling salesman problem with respect to a small-sized neighborhood. This means that local search algorithms using this neighborhood are very suitable for this problem, which is confirmed in Ref. [40]. In addition, the correlation between objectives seems to have a strong effect on the choice for the search model; in Ref. [18], experimental results indicate that simple SLS algorithms based on the SAC and CWAC search model, respectively, can behave very differently for the multiobjective quadratic assignment problem as the correlation between objectives is changed. Therefore, an interesting future line of research is to investigate, both experimentally and analytically, which and how instance features affect the performance of SLS algorithms.

While the research field of applying SLS algorithms to MCOPs poses many open questions and significant research issues, the set of available SLS algorithms shows that nowadays it is becoming increasingly feasible to tackle MCOPs with respect to the notion of Pareto optimality and that, therefore, these approaches are very likely to receive more attention for the solution of difficult real-world multiobjective problems.

Sensitivity Analysis in Combinatorial Optimization

David Fernández-Baca
Iowa State University

Balaji Venkatachalam
University of California, Davis

30.1 Introduction

Anyone formulating an optimization problem faces uncertainty in selecting the model parameters. Transportation costs, probabilities of different events, and budget constraints, among other parameters, are all unlikely to be known with any degree of accuracy. There may also be doubts about the structure of the model, such as whether to add or remove constraints. Understanding the effect of changes in parameter values and model structure on the optimum solution is the subject matter of *sensitivity analysis*. This chapter gives an overview of the main algorithmic ideas in sensitivity analysis for combinatorial optimization.

Research in sensitivity analysis started shortly after the development of the simplex method [1,2]. Since then, the literature has grown rapidly: as of 1997, over 1000 journal articles had been published on the subject [3]. To keep things manageable, this chapter focuses on *parametric analysis*, which studies problems whose structure remains fixed, but where cost coefficients vary continuously as a function of one or more parameters. The reader interested in more information on topics not covered here has other good sources to turn to. Starting points into the literature include Geoffrion and Nauss' classical survey of the field in the late 1970s [4], the Ph.D. thesis of Wagelmans [5], the collection of articles edited by Gal and Greenberg [3], and Greenberg's bibliography [6].

Parametric analysis is a rich field, whose applications extend beyond the examination of alternative scenarios. In fact, parametric problems arise as auxiliary problems in other areas, such as Lagrangian relaxation and minimum-ratio optimization (see Section 30.2). Parametric analysis should not, however, be confused with the study of *parameterized complexity* [7]. The latter deals with finding efficient algorithms for problems when one of the input parameters is fixed. These parameters are typically discrete (e.g., the maximum size of a vertex cover), and the goal is to obtain the best solution, not to study its stability.

More in the spirit of parametric analysis, but also beyond the scope of this chapter, is the study of *stability of approximation*, which considers how the complexity of a problem depends on a parameter whose variation alters the space of allowable instances (Chapter 31 and Ref. [8]). An example is analyzing how the approximability of the traveling salesman problem varies as intercity distances are allowed to deviate from the triangle inequality as a function of a continuous parameter [9].

This chapter consists of five parts, in addition to this section. Section 30.2 gives basic definitions and notation. Section 30.3 introduces the key issues in sensitivity analysis. Section 30.4 is devoted to general-purpose techniques for sensitivity analysis. Section 30.5 discusses selected results on sensitivity analysis of polynomially solvable problems. Section 30.6 is devoted to sensitivity analysis of NP-hard problems.

30.2 Preliminaries

This chapter deals with combinatorial optimization problems of the form

$$z^* = \min\{\mathrm{cost}(x) : x \in X\} \tag{30.1}$$

where $X \subset \mathbb{R}^n$ is the set of *feasible solutions* and *cost*, referred to as the *cost function* or the *objective function*, maps each feasible solution x to a positive real number. Problem (30.1) is called a 0/1 *problem* when $X \subseteq \{0, 1\}^n$. The cost function is *linear* if $cost(x) = \sum_{i=1}^{n} c_i \cdot x_i$. The cost function is a *bottleneck* (or *min–max*) function when $cost(x) = \max_{1 \leq i \leq n} c_i \cdot x_i$. The c_i's are the *coefficients* of the objective function and $c = (c_1, \ldots, c_n)$ is the *coefficient vector.*

The minimum spanning tree and traveling salesman problems can be formulated as 0/1 problems with linear cost functions. In both cases, the coefficient vector consists of the edge costs and x_i is 1 or 0 depending on whether or not edge i is chosen. Bottleneck versions of both problems can also be defined. For example, in the bottleneck traveling salesman problem, the cost of a tour is determined by its costliest edge. Unless stated otherwise, our discussion will center on optimization problems with linear cost functions.

For any problem of the form (30.1), one can define a corresponding *parametric cost problem* where the cost of each feasible solution depends on a *parameter vector* λ:

$$Z(\lambda) = \min\{cost(x, \lambda) : x \in X\} \tag{30.2}$$

Eq. (30.2) defines an infinite family of optimization problems of the form (30.1), one for each fixed λ. Function $Z(\lambda)$ is called the *optimum cost function.* An *evaluator* for problem (30.2) is an algorithm that, for any given λ, computes $Z(\lambda)$ and an optimum solution at λ.

The optimum cost function Z induces a decomposition $\mathcal{M}(Z)$ of the parameter space into maximal connected regions, such that within each of region A, there exists a feasible solution x that is optimum for every $\lambda \in A$. The *combinatorial complexity* of $\mathcal{M}(Z)$ is the size of the description of $\mathcal{M}(Z)$ as a function of the input size.

Unless stated otherwise, the coefficients of the objective function of the parametric problems considered here are linear in λ; that is, $c_i(\lambda) = c_{i0} + \sum_{j=1}^{d} c_{ij}\lambda_j$ for $i = 1, \ldots, n$. In this case, $Z(\lambda)$ is a piecewise linear concave function of λ (assuming X corresponds to any reasonable combinatorial optimization problem), since it is the lower envelope of the set of cost functions of the feasible solutions. Hence, $\mathcal{M}(Z)$ subdivides the parameter space into convex polyhedral regions; its combinatorial complexity is its total number of facets of dimensions 0 through d.

An important subcase is the one where the parameter vector λ is precisely the coefficient vector c. This occurs, for example, when studying the sensitivity of a minimum spanning tree or of an optimum traveling salesman tour to variations in the edge costs. The special case where $d = 1$ is also of interest. Here the optimum cost function Z consists of a concave sequence of straight-line segments and the points at which these segments meet are called *breakpoints*; the combinatorial complexity of $\mathcal{M}(Z)$ is proportional to the number of breakpoints.

In addition to their applications to sensitivity analysis, parametric problems arise as auxiliary problems in other contexts. Two important cases are discussed next.

Lagrangian relaxation [10,11] is a well-known technique to handle certain kinds of hard optimization problems. Specifically, consider an NP-hard problem of the form

$$z^* = \min\{cx : Ax = b, x \in X\} \tag{30.3}$$

that is polynomially solvable in the absence of constraints $Ax = b$. For instance, the minimum spanning tree problem with degree constraints (known to be NP-hard [12]) can be expressed in the form (30.3): $X$is the set of spanning trees and the degree constraints are given by a system of linear equalities.

The *Lagrangian function* for problem (30.3) is

$$Z_L(\lambda) = \min\{cx + \lambda(Ax - b) : x \in X\} \tag{30.4}$$

Observe that Eq. (30.4) defines a linear parametric problem. For example, the Lagrangian function for the degree-constrained minimum spanning tree yields a minimum spanning tree problem where edge weights are functions of a parameter vector. It can be shown that for all λ, $z^* \geq Z_L(\lambda)$. The best lower bound obtainable from Eq. (30.4) is therefore $\max_\lambda Z_L(\lambda)$. In practice, this can be a quite accurate estimate of the optimum solution to problem (30.3) [13,14].

Minimum-ratio optimization, also known as *fractional programming*, deals with problems of the form

$$z^* = \min\{f(x)/g(x) : x \in X\} \tag{30.5}$$

where $g(x) > 0$ for all $x \in X$. One setting for this question arises in graph problems where each edge has a cost and a profit and the goal is to find a subgraph with a certain property that minimizes the ratio of total cost to total profit. Two examples are the minimum-ratio spanning tree problem [15] and the minimum ratio cycle problem [16].

Define

$$Z_R(\mu) = \min\{f(x) - \mu \cdot g(x) : x \in X\} \tag{30.6}$$

where μ is a scalar parameter. It is well known (see, e.g., Ref. [15]) that $z^* = \max\{\mu : Z_R(\mu) > 0\}$. Observe that $Z_R(\mu)$ is a concave piecewise linear decreasing function of μ. For the weighted graph problems mentioned above, Eq. (30.6) defines a parametric problem where edge costs are decreasing linear functions of μ.

Problems with parametric constraint set are also of interest. An example is the knapsack problem with variable knapsack size, which can be expressed as

$$Z_K(\mu) = \max\left\{\sum_{i=1}^{n} c_i x_i : \sum_{i=1}^{n} s_i x_i \leq b + \mu b', x \in \{0,1\}^n\right\} \tag{30.7}$$

where μ is a scalar parameter.

For reasons of space, problems with parametric constraint set are not treated in much depth here. It should be noted that these problems generally behave quite differently from those with parametric objective function. Indeed, the optimum cost function is typically not continuous, as the reader may verify for function Z_K above. An exception to this rule is linear programming with parametric right-hand side, which, because of duality, has the same behavior as linear programming with parametric objective function (see Section 30.5.1).

30.3 Issues in Sensitivity Analysis

Sensitivity analysis questions can be formulated in different ways. The first important class of problems considered here are collectively referred to as *posterior* analysis problems. Here, an optimum solution $x^{(0)}$ for some parameter vector $\lambda^{(0)} = (\lambda_1^{(0)}, \ldots, \lambda_d^{(0)}) \in \mathbb{R}^d$ is known and the question is to determine the *stability* of $x^{(0)}$ with respect to parameter variation around $\lambda^{(0)}$. Some common notions of stability are defined next.

Definition 30.1

The lower tolerance *and the* upper tolerance *of parameter i at $\lambda^{(0)}$ are the largest values l_i and u_i such that $x^{(0)}$ is optimum for every λ' such that $\lambda'_i \in [\lambda_i^{(0)} - l_i, \lambda_i^{(0)} + u_i]$ and $\lambda'_j = \lambda_j^{(0)}$ for $j \neq i$.*

A related problem is *ray shooting*: Given a ray ρ originating at $\lambda^{(0)}$, the question is to find the point $\lambda^* \in \rho$ farthest from $\lambda^{(0)}$ such that $x^{(0)}$ is optimum for every $\lambda \in \rho$ between $\lambda^{(0)}$ and λ^*. By suitable reparametrization, ray shooting can be expressed as a question of computing tolerances.

Definition 30.2

The stability region *of $x^{(0)}$ at $\lambda^{(0)}$ is the largest connected subset F of $\mathbb{R}^d$ containing $\lambda^{(0)}$ such that $x^{(0)}$ is an optimum solution for all $\lambda \in F$.*

Observe that each region of $\mathcal{M}(Z)$ is a stability region of some feasible solution x. Thus, stability regions are convex polyhedral subsets of the parameter space. In the important special case where the parameter vector is precisely the coefficient vector, the stability regions are polyhedral cones that meet at the origin. This is because all solutions have cost 0 at the origin of the parameter space. Note also that, in the one-parameter case, computing tolerances and stability regions are equivalent problems.

Definition 30.3

The stability radius *of $x^{(0)}$ at $\lambda^{(0)}$ is the radius of the largest ball B such that $x^{(0)}$ is optimum for all $\lambda \in B$.*

The notion of a ball in the definition above depends on the metric used. A common choice is the L_∞ norm, where the distance between parameter vectors λ and λ' is given by $\max_i |\lambda_i - \lambda'_i|$.

The *robustness function* [17] provides an alternative way to measure the effect of multiparameter variation.

Definition 30.4

The robustness function *at $\lambda^{(0)}$, is the function $R : \mathbb{R} \to \mathbb{R}$ given by*

$$R(b) = \max \left\{ Z(\lambda^{(0)} + \delta) : \sum_{i=1}^{d} w_i \cdot \delta_i \leq b, \quad \delta_i \geq 0 \text{ for } i = 1, \ldots, n \right\} \tag{30.8}$$

where $b \geq 0$ is the budget, *$\delta = (\delta_i, \ldots, \delta_d)$ is the* increment vector, *and $w_i \geq 0$ is the unit cost of increasing parameter λ_i, for each $i \in \{1, \ldots, n\}$.*

Intuitively, the robustness function yields the maximum effect that a total weighted increase of the parameters within a given budget can have on the cost of the optimum solution.

The next problems do not depend on advance knowledge of an optimum solution at some parameter value; questions of this kind are traditionally referred to as *prior analysis* problems. The following notion has some relationships with computing tolerances.

Definition 30.5

A most vital variable *in a* 0/1 *combinatorial optimization problem is a variable x_i such that forcing x_i to equal zero increases the value of the optimum solution as much as possible.*

In the context of network optimization problems, such as the minimum spanning tree problem, the shortest path problem, or the traveling salesman problem, identifying most vital variables often translates into finding most vital edges (see Sections 30.5, 30.6, and Chapter 62).

Parametric search encompasses a broad class of problems whose goal is to locate a point λ^* in the parameter space, where the optimum cost function satisfies some specified property. For example, ray shooting is a parametric search problem, although it is not an instance of prior analysis. Lagrangian relaxation and minimum-ratio optimization lead to two basic parametric search problems: *maximization*, that is, locating $\lambda^* = \arg\max_\lambda Z(\lambda)$, and *root finding*, that is, solving $Z(\lambda) = 0$ for λ.

Inverse optimization is another parametric search problem. The input here is a *reference solution* $x^{(0)}$, and the problem is to locate a parameter vector $\lambda^{(0)}$ such that $x^{(0)}$ is optimal, or as close to optimum as possible, at $\lambda^{(0)}$. Examples of inverse parametric minimum spanning tree, shortest path, matching, and other optimal subgraph problems are given in Ref. [18]; applications to biological sequence alignment are discussed in Refs. [19,20].

The *construction problem* is to build a complete representation of $\mathcal{M}(Z)$. This is the most general problem considered here, since almost any sensitivity analysis question can be answered given $\mathcal{M}(Z)$. Clearly, the time required to solve the construction problem depends heavily on the combinatorial complexity of Z.

30.3.1 Stability of Approximate Solutions and Heuristics

Variants of all the issues outlined so far arise when considering approximate solutions or the behavior of heuristic algorithms. These questions are of particular interest when studying NP-hard problems (see Section 30.6).

Analogs to the notions of tolerance, stability radius, and stability region for ϵ-approximate solutions are straightforward to define: simply replace "optimum" by "ϵ-approximate" in Definitions 30.1, 30.2, and 30.3. As observed in Ref. [21], the stability region for an ϵ-approximate solution x has properties similar to those of an ordinary stability region; e.g., it is closed, convex, and polyhedral. Unlike ordinary stability regions, however, the intersection between the stability regions of two different ϵ-approximate solutions, $\epsilon > 0$, can have dimension d. Note also that, for $\epsilon_1 < \epsilon_2$, the region where x is ϵ_1-approximate is contained in the region where x is ϵ_2-approximate [21].

So far, only the stability of *solutions* has been discussed. However, it is also natural to enquire about the sensitivity of an *algorithm* to changes in parameter values (see Section 30.6.3). Suppose A is an algorithm (typically a heuristic) for some optimization problem and let $x^{(0)}$ be the solution returned by A at parameter vector $\lambda^{(0)}$. Then, the *upper tolerance* of parameter i for A at $\lambda^{(0)}$ is the largest value u_i such that $x^{(0)}$ is the solution returned by A for all λ' such that $\lambda'_i \in [\lambda_i^{(0)}, \lambda_i^{(0)} + u_i]$ and $\lambda'_j = \lambda_j^{(0)}$ for all $j \neq i$. Lower tolerances, stability regions, and radii are defined similarly.

30.4 General Techniques

Several general-purpose methods for parametric analysis problems are known, including methods for parametric search, construction of the space decomposition, and determining the combinatorial complexity of low-dimensional problems. These techniques are surveyed next.

30.4.1 Parametric Search

Four methods of parametric search are reviewed here: bisection search, Newton's method, gradient descent, and Megiddo's method. The focus is on one-parameter problems, where the cost of a solution is a linear function of a single scalar parameter μ and the goal is to locate a value μ^* satisfying certain properties.

Newton's method. The classic root-finding method of Newton directly applies to the problem of finding a zero of $Z(\mu)$, when Z is a concave decreasing function of μ: Assume that a parameter value $\mu^{(1)}$ and the optimum solution $x^{(1)}$ at $\mu^{(1)}$ are given. Furthermore, assume that $\mu^{(1)} \leq \mu^*$. To locate μ^*, proceed as follows. Let $\mu^{(2)}$ be the value such that $cost(x^{(1)}, \mu^{(2)}) = 0$. Now compute $v = Z(\mu^{(2)})$ and the optimum solution $x^{(2)}$ at $\mu^{(2)}$. Note that $v \geq 0$. If $v = 0$, stop and return $\mu^* = \mu^{(2)}$. Otherwise, set $\mu^{(1)} = \mu^{(2)}$ and $x^{(1)} = x^{(2)}$ and repeat the process. This procedure generates an increasing sequence of μ values, each of which corresponds to a different feasible solution. Thus, the number of evaluations required by Newton's method is at most equal to the number of breakpoints of Z. This naive bound can be improved substantially in certain applications. In fact, Newton's method yields the fastest-known algorithms for several parametric search problems, including certain minimum-ratio network flow and minimum-cut problems [22,23]. Newton's method can also be applied to other parametric search problems, including finding the maximizer of Z or ray shooting [24].

Bisection search. Suppose that the parametric search problem under consideration has an *oracle*; that is, a procedure that determines whether a given parameter value μ is less than or equal to the parameter value μ^* being sought. Suppose, additionally, that one is given an interval $\mathcal{I}$ known to contain μ^*. Bisection search locates μ^* by repeatedly halving $\mathcal{I}$, taking the left or right half depending on the outcome of an oracle call at the midpoint. The search stops when $\mathcal{I}$ is small enough, according to some criterion.

Oracles can often be constructed from evaluators. For example, consider the one-parameter upper tolerance problem. Let $x^{(0)}$ be the optimum solution at $\mu^{(0)}$, and let u be the upper tolerance at $\mu^{(0)}$. Then, the parameter value being sought is $\mu^* = \mu^{(0)} + u$. The oracle must determine whether a given $\mu \geq \mu^{(0)}$ is less than or equal to μ^*. To test this, first use the evaluator to find an optimum solution $x^{(1)}$ at μ. If $cost(x^{(0)}, \mu) = \text{cost}(x^{(1)}, \mu)$, then $\mu \leq \mu^*$. Otherwise (since $x^{(1)}$ is optimum at μ), the only possibility is that $\text{cost}(x^{(0)}, \mu) < \text{cost}(x^{(1)}, \mu)$, and thus $\mu > \mu^*$.

Bisection search leads to fast algorithms for certain inverse sequence alignment problems with one or two parameters [20].

Megiddo's method. Megiddo's method [25,26] solves parametric search problems by simulating the execution of an evaluator for the underlying fixed-parameter problem to find its computation path at μ^*. This evaluator must be *piecewise linear*; that is, each value it computes must be a linear combination of the input parameters. This condition is not particularly restrictive, as many combinatorial optimization algorithms have this property. For example, most minimum spanning tree, maximum flow, and dynamic programming sequence alignment algorithms are piecewise linear. Like bisection search, Megiddo's method relies on repeated invocations of an oracle to narrow down the search range for μ^*. Indeed, the following result can be proved.

Theorem 30.1

Let $\mathcal{P}$ be a parametric search problem that has an oracle that runs in worst-case time b. Suppose that there exists a piecewise linear algorithm to evaluate $Z(\lambda)$ that executes t steps in the worst case. Then, $\mathcal{P}$ can be solved in time $O(t \cdot b)$. If the evaluator for $Z(\mu)$ is a piecewise linear parallel algorithm that has d parallel steps, using w processors, then $\mathcal{P}$ can be solved in time $O(d \cdot b \cdot \log w + d \cdot w)$.

The second of the above time bounds can be improved by a factor of $\log n$ for some problems [27]. Among these are several parametric search problems related to minimum spanning trees, including finding the maximizer of Z_G and the root of Z_G, when this function is strictly decreasing (as is the case for the minimum-ratio spanning tree problem). All these questions can be answered in $O(T_{MST}(n, m) \log n)$ time, where $T_{MST}(n, m)$ is the time to compute a minimum spanning tree in an n-vertex, m-edge graph. Megiddo's method also yields efficient algorithms for the minimum ratio cycle problem [27]. Theorem 30.1 can be extended to nonlinear problems and to any fixed number of parameters [28–31].

In some cases, such as parametric minimum spanning trees on planar or dense graphs or for certain optimization problems on graphs of bounded tree width, the polylogarithmic slowdown of Megiddo's technique relative to the fixed-parameter problem can be eliminated entirely [32–35]. This yields parametric algorithms that are asymptotically as fast as fixed-parameter evaluators.

Gradient ascent. *Gradient ascent* [14,36] can be used to search for the maximizer λ^* of the optimum cost function $Z(\lambda)$. The method is iterative, generating a sequence of points that converges to λ^*. If the current point $\lambda^{(0)}$ is not minimum, the algorithm chooses the next point by moving some distance (given by some predetermined increment sequence) in the direction of a *subgradient* of $Z(\lambda)$. Informally, a vector $s \in \mathbb{R}^d$ is a subgradient of Z at $\lambda^{(0)} \in \mathbb{R}^d$ if s points in a direction along which Z is nondecreasing; that is, s plays the role a gradient plays for a differentiable function. A subgradient of Z at $\lambda^{(0)}$ can be computed using an evaluator: If $x^{(0)}$ is an optimum solution at $\lambda^{(0)}$, then, the function $cost(x^{(0)}, \lambda)$ has the form $a_0 + \sum_{i=1}^{d} a_i\lambda_i$ and the vector $(a_1, \ldots, a_d)$ is a sub-gradient at $\lambda^{(0)}$. It can be shown that $\lambda^{(0)}$ is a maximizer of Z if the 0 vector is a subgradient at $\lambda^{(0)}$ [14]. In practice this termination condition can be hard to test, since only one subgradient is computed at any point. One way to handle this is by ending the search if the function has not decreased by a certain amount after some number of iterations. Although gradient ascent is fast in practice (indeed, it is widely used in Lagrangian relaxation), it is not in general possible to establish combinatorial bounds on its running time, since the convergence time of the algorithm depends on the choice of the increment sequence [14].

30.4.2 Construction Algorithms

Constructing the space decomposition $\mathcal{M}(Z)$ induced by the optimum cost function Z requires producing all the regions of $\mathcal{M}(Z)$, along with the incidence relationships between regions, and the optimum solution associated with each region. The construction problem can be solved by evaluating Z at various points in the parameter space, producing a sequence of hyperplanes, each of which is the cost function of some optimum solution. Each new hyperplane is used to incrementally update the current estimate of Z. The technique is reminiscent of the methods used to determine the shape of a convex polyhedron through a series of hyperplane probes [37,38] (see also Refs. [39,40]). Indeed, these results can be used to prove the following:

Theorem 30.2

Let d denote the number of parameters, let f and v be, respectively, the number of regions and vertices of $\mathcal{M}(Z)$, and let t be the time needed to evaluate Z. Then, $\mathcal{M}(Z)$ can be constructed in $O(t \cdot (f + dv))$ time, plus the time needed to construct the lower envelope of all the score functions generated during the computation. In particular, for $d = 1$ and 2, $\mathcal{M}(Z)$ can be constructed in time $O(t \cdot f)$ and $O(t \cdot f + f^2)$, respectively.

Lower envelope construction is dual to constructing the upper convex hull of a set of points in $\mathbb{R}^{d+1}$, a problem for which an extensive literature exists [41]. The time needed to construct a lower envelope depends heavily on the complexity of the output produced, as measured by its total number of faces of dimensions 0 through d. By the *Upper Bound Theorem* [42], the complexity of Z is $\Theta(f^{\lfloor (d+1)/2 \rfloor})$, where f is the number of regions. Thus, for $d \geq 3$, the time needed to build the lower envelope can dominate the total computation time.

An alternative method for building $\mathcal{M}(Z)$ is *lifting*, which works by executing the fixed-parameter problem for *all* parameter values simultaneously. Another construction technique relies on ray shooting (see Section 30.3). Applications of these techniques to parametric sequence alignment are given in Refs. [19,43,44].

30.4.3 Combinatorial Complexity Bounds for Small-Dimensional Problems

In some problems, the cost of a feasible solution is the weighted sum of a relatively small number of aggregate *features*. For example, in one common sequence alignment scoring scheme, while the number of feasible solutions (alignments) is exponentially large, the cost of a feasible solution depends only on the total number of matches, mismatches, and indels, each weighted by separate parameters Ref. [43]. In instances of this kind, the theorem below, from Ref. [45], is useful.

Theorem 30.3

Consider an instance of problem (30.2) where the cost of every feasible solution $x \in X$ can be expressed as $cost(x, \lambda) = \sum_{i=1}^{d} \lambda_i \cdot f_i(x)$, where $f_1(x), f_2(x), \ldots, f_d(x)$ are integers, called the features *of x. Suppose that there exist integers $n_1, \ldots, n_d$ such that for every $x \in X$ and each $i \in \{1, \ldots, d\}$, $0 \leq f_i(x) \leq n_1$. Then, $\mathcal{M}(Z)$ has $O\left(\left(\prod_{i=1}^{d} n_i\right)^{(d-1)/(d+1)}\right)$ regions.*

Two examples of the use of Theorem 30.3 are given next; applications to sequence alignment can be found in Ref. [43]. Note that Theorem 30.3 applies to certain NP-hard problems as well—for an example of this, see Ref. [46].

- An instance of the *stable marriage problem* has n men and n women. Each man m assigns a rank $r(m, w) \in [n]$ to every woman w, and each woman w assigns a rank $r(w, m) \in [n]$ to each man m.

A feasible solution is a pairing M of men and women called a *marriage*; M is *stable* if there is no man–woman pair $(m, w) \notin M$ such that m and w prefer each other to their current mate. The cost of M is $\lambda_1 x_M + \lambda_2 y_M$, where $x_M = \sum_{(m,w)\in M} r(m, w)$, $y_M = \sum_{(m,w)\in M} r(w, m)$, and λ_1 and λ_2 weigh the relative preference of men over women in forming M; x_M and y_M are the features of M. The goal is to find the stable marriage of minimum cost [47]. Since x_M and y_M are $O(n^2)$, Theorem 30.3 gives a bound of $O((n^2)^{2(1/3)}) = O(n^{4/3})$ on the number of regions of $\mathcal{M}(Z)$ (see also Ref. [48]).

- The input to the *ancestral reconstruction problem* [49] consists of an n-leaf-rooted binary tree T and a labeling $S_1, \ldots, S_n$ of T's leaves by DNA sequences of length k. A feasible solution (called an *ancestral reconstruction*) is a labeling of the internal nodes of T by DNA sequences of length k. Let $e = (x, y)$ be an edge of T whose endpoints are labeled by sequences X and Y and let $i \in [k]$ be an index for which $X[i] \neq Y[i]$. Then, there is a *transition* at i if either both $X[i]$ and $Y[i]$ are purines (A or G nucleotides) or both are pyrimidines (C or T nucleotides); otherwise, there is a *transversion* at i. The cost of a labeling L is $\lambda_1 v + \lambda_2 t$, where v and t are the total number of transversions and transitions over all the edges of T and all indices i; v and t are the features of L. The goal is to find a labeling of minimum cost. Since $0 \leq v, t \leq 2(n-1)k$, Theorem 30.3 implies that $\mathcal{M}(Z)$ has $O((nk)^{2(1/3)}) = O(n^{2/3}k^{2/3})$ regions.

In combination with Theorem 30.2, Theorem 30.3 allows us to bound the time needed to construct $\mathcal{M}(Z)$. For instance, the time to construct the optimum score function for the maximum parsimony problem is $O(n^{5/3}k^{5/3})$, since the number of regions is $O(n^{2/3}k^{2/3})$ and each evaluation takes $O(kn)$ time [49].

30.5 Sensitivity Analysis for Polynomially Solvable Problems

A number of sensitivity analysis algorithms are known for polynomially solvable problems. In addition to their intrinsic interest, these results are also useful in analyzing the stability of NP-hard problems. Some of this work has already been described in Section 30.4.1. The present section surveys problem-specific approaches, concentrating on linear programming, matroids, shortest paths, and network flows. In what follows, for graph problems, n and m denote the number of vertices and edges of the input graph, respectively.

30.5.1 Linear Programming

Parametric linear programming seems to have the distinction of being the first sensitivity analysis problem to be studied [1]. Consider first the simplest case, where the objective function depends on a single scalar parameter μ:

$$Z_{LP}(\mu) = \min\left\{\sum_{i=1}^{n}(c_i + \mu c_i')x_i : \sum_{i=1}^{n} a_{ij}x_i = b_j,\ \text{for } j \in \{1, \ldots, m\}, x_i \geq 0 \text{ for } i \in \{1, \ldots, n\}\right\} \tag{30.9}$$

If problem (30.9) is feasible, then it must have an optimum basic feasible solution (bfs) [50]. Since the number of such solutions is finite, function Z_{LP} is piecewise linear and concave. Its worst-case number of breakpoints is known to be exponential in n [51]. The upper and lower tolerances for an optimum bfs $x^{(0)}$ at $\mu^{(0)}$ can be computed using the *parametric simplex method* [50]. Parametric linear programming has also been studied from the perspective of interior point methods [52–54].

When the objective function depends on more than one parameter, the optimum cost function is again piecewise linear and concave; however, little is known about the complexity of the associated decomposition, other than that it must be exponential in the number of variables. Methods for multiparameter sensitivity analysis were first discussed in Ref. [55] (see also Refs. [56,57]).

By linear programming duality, all the results obtained for parametric linear programming apply to linear programming problems where the right-hand side of the constraint set is a function of a parameter vector [50].

30.5.2 Parametric Minimum Spanning Trees and Matroids

The minimum spanning tree problem is a special case of *matroid optimization* . A *matroid* [58] is a pair $M = (E, \mathcal{I})$, where E is a finite nonempty set of elements and $\mathcal{I}$ a family of subsets of E, called *independent sets*, satisfying two axioms: (i) any subset of an independent set is independent and (ii) if A and B are independent, with $|A| < |B|$, then there exists some $x \in B$ such that the set $A \cup \{x\}$ is independent. The *rank* of M is the cardinality of its largest independent set. A *base* of a matroid is a maximal independent set. A *weighted matroid* is one whose elements have real-valued weights. The *matroid optimization problem* is to find a minimum-weight base, in a weighted matroid; that is, a base minimizing the sum of the element weights.

The *graphic matroid* of an undirected graph G, denoted as $M(G)$, is a matroid whose elements are the edges of G, whose independent sets are the subforests of G, and whose bases are the spanning forests of G. Thus, when G is connected, a minimum-weight base in $M(G)$ is a minimum spanning tree of G, and the rank of $M(G)$ is $n - 1$. For further examples of matroids see Ref. [58].

Let $Z_M(\mu)$ be the function giving the weight of the optimum base of a matroid M where the weight of each element is a linear function of a scalar parameter μ. Then, $Z_M(\mu)$ has $O(mr^{1/3})$ breakpoints, where m and r are the number of elements and the rank of M, respectively [59]; this bound is tight in general [60]. The upper bound implies that the number of breakpoints for the parametric minimum spanning tree problem is $O(mn^{1/3})$. However, the best known lower bound for this special case is $\Omega(m\alpha(n))$, where α is the inverse Ackermann function [60].

The optimum cost function for the one-parameter minimum spanning tree problem can be constructed in time $O(n^{2/3} \log^{4/3} n)$ per breakpoint or in randomized expected time $O(n^{2/3} \log n)$, per breakpoint [61]. For planar graphs, the time bound can be improved to deterministic $O(n^{1/4} \log^{3/2} n)$ or randomized expected $O(n^{1/4} \log n)$ time per breakpoint. Further results for minor-closed families of graphs are given in Ref. [61]. The latter reference also offers algorithms for the *kinetic* minimum spanning tree problem, which extends the parametric minimum spanning tree problem by allowing arbitrary insertions or deletions of parametrically weighted edges.

All edge tolerances of a minimum spanning tree can be computed in deterministic $O(m \log \alpha(m, n))$ time [62] (see also Ref. [63]), where α is the inverse Ackerman function, and in randomized $O(m)$ time [64]. A deterministic $O(n)$-time algorithm exists for planar graphs [65]. These bounds match the bounds known for solving the minimum spanning tree problem with fixed-edge costs; indeed, it has been shown that any minimum spanning tree algorithm can be used to calculate minimum spanning tree edge tolerances, without an asymptotic loss in efficiency [62].

Algorithms for finding the most vital edges in minimum cost spanning trees can be found in Refs. [66–69] and in Chapter 62.

The robustness function for the minimum spanning tree problem is concave, piecewise linear, with $O(mn)$ breakpoints and can be constructed in $O(m^2 n^3 \log(n^2/m))$ time [17]. More generally, the robustness function of a weighted matroid can be constructed in $O(m^5 n^2 + m^4 n^4 \tau)$ time, where τ is the time needed to test the independence of a set of at most n elements [70].

When the number of parameters is fixed, the inverse parametric minimum spanning tree problem can be solved in randomized linear expected time, and deterministically in $O(m \log^2 n)$ worst-case running time. The inverse problem can be solved in polynomial time by means of the ellipsoid method for linear programming, even when the number of parameters is large [18]. This result extends to shortest path, matching, and other "optimal subgraph" problems.

30.5.3 Shortest Paths and Related Problems

Two kinds of shortest path sensitivity analysis problems have been considered in the literature. The first deals with the sensitivity of the shortest path tree rooted at a specified source vertex s. The edge tolerance problem for this case has been studied by several authors, often alongside the tolerance problem for minimum spanning trees [63,71,72]. Thus, all edge tolerances of a shortest path tree can be computed in deterministic $O(m \log \alpha(m, n))$ time [62]; for planar graphs, the same problem can be solved in $O(n)$ time [65]. Algorithms for the most vital edge problems on shortest path trees on undirected graphs have also been developed in Refs. [73,74] and Chapter 62.

The other kind of problem studies the sensitivity of the shortest path from a source s to a destination t. Ramaswamy et al. [75] have devised algorithms for two related questions. Let P^* be a shortest s–t path in an edge-weighted undirected graph G. Then, there is an $O(m + |P^*| \log |P^*|)$ algorithm for finding all upper and lower tolerances of all edges in G with respect to P^*. Ramaswamy et al. also consider the following max–min problem. Let G be an undirected graph where each edge has a real-valued capacity. The *capacity* of a path is the minimum capacity of an edge on the path. Let Q^* be the maximum capacity s–t path in G. Then, all upper and lower tolerances of the edges with respect to Q^* can be computed in $O(m + |Q^*| \log |Q^*|)$ time. These questions have applications to the pricing of edges in networks [76,77]. Note that, for the shortest path problem, there is a close relationship between computing tolerances and finding most vital edges. For instance, the most vital edge with respect to the shortest s–t path is the edge with the largest upper tolerance. In contrast, the most vital edge problem for minimum cost spanning trees is not directly related to the problem of computing edge tolerances.

Let $Z(\mu)$ be the weight of the shortest s–t path when each edge weight varies linearly as a function of a scalar parameter μ. Gusfield [78] shows that Z has $O(n^{\log n})$ breakpoints. Carstensen [79] provides evidence that this bound is tight.

30.5.4 Parametric Maximum Flow

The *maximum-flow problem* asks to find a source-to-sink flow of maximum value in a capacitated network G. A closely related question is the *minimum-cut problem*, which asks to find a partition (S, T) of the vertex set—that is, a *cut*—in G such that the source is in S and the sink is in T, and such that the total capacity of the edges from S to T is minimized. By the *max-flow min-cut theorem* [80], the value of the maximum flow in G equals that of the minimum cut in G.

In the parametric maximum-flow problem, the capacities are functions of a parameter vector. Not much is known about the properties of the general version of the problem, even for a single parameter; however, the following important special case has received considerable attention. A parametric flow network is *simple* if the capacity of each edge out of the source is a nondecreasing linear function of μ, the capacity of each edge into the sink is a nonincreasing function of μ, and the capacity of every other edge is constant; no arcs between source and sink are allowed. Simple parametric flow networks arise in diverse applications, including scheduling, stable marriage problems, finding maximum density subgraphs, and baseball elimination problems [81,82].

In simple networks the series of minimum cuts $(S_i, T_i), \ldots, (S_r, T_r)$ encountered as μ is increased have a *nesting property*; that is, $S_i \subset S_{i+1}$, for $i = 1, \ldots, r-1$ [39]. Thus, the function $Z_C(\mu)$ giving the capacity of the minimum cut has at most $n-2$ breakpoints. Remarkably, Gallo et al. [81] show that the preflow-push algorithm [83] can be modified to construct $\mathcal{M}(Z_C)$ in $O(nm \log(n^2/m)$ time, the same time as that algorithm takes to compute a *single* maximum flow. They also show how to achieve the same running time for finding the value of μ at which $Z_C(\mu)$ is 0, as required in certain minimum-ratio applications, and for locating a maximizer of $Z_C(\mu)$. Further applications and extensions are given in Ref. [82]; improvements for bipartite flow networks are given in Ref. [84]. Instances with piecewise-linear capacities or where certain arcs not incident on s or t have varying capacities—which have applications to preemptive scheduling with release times and deadlines, where processing times are varied, at a cost—have also been studied [85].

30.6 Sensitivity Analysis of NP-Hard Problems

This section gives an overview of the work on sensitivity analysis for NP-hard problems, primarily with respect to changes in the coefficient vector.

30.6.1 Complexity of Sensitivity Analysis

Unsurprisingly, several results exist indicating that analyzing the sensitivity of NP-hard problems is itself hard. Thus, Hall and Posner [86] have shown that, for a large class of NP-hard scheduling problems, performing sensitivity analysis relative to the processing times is itself NP-hard. Their results (which actually apply to the problem of recomputing the optimum solution after a specific change of parameters) strongly suggest that the computation of tolerances, stability regions, and radii is hard.

van Hoesel and Wagelmans [87] have proved a variety of hardness results for 0/1 problems with linear objective function, including the following:

- If the tolerances can be computed in polynomial time, then (under some mild assumptions) the fixed-parameter version of the problem can be solved in polynomial time as well. Thus, for instance, there is no polynomial-time algorithm for determining the edge tolerances for the traveling salesman problem unless P = NP.
- If it can be checked in polynomial time whether an optimum solution $x^{(0)}$ for a given cost vector $c^{(0)}$ is also optimum for another cost vector $c^{(1)}$, then the upper and lower tolerances at $c^{(0)}$ can be computed in polynomial time. Thus, it is NP-hard to test whether the optimum solution to an NP-hard 0/1 optimization problem remains optimum after arbitrary parameter changes.
- If there is a polynomial-time ϵ-approximate algorithm for computing all the upper tolerances for a 0/1 problem, then there exists a polynomial-time algorithm to compute the upper tolerances exactly. Thus, it is NP-hard to compute the upper tolerances of the optimum solution to an NP-hard 0/1 optimization problem approximately.
- If all upper tolerances for an ϵ-approximate solution $x^{(0)}$ at $c^{(0)}$ can be computed in polynomial time, then the optimum solution at $c^{(0)}$ can be computed in polynomial time. Thus, for instance, the existence of a polynomial algorithm to determine upper tolerances for an ϵ-approximate solution to the minimum-cost knapsack problem, would imply that P = NP.

From the above results, one can conclude that computing stability regions and radii for ϵ-approximate solutions are hard problems in general.

Sotskov et al. [21] establish a relationship between the complexity of computing exact solutions and that of multiparameter sensitivity analysis. Let x be an ϵ-optimal solution and let $\nu(x)$ denote the number of 1's in x. Let $c^{(0)}$ be a coefficient vector and $x^{(0)}$ an ϵ-approximate solution at $c^{(0)}$. Then, if the optimum cost $Z(c)$ can be calculated in $O(g(n))$ time for any coefficient vector $c \in \mathbb{R}^n$, the stability radius of x at $c^{(0)}$ can be computed in $O(2^{\nu(x)}ng(n))$ time. In contrast, Chakravarti and Wagelmans [88] show that the stability radius can be computed in polynomial time for problems with linear objective functions whose fixed-parameter versions can be solved in polynomial time.

While the preceding discussion was limited to problems with linear objective function, it should be noted that several results are known for bottleneck problems. See, for example, Refs. [89–91]; the last of these references surveys the extensive treatment of the subject in the Russian literature.

30.6.1.1 Graphs of Bounded Tree Width

Many NP-complete graph optimization problems are polynomially solvable on graphs of constant-bounded tree width [92–95] (for a definition of tree width, see Refs. [96,97]). Indeed, parametric versions of several of these problems, where edge and/or vertex costs are linear functions of a single scalar parameter μ, are often themselves efficiently solvable [34,98]. This has some implications to the approximate parametric analysis of NP-hard problems, through Baker's [99] technique for obtaining polynomial-time approximation schemes for certain (nonparametric) problems on weighted planar graphs. Among these problems are maximum independent set, maximum tile salvage, partition into triangles, maximum H-matching, minimum vertex cover, minimum dominating set, and minimum edge dominating set.

Baker's approach is based on decomposing the input planar graph into k-*outerplanar* graphs, which are graphs of constant-bounded tree width. Thus, one can use parametric algorithms for bounded-tree width graphs to obtain approximation algorithms for constructing the optimum cost function for all of

Baker's problems. More precisely, let $Z(\mu)$ denote the optimal cost function for one of Baker's problems. Then, for every fixed ϵ, there exists a polynomial-time algorithm that produces a function $Z_\epsilon(\mu)$ that has polynomially many breakpoints and such that for each μ, $Z_\epsilon(\mu)$ is ϵ-approximate to $Z(\mu)$ [34].

30.6.2 Bounding the Stability Region

The notions of *restriction* and *relaxation* can help in obtaining bounds on the stability region. Let $cost_A$ and X_A denote the cost function and set of feasible solutions of a problem A of the form (30.1). Problem Q is a *restriction* of problem P if $X_Q \subseteq X_P$ and $cost_Q(x) \geq cost_P(x)$ for every $x \in X_Q$. Problem R is a *relaxation* of problem P if $X_R \supseteq X_P$ and $cost_R(x) \leq cost_P(x)$ for every $x \in X_P$. Note that restriction and relaxation are inverse relations; that is, R is a relaxation of P if and only if P is a restriction of R. Also, the cost of the optimum solution of any relaxation (restriction) of P is a lower (upper) bound on the cost of the optimum solution for P. These facts lead to the following elementary, but useful, observations [4]:

(GN1) If an optimum solution x^* of P is feasible for a restriction Q of P and $cost_Q(x^*) = cost_P(x^*)$, then x^* is optimum for Q.

(GN2) If $x^{(0)}$ is a feasible solution for P and $cost_P(x^{(0)})$ equals the cost of an optimum solution for some relaxation of P, then $x^{(0)}$ must be optimum for P.

Observation (GN1) allows one to make statements about the sensitivity of an optimum solution x^* to changes in the coefficient vector. For example, x^* remains optimum if c is replaced by any c' such that $c'_j \geq c_j$ for every j such that $x^*_j = 0$ and $c'_j = c_j$ otherwise; that is, each such c_j has infinite upper tolerance. Similarly, for a 0/1 optimization problem, x^* remains optimum if c is replaced by any c' such that $c'_j \leq c_j$ for every j such that $x_j = 1$ and $c'_j = c_j$ otherwise; that is, each such c_j has infinite lower tolerance.

Hall and Posner [86] note that observation (GN1) can be used to study the sensitivity of scheduling problems. As a simple example, an optimal schedule remains optimal if the release date of a job is increased, but not beyond the time when the job starts processing.

Observation (GN2) applies to Lagrangian relaxation (Section 30.2): Suppose that λ^* is the maximizer of the Lagrangian function (Eq. [30.4]), and that x^* is optimum solution for this parametric problem at λ^*. Then, if x^* is also feasible for the original problem (30.3), x^* must be optimum for the latter problem. Thus, one can estimate the stability of x^* in the original (hard) problem, by analyzing the sensitivity of x^* in the relaxed (usually polynomially solvable) problem, relying on results such as those presented in Section 30.5. Along these lines, Libura [100] presents methods for computing lower bounds on the edge tolerances for the traveling salesman problem and the minimum-weight Hamiltonian path problems, which rely on relaxations to minimum spanning tree problems. This allows one to use the results on sensitivity analysis for minimum spanning trees described in Section 30.5.2.

Sotskov et al. [21] study the stability region of ϵ-optimal solutions and prove certain necessary and sufficient conditions to obtain lower and upper bounds on the stability radius. They considered the stability of non-preemptive general shop scheduling with precedence constraints, when the processing times of the jobs are varied and provide conditions for the stability radius to be strictly larger than 0 or for it to be infinite. Unfortunately, verifying these conditions is not easy.

30.6.2.1 *k* Best Solutions and Sensitivity Analysis

Intuitively, the boundaries of the stability region of an optimum $x^{(0)}$ at $\lambda^{(0)}$ are determined by a set of near-optimum solutions at $\lambda^{(0)}$. This observation motivated Libura et al. [101] and van der Poort [102] to study the connections between near optimality and sensitivity analysis for the traveling salesman problem. Unsurprisingly, they show that it is NP-hard to find the smallest k such that the k best solutions at $c^{(0)}$ suffice to determine the stability region of an optimum tour at $c^{(0)}$. Nevertheless, they do obtain some positive results, which are reviewed below.

Suppose one is given a set S containing the k best tours for some edge cost vector $c^{(0)}$; S of course includes an optimal tour, $H^{(0)}$. Let E_1 be the set of edges that are present in $H^{(0)}$, but not in every tour in S. Then, the upper tolerances of the costs of the edges in E_1 can be computed exactly and one can obtain lower bounds on the upper tolerances of the other edges. Similarly, let E_2 be the set of edges present in some tour in S. Then, one can calculate the lower tolerances of the edges present in E_2 and lower bounds on the lower tolerances of the other edges. The authors also show how to derive upper and lower bounds for the stability radius and how to use this information to derive subsets of the stability region. The authors evaluated their results experimentally on instances from TSPLIB [103]. They observe that the number of edges for which the tolerances can be computed increases quickly for smaller values of k, but that the growth rate decreases for larger values of k.

30.6.3 Sensitivity of Heuristics

Analyzing the stability of a heuristic algorithm is conceivably easier than analyzing the stability of an exact or ϵ-approximate solution, since the heuristic need not have any sort of performance guarantee (recall the distinction between algorithm and solution stability, explained at the end of Section 30.3). For example, Ghosh et al. [104] consider the greedy heuristics for binary knapsack and subset-sum problems. They show that the upper and lower tolerances of this algorithm for any parameter (the knapsack capacity, the weights, and the profits of the items) can be computed in polynomial time. They also study the conditions under which the sensitivity analysis of the heuristic generates bounds for the tolerances for the optimal solutions, and the empirical behavior of the greedy output when there is a change in the problem data. Hall and Posner [86] study the behavior of greedy heuristics for two NP-hard problems: scheduling two machines to minimize the weighted completion time and scheduling two machines to minimize the makespan. They provide approaches to obtain bounds on the upper tolerances of each heuristic to changes in the processing times.

Intuitively, since a simple heuristic uses less of the input information than an exact algorithm, it may produce a poor result, but the solution should be less susceptible to parameter changes than the optimal solution. This intuition is supported by the work of Kolen et al. [105] comparing two heuristics for scheduling jobs on identical parallel machines to minimize the makespan: *Shortest Processing Time* (SPT) and *Longest Processing Time* (LPT). The ratios between the solution returned and the optimum are $2 - 1/m$ for SPT, where m is the number of machines and $4/3 - 1/(3m)$ for LPT [106,107].

Suppose the processing time μ of one of the jobs is varied from 0 to ∞. For $H \in \{SPT, LPT\}$, let $Z_H(\mu)$ be the length of the makespan of the schedule returned by H, let $B_H(n, m)$ denote the worst-case number of breakpoints of Z_H, and let $A_H(n, m)$ be the number of different assignments of jobs to machines. The latter two values serve as an indication of sensitivity of H. Kolen et al. show that $Z_H(\mu)$ is a continuous piecewise linear function. They also prove that $A_{SPT}(n, m) \leq n$ and $B_{SPT}(n, m) \leq 2\lceil n/m \rceil$ and that both bounds are tight. In contrast, $A_{LPT}(n, m) \leq 2^{n-m}$ and $B_{LPT}(n, m) \leq 2^{n-m+1}$. The first bound is tight and there exists an example for which $B_{LPT}(n, m) > 2^{(n-m)/2}$. These results support the intuition that the sensitivity of a list scheduling rule increases with the quality of the schedule produced.

31.1 Introduction

The design of approximation algorithms has evolved as one of the most successful approaches for dealing with hard optimization problems. The first approximation algorithms were introduced in the 1960s [1,2]. A short time after introducing NP-hardness (and completeness) as a concept for proving the intractability of computational problems [3,4], a large range of successful approximation algorithms was proposed [5–10]. Since then, a wealth of approximation algorithms for very many practically relevant problems have been developed, as large parts of this handbook stand witness to. Also, overviews on approximation algorithms can be found, for example, in Refs. [11–14] and in Chapter 1 of this handbook.

Approximation algorithms allow us to jump from exponential time complexity (unless P=NP) to polynomial time complexity by a small change in the requirement from searching for the optimal solution to searching for a near-optimal solution. This effect is especially strong in the case of so-called approximation schemes, where one can guarantee to find a solution whose cost can become arbitrarily close to the optimal value (see Chapter 9 for more details).

Another possibility to make intractable problems tractable is to consider only a subset of input instances satisfying some special properties instead of the set of all inputs for which the problem is well defined. A good example is the Traveling Salesman Problem (TSP) which has served from the beginning as an archetype of a hard problem [15,16]. The traveling salesman problem is not only NP-hard, but also the search for an α-approximate solution for TSP is NP-hard for every constant α [6]. But if one considers TSP for inputs satisfying the triangle inequality (the so-called Δ-TSP), one can even design an approximation algorithm [10] with approximation ratio $\alpha = \frac{3}{2}$. The situation is still more interesting, if one considers the Euclidean TSP, where the vertices are points in the Euclidean space and the edge weights correspond to the distances between the vertices in the Euclidean metrics. The Euclidean TSP is strongly NP-hard [17], but for every small $\varepsilon > 0$ one can design a polynomial-time $(1 + \varepsilon)$-approximation algorithm [18–20] (or polynomial-time approximation scheme [PTAS]).

The fascinating observations of huge quantitative changes as mentioned above have lead to the proposal of considering the "stability" of approximation algorithms. Let us consider the following scenario. One has an optimization problem P for two sets of inputs L_1 and L_2, $L_1 \subset L_2$. For L_1 there exists a polynomial-time α-approximation algorithm A, but for L_2 there is no polynomial-time δ-approximation algorithm for any $\delta > 1$ (unless NP=P). We pose the following question: Is the algorithm A really useful for inputs from L_1 only? Let us consider a metrics M in L_2 determining the distance between any two inputs in L_2. Now, one can consider an input $x \in L_2 - L_1$, for which there exists an $y \in L_1$ such that $distance_M(x, y) \leq k$ for some positive real number k. One can look for how "good" the algorithm A is for the input $x \in L_2 - L_1$. If, for every $k > 0$ and every x with distance at most k to L_1, A computes a $\delta_{\alpha,k}$-approximation of an optimal solution for x (where $\delta_{\alpha,k}$ is considered to be a constant depending on k and α only), then one can say that A is "(approximation) stable" according to the metrics M.

The idea of this concept is similar to the concept of stability of numerical algorithms. But instead of observing the size of the change of the output value according to a small change of the input value, we look for the size of the change of the approximation ratio according to a small change in the specification (some parameters, characteristics) of the set of problem instances considered. If the change of the approximation ratio is small for every small change in the specification of the set of problem instances, then we have a stable algorithm. If a small change in the specification of the set of problem instances causes an essential (depending on the size of the input instances) increase of the relative error, then the algorithm is unstable.

The concept of stability enables us to show positive results extending the applicability of known approximation algorithms. As we shall see later, the concept also motivates to modify an unstable algorithm A to get a stable algorithm B that achieves the same approximation ratio on the original set of problem instances as A has, but can also be successfully used outside of this original set. This concept is useful because there are a number of problems for which an additional assumption on the "parameters" of the problem instances leads to an essential decrease of the hardness of the problem. Such effects are the starting points for trying to partition the whole set of problem instances into a spectrum of classes according to their polynomial-time approximability.

As one can observe, this approach is similar to the concept of parameterized complexity, introduced by Downey and Fellows [21,22], in trying to overcome the troubles caused by measuring complexity and approximation ratio in the worst-case manner. The main aim of both concepts is in partitioning the set of all instances of a hard problem into infinitely many classes with respect to the hardness of particular instances. We believe that approaches like these will be the core of future algorithmics, because they provide a deeper insight into the nature of the hardness of specific problems. In many applications we are not interested in the worst-case problem hardness, but in the hardness of forthcoming problem instances.

This chapter is organized as follows. In Section 31.2, we formally define the concept of approximation stability. In Section 31.3, we apply the concept of stability to the TSP and exhibit a partition of the general TSP input instances into infinitely many classes, according to their approximability in dependence of a relaxation of the triangle inequality. In Section 31.4, we then complement the picture by introducing also a partition into infinitely many approximability classes inside the metric TSP. Moreover, lower bounds are exhibited for all these classes, inside as well as outside the metric case. They serve for judging the quality of the obtained algorithms, and they show that one cannot, in principle, expect much better results. Section 31.5 concludes the chapter with a survey of other successful applications of approximation stability and a discussion of the concept.

31.2 Definition of the Stability of Approximation Algorithms

We assume that the reader is familiar with the basic concepts and notions of algorithmics and complexity theory as presented in standard textbooks like in Refs. [13,15,23–25]. Next, we give a formal definition of the notion of an optimization problem, which is an extended version of the standard definition. This extended definition allows us to study the influence of the input sets on the hardness of the problem considered.

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$ be the set of nonnegative integers, and let $\mathbb{R}^+$ be the set of positive reals.

Definition 31.1

An optimization problem *U is a 7-tuple $U = (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, goal)$, where*

(i) Σ_I *is an alphabet called* input alphabet,
(ii) Σ_O *is an alphabet called* output alphabet,
(iii) $L \subseteq \Sigma_I^*$ *is a language over* Σ_I *called the* language of consistent inputs,
(iv) $L_I \subseteq L$ *is a language over* Σ_I *called the* language of actual inputs,
(v) $\mathcal{M}$ *is a function from* L *to* $2^{\Sigma_O^*}$, *where, for every* $x \in L$, $\mathcal{M}(x)$ *is called the* set of feasible solutions *for the input x,*
(vi) cost is a function, called cost function *that, for every pair (u, x), where $u \in \mathcal{M}(x)$ for some $x \in L$, assigns a positive real number $cost(u, x)$,*
(vii) goal $\in \{\min, \max\}$.

For every $x \in L$, we define

$$\boldsymbol{SolOpt_U(x)} = \{y \in \mathcal{M}(x) | cost(y) = goal\{cost(z) | z \in \mathcal{M}(x)\}\}$$

as the set of optimal solutions, and $\boldsymbol{Opt_U(x)} = cost(y)$ *for some* $y \in SolOpt_U(x)$.

Clearly, the meaning for Σ_I, Σ_O, $\mathcal{M}$, *cost*, and *goal* is the usual one. L may be considered as the set of consistent inputs, that is, the inputs for which the optimization problem is consistently defined. L_I is the set of inputs actually considered and only these inputs are taken into account for determining the complexity of the optimization problem U. This kind of definition is useful for considering the complexity of optimization problems parameterized according to their languages of actual inputs.

Definition 31.2

Let $U = (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, goal)$ be an optimization problem. We say that an algorithm A is a consistent algorithm for *U if, for every input $x \in L_I$, A computes an output $A(x) \in \mathcal{M}(x)$. We say that A* solves *U if, for every $x \in L_I$, A computes an output $A(x)$ from $SolOpt_U(x)$. The time complexity of A is defined as the function*

$$Time_A(n) = \max\{Time_A(x) \mid x \in L_I \cap (\Sigma_I)^n\}$$

from $\mathbb{N}$ to $\mathbb{N}$, where $Time_A(x)$ is the length of the computation of A on x.

In this chapter, we deal with the case $Time_A(n) \in O(p(n))$, for some polynomial p, only. That is, we just speak of an approximation algorithm when meaning *polynomial-time approximation algorithm.* Next, we recall the definitions of standard notions in the area of approximation algorithms.

Definition 31.3

Let $U = (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, goal)$ be an optimization problem, and let A be a consistent algorithm for U.

- *For every $x \in L_I$, the approximation ratio $R_A(x)$* of A on x *is defined as*

$$R_A(x) = \max\left\{\frac{cost(A(x))}{Opt_U(x)}, \frac{Opt_U(x)}{cost(A(x))}\right\}.$$

- *For any $n \in \mathbb{N}$, we define the* approximation ratio of A *as*

$$R_A(n) = \max\{R_A(x) \mid x \in L_I \cap (\Sigma_I)^n\}.$$

For any positive real $\delta \geq 1$, we say that A is a δ-approximation algorithm for *U if $R_A(x) \leq \delta$ for every $x \in L_I$.*

- *For every function $f : \mathbb{N} \to \mathbb{R}$, we say that A is an $f(n)$*-approximation algorithm for *U if $R_A(n) \leq f(n)$ for every $n \in \mathbb{N}$.*

To define the notion of stability of approximation algorithms we need to consider something like a distance between a language L and a word outside L.

Definition 31.4

Let $U = (\Sigma_I, \Sigma_O, L, L, \mathcal{M}, cost, goal)$ *and* $\overline{U} = (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, goal)$ *be two optimization problems with* $L_I \subset L$. *A* distance function for U according to L_I *is any function* $h_L : L \to \mathbb{R}^+$ *satisfying the property*

$$h_L(x) = 0 \textit{ for every } x \in L_I$$

We define, for any $r \in \mathbb{R}^+$,

$$Ball_{r,h}(L_I) = \{w \in L \mid h(w) \leq r\}$$

Let A be a consistent algorithm for $\overline{U}$, *and let A be an* ε*-approximation algorithm for U for some* $\varepsilon \in \mathbb{R}^+$. *Let p be a positive real. We say that A is* p-stable according to h *if, for every real* $0 \leq r \leq p$, *there exists a* $\delta_{r,\varepsilon} \in \mathbb{R}^+$ *such that A is an* $\delta_{r,\varepsilon}$*-approximation algorithm for* $U_r = (\Sigma_I, \Sigma_O, L, Ball_{r,h}(L_I), \mathcal{M}, cost, goal)$.[1]

A is stable according to h *if A is p-stable according to h for every* $p \in \mathbb{R}^+$. *We say that A is* unstable according to h *if A is not p-stable for any* $p > 0$.

For every positive integer r, and every function $f_r : \mathbb{N} \to \mathbb{R}^+$ *we say that A is* $(r, f_r(n))$-quasi-stable according to h *if A is an* $f_r(n)$*-approximation algorithm for* $U_r = (\Sigma_I, \Sigma_O, L, Ball_{r,h}(L_I), \mathcal{M}, cost, goal)$.

One may see that the notion of stability can be useful for answering the question how broadly a given approximation algorithm is applicable. If one is interested in negative results, then one can try to show that for any reasonable distance measure the considered algorithm cannot be extended to work for a much larger set of inputs than the original one. In this way one can search for some more exact boundaries between polynomial approximability and polynomial inapproximability.

31.3 Stable Approximation Algorithms for the TSP

To illustrate the concept of approximation stability, we consider the well-known TSP. The TSP in its general form is very hard to approximate, but if one considers complete graphs in which the triangle inequality holds, then we have a 1.5-approximation algorithm due to Christofides [10].

To extend the part of the TSP that can be considered solvable reasonably well, it is therefore a natural idea to look at instances that "violate the triangle inequality not by much." This is formalized by the idea of the parameterized triangle inequality.

Definition 31.5

For fixed $\beta \geq \frac{1}{2}$, *a weighted graph* (G, c), $G = (V, E)$ *obeys the* β*-triangle inequality iff*

$$c(u, w) \leq \beta\,(c(u, v) + c(v, w)) \textit{ for all } u, v, w \in V$$

In case of $\beta > 1$ we speak of the *relaxed triangle inequality,* which is the the case we want to investigate in this section. The case of the *sharpened triangle inequality* is considered in Section 31.4. We call Δ_β-TSP the TSP subcase consisting of all instances obeying the β-triangle inequality (Δ_β-inequality for short).

In terms of stability, we start from Δ-TSP $= (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, \min)$, where we assume $\Sigma_I = \Sigma_O = \{0, 1, \#\}$. L contains codes of all weight functions for edges of complete graphs, and L_I contains codes of weight functions that satisfy the triangle inequality. Let, for every $x \in L$, $G_x = (V_x, E_x, c_x)$ be the complete weighted graph coded by x.

[1] Note that $\delta_{r,\varepsilon}$ is a constant depending on r and ε only.

For every TSP input outside L_I (i.e., not obeying the standard triangle inequality), we obtain a distance from L_I as follows. Let β be minimal such that the given input belongs to Δ_β-TSP, then $\beta - 1$ is the distance from L_I.

Definition 31.6

For every $x \in L$,

$$dist(x) = \max\left\{0, \max\left\{\frac{c_x(\{u, v\})}{c_x(\{u, p\}) + c_x(\{p, v\})} - 1 \,\middle|\, u, v, p \in V_x\right\}\right\}$$

Now let us look at known algorithms for Δ-TSP. We can easily observe that these algorithms work on any TSP-instance, that is, they are consistent for $(\Sigma_I, \Sigma_O, L, L, \mathcal{M}, cost, \min)$. Only the guarantee for the approximation ratio depends on the triangle inequality. It is therefore natural to ask how these algorithms perform on other inputs.

We start with a 2-approximation algorithm that simply converts a doubled minimal spanning tree (MST) into a Hamiltonian path, see, for example, Ref. [16], where also a few equivalent variants are shown.

```
DOUBLE SPANNING TREE ALGORITHM
Input: A complete graph $G = (V, E)$, and a cost function $c : E \to \mathbb{R}^+$.
Step 1: $T :=$ MST of $(G, c)$.
Step 2: $\omega :=$ Eulerian tour in the multigraph obtained from $T$ by doubling each edge.
Step 3: Construct a Hamiltonian tour $H$ of $G$ by shortening $\omega$ (i.e., by removing all repetitions of the
    occurrences of every vertex in $\omega$ in one run via $\omega$ from the left to the right).
Output: $H$.
```

As each Hamiltonian tour after removing any one edge becomes a spanning tree, clearly, an MST is at most as expensive as an optimal TSP solution for the same graph. Consequently, ω costs at most twice as much as an optimal solution.

Though this holds for any TSP instance, the "shortening" in step 3 is reducing or at least not increasing the cost only under the triangle inequality. It is executed by repeatedly replacing a path $x, u_1, \ldots, u_m, y$ by the edge $\{x, y\}$ (because $u_1, \ldots, u_m$ have already occurred before in the prefix of ω). Before further pursuing that thought, let us see how the Christofides algorithm builds on the previous one.

At closer inspection it occurs that the doubling of the spanning tree was needed only to get an Eulerian subgraph. Consequently, in the Christofides algorithm the idea is to add only one edge each to the vertices of odd degree in T to get an Eulerian subgraph as cheap as possible.

```
CHRISTOFIDES ALGORITHM
Input: A complete graph $G = (V, E)$, and a cost function $c : E \to \mathbb{R}^+$.
Step 1: $T :=$ MST of $(G, c)$.
Step 2: $S := \{v \in V \mid deg_T(v)$ is odd$\}$.
Step 3: Compute a minimum-weight perfect matching $M$ on $S$ in $G$.
Step 4: $\omega :=$ Eulerian tour in the multigraph $G' = (V, E(T) \cup M)$.
Step 5: Construct a Hamiltonian tour $H$ of $G$ by shortening $\omega$.
Output: $H$.
```

In addition to the above reasoning for the Double Spanning Tree Algorithm, here we have to convince ourselves that M costs at most half as much as an optimal TSP solution. The reasoning is that by identifying the vertices of S in an optimal solution H_{opt}, we cut the circle H_{opt} at every vertex from S. Assigning the resulting paths segments alternately into two sets and shortening each into single edges, we obtain two matchings M_1, M_2. Obviously, M_1, M_2 each cost as least as much as M.

But from this, $cost(M) \leq \frac{1}{2} cost(H_{opt})$ follows only under triangle inequality since we had to shorten the path segments from H_{opt} into single edges to apply our argument.

We can see how the Christofides algorithm depends on the triangle inequality even more intricately than the Double Spanning Tree Algorithm. Here, the inequality is not only used in a constructive step but also already in the argument to show that the initial component M of the solution is suitable.

When applying these two algorithms to input instances from Δ_β-TSP for $\beta > 1$, one has to expect the approximation ratio to grow at least with β since β factors immediately in the "shortening" of paths. Unfortunately, however, for $\beta > 1$, the approximation ratio becomes dependent on the input size as we will see now.

Lemma 31.1

The Christofides Algorithm is unstable for dist.

More precisely, for every $r \in \mathbb{R}^+$, if the Christofides algorithm is $(r, f_r(n))$-quasi-stable for dist., then

$$f_r(n) \geq n^{\log_2(1+r)}/(2 \cdot (1+r))$$

Remember that the distance r from Δ-TSP of an input x is the minimal $\beta - 1$ such that x is a Δ_β-TSP instance, that is, we may use $\beta = 1 + r$ in the following as a shorthand.

Proof

We construct a weighted complete graph from $Ball_{r,dist}(L_I)$ as follows (Figure 31.1). We start with the path $p_0, p_1, \ldots, p_n$ for $n = 2^k$, $k \in \mathbb{N}$, where every edge $\{p_i, p_{i+1}\}$ has weight 1. Then we add edges $\{p_i, p_{i+2}\}$ for $i = 0, 1, \ldots, n-2$ with weight $2 \cdot \beta$. Generally, for every $m \in \{1, \ldots, \log_2 n\}$, we define $c(\{p_i, p_{i+2^m}\}) = 2^m \cdot \beta^m$ for $i = 0, \ldots, n - 2^m$. For all other edges one can take maximal possible weights in such a way that the constructed input is in $Ball_{r,dist}(L_I)$.

Let us have a look on the work of the Christofides Algorithm on the input (G, c). There is only one MST that corresponds to the path containing all edges of weight 1 (Figure 31.1). Since every path contains exactly two vertices of odd degree, the Eulerian graph constructed in step 4 is the cycle $D = p_0, p_1, p_2, \ldots, p_n, p_0$ with the n edges of weight 1 and the edge of the maximal weight $n \cdot \beta^{\log_2 n} = n^{1+\log_2 \beta}$. Since the Eulerian tour is a Hamiltonian tour (Figure 31.1), the output of the Christofides algorithm is unambiguously the cycle $p_0, p_1, \ldots, p_n, p_0$ with cost $n + n\beta^{\log_2 n}$. The optimal tour for this input is

$$H_{Opt} = p_0, p_2, p_4, \ldots, p_{2i}, p_{2(i+1)}, \ldots, p_n, p_{n-1}, p_{n-3}, \ldots, p_{2i+1}, p_{2i-1}, \ldots, p_3, p_1, p_0$$

This tour contains two edges $\{p_0, p_1\}$ and $\{p_{n-1}, p_n\}$ of weight 1 and all $n - 2$ edges of weight $2 \cdot \beta$. Thus, $cost(H_{Opt}) = 2 + 2 \cdot \beta \cdot (n-2)$ and

$$\frac{cost(D)}{cost(H_{Opt})} = \frac{n + n \cdot \beta^{\log_2 n}}{2 + 2 \cdot \beta \cdot (n-2)} \geq \frac{n^{1+\log_2 \beta}}{2n \cdot \beta} = \frac{n^{\log_2 \beta}}{2\beta} \qquad \square$$

Roughly the same happens for the Double Spanning Tree Algorithm. Only the fact that the choice of the root of the MST is not fixed may allow that algorithm to gain a factor of β at best (if two edges replacing paths of about $n/2$ edges each are used).

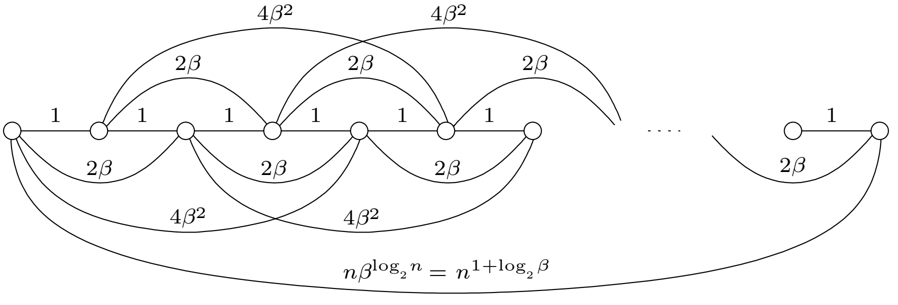

FIGURE 31.1 Unstability of the Christofides algorithm.

One may observe that in this example, the Double Spanning Tree Algorithm can fare much better if, in shortening the Eulerian tour into a Hamiltonian one, a more clever strategy is used. The Eulerian tour is in this case just a double traversal of the path that forms the MST. If on each traversal every other vertex is used, an optimal solution will be obtained. This idea might not work on every MST, but it is the basis for the first Δ_β-TSP algorithm by Andreae and Bandelt discussed below.

Afore, we just note that the above example marks roughly the worst case for both algorithms.

Lemma 31.2

For every positive real number r, the Christofides Algorithm and the Double Spanning Tree Algorithm are $(r, O(n^{\log_2((1+r)^2)}))$-quasi-stable for dist.

Now we turn to the question how to modify those algorithms to get algorithms that are stable according to *dist*.

As we have observed, the main problem is that shortening a path $u_1, u_2, \ldots, u_{m+1}$ to the edge u_1, u_{m+1} can lead to

$$cost(\{u_1, u_{m+1}\}) = \beta^{\lceil \log_2 m \rceil} \cdot cost(u_1, u_2, \ldots, u_{m+1})$$

Obviously, we need to limit by a constant the number of consecutive edges replaced by a single new edge. For a spanning tree being just a path, we have mentioned that it suffices to replace at most two consecutive edges. For a general spanning tree, the following result implies that replacing at most three consecutive edges suffices.

We use, for any graph $G = (V, E)$ and $k \in \mathbb{N}_{\geq 2}$, the notation

$$G^k = (V, \{\{x, y\} \mid x, y \in V, \text{ there is a path } x, P, y \text{ in } T \text{ of a length at most } k\})$$

Theorem 31.1 (Sekanina [26])

For every tree $T = (V, E)$, the graph T^3 contains a Hamiltonian tour H.

This means that every edge $\{u, v\}$ of H has a corresponding unique path $u, P_{u,v}, v$ in T of length at most three. This is a positive development, but it still does not solve our problem completely. The remaining task is that we need to estimate a good upper bound on the cost of the path

$$P(H) = u_1, P_{u_1,u_2}, u_2, P_{u_2,u_3}, u_3, \ldots, u_{n-1} P_{u_{n-1},u_n}, u_n, P_{u_n,u_1}, u_1$$

(in T) that corresponds to the Hamiltonian tour $u_1, u_2, \ldots, u_n, u_1$ in T^3.

The problem is that we do not know the frequency of the occurrences of particular edges of T in $P(H)$. It may happen that the most expensive edges of T occur more frequently in $P(H)$ than the cheap edges. Observe also that $cost(T^3)$ cannot be bounded by $c \cdot cost(T)$ for any constant c independent on T, because T^3 may be even a complete graph for some trees T. Thus, we need the following refinement of the above theorem which is obtained by a slight modification of the original proof.

Lemma 31.3 (Andreae and Bandelt [27])

Let T be a tree with $n \geq 3$ vertices, and let $\{p, q\}$ be an edge of T. Then, T^3 contains a Hamiltonian path $U = v_1, v_2, \ldots, v_n$, $p = v_1$, $v_n = q$, such that every edge of $E(T)$ occurs exactly twice in $P_T(H)$, where $H = U, p$ is a Hamiltonian tour in T^3.

Let us call a Hamiltonian path of the type described in the lemma *admissible*. Then we have the following refinement of the Double Spanning Tree Algorithm, developed by Andreae and Bandelt [27].

```
T^3-ALGORITHM
Input: A complete graph $G = (V, E)$, and a cost function $c : E \to \mathbb{R}^+$.
Step 1: $T :=$ MST of $(G, c)$.
Step 2: Construct an admissible Hamiltonian tour $H$ of $T$.
Output: $H$.
```

Originally, the approximation ratio was estimated to be $\frac{3}{2}\beta^2 + \frac{1}{2}\beta$, but by further refining step 2, Andreae [28] could lower this a bit.

Theorem 31.2 **(Andreae and Bandelt, and Andreae [27,28])**

The refined T^3-algorithm is a $\beta^2 + \beta$-approximation algorithm for Δ_β-TSP, and it runs in time $O(n^2)$ on a graph with n vertices.

Taking into account the fact that T^2 does not always contain a Hamiltonian tour, if one wants to get below the β^2 factor one needs to consider a suitable replacement for a spanning tree as starting point.

This is the approach followed by Bender and Chekuri [29], building on a 2-vertex-connected spanning subgraph (2VCSS) of G.

Theorem 31.3 **(Fleischner [30])**

For every 2-vertex-connected graph S, the graph S^2 contains a Hamiltonian tour H.

As desired, now we need to replace only two consecutive edges by one. However, as opposed to an MST, a minimal spanning 2VCSS of G cannot be computed in polynomial time, unless P=NP. Therefore, one has to use an approximation instead.

Theorem 31.4 **(Penn and Shasha-Krupnik [31])**

There is a polynomial-time 2-approximation algorithm for the minimal 2VCSS problem.

Additionally, as for the T^3-algorithm, the existence of a Hamiltonian tour is not enough. From a constructive version of Fleischner's proof by Lau [32], one can get an 8β-approximation. By refining this such that the resulting Hamiltonian tour uses every edge of S at most twice, one gets the following result. Again, we call such a tour *admissible.*

```
$S^2$-ALGORITHM
Input: A complete graph $G = (V, E)$, and a cost function $c : E \to \mathbb{R}^+$.
Step 1: $S :=$ 2-approximation of a minimal 2VCSS of $(G, c)$.
Step 2: Construct an admissible Hamiltonian tour $H$ of $S$.
Output: $H$.
```

Theorem 31.5 **(Bender and Chekuri [29])**

The S^2-Algorithm is a 4β-approximation algorithm for Δ_β-TSP, and it runs in time $O(n^5)$ on a graph with n vertices.

The impractical running time is clearly a drawback. It comes from computing the 2VCSS. Obviously, any improvement on the 2VCSS approximation would also improve the S^2-algorithm, w.r.t. running time or approximation ratio. However, since the algorithm by Penn and Shasha-Krupnik is already the result on several improvements in smaller and smaller steps, one cannot be too optimistic in that regard. At the current state, the S^2-algorithm surpasses the much faster T^3-algorithm only for $\beta > 3$, at which point the approximation ratio already is 12.

Another downside to both algorithms is that for inputs close to Δ-TSP they cannot get close to the results by the Christofides algorithm. Especially, for instances where only a few edge costs violate the triangle inequality, an algorithm based on the Christofides algorithm should in most cases get close to or reach the 1.5-approximation ratio, where S^2- and T^3-algorithms can only hope to return about a 2-approximation in such cases.

The difficulty, as mentioned before, is that the Christofides algorithm uses a matching as one of its starting points, and the estimate that this does not cost more than half of a Hamiltonian tour fails if the triangle inequality does not hold. Therefore, it was even conjectured in Ref. [27] that the Christofides algorithm cannot be adopted to Δ_β-TSP for $\beta > 1$.

However, there is a way around this by computing a so-called path matching.

Definition 31.7

For a weighted graph (G, c), $G = (V, E)$ and an even set $W \subseteq V$, a path matching *is a set M of paths in G such that each vertex from W is the endpoint of exactly one path from M.*

A path matching of minimal cost can be computed in time $|V|^3$. First, one solves the all-pairs cheapest path problem on (G, c) and let $c'(u, v)$ be the cost of cheapest path between u and v. Then one computes a minimum matching M' for (G, c'), and M is obtained from M' by replacing every edge u, v by the cheapest path from u to v computed previously on (G, c).

It is easy to see that for every TSP instance, independent of the triangle inequality, a minimum path matching costs at most half as much as an optimum TSP solution. This holds because an optimum TSP solution can simply be divided into two path matchings.

Now that this initial problem is solved, one is left with a combination of spanning tree T and path matching M. This is a structure where no result like the ones of Sekanina and Fleischner is known. To construct in the end a Hamiltonian path without replacing more than four consecutive edges by a new one, one needs some detail work additionally. ("PMCA" stands for path matching and the Christofides algorithm-based approach.)

```
ALGORITHM PMCA [33]
Input: A complete graph $G = (V, E)$, and a cost function $c : E \to \mathbb{R}^+$.
Step 1: $T := $ MST of $(G, c)$.
Step 2: $S := \{v \in V \mid deg_T(v)$ is odd$\}$.
Step 3: Compute a minimum-weight path matching $M_1$ on $S$ in $G$.
Step 4: Replace $M_1$ by vertex-disjoint path matching $M_2$.
Step 5: $\omega_1 := $ Eulerian tour in the multigraph $G' = (V, E(T) \cup M_2)$.
Step 6: Modify parts from $T$ in $\omega_1$ such that they form a forest of degree at most 3, obtain $\omega_2$
Step 7: Construct a Hamiltonian tour $H$ of $G$ by shortening $\omega_2$.
Output: $H$.
```

The detail work happens in steps 4, 6, and 7.

While any minimum-weight path matching can easily be shown to be edge-disjoint, for obtaining vertex-disjointness in step 4 a price has to be paid. At vertices used by two paths, one of them has to give way by "bridging" the two edges to and from that vertex, that is, replacing them by a new one. This can be done such that a new edge is never replaced again later. Thus, the costs increase at most by β, that is, $cost(M_2) \leq \beta cost(M_1)$.

Similarly, we look in step 6 at partial paths from ω_1 in T, that is, at those pieces we obtain after dividing ω_1 into parts from T and parts from M_2 alternately. At a vertex of degree ≥ 4 in T, two or more path pieces from ω_1 in T will cross, and we can bridge some of them like in step 4, replacing at most two consecutive edges from T by a new one. Thus, we have

$$cost(\omega_2) \leq cost(M_2) + \beta cost(T) \leq \beta\,(cost(M_1) + cost(T))$$

After this preparation, in ω_2 each vertex will occur not more than twice, and bridging one of the occurrences for each such vertex is performed in step 7 again by replacing at most two consecutive edges from ω_2 by a new one. This gives the resulting estimate, where H_{opt} is an optimal TSP solution.

$$cost(H) \leq \beta cost(\omega_2) \leq \beta^2\,(cost(M_1) + cost(T)) \leq \beta^2 \cdot 1.5 cost(H_{opt})$$

Theorem 31.6 **(Böckenhauer et al. [33])**

The Algorithm PMCA is a $1.5\beta^2$-approximation algorithm for Δ_β-TSP, and it runs in time $O(n^3)$ on a graph with n vertices.

This algorithm has a practical running time, and it gives the best approximation ratio so far for cases $\beta \leq 2$. Note that for $\beta = 2$ the approximation ratio of algorithms PMCA and T^3 is 6 already. Thus algorithm PMCA covers the cases close to the kernel L_I that are in practice the most interesting ones.

Probably, it is the most prominent open question in this area whether this algorithm can be improved to ratio 1.5β, respectively whether another approach can reach that goal. Certainly, one should not hope for anything better in view of the lower bounds discussed in the next section.

Let us finish this section by summarizing what we have seen by studying stability for the TSP, this archetype of a hard problem. It has been very fruitful, starting from known algorithms for a kernel problem, first to identify how they depend on properties of that kernel, and then to look for modifications or similar approaches. There, the crucial point was to transform a dependency of a kernel property into one that holds for each distance from the kernel, albeit with a worse ratio but independent of the input size. One can see that different tools may come into play, modifying the starting point, using general graph properties, or fine-tuning the algorithm's behavior at points where it did not matter for the original kernel problem.

31.4 Lower Bounds and the Situation Inside Δ-TSP

We have seen in the previous section how to use the concept of stability to partition all TSP instances into infinitely many classes according to their approximability, depending on the parameter β of a relaxed β-triangle inequality. Our aim in this section is twofold: We will first exhibit a similar partition into infinitely many classes also for the input instances inside the Δ-TSP, based on the parameter β, and we will show that the concept of stability can also be used to obtain lower bounds on the approximability for all of these classes.

Recall that for a complete edge-weighted graph $G = (V, E, c)$, we say that it satisfies a *sharpened triangle inequality*, if, for all $u, v, w \in V$,

$$c(\{u, v\}) \leq \beta \cdot (c(\{u, w\}) + c(\{w, v\})$$

holds for some $\frac{1}{2} \leq \beta < 1$. Note that $\beta = \frac{1}{2}$ corresponds to the trivial case where all edge weights are equal.

In Ref. [34] it was shown how to estimate the approximation ratio of any approximation algorithm for Δ-TSP on instances of Δ_β-TSP for $\frac{1}{2} < \beta < 1$.

Theorem 31.7 **(Böckenhauer et al. [34])**

Let A be an approximation algorithm for Δ-TSP with approximation ratio α, and let $\frac{1}{2} < \beta < 1$.

Then A can be used as an approximation algorithm for Δ_β-TSP with approximation ratio $\frac{\alpha \cdot \beta^2}{\beta^2 + (\alpha - 1) \cdot (1 - \beta)^2}$.

The proof of Theorem 31.7 is based on the following idea: For any input instance for the Δ_β-TSP, we can subtract a certain amount (depending on β and the value of the minimum edge weight) from all edge weights such that the resulting TSP instance still satisfies the triangle inequality. Furthermore, the optimal Hamiltonian tours for both instances coincide. Using the observation that, in a weighted graph obeying a sharpened β-triangle inequality, the maximum edge weight is bounded from above by $\frac{2\beta^2}{1-\beta}$ times the minimum edge weight, we can then estimate the length of a Hamiltonian tour as computed by algorithm A as stated in Theorem 31.7.

Note that the approximation ratio guaranteed by Theorem 31.7 tends to 1 for β tending to $\frac{1}{2}$, and it tends to α for β tending to 1. Applied to the Christofides algorithm, we obtain an approximation ratio of $1 + \frac{2\beta - 1}{3\beta^2 - 2\beta + 1}$.

For $\frac{1}{2} \leq \beta < \frac{2}{3}$, this result can be improved by a specific algorithm, called Cycle Cover Algorithm, which we will explain below.

Theorem 31.8 **(Böckenhauer et al. [34])**

For $\frac{1}{2} \leq \beta < 1$, the Cycle Cover Algorithm is a $(\frac{2}{3} + \frac{1}{3} \cdot \frac{\beta}{1-\beta})$-approximation algorithm for Δ_β-TSP.

This algorithm is based on the idea of first computing a minimum cycle cover of the given graph, this can be done in polynomial time [35]. Then the cycles are joined together to form a Hamiltonian tour by removing the cheapest edge from every cycle and replacing it by an edge to the next cycle. One can easily observe that, in a graph satisfying a sharpened β-triangle inequality, for any two adjacent edges the costs differ by a factor of at most $\frac{\beta}{1-\beta}$. Since every cycle of the cover has at least three edges, this possible growth of the costs affects at most one third of the total cost of the cycle cover, which gives the claimed approximation ratio.

We have seen so far that we can partition the set of TSP input instances into infinitely many classes according to their approximability. We have used the relaxed and sharpened triangle inequality to define these classes. In the following we will show that it is also possible to give an explicit lower bound on the approximability of the TSP for each of these classes, for any $\beta > \frac{1}{2}$. These lower bounds imply that, unless P $=$ NP, one can expect to obtain only gradually better results, not principally better ones. Specifically, as we will see, no polynomial-time approximation scheme can exist for Δ_β-TSP for $\beta > \frac{1}{2}$, even when getting arbitrarily close to the trivial case of $\beta = \frac{1}{2}$. Also, for growing β, we will see the necessity for the approximation ratio of any polynomial-time algorithm to grow at least linearly with β.

The first in-approximability proof for the metric TSP, that is, for $\beta = 1$, goes back to Papadimitriou and Yannakakis [36], who proved that even TSP restricted to edge weights from the set {1, 2} does not admit a PTAS.

The first explicit lower bound on the approximability of the metric TSP was given by Engebretsen [37], who proved that it is NP-hard to approximate the Δ-TSP within a factor of $\frac{5381}{5380} - \varepsilon$ for any small $\varepsilon > 0$, even in the case where all edge weights are from {1, 2}.

This result was not only improved for the metric case, but also extended to the cases of a relaxed or sharpened triangle inequality by Böckenhauer and Seibert [38], who proved the following theorem.

Theorem 31.9 **(Böckenhauer and Seibert [38])**

Unless P≠NP, there is no polynomial-time α-approximation algorithm, if

$$\alpha < \begin{cases} \dfrac{7611 + 10\beta^2 + 5\beta}{7612 + 8\beta^2 + 4\beta} & \textit{for the case } \dfrac{1}{2} < \beta \leq 1 \\ \dfrac{3803 + 10\beta}{3804 + 8\beta} & \textit{for the case } \beta \geq 1 \end{cases}$$

For the metric TSP, that is, for $\beta = 1$, this leads to a lower bound of $\frac{3813}{3812}$. The currently best known lower bound of $\frac{220}{219}$ for the metric TSP is due to Papadimitriou and Vempala [39]. However, since in Ref. [39] edge weight 0 was used, this result cannot be adapted to Δ_β-TSP for $\beta < 1$.

The proof of Theorem 31.9 is based on a gap-preserving reduction from the LinEq2-2(3) problem.[2] LinEq2-2(3) is the following problem: Given a system of linear equations modulo 2 with exactly two variables in each equation, and with exactly three occurrences of each variable, find the maximum number of equations that can be simultaneously satisfied. This problem was proven to be not approximable in polynomial time within $\frac{332}{331} - \varepsilon$ for an arbitrarily small $\varepsilon > 0$ by Berman and Karpinski [41].

The idea of the reduction is based on building so-called gadgets. For each equation and for each variable a small graph is built, and all these graphs are put together into a large graph that serves as the input for the TSP. In this construction, only three different edge weights are used, such that, for each nonsatisfied equation in an optimal variable assignment, the optimal Hamiltonian tour through the constructed graph has to pass through one edge of highest cost. All other edges of an optimal tour are shown to be of lowest cost.

Theorem 31.9 is most interesting for the case $\beta < 1$. It shows the strong result that the TSP with sharpened triangle inequality does not admit a PTAS even if β comes arbitrarily close to the trivial case $\frac{1}{2}$.

For the case of a relaxed triangle inequality, the result from Theorem 31.9 tends to $\frac{5}{4}$ for β tending to infinity. Bender and Chekuri [29] extended the result from Ref. [36] to the case of the relaxed triangle

[2] For an introduction into the theory of gap-preserving reductions see Chapters 15 and 17 or, for a broader treatment, see Ref. [40].

inequality and showed a lower bound of $1 + \varepsilon\beta$ for some very small ε, not given explicitly in the proof. This result shows that the approximation ratio of any polynomial-time algorithm for the Δ_β-TSP has to grow at least linearly with β.

31.5 Discussion and Related Work

In the previous sections we have introduced the concept of stability of approximation. Here we discuss the potential applicability and usefulness of this concept.

Using this concept, one can establish positive results of the following types:

(1) An approximation algorithm or a PTAS can be successfully used for a larger set of inputs than the set usually considered.
(2) We are not able to successfully apply a given approximation algorithm A (a PTAS) for additional inputs, but we can simply modify A to get a new approximation algorithm (a new PTAS) working for a larger set of inputs than the original set of inputs of A.
(3) To learn that an approximation algorithm is unstable for a distance measure could lead to the development of completely new approximation algorithms that would be stable according to the considered distance measure.

The following types of negative results may be achieved:

(1) The fact that an approximation algorithm is unstable according to all "reasonable" distance measures and so that its use is really restricted to the original input set.
(2) Let $Q = (\Sigma_I, \Sigma_O, L, L_I, \mathcal{M}, cost, goal) \in NPO$ be well approximable. If, for a distance measure D and a constant r, one proves the nonexistence of any polynomial-time approximation algorithm for $Q_{r,D} = (\Sigma_I, \Sigma_O, L, Ball_{r,D}(L_I), \mathcal{M}, cost, goal)$, then this means that the problem Q is "unstable" according to D.

Thus, using the notion of stability one can search for a spectrum of the hardness of a problem according to the set of inputs. For instance, considering a hard problem such as the TSP or the Clique problem, one could get an infinite sequence of input languages $L_0, L_1, L_2, \ldots$ given by some distance measure, where $R_r(n)$ is the best achievable approximation ratio for the language L_r. Results of this kind can essentially contribute to the study of the nature of hardness of specific problems.

In case of the TSP with relaxed triangle inequality, this approach has been followed successfully as seen in the preceding sections. A variety of new and adapted algorithms has been developed after the known ones have proven to be unstable. All in all, an approximation ratio of $\min\{\beta^2 + \beta, \frac{3}{2}\beta^2, 4\beta\}$ has been reached so far, and the proven lower bounds show the β-dependency to be invariable.

Further applications of these ideas for different versions of the Hamiltonian path problem were developed by Forlizzi et al. in Ref. [42], where a few stable algorithms with respect to relaxed triangle inequality were designed.

Also we have seen how these studies gave rise to looking into subcases inside the metric one. Though not a direct application of the stability concept, the treatment here was inspired by the stability approach, and it has proven successful, too. The combined approximation ratio in this case was $\min\{\frac{2}{3} + \frac{1}{3} \cdot \frac{\beta}{1-\beta}, 1 + \frac{2\beta-1}{3\beta^2-2\beta+1}\}$.

Moreover, Chandran and Ram [43], and then Bläser [44], succeeded in transferring this approach to the asymmetric TSP. Remember that no constant-factor approximation algorithm for the metric case is known, so the combined approximation factor of $\min\{\frac{\beta}{1-\beta}, \frac{1}{1-\frac{1}{2}(\beta+\beta^2)}\}$ is quite an achievement in the asymmetrical case.

The subproblems with sharpened triangle inequality were also successfully attacked for a variety of minimum connected spanning subgraph problems in Refs. [45,46]. Since these problems allow constant approximation algorithms in their general case, a treatment analogous to the TSP could not be expected.

However, the approach guided by the parameterized triangle inequality led to the development of a few new simple and fast algorithms that improve the best known approximation ratio at least for a part of the sharpened triangle inequality case.

All in all, we have seen that the stability of approximation approach leads to rethinking known algorithms and developing new ones. The common goal is to provide a variety of algorithms for the whole range of a problem that deliver approximation ratios depending not on the input size but on a suitable parameter indicating the hardness of each input instance.

Performance Guarantees for One-Dimensional Bin Packing

Edward G. Coffman, Jr.

32.1 Introduction

Let $a_1, \ldots, a_n$ be a given collection of *items* with *sizes* $s(a_i) > 0,\ 1 \leq i \leq n$. In mathematical terms, *bin packing* is a problem of partitioning the set $\{a_i\}$ under a sum constraint: Divide $\{a_i\}$ into a minimum number of blocks, called *bins*, such that the sum of the sizes of the items in each bin is at most a given *capacity* $C > 0$. To avoid trivialities, it is assumed that all item sizes fall in $(0, C]$. Research into bin packing and its many variants, which began some 35 years ago [1,2], continues to be driven by a countless variety of applications in the engineering and information sciences. The following examples give an idea of the scope of the applications:

- (Stock cutting) Lumber with a fixed cross section comes in a standard board C units in length. The items are demands for pieces that must be cut from such boards. The objective is to minimize the number of boards (bins) used for the pieces $\{a_i\}$, or equivalently, to minimize the *trim loss* or waste (the total board length used minus the sum of the $s(a_i)$). It is easy to see that this type of application extends to industries that supply cable, tubing, cord, tape, and so on from standard lengths.
- (Television programming) Fixed duration time slots are provided between segments of entertainment programs for the use of commercials. The objective is to minimize the number of time slots (bins) that need to be devoted to a given collection of variable length commercials $\{a_i\}$.
- (Transportation) The a_i are items to be loaded onto a collection of identical transports (e.g., trucks, railway cars, and airplanes) with given weight and volume limits. The objective is to minimize the number of transports (bins) needed; if only the weight limit is operative then the $s(a_i)$ denote weights, and if only the volume limit is operative then the $s(a_i)$ represent volumes.
- (Computer storage allocation) In this application, the items are files to be stored on a set of identical disks with the constraint that each file must be stored entirely on one disk; and the objective is to minimize the number of disks (bins) needed for the set of files.

In the above applications, bin packing has been presented as the *primary* combinatorial problem. In many applications, it is a secondary problem or an embedded special case. For example, capacitated vehicle routing is a classic problem in which bin packing is embedded.

Bin packing is an NP-hard problem, so a large majority of the research on bin packing focuses on the design and analysis of approximation algorithms. Apart from applications, bin packing has acquired an added, more general importance in the development of complexity theory and algorithms. It was one of a relatively few "test" problems, such as satisfiability and chromatic index, in which reducibility arguments were most often formulated in NP-completeness proofs. Bin packing has also served as a testbed for advances in algorithmics such as approximation schemes and average-case analysis.

We normalize the problem by dividing all item sizes by C and letting the bin capacity be 1. Let $A(L)$ denote the number of bins needed by algorithm A to pack the items of L. The symbol *OPT* stands for an optimal algorithm. Define V_α as the set of all lists of items with sizes no larger than α and consider, for given k and α, the upper bound

$$R_A(k, \alpha) := \sup\left\{ \frac{A(L)}{k} : L \in V_\alpha \text{ and } \mathrm{OPT}(L) = k \right\}$$

The limit $k \to \infty$ of this bound is the *asymptotic worst-case ratio* for algorithm A:

$$R_A^\infty(\alpha) := \limsup_{k \to \infty} R_A(k, \alpha)$$

A less formal, but more instructive, definition states that $R_A^\infty(\alpha)$ is the smallest constant such that there exists a constant $K < \infty$ for which

$$A(L) \le R_A^\infty(\alpha) \cdot \mathrm{OPT}(L) + K$$

for every list $L \in V_\alpha$; the asymptotic ratio, a multiplicative constant, hides the additive constant K. This ratio is of most interest in those applications where K is small relative to $A(L)$.

The effect of the additive constant is preserved in the *absolute worst-case ratio* for algorithm A:

$$R_A(\alpha) = \sup_{L \in V_\alpha} \left\{ \frac{A(L)}{\mathrm{OPT}(L)} \right\} \tag{32.1}$$

An algorithm A is either *online* or *offline*. If online, A assigns items to bins in the order they are given in the original list, without using any knowledge about subsequent items in the list. If offline, the entire list is available to A as it computes the packing.

Online algorithms may be the only ones that can be used in certain situations, where the items arrive in sequence according to some physical process and must be assigned to a bin at arrival time. In many cases an algorithm is offline only in that it performs an initial ordering of the items before applying an online rule. An algorithm is *bounded-space* if the bins available for packing (called "open" bins) are limited in number.

32.2 Online Algorithms

Let $B_1, B_2, \ldots$ denote the sequence of initially empty bins. The NEXT FIT (NF) algorithm was one of the first, and simplest, approximation algorithms to be analyzed: NF begins by packing $a_1, a_2, \ldots$ into B_1 until an item, say a_i, is encountered that does not fit, that is, $a_i > 1 - \sum_{1 \le j < i} a_j$. Item a_i is packed in B_2 and B_1 is *closed*, that is, no further items are packed in B_1. Bin B_2 becomes the new *open* bin and, like B_1, is packed with items until one that does not fit is encountered, whereupon B_2 is closed; this bin-by-bin process repeats until all items are packed. NEXT FIT is obviously linear-time; it is also bounded-space, since the number of open bins never exceeds 1.

Johnson's [2,3] parametric analysis of NF showed that

$$R^{\infty}_{NF}(\alpha) = \begin{cases} 2 & \text{if } \frac{1}{2} \le \alpha \le 1 \\ \frac{1}{1-\alpha} & \text{if } \alpha < \frac{1}{2} \end{cases}$$

As observed by Fisher [4], NF uses the same number of bins for the reverse of $L(a_n, a_{n-1}, \ldots, a_1)$, as it does for L, for every L.

An obvious drawback of NF is that it cannot make use of the empty space in closed bins. When packing a new item, the FIRST FIT (FF) algorithm tries to exploit this empty space by scanning all bins each time an item is packed; thus, bins are never closed. When packing a new item, FF puts it into the lowest indexed bin in which it fits; a new bin is started only if the current item does not fit into any nonempty bin. With an appropriate data structure, the running time of FF is $O(n \log n)$ and thus greater than the $O(n)$ running time of NF. However, FF has a much better asymptotic ratio. Johnson et al. [5] proved that, if m is a positive integer such that $1/(m+1) < \alpha \le 1/m$, then

$$R^{\infty}_{FF}(\alpha) = \begin{cases} \frac{17}{10} & \text{if } m = 1 \\ \frac{m+1}{m} & \text{if } m \ge 2 \end{cases}$$

A worst-case list proving that the 17/10 ratio cannot be improved is quite complicated. Much simpler lists showing behavior nearly as bad, in particular a 5/3 ratio, are

$$L_{6k} = \Bigg(\underbrace{\frac{1}{6} - 2\varepsilon, \ldots, \frac{1}{6} - 2\varepsilon,}_{6k} \underbrace{\frac{1}{3} + \varepsilon, \ldots, \frac{1}{3} + \varepsilon,}_{6k} \underbrace{\frac{1}{2} + \varepsilon, \ldots, \frac{1}{2} + \varepsilon}_{6k} \Bigg)$$

Then $\mathrm{OPT}(L_{6k}) = 6k$, $FF(L_{6k}) = 10k$, and the 5/3 ratio follows.

Other classical online algorithms are BEST FIT (BF), WORST FIT (WF), and ALMOST WORST FIT (AWF). BEST FIT behaves like FF, except that it puts the next item into the bin in which it fits with the smallest gap left over; ties are broken arbitrarily. WORST FIT puts the next item into a nonempty bin with the largest gap, starting a new bin only if this largest gap is too small. ALMOST WORST FIT first tries to put the next item into a nonempty bin with the second largest gap; if the item does not fit there then AWF behaves like WF. All three variants belong to the class of so-called ANY FIT (AF) algorithms: An AF algorithm scans once through the list L packing items as they are encountered. It never puts an item into an empty bin, unless it does not fit into any available partially filled bin. Similarly, an ALMOST ANY FIT (AAF) algorithm is an AF algorithm that never puts an item into a partially filled bin with the lowest level unless there is more than one bin having this level, or unless the bin of lowest level is the only one that has enough room. Johnson [3] proved that, although the class of AF algorithms is clearly large, no algorithm in this class can improve upon FF. Moreover, all AAF algorithms have the same asymptotic ratio as FF; these statements hold even for the parametric ratios. One simple consequence is that the AAF algorithms BF and AWF have asymptotic ratios 17/10. However the asymptotic ratio of the AF algorithm WF is 2, the same as that for NF.

32.2.1 Bounded-Space Online Algorithms

An online bin packing algorithm is said to use *k-bounded-space* if, for each new item, the number of bins in which it may be packed is at most k. NEXT FIT uses 1-bounded-space, whereas FF, WF, and AWF each use unbounded space. There are four very natural bounded-space bin packing algorithms that are defined via simple *packing* rules for items and simple *closing* rules for bins: A new item can always be packed into the lowest indexed bin (as in FF) or into the bin with the smallest remaining gap (as in BF). If the new item does not fit into any active bin, some active bin has to be closed; in this case one can always choose the lowest indexed bin (the FIRST bin) or the bin with the greatest sum of item sizes (the BEST bin). The corresponding four algorithms are called AFF_k, AFB_k, ABB_k, and ABF_k. Here A stands for algorithm, the second letter denotes the packing rule (best fit or first fit), the third letter denotes the closing rule (best bin or first bin), and k is the upper bound on the number of active bins. Results are as follows:

- *Algorithm AFF$_k$*. This algorithm was termed NEXT-k FIT by Johnson [3]. Provably tight bounds were not in hand until almost 20 years later. Csirik and Imreh [6] constructed a sequence of worst-case examples which show that $R^{\infty}_{AFF_k} \geq \frac{17}{10} + \frac{3}{10(k-1)}$, and Mao [7] proved a matching upper bound on $R^{\infty}_{AFF_k}$.
- *Algorithm ABF$_k$*. Mao [8] proved that $R^{\infty}_{ABF_k} = \frac{17}{10} + \frac{3}{10k}$.
- *Algorithm AFB$_k$*. Zhang [9] adapted the analysis of Mao [8] to this algorithm and proved that $R^{\infty}_{AFB_k} = \frac{17}{10} + \frac{3}{10(k-1)}$, that is, this algorithm has the same ratio as AFF$_k$.
- *Algorithm ABB$_k$*. This algorithm was investigated by Csirik and Johnson [10,11]. Compared with the other three algorithms, ABB$_k$ uses the best packing and closing rules and it has the best asymptotic ratio; $R^{\infty}_{ABB_k} = \frac{17}{10}$ holds for any $k \geq 2$.

So, except for small k, the asymptotic ratios of all four algorithms are around 17/10; since they are of the AF type, they of course cannot outperform FF.

Lee and Lee [12] introduced a new class of bounded-space algorithms using bin reservation techniques. Their algorithm HARMONIC$_k$ (H_k) is based on a partition of the interval (0, 1] into k subintervals, where the partitioning points are $1/2, 1/3, \ldots, 1/k$. To each of these subintervals there corresponds a different active bin; items belonging to a given subinterval are packed only into the corresponding active bin. If a new item arrives that does not fit into its corresponding active bin, the bin is closed and a new bin is activated. Thus, the packing in bins containing items with sizes in one of the subintervals is a NF packing. Note that H_k is not an AF algorithm because it may close a bin even when the next item could be packed in one of the active bins (belonging to a different subinterval). In Ref. [12] it was proved that

$$R^{\infty}_{H_k} \to h_{\infty} \approx 1.69103$$

This number occurs frequently in bin packing and is defined by

$$h_{\infty} = \sum_{i=1}^{\infty} \frac{1}{t_i - 1}$$

where

$$t_{i+1} = t_i(t_i - 1) + 1, \quad i \geq 1, \quad t_1 = 2 \tag{32.2}$$

Tight bounds for $R^{\infty}_{H_k}$ are not known for every value of k, so Table 32.1 gives the best upper and lower bounds currently known. The upper bounds for every value of k except 4 and 5 are from Ref. [12]. Tight upper bounds for $k \in \{4, 5\}$ are due to van Vliet, as are the lower bounds for $k \geq 4$ [13,14].

Woeginger [15] introduced the SIMPLIFIED HARMONIC (SH$_k$) algorithm, a modification of HARMONIC with a different interval structure (basically using the sequence t_i) and with a slightly better

TABLE 32.1 Asymptotic Ratios for Bounded-Space Bin Packing Algorithms, Rounded to Five Decimal Places

k	AFF$_k$	ABF$_k$	ABB$_k$	H$_k$ $\geq$	H$_k$ $\leq$	SH$_k$	Champion
2	2.00000	1.85000	1.70000	2.00000	2.00000	2.00000	ABB
3	1.85000	1.80000	1.70000	1.75000	1.75000	1.75000	ABB
4	1.80000	1.77500	1.70000	1.71429	1.71429	1.72222	ABB
5	1.77500	1.76000	1.70000	1.70000	1.70000	1.70000	ABB, H, SH
6	1.76000	1.75000	1.70000	1.70000	1.70000	1.69444	SH
7	1.75000	1.74286	1.70000	1.69444	1.69444	1.69388	SH
8	1.74286	1.73750	1.70000	1.69377	1.69388	1.69106	SH
9	1.73750	1.73333	1.70000	1.69326	1.69345	1.69104	SH
∞	1.70000	1.70000	1.70000	1.69103	1.69103	1.69103	H, SH

asymptotic ratio for small values of k. He proved that SH_k only needs $O(\log k)$ open bins to achieve the performance ratio H_k.

A summary of the asymptotic ratios of the bounded-space algorithms for some small values of k is given in Table 32.1. The asymptotic ratios of all five algorithms always remain above h_∞. In fact, Lee and Lee [12] showed that a bounded-space algorithm cannot have an asymptotic ratio better than h_∞. However, at present no online bounded-space algorithm A is known for which $R_A^\infty = h_\infty$.

Csirik and Woeginger [16] compared online bounded-space algorithms that pack into bins of size $b \geq 1$, with optimal offline algorithms that pack into bins of size 1. In a decreasing scan, choose reciprocals iteratively so long as those chosen sum to no more than $1/b$. If $1/b_i$ is the ith one chosen then $1/b = \sum_{i\geq 1} 1/b_i$, with $b_1 > b_2 > b_3 > \cdots$. The authors showed that, for every bin size $b \geq 1$, there exist online bounded-space algorithms packing into bins of size b which have a worst-case performance arbitrarily close to

$$\rho(b) := \sum_{i=1}^{\infty} \frac{1}{b_i - 1}$$

They also showed that for every $b \geq 1$, the bound cannot be beaten by any online bounded-space bin packing algorithm.

32.2.2 Better Online Algorithms

The first online algorithm for bin packing with $R_A^\infty < h_\infty$ was Yao's [17] REVISED FF (RFF). Both the definition and analysis of RFF are fairly involved. It is essentially based on FIRST FIT, but like H_k it uses separate bins for items from the intervals (0, 1/3], (1/3, 2/5], (2/5, 1/2], and (1/2, 1], respectively. Moreover, every sixth item from the interval (1/3, 2/5] is treated differently, the idea being to occasionally start a new bin with an item of this size in the hope of subsequently adding an item of size greater than 1/2 to that bin. Yao showed that

$$R_{RFF}^\infty = \frac{5}{3}$$

All other known online algorithms that beat the h_∞ bound are variants of HARMONIC that give special treatment to items $\geq 1/3$. Lee and Lee [12] described the REFINED HARMONIC (RH_K) algorithm, which was based on H_{20}. It uses the partitioning scheme of H_{20}, with the modification that the two size intervals (1/3, 1/2] and (1/2, 1] are replaced by the four intervals $(1/3, y]$, $(y, 1/2]$, $(1/2, 1-y]$, and $(1-y, 1]$, where $y = 37/96$. Packing proceeds as in a HARMONIC algorithm, except one now attempts to pair items whose sizes are in the first of the new intervals with items whose sizes are in the third interval, since such pairs can always fit in the same bin. Every seventh item with sizes in the first interval is handled differently. Lee and Lee proved that

$$R_{RH_{20}}^\infty \leq 373/228 = 1.6359\ldots$$

Ramanan et al. [18] introduced the MODIFIED HARMONIC (MH) algorithms, which added the possibility of packing still smaller items together with items having sizes in $(1/2, 1/2 + y]$, and consequently created a more complicated algorithmic structure (as well as a different value for y – in this case $y = 265/684$). For this first variant they showed that

$$1.6156146 < R_{MH_{38}}^\infty \leq 1.615615\ldots$$

and gave a general lower bound of 1.6111... for this type of algorithm. They introduced a second variant of MF (MF-2), which divides (1/3, 1/2] and (1/2, 1] into more than two parts. MF-2 has an asymptotic ratio < 1.61217 and the general lower bound 1.58333.... Hu and Kahng [19] used similar principles to construct an unnamed variant for which they claimed $R_A^\infty \approx 1.6067$.

Richey [20] introduced the HARMONIC+1 algorithm, and claimed that it has a performance ratio of 1.58872. HARMONIC+1 uses a partition of [0, 1], dividing it into more than 70 intervals. Its design and analysis were carried out with the help of linear programming.

Seiden [21] presented a general framework for analyzing a large class of online algorithms. This class includes HARMONIC, REFINED HARMONIC, MODIFIED HARMONIC, MODIFIED HARMONIC-2, and HARMONIC+1. He showed that all of these algorithms are merely instances of a general class of algorithms, which he called SUPER HARMONIC. In his new approach, he reduced the problem of analyzing an instance of SUPER HARMONIC to that of solving a specific knapsack instance. He developed a branch-and-bound algorithm for solving such knapsack problems, and furnished a general computer-assisted method of proving upper bounds for every algorithm that can be expressed in terms of SUPER HARMONIC. As a result of this new technique, Seiden found a flaw in the analysis of HARMONIC+1 and showed that the performance ratio of HARMONIC+1 is at least 1.59217. He developed a new algorithm called HARMONIC++ and showed that it has an asymptotic performance ratio of at most 1.58889. This is the current champion. He also proved that 1.58333 is a lower bound for any SUPER HARMONIC algorithm.

32.2.3 Lower Bounds for Online Algorithms

Consider next lower bounds on performance that the asymptotic worst-case ratios of *all* online bin packing algorithms must satisfy. Roughly speaking, one way to prove such lower bounds is to argue as follows. Suppose an online algorithm A is confronted initially with a huge set of tiny items. If A packs these tiny items very tightly, it would not be able to find an efficient packing for the larger items that might arrive later; if such items actually do arrive, A is going to lose. However, if A leaves lots of room for large items while packing the tiny items, the large items might not arrive; and in that case, A is again going to lose. To illustrate this idea let us consider a simple example involving two lists L_1 and L_2, each containing n identical items. The size of each item in list L_1 is $1/2 - \varepsilon$, and the size of each item in list L_2 is $1/2 + \varepsilon$. We will investigate the performance of an arbitrary online algorithm A on the following two lists: L_1 alone and the concatenation, L_1L_2, of L_1 and L_2. The items of L_1 should be packed first. The algorithm will pack some items separately (j of them, say) and it will match up the remaining $n - j$. If we stop after L_1 has been packed then, obviously, $A(L_1)/OPT(L_1) = (n + j)/n$. If L_2 comes after L_1, then the best our algorithm can do is to add one element of L_2 to each of j bins containing a single element of L_1, and to pack separately the remaining $n - j$ elements. Clearly, $A(L_1L_2)/OPT(L_1L_2) = (3n - j)/(2n)$. The best choice of j is where the maximum of the two previous ratios is minimal. It is attained when $j = n/3$, implying a lower bound of 4/3 for the asymptotic worst-case performance ratio of any online algorithm A.

Yao [17] formalized this idea using three item sizes: $1/7 + \varepsilon$ as the size of small items, and $1/3 + \varepsilon$ and $1/2 + \varepsilon$ as sizes of larger items. (Note that these item sizes are simply $1/t_i + \varepsilon$, $1 \leq i \leq 3$ as given in Eq. [32.2].) Yao proved that, given such a list, the asymptotic ratio of every online bin packing algorithm A must satisfy $R_A^\infty \geq 1.5$. Brown [22] and Liang [23] independently generalized this lower bound to 1.53635 using Yao's construction for $1 \leq i \leq 5$. Ten years later, van Vliet [13,24] found an elegant linear programming formulation for the Brown–Liang construction. Van Vliet gave an exact analysis and increased the lower bound to

$$R_A^\infty \geq 1.5401$$

This is currently the best lower bound known for online bin packing. Note that the gap between this lower bound and the upper bound of 1.58889 described in Section 32.2.2 is less than 0.05.

Galambos [25] and Galambos and Frenk [26] simplified and extended the Brown–Liang construction to the parametric case. Combining these results with the linear programming formulation of van Vliet [24] yields the lower bounds given in Table 32.2. For comparison, corresponding upper bounds for some algorithms have also been included.

Applying the above general argument, Csirik et al. [27] proved that for lists of items in nonincreasing order, no online algorithm can have an asymptotic performance ratio smaller than 8/7. Faigle et al. [28] showed that, when lists are restricted to those with only the item sizes $1/2-\epsilon$ and $1/2+\epsilon$, this lower bound becomes 4/3. Chandra [29] argued that all of these lower bounds can be carried over to *randomized* online bin packing algorithms in which the choice of an allowable packing decision can be made at random.

TABLE 32.2 Lower Bounds for the Parametric Case

α	1	1/2	1/3	1/4	1/5
Lower bound on $R_A^\infty(\alpha)$	1.540	1.389	1.291	1.229	1.188
Current champion	1.588	1.423	1.302	1.234	1.191
$R_{H_k}^\infty(\alpha)$	1.691	1.423	1.302	1.234	1.191
$R_{FF}^\infty(\alpha)$	1.700	1.500	1.333	1.250	1.200

32.3 Semionline Algorithms

Better bounds can be achieved when we relax the online condition by allowing the repacking of items. In these cases, we have to bound the number of times items are repacked, for otherwise, we would end up with an offline algorithm. Gambosi et al. [30] proposed two algorithms of this type. The first is based on a nonuniform partition of (0, 1] into four subintervals: $I_0 = (2/3, 1]$, $I_1 = (1/2, 2/3]$, $I_2 = (1/3, 1/2]$, $I_3 = (0, 1/3]$. Essentially, their first algorithm uses a HARMONIC type algorithm for each interval, but it tries to fill bins packed with items from I_1 (i.e., items with sizes in I_1) up to 2/3 with already-packed I_3 items (by repacking) or with I_3 items from the remaining part of the list. This is a linear-time algorithm (items can be packed at most twice) and it is quite easy to see that its asymptotic ratio is 3/2. Their second algorithm uses six intervals. Its time complexity is $O(n \log n)$ and the corresponding ratio is 4/3. In a subsequent paper, the same authors offered a more detailed analysis of the same set of algorithms [31].

Ivković and Lloyd [32] investigated dynamic bin packing, but as a side result they produced a quite complicated semionline algorithm with an asymptotic ratio of 5/4. They also proved a lower bound for the special class of semionline algorithms that only use *atomic* repacking moves; such a move is limited to the transfer of a single item from one bin to another. They proved that for any semionline algorithm that performs only a bounded number of atomic repacking moves at each step, the asymptotic worst-case ratio is at least 4/3 [33].

One may only be willing to consider bounded-space algorithms of the semionline type. There are such algorithms whose worst-case ratios match the limiting value, as has been shown by Galambos and Woeginger [34] and Grove [35]. The relaxation used by Ref. [34] is to allow the repacking of currently open bins, that is, items can be removed from current open bins and reassigned before packing the current item. Galambos and Woeginger presented an "online with repacking" algorithm REP$_3$ that uses a weighting function w and three open bins concurrently as follows. The current item is always packed in an open bin. Then all elements in the three open bins are repacked by the FIRST FIT DECREASING (FFD) algorithm, with the result that either one bin becomes empty or at least one bin B has $w(B) := \sum_{a_i \in B} w(a_i) \geq 1$. All bins with $w(B) \geq 1$ are then closed and replaced by empty bins. The authors proved that

$$R_{REP_3}^\infty = h_\infty$$

Grove [35] independently designed an algorithm with the same behavior using an alternative notion that he calls *lookahead*. In his algorithm, one is given a fixed *warehouse size, W*; an item a_i need not be packed until one has looked at every item a_i through a_j, for $j > i$ such that $\sum_{h=i}^{j} s(a_h) \leq W$. Allowing lookahead, an appropriate choice of parameters again gives an algorithm with an asymptotic worst-case ratio of h_∞.

32.4 Offline Algorithms

As unconstrained algorithms for partitioning the sets $\{a_i\}$, offline algorithms need not be thought of in terms of sequential packings of an ordered list. However, the best known offline algorithms are usually expressed in just these terms, but with an initial ordering of the list allowed. That this is a natural first approach can be seen from the bad examples for online algorithms, which were either increasing (FF) or alternating (NF) sequences of item sizes. Thus, sorting the items in decreasing order and then employing

NF, FF, or BF creates three interesting candidates for simple, but effective offline algorithms; they are denoted by NFD, FFD, and BFD, with the "D" standing for "Decreasing." The sorting needs $O(n \log n)$ time and so the total running time of each algorithm will be $O(n \log n)$.

Baker and Coffman [36] proved that $R^{\infty}_{NFD} = h_{\infty}$, and they gave a parametric bound as well: if $\alpha \in (1/(s+1), 1/s]$, $s \geq 1$ then

$$R^{\infty}_{NFD}(\alpha) = h_{\infty}(\gamma_s^*)$$

where $h_{\infty}(\gamma_s^*) = \frac{s-1}{s} + \gamma_s$. Here γ_s is a slight generalization of the previous t_i sequence, as follows: $t_1(s) = s+1$, $t_2(s) = s+2$, and $t_{i+1}(s) = t_i(s)(t_i(s)-1)+1$, for $i \geq 2$. Then $\gamma_s = \sum_{i=1}^{\infty} \frac{1}{t_i(s)-1}$.

As expected, better results are achieved when using FF (or BF) after the initial sort. Johnson [2] showed that for every list L

$$FFD(L) \leq \frac{11}{9} \cdot OPT(L) + 4$$

He could also prove that this bound is tight, that is, $R^{\infty}_{FFD} = 11/9$. Later, Baker [37] gave a shorter and simpler proof and cut the constant to 3. Further shortening in the proof and reducing the constant to 1 was given by Yue [38]. Later, even this value was cut to 7/9 by Li and Yue [39].

For the parametric case, Johnson [2] showed that

$$R^{\infty}_{FFD}(\alpha) = \begin{cases} \frac{71}{60} & \text{for } \frac{8}{29} < \alpha \leq \frac{1}{2} \\ \frac{7}{6} & \text{for } \frac{1}{4} < \alpha \leq \frac{8}{29} \\ \frac{23}{20} & \text{for } \frac{1}{5} < \alpha \leq \frac{1}{4} \end{cases}$$

and he conjectured that

$$R^{\infty}_{FFD}\left(\frac{1}{m}\right) = 1 + \frac{1}{m+2} - \frac{2}{m(m+1)(m+2)} = F_m$$

for all integers $m \geq 4$.

Csirik [40] proved that this conjecture is true when m is even but is false when m is odd. Defining

$$G_m = 1 + \frac{1}{m+2} - \frac{1}{m(m+1)(m+2)} = F_m + \frac{1}{m(m+1)(m+2)}$$

he was able to prove that

$$R^{\infty}_{FFD}\left(\frac{1}{m}\right) = \begin{cases} F_m & \text{if } m \text{ is even} \\ G_m & \text{if } m \text{ is odd} \end{cases}$$

for all $m \geq 5$.

Xu [41] completed the proof for arbitrary values of $\alpha \leq 1/4$. He showed that when m is even, F_m holds true for any $\alpha \in (1/(m+1), 1/m]$, while for m odd the interval has to be divided into two parts with

$$R^{\infty}_{FFD}(\alpha) = \begin{cases} F_m & \text{if } \frac{1}{m+1} < \alpha \leq d_m \\ G_m & \text{if } d_m < \alpha \leq \frac{1}{m} \end{cases}$$

where $d_m := (m+1)^2/(m^3 + 3m^2 + m + 1)$.

The lower bound for FFD is given via the following lists:

$$L_{6k} = \Bigg(\underbrace{\frac{1}{2}+\varepsilon, \ldots, \frac{1}{2}+\varepsilon}_{6k}, \underbrace{\frac{1}{4}+2\varepsilon, \ldots, \frac{1}{4}+2\varepsilon}_{6k}, \underbrace{\frac{1}{4}+\varepsilon, \ldots, \frac{1}{4}+\varepsilon}_{6k}, \underbrace{\frac{1}{4}-2\varepsilon, \ldots, \frac{1}{4}-2\varepsilon}_{12k}\Bigg)$$

It is then straightforward to check that $\text{OPT}(L_{6k}) = 9k$ and $FFD(L_{6k}) = 11k$.

After sorting the items we may use an AF algorithm to pack the list. Unfortunately, there are no exact bounds for this case. We only know [2,3,5] that

$$\frac{11}{9} \le R^{\infty}_{AF}(1) \le \frac{5}{4}$$

and

$$\frac{1}{m+2} - \frac{2}{m(m+1)(m+2)} \le R^{\infty}_{AF}(\alpha) \le \frac{1}{m+2}$$

where $m = \left\lfloor \frac{1}{\alpha} \right\rfloor$ and $\alpha < 1$.

Johnson [2] made an interesting attempt to get a better offline algorithm. He proposed the MOST-k FIT (MF$_k$) algorithm, which first sorts the list in decreasing order. The next bin to be packed will first be filled with the largest as yet unpacked element. If the smallest item in the list does not fit in the bin, we close the bin and continue with the next bin. If the smallest item does fit, we pack at most k additional items with the least space left over. The running time is $O(n^k \log n)$. For a long time, Johnson conjectured that $\lim_{k\to\infty} R^{\infty}_{MF_k} = 10/9$, but Friesen and Langston [42] provided a counterexample showing that $R^{\infty}_{MF_k} \ge 5/4$ for $k \ge 2$.

For several years FFD had the provably smallest asymptotic bound. Yao [17] proposed a complicated algorithm A with a $O(n^{10} \log n)$ running time and with $R^{\infty}_{A} \le 11/9 - 10^{-7}$, which proved that FFD could in fact be beaten. A much larger improvement was achieved by Garey and Johnson [43]. They proposed the MODIFIED FIRST FIT DECREASING (MFFD), which differs from FFD only when packing the items from $(1/6, 1/3]$, called *key* items, just after packing all items $> 1/3$. MFFD attempts to pack 2 key items in every *key* bin, defined as a bin having only an item $> 1/2$. The key bins are packed in largest-gap-first order. If the gap in the current key bin can accommodate the two smallest items in the set S_U of the as yet unpacked key items, then the first key item packed is the smallest in S_U and the second one packed is the one remaining in S_U that would be chosen by BF. As soon as at most one key item remains or a key bin is encountered that cannot accommodate the smallest two remaining key items, MFFD reverts to FFD for the remainder of the packing. Garey and Johnson proved that

$$R^{\infty}_{MFFD} = \frac{71}{60} = 1.183333\ldots.$$

This is the best known offline algorithm. It is interesting to note that $R^{\infty}_{MFFD} = R^{\infty}_{FFD}\left(\frac{1}{2}\right)$.

In their attempt to find a better algorithm, Friesen and Langston [42] investigated the BEST TWO FIT (B2F) algorithm, which is basically a MF$_k$-type algorithm with $k = 2$: B2F first pack a bin by FFD. If the bin contains more than a single item, then the list is checked to see if the smallest item in the bin could be replaced by two items that would occupy more of the bin. If so, the two largest such items are inserted in place of the smallest item. The algorithm is also simplified by requiring all items smaller than 1/6 be withheld until all larger items have been packed. FFD is used to complete the packing when only items no greater than 1/6 are left. The authors proved that

$$R^{\infty}_{B2F} = \frac{5}{4} = 1.25$$

which is worse than those of FFD. The bad lists for this algorithm have the following optimal packing:

$$\left(\underbrace{\frac{1}{3} - 4^k\frac{\varepsilon}{2}, \frac{1}{3} - 4^k\frac{\varepsilon}{2}, \frac{1}{3} + 4^k\varepsilon,}_{2\text{ bins}} \underbrace{\frac{1}{3} - 4^{k-1}\frac{\varepsilon}{2}, \frac{1}{3} - 4^{k-1}\frac{\varepsilon}{2}, \frac{1}{3} + 4^{k-1}\varepsilon,}_{8\text{ bins}} \ldots, \right.$$

$$\left. \underbrace{\frac{1}{3} - 2\varepsilon, \frac{1}{3} - 2\varepsilon, \frac{1}{3} + 4\varepsilon,}_{2\cdot 4^{k-2}\text{ bins}} \underbrace{\frac{1}{3} + \varepsilon, \frac{1}{3} + \varepsilon}_{4^{k-1}\text{ bins}} \right)$$

Fortunately, the counterexamples for FFD and B2F are complementary and so the authors defined a compound algorithm (CFB) that runs both FFD and B2F on the list and takes the better result. The running time may double, but for the performance ratio we get

$$1.164\ldots = \frac{227}{195} \le R^{\infty}_{CFB} \le \frac{6}{5} = 1.2$$

The worst-case example is given by an example where the bin size is 559, and lists where the optimal packing consists of $60k$ bins each having three items of size 381, 98, 80, of $120k$ bins each having five items of size 191, 96, 96, 96, 80, and of $15k$ bins each having six items of size 99, 99, 99, 99, 80, 80. Then the optimal packing clearly uses $195k$ bins, and CFB will use $227k$ bins. The exact bound for CFB has not yet been determined and so it is not known whether it is better than MFFD.

An earlier step in this direction (i.e., sequentially packing each bin as well as possible) did not entail orderings by size. Graham [44] proposed a greedy algorithm in which, at each step, packing the next bin solved a knapsack problem. Surprisingly, however, the worst-case behavior of this algorithm A is rather poor:

$$R^{\infty}_{A} \ge \sum_{k=1}^{\infty} \frac{1}{2^k - 1} = 1.6067\ldots$$

This lower bound is proved by instances L_b that have b items of size $1/2^k + \varepsilon$ for $k = 1, 2, \ldots, p$, with $0 < \varepsilon \le 1/2^{2p}$ and for values of b that are multiples of $2^k - 1$, $k = 1, 2, \ldots, p$, for example, $b = a\prod_{k=1}^{p}(2^k - 1)$ for some positive integer a. Then the optimal packing of L_b has b bins, each bin consisting of one item from each size. Grahams's algorithm first packs $b/(2^p - 1)$ bins, each with $2^p - 1$ items of size $1/2^p + \varepsilon$, then $b/(2^{p-1} - 1)$ bins, each with $2^{p-1} - 1$ items of size $1/2^{p-1} + \varepsilon$, and so on, ending with b bins, each with one item of size $1/2 + \varepsilon$. Summing up, the lengths of the subpackings gives the lower bound.

Caprara and Pferschy [45] recently proved an upper bound on the asymptotic performance of Graham's algorithm:

$$R^{\infty}_{SS} \le \frac{4}{3} + \ln\left(\frac{4}{3}\right) \approx 1.6210$$

They also dealt with the parametric case, showing that, if $\frac{1}{m+1} < \alpha \le \frac{1}{m}$, then

$$R^{\infty}_{SS}(\alpha) \ge \sum_{k=1}^{\infty} \frac{m}{(m+1)^k - 1}$$

and

$$R^{\infty}_{SS}(\alpha) \le \begin{cases} 2 - \frac{4m}{3(m+1)} + \ln\left(\frac{4}{3}\right) & \text{if } m \le 2 \\ 1 + \ln\frac{m+1}{m} & \text{if } m \ge 3 \end{cases}$$

32.5 Other Worst-Case Issues

32.5.1 Special Case Optimality

One of the easiest cases is when the number of different items in the lists is bounded, that is, we have k different item sizes. Let us denote the item sizes by $s_1, s_2, \ldots, s_k$. In this case we have a smallest item size. Then let us denote the smallest integer by j so that all item sizes are $\ge 1/j$. It is quite clear that we cannot pack more than j items in one bin. So a legal packing (we call it here a configuration) of a bin can be given by a k-tuple,

$$p_i = (p_{i1}, p_{i2}, \ldots, p_{ik}), \sum_{l=1}^{k} p_{il} \le j, \sum_{l=1}^{k} s_l \cdot p_{il} \le 1$$

where p_{ij} denotes the number of s_j items in configuration i. The total number of lists having not more than j items is $O(k^j)$, a part of them form a configuration. But then the total number of all possible packings of a list $L = (a_1, a_2, \dots, a_n)$ where $a_i \in \{s_1, s_2, \dots, s_k\}$ is $O(n^{k^j})$, that is, a polynomial in n. This is a brute force method—the optimum can be computed more easily in this case, as proposed by Blazewicz and Ecker [46]. Let us denote the number of items s_i in the list L by m_i, $1 \le i \le k$. Then the problem of finding the optimal packing of L can be formulated as the following integer programming problem:

$$\min \sum_{i=1}^{N} b_i, \quad w.r.t \sum_{i=1}^{N} p_{ij} b_i = m_j \quad (j = 1, \dots, k)$$

and $b_i \ge 0$ are integers $(i = 1, \dots, N)$. Here N is the number of all possible configurations and b_i gives the number of bins of configuration p_i. This matrix has k rows and $O(k^j)$ columns and can be solved in polynomial time in the number of constraints [47]. The optimal packing can then be constructed in linear time. If we do not need the exact optimum but just a good approximation of it then we can relax the integer condition from the above inequalities and compute the optimum of the remaining problem. Then we may round down the solution, as proposed by Gilmore and Gomory [48,49].

A different approach was chosen by Hochbaum and Schmoys [50]. They investigated the classical bin packing problem with item sizes bounded from below. They found an easily solvable case: if all item sizes are $\ge 1/3$, then a relatively straightforward polynomial algorithm will furnish an optimal packing. This algorithm will pack, in the first stage, all items larger than a half separately in bins. In the second stage all items $= 1/3$ are packed by three items in bins. In the third stage the remaining items, that is, those with size $> 1/3$ and $\le 1/2$ are paired up with items from stage one, and those items where the pairing is not possible are packed by two. The second step in this direction was to prove that if item sizes are $\ge 1/3 - \varepsilon$ for any fixed ε, $0 < \varepsilon < 1/3$, then the problem becomes strongly NP-complete. Even for this case, supposing $0 < \varepsilon \le 1/12$, and slightly relaxing the problem allowing the bins to be overpacked a little bit, they gave a polynomial-time algorithm that gives the optimal number of bins but an overpacking with at most $3\varepsilon/2$.

Leung [51] derived the limits for polynomially solvable cases. He proved that the bin packing problem remains NP-hard even if the bin capacity is one and if item sizes must be drawn from the set $\{1, r, r^2, r^3, \cdots\}$, where r is an arbitrary positive rational number < 1.

Another type of optimality result was covered by Coffman et al. [52]. They introduced the restricted lists L where the item sizes form *divisible sequences.* Now let us suppose that the bin capacity is an integer. A sequence of item sizes $s_1 > s_2 > \dots > s_i > s_{i+1} > \dots$ is called *divisible* if for each $i \ge 1$, s_{i+1} exactly divides s_i. A list L is called *weakly divisible* if its items when sorted forms a divisible sequence. If, in addition, the largest item size exactly divides the bin capacity, then the list is called *strongly divisible.* In Ref. [52] it was proven that when L is weakly divisible FFD gives optimal packing. If L is strongly divisible then even FF produces optimal packing.

32.5.2 Linear-Time Algorithms

Most algorithms investigated up till now have a running time superlinear in n. It would be interesting to know what could be said about algorithms that have a linear running time. Naturally, NF is one of these, but it has poor performance. Johnson quite early on [3] proposed a better linear-time algorithm, GROUP-X FIT GROUPED (GXFG). First he defined the GROUP-X FIT (GXF) algorithm. Let a *schedule of intervals* be the set $X = \{x_0, x_1, \dots, x_k\}$, where $x_0 = 0$, $x_k = 1$, and $x_i < x_{i+1}$, $0 \le i < k$. X can be thought of as a partition of the unit interval $[0, 1]$ into the subintervals $(0, x_1]$, $(x_1, x_2]$, $\dots$, $(x_{k-1}, 1]$. Interval $(x_{i-1}, x_i]$ will be called the X_i, $1 \le i \le k$ interval, and the points in X will be called breakpoints. Items from the list are classified similarly: a_j will be called an I_l item if it belongs to X_l. Note that this is a more general definition than that given for the Harmonic algorithm, the latter having $x_i = 1/i$ as breakpoints. GROUP-XFIT will round down the free space in open bins to the next breakpoint (if the free space is equal to a breakpoint then it is kept). The algorithm is actually a variant of best fit: an I_l item will be packed in a bin with the least free space left over (if no bin has enough space for the item, a new bin will be used). The algorithm has linear running time and is online. Johnson [2,3] did show that for $m = \lfloor 1/\alpha \rfloor \geq 2$,

$$R^{\infty}_{GXF}(\alpha) = R^{\infty}_{FF}(\alpha)$$

when $\{1/(m+1), 1\} \subseteq X$. He also proved that if $m = 1$, then $1.7 \leq R^{\infty}_{GXF} \leq 2$ whenever $\{1/6, 1/3, 1/2\} \subseteq X$ and conjectured that the lower bound is the tight value.

The better algorithm GXFG first scans through the list and collects items from the same intervals together. The second step is just GXF, which starts with items from interval X_k, followed by items from X_{k-1}, X_{k-2}, ... Johnson also proved, for all $m = \lfloor 1/\alpha \rfloor \geq 1$, if X contains $1/(m+2)$, $1/(m+1)$, $1/m$, that

$$R^{\infty}_{GXFG}(\alpha) = \frac{m+2}{m+1}$$

Because of the first scan GXFG is not an online algorithm. Basically, it uses the idea of FFD (it first starts to pack the large elements) but without really sorting the elements.

A further improvement was achieved by Martel [53]. He used subintervals too, but packed items more freely than Johnson in his GXFG. The algorithm is the following. First, we partition the items using the following five sets:

$$C_1 = \{x_i \mid 2/3 < x_i \leq 1\}$$
$$C_2 = \{x_i \mid 1/2 < x_i \leq 2/3\}$$
$$C_3 = \{x_i \mid 1/3 < x_i \leq 1/2\}$$
$$C_4 = \{x_i \mid 1/4 < x_i \leq 1/3\}$$
$$C_5 = \{x_i \mid x_i \leq 1/4\}$$

Let $c_i = \mid C_i \mid$, $i = 1, 2, \ldots, 5$, be the numbers of items in intervals. An item in C_i will be called a C_i-piece. The motivation behind this partitioning is to allow items to be packed based on the set to which they belong. Items in C_1 can only be combined with items in C_5. Items in C_2 can always be combined with an item in C_4, but never with an item in C_2. Items in C_3 can be packed together two to a bin, items in C_4 can be packed three to a bin, and items in C_5 can be packed at least four to a bin. The algorithm OffBP is based on these observations and is defined in the following:

Step 1. Form the sets C_i, $i = 1, 2, \ldots, 5$.

Step 2. Let $k = \lceil \min\{c_2, c_3\}/2 \rceil$. Split C_2 into the two sets C_2^s that contains the smallest k elements in C_2 and C_2^b, which contains the remaining elements. In a similar way, split C_3 into C_3^s and C_3^b. Pair up each element in C_2^s with an element in C_3^s. If the pair fits in a bin, create a bin containing both items. If the pair does not fit, create a bin containing only the element from C_2^s.

Step 3. Put each C_1-piece into its own bin and put each C_2^b-piece into its own bin.

Step 4. Put all C_3^b-pieces and all C_3^s-pieces which were not combined with a C_2^s-piece in step 2 into bins, two into each bin.

Step 5. Each bin with a single C_2-piece has a C_4-piece added to it (until one runs out of C_4-pieces).

Step 6. Any C_4-pieces not packed in step 5 are put three to a bin into empty bins.

Step 7. Pack C_5-pieces into the bins created in steps 1–6 using NF: for each bin we add C_5-pieces until the next C_5-piece does not fit; then go to the next bin and never consider the previous bin again.

Step 8. Any remaining C_5-pieces are packed into empty bins using NF.

Martel has shown that the performance ratio of OffBP is 4/3. He also gave hints on how the algorithm could perhaps be improved. These were followed up by Békési et al. [54]. They used the breakpoints {1/5, 1/4, 1/3, 3/8, 1/2, 2/3, 4/5} and a much more complicated algorithm and obtained a performance bound of 5/4.

32.5.3 Randomization

Bin packing was a pioneering theme in many fields of analysis of algorithms. This is the case for randomized algorithms as well. Perhaps AF is the first randomized algorithm that was really analyzed in detail. This is certainly a classical result for randomized algorithms.

Only a few additional results are known for randomized algorithms in bin packing. As mentioned earlier, Chandra [29] proved that the general lower bound for online algorithms hold for randomized algorithms too.

Kenyon [55] analyzed BF from a new point of view and defined a new measure of performance. This new measure is the expectation over random packing orders of a *worst-case list* of input items; packing orders are drawn uniformly at random from the set of all permutations. She defined the random-order performance-ratio RC(A) of an online algorithm A as

$$RC(A) = \limsup_{OPT(L)\to\infty} \frac{E_\sigma A(L_\sigma)}{OPT(L)}$$

where L_σ is the permuted list $(x_{\sigma(1)}, x_{\sigma(2)}, \ldots, x_{\sigma(n)})$ and the summation for the expectation is taken over all permutations $\sigma \in \mathcal{S}_n$. She proved that for BF

$$1.08 \leq RC(BF) \leq 1.5$$

a quite large gap between the lower and upper bound! She also conjectured that the true answer was probably close to 1.15. To estimate the lower bound she used a nice simplification: if we have only two different item sizes then the permutations can be simulated by drawing each item independently with the appropriate probabilities. So the sequence can be viewed as an unbiased random walk in the plane, which can be analyzed with help of the Markov chains. The lower bound was found with the aid of the lists where we have 1/2 items with probability p and 1/3 items with probability $1 - p$. In this case we have a Markov chain with five states:

(a) There is no open bin.
(b) There is one open bin whose current content is 1/2.
(c) There is one open bin whose current content is 1/3.
(d) There is one open bin whose current content is 2/3.
(e) There are two open bins, one containing 1/2 and the other containing 2/3.

A quite standard analysis of this Markov chain leads to the lower bound 1.08. The proof of the upper bound is much more complicated and uses some deeper results from probability theory.

No further results are available for this type of investigation. We are not aware of any estimates for $RC(NF)$!

32.5.4 Absolute Worst-Case Ratios

Up till now we have considered the asymptotic worst-case ratios of bin packing heuristics. For lists where OPT(L) is small, a different ratio may also be helpful. This is the absolute worst-case ratio, which is defined by Eq. (32.1). It can readily be seen that bin packing is hard even for lists for which $OPT(L)$ is small. This is true because the 2-partition problem, which is known to be NP-complete [56], can be polynomially reduced to the problem whether or not it is possible to pack all items in two bins. This also implies that no polynomial-time heuristic has an absolute worst-case ratio smaller than 1.5 for the bin packing problem, unless $P = NP$. This is obvious as such a heuristic could solve the 2-partition in polynomial time [56]. However, for the list $L = (0.4, 0.4, 0.3, 0.3, 0.3, 0.3)$, $OPT(L)) = 2$ and $FFD(L) = 3$, so FFD has the best possible absolute worst-case bound. From Ref. [39] it is known that

$$FFD(L) \leq \frac{11}{9} \cdot OPT(L) + \frac{7}{9}$$

for all lists. This gives an upper bound of 4 for lists with OPT(L)=3 and bound of 5 for lists with OPT(L)=4. The same numbers apply to BF too.

As regards FF (and BF), we have already mentioned [57] that, for any list L,

$$FF(L) \le \left\lceil \frac{17}{10} \cdot OPT(L) \right\rceil$$

and Ref. [5] gave examples showing that $FF(L)/OPT(L) = 17/10$ could be actually attained. Simchi-Levi [58] once proved that for all lists $FF(L) \le 1.75 \cdot OPT(L)$.

Xie and Liu [59] improved the upper bound, giving a proof for

$$FF(L) \le \min\left(\left\lfloor \frac{33}{19} \cdot \mathrm{OPT}(L) \right\rfloor , \left\lceil \frac{17}{10} \cdot \mathrm{OPT}(L) \right\rceil \right)$$

Summarizing the results we currently know that

$$1.7 \le FF(L) \le \min\left(\left\lfloor \frac{33}{19} \cdot \mathrm{OPT}(L) \right\rfloor , \left\lceil \frac{17}{10} \cdot \mathrm{OPT}(L) \right\rceil \right)$$

Berghammer and Reuter [60] gave a linear-time algorithm with an absolute worst-case bound of 3/2. This bound holds for FFD and BFD too, but in $O(n \log n)$ time. The algorithm is based on the BF idea. It works with two partial solutions P_1 and P_2 and two auxiliary bins B_1 and B_2—one for each partial solution. The algorithm proceeds as follows: First, the items are packed one by one into B_1 until its capacity would be exceeded by the packing of some item u. In this situation the contents of B_1 is inserted into P_1, the bin B_1 is cleared, u is packed into B_2, and the process is repeated with the remaining items. If, however, the packing of u would lead to an overfilling of B_1 as well as B_2 then, in addition, the contents of B_2 is inserted into P_2 and u is packed into the cleared B_2. This bookkeeping combined with a suitable selection of the next object (based on a partition of the objects into small and large ones at the beginning of the algorithm) allows us to avoid the costly search of a bin the next item will optimally fit in.

Zhang et al. [61] furnished a different offline algorithm with absolute worst-case ratio 3/2 using an *extra* bin. The algorithm is the following:

Step 1. Put large items (>1/2) each into a bin. Index the unfilled bins in arbitrary order. Set all bins as active bins. Then repeatedly arrange small items as follows.

Step 2. If there is an active open bin, put the current item a_i into the open active bin with the lowest index if the bin has enough room for a_i, otherwise close this active bin and consider the extra bin as follows. If there is an extra bin open and it has enough room for a_i, place a_i into it. Otherwise close the extra bin. Open a new bin for a_i and set this bin as the extra bin.

Step 3. If there is no active bin open, create a new bin for a_i and set this new bin as the active bin.

Actually, in step 1, we need to only arrange one large item at a time. As soon as the active bin containing a large item is closed, we open a new bin and put the remaining large item into it first and set it as the active bin. At any one time we keep at most one active bin and at most one extra bin open. So it is a bounded-space algorithm. The authors proved that its tight absolute worst-case ratio is 3/2.

They also defined an online algorithm of the same type. This is again a bounded-space algorithm and has a tight absolute worst-case ratio of 7/4. In this algorithm, a bin is called an L-bin if the first item it accepts is a large item and has not been set as an active bin. Once such bin becomes an active bin it will no longer be called an L-bin. The algorithm is the following:

Step 1. Open a bin for the first item. Set it as the active bin.

Step 2. If there is an active bin B_j open, put the current item a_i into B_j if it has enough room for this item. But suppose that B_j does not have enough space for the item:

(a) If a_i is a large item, create a new bin for it. If there are two L-bins, close them.

(b) If a_i is a small item, close the active bin. Set an open L-bin as the active bin if such a bin exists. If there is an extra bin open and this bin has enough room for a_i, pack a_i into it. Otherwise open a new bin for a_i and set the new bin as the extra bin.

Step 3. If there is no active bin open, create a new bin for item a_i and set it as the active bin.

32.5.5 Bounds on Anomalous Behavior

As we have already seen, the two well-known algorithms FF and BF have the same asymptotic ratios. However they can give strikingly different packings for individual lists. Examples are given in Ref. [2] of lists L with arbitrarily large values of OPT(L), both such that BF(L) = (4/3)·FF(L) and FF(L) = (3/2)·BF(L). Similarly, AWF can be just as far away from FF, and examples exist such that AWF(L) = (5/4)·FF(L) and that FF(L) = (9/8)·AWF(L).

The decreasing-type algorithms FFD and BFD may be likewise compared. In Ref. [2] lists are given for which BFD(L) = (10/9)·FFD(L). However, BFD can produce better packings than FFD as well: There are lists for which FFD(L) = (11/10)·BFD(L).

It has been shown that certain algorithms possess the undesirable property of sometimes performing "worse" when their inputs are made "better." Let us start from a list L and let us form a new list L' by deleting some elements of L and/or reducing the size of some elements of L. We will say in this case that *L dominates L'*. If an algorithm never uses more bins to pack L' than it uses to pack L we will say that the algorithm is monotonic, otherwise we will say the algorithm is nonmonotonic. Graham [44] and Johnson [2] once showed that FF is nonmonotonic. Murgolo [62] introduced a technique that allows one to completely characterize the monotonic behavior of any algorithm in a large, natural class. He provided upper bounds on nonmonotonic behavior for any *reasonable* algorithm. (A reasonable algorithm is one which never packs an item into an empty bin if it can fit into an already allocated bin.) We note that a reasonable algorithm is an AF algorithm. For example, he showed that there exist arbitrarily long lists satisfying *L dominates L'* such that $FF(L') \geq FF(L) + \frac{1}{75}FF(L)$, and this bound is tight to within a constant factor. Similar results hold for BF (with a constant of $\frac{1}{42}$) and WF (with a constant of $\frac{1}{15}$).

32.5.6 Parallel Algorithms

Anderson, Mayr, and Warmuth have investigated the FFD algorithm from a parallel computational view. They used the PARALLEL RANDOM ACCESS MACHINE (PRAM) model of parallel computation of Fortune and Wyllie [63]. They considered a parallel algorithm to be fast if it is an NICK'S CLASS ($\mathcal{N}C$) algorithm, that is, if it runs in polylogarithmic time using a polynomial number of processors. The main algorithm they gave has a more reasonable bound, running in $O(\log n)$ time on an $n/\log n$ processor EREW (exclusive read, exclusive write) PRAM, and so is asymptotically optimal. A problem is called inherently sequential if it is $\mathcal{P}$-complete. This furnishes a relatively strong evidence that the problem is not in $\mathcal{N}C$, since if it were, we would have $\mathcal{P} = NC$. The interpretation of this is that deciding the value of a specific bit of the output of the algorithm is $\mathcal{P}$-complete.

The main result of Ref. [63] is that the FFD heuristic is a $\mathcal{P}$-complete algorithm, and that a packing which obeys the same performance bound as FFD can be computed by a fast parallel algorithm. The algorithm packs the large items (items of size $\geq 1/6$) in the same manner as FFD and then fills in the remaining items. Now let $u_1, u_2, \ldots, u_r$ be the list of remaining items, all with a size less than 1/6. We first combine these items into chunks so that every chunk (except possibly the last) has a size between 1/24 and 1/6. The items with a size 1/24 or larger are big enough and each is put into a chunk by itself. For the remaining items, the partial sums $s_k = \sum_{1<j\leq k} u_j$ are determined and for each i, we combine the set of items $\{u_k \mid i/12 \leq s_k < (i+1)/12\}$ to form a chunk. Since the item sizes are less than 1/24, each chunk will have a size between 1/24 and 3/24.

Now the bins packed using the FFD algorithm with items of size 1/6 or larger will be filled in. We will add, in parallel, a distinct chunk to each bin filled less than 5/6. Since the sizes are at least 1/24, only a constant number of passes are needed. If there are any leftover items they are packed in new bins, just as in the method used in FFD packing.

The algorithm runs in $O(\log n)$ time using $n/\log n$ processors.

33 Variants of Classical One-Dimensional Bin Packing

Edward G. Coffman, Jr.

Joseph Y.-T. Leung
New Jersey Institute of Technology

33.1 Introduction

Few problems compete with the bin packing problem in having fascinated so many people for so long a time. Research into the classical bin packing problem dates back over three decades to the early 1970s. In the original version, a list $L = (a_1, a_2, \ldots, a_n)$ of n items, each with a size no larger than 1, is given along with an infinite supply of unit capacity bins. The goal is to pack the list into as few bins as possible so that no bin capacity is exceeded. Because the problem is NP-hard, most research has concentrated on designing fast approximation algorithms with good performance guarantees. The studies have spanned both online and offline algorithms, and have applied both combinatorics and probabilistic analysis.

In parallel with the development of approximation algorithms for the classical problem, several variants have been proposed and studied. In this and the next chapter we survey some of the results for these variants. Because of the extensive work done in this area, we cannot possibly hope to cover every problem. Rather, we choose some of the representative ones, and hope that they will give the reader a flavor of the richness of the problem area.

In Section 33.2, we survey the variant in which the number of items packed is maximized. In this problem the number of bins, m, is fixed and the goal is to pack a maximum number of pieces into the m bins. This problem was first proposed by Coffman et al. [1] in 1978, and studied more recently by Boyar et al. [2].

Section 33.3 surveys the variant that places a bound on the number of items that can be packed in each bin. This problem is identical to the classical bin packing problem, except that, for given $k > 0$, each bin can contain at most k items. The problem was first proposed and studied by Krause et al. [3] in 1975.

In Section 33.4, we survey dynamic bin packing, in which packings change with time; each item has an arrival and departure time, which define the time interval during which an item occupies a bin. This problem was first studied by Coffman et al. [4] in 1983.

Section 33.5 surveys several variants that put constraints on the data. The first problem, first studied by Liu and Sidney [5], is concerned with bin packing under the ordinal data scenario: the item sizes are not known but the order of the weights is known. The second problem, first proposed by Mandal et al. [6], allows the items to be fragmented while packing them into bins of fixed capacity. The last problem, first studied by Jansen and Öhring [7], considers the bin packing problem where certain items cannot be put into the same bin. An undirected graph $G = (V, E)$ is used to describe these relationships, where V is a set of vertices representing the items and E a set of edges such that items connected by an edge $(a_i, a_j) \in E$ have to be packed into different bins.

In the final section, we survey the bin stretching problem, first studied by Azar and Regev [8]. In this problem, the optimal bin capacity is known and the goal is to find a good heuristic, given this information. The supremum of the bin capacity ratio of an algorithm and the optimal value is the stretching factor. The goal is to find a simple algorithm with a small stretching factor.

In the next chapter, we survey bin packing into bins of different sizes. The variable-sized bin packing problem was first studied by Friesen and Langston [9] in 1986, and it has attracted much attention since then. We then survey bin covering problems, which ask us to partition a set of items into the maximum number of subsets such that, in every subset, the total size of the items is never less than some lower bound. The problem was first studied by Assman et al. [10] in 1984.

33.2 Maximizing the Number of Items Packed

Coffman et al. [1] introduced the following bin packing variant to model processor and storage allocation problems. For example, it might be desirable to maximize the number of records stored in multiple, autonomous storage units, or to maximize the number of tasks that can be executed on multiple processors during a fixed time interval. The formal model is as follows: given a set of m unit capacity bins $B_1, B_2, \ldots, B_m$ and a list of $L = (a_1, a_2, \ldots, a_n)$ of items, the goal is to pack a maximum subset of L into the bins such that no bin capacity is exceeded. It is intuitively clear that any algorithm having a reasonable worst-case performance relative to an optimal algorithm must attempt to pack a maximum number of the smaller pieces. So it is quite natural to start by sorting pieces in ascending order of size and then to pack a maximum prefix of the sorted list. It is obvious that for every sublist $L' \subseteq L$ that can be packed into m bins there is a prefix of L having at least as many pieces that can also be packed into the m bins. Coffman et al. always used the sorted lists for their algorithms.

Let n_O denote the optimal number of items packed into m bins and n_A the number of items packed by an algorithm A. Coffman et al. considered the absolute worst-case ratios, giving bounds on n_A/n_O. They first considered the SMALLEST-PIECE-FIRST (SPF) algorithm, which is defined as follows: the list is sorted in ascending order of piece size and each piece is assigned in turn to the bin having the least filled space, with ties broken in favor of the bin having the lowest index. The algorithm halts when it first encounters a piece that is too large to fit in any bin. It is quite easy to see that the asymptotic worst-case performance of SPF is 1/2.

The next algorithm they investigated was the FIRST-FIT-INCREASING algorithm (FFI), that is, the First Fit (FF) rule applied to the sorted list. They proved that, for any list packed into m bins,

$$\frac{n_{FFI}}{n_O} \geq \frac{3}{4}$$

and that, for every m, there exists a list which realizes this bound. A straightforward example can be given as follows:

$$\Bigg(\underbrace{\frac{1}{2} - \varepsilon, \ldots, \frac{1}{2} - \varepsilon}_{m \text{ items}}, \underbrace{\frac{1}{2} + \varepsilon, \ldots, \frac{1}{2} + \varepsilon}_{m \text{ items}}\Bigg)$$

where m is even. The optimal packing will pack all items ($2m$) into m bins, while FFI will pack $3m/2$ items.

They also provided a more precise bound from which parametric results can be derived. Let k_i denote the number of items in bin B_i in the FFI packing. For FFI, it is easy to see that $k_1 \geq k_2 \geq \cdots \geq k_m$. With the help of k_m they proved that

$$n_{FFI} \geq \begin{cases} \frac{mk_m+1}{m(k_m+1)} n_O, & m \leq k_m + 1 \\ \frac{k_m^2+k_m+1}{(k_m+1)^2}(n_O - 1), & m > k_m + 1 \end{cases}$$

Both bounds are attainable.

Coffman and Leung [11] described a better algorithm for this problem, which is much more difficult to analyze. They introduced the ITERATED-FIRST-FIT-DECREASING rule (FFD*) that works as follows. Again, assume that the elements of L are in ascending size order. FFD* first scans L to find the maximum length prefix $L^{(1)} = (a_1, a_2, \ldots, a_t) \subseteq L$ such that $\sum_{i=1}^{t} a_i \leq m$. The algorithm then packs $L^{(1)}$ into as many bins as required (say m'), by scanning right to left and placing the next smaller piece into that bin with the lowest index into which it will fit. The algorithm terminates successfully if $m' \leq m$; otherwise, the algorithm constructs $L^{(2)} \subset L^{(1)}$ by discarding the largest piece in $L^{(1)}$ and then proceeds as above to pack $L^{(2)}$ by the FFD rule. The process is repeated until, for some j, $L^{(j)}$ has been packed into $m' \leq m$ bins. They proved that, for all L and $m \geq 1$,

$$n_{FFD^*}(L, m) \geq \frac{6}{7} n_O(L, m) - \frac{18}{7}$$

and there exist lists for each m such that FFD* will pack 7/8 times the optimum number of pieces. A tight bound has not yet been found.

These are, of course, not online algorithms. It is quite easy to see that without some restriction on the lists to be processed, all online algorithms can perform very poorly; just take lists starting with large items so that, after all of the bins are filled with these items, many very small items remain. Here we need some restrictions so as to have reasonably good online algorithms. With the classical bin packing problem all items have to be packed, so it seems natural to restrict the input sequences to those that can be completely packed by an optimal offline algorithm. Such sequences are called *accommodating sequences* [2].

Boyar et al. [2] considered *greedy* algorithms: an item is rejected only if there is not enough space to pack it (the authors called them fair algorithms). Boyar et al. analyzed the FF algorithm and proved that it has a competitive ratio of at least 5/8 on accommodating sequences. Azar et al. [12] showed that this bound is asymptotically tight, that is, the competitive ratio on accommodating sequences comes arbitrarily close to 5/8 for large enough n. Specifically, for any n, the competitive ratio is bounded by $5/8 + O(1/\sqrt{n})$.

Azar et al. [12] investigated *unrestricted* algorithms that have the power of performing admission control on the pieces, that is, rejecting pieces while there is enough space to pack them. They designed an algorithm for unrestricted bin packing called UNFAIR-FIRST-FIT (UFF) whose competitive ratio is $2/3 \pm \theta(1/n)$. UFF uses two sets of pieces: A (accepted) and R (rejected). Since every piece has the same value, it seems reasonable to reject large pieces. So UFF examines whether the piece is larger than 1/2 and whether the performance ratio would still be at least 2/3 if the piece were rejected. If both conditions are satisfied, the piece is rejected (placed in R); otherwise, it is accepted (placed in A). All accepted pieces will be packed according to the FF rule.

Azar et al. [12] also showed that the competitive ratio of any online algorithm on accommodating sequences is no better than $0.857 + O(1/n)$ even when randomized algorithms are considered. For deterministic fair algorithms, they proved a slightly better bound of $0.809 + O(1/n)$.

Boyar et al. [2] gave additional results for the following special case: they assumed that the item size and bin size were integers. Let k be the bin size here. They investigated special lists where they know that the optimal offline algorithm would use no more than α times the given number of bins, with $\alpha \geq 1$ (for $\alpha = 1$ we get the accommodating sequences). They called these sequences α-*sequences.* Algorithm A is called c-accommodating with respect to α-sequences if $c \leq 1$ and for every α-sequence L,

$$A(L) \leq c \cdot OPT(L) - b$$

where b is a fixed constant. Let $\mathcal{C}_\alpha = \{c \mid A \text{ is } c\text{-accommodating with respect to } \alpha\text{-sequences}\}$. The *accommodating function* $\mathcal{A}$ is defined as $\mathcal{A}(\alpha) = \sup\, \mathcal{C}_\alpha$.

To maximize the number of pieces packed, Boyar et al. proved that if $\alpha \le 5/4$ and $k \ge 3$, then

$$\mathcal{A}(\alpha) \le \frac{2}{2 + (\alpha - 1)(k - 2)}$$

Boyar et al. [13] used the same restrictions—integer-sized items with an integer bin capacity of k. Under these conditions it is quite easy to see that the competitive ratio of FF is $1/k$. They introduced a new algorithm Dlog and compared it with FF from various points of view. The Dlog algorithm works as follows. Let us first suppose that we have m bins. We assume that $m \ge c\lfloor \log_2 k \rfloor$, for some constant c. Divide the bins into $\lceil \log_2 k \rceil$ groups $G_1, G_2, \ldots, G_{\lceil \log_2 k \rceil}$. Let $p = \lfloor \frac{n}{\lceil \log_2 k \rceil} \rfloor$ and let $s = n - p\lceil \log_2 k \rceil$. Groups $G_1, G_2, \ldots, G_s$ consist of $p + 1$ bins and the other groups consist of p bins. Let $S_1 = \{x \mid \frac{k}{2} \le x \le k\}$ and $S_i = \{x \mid \frac{k}{2^i} \le x \le \frac{k}{2^{i-1}}\}$ for $2 \le i \le \lceil \log_2 k \rceil$. When Dlog receives an item o of size $s_o \in S_i$, it decides which G_j group of bins to pack it in by calculating $j = \max\{j \le i \mid \text{there is a bin in } G_j \text{ that has room for } o\}$. If j exists, o is packed into G_j according to the FF rule. Otherwise, the item o is rejected.

The authors proved that for every $\alpha \ge 1$, if $m \ge c\lfloor \log_2 k \rfloor$, the competitive ratio of Dlog on α-sequences is $\Theta(\frac{1}{\log k})$.

They also defined a randomized version of log and proved that, on accommodating sequences, its competitive ratio is $\Theta(\frac{1}{\log k})$. This is quite close to the best possible, as they have already shown that any deterministic or randomized online algorithm for this problem has a competitive ratio of less than $\frac{4}{\lfloor \log_2 k \rfloor}$. Some other results were given where we know the optimum value in advance.

Coffman et al. [14] investigated the previous FFI and ITERATED-FIRST-FIT-DECREASING algorithms for lists with divisibility conditions. They proved that if L is weakly divisible, then FFD* will produce an optimal packing. Moreover, if L is strongly divisible, even FFI gives an optimal packing.

33.2.1 Generalizations of the Objective Function

In the classical bin packing problem the cost associated with a given bin is either zero or one, depending on whether it is empty or not. Anily et al. [15] defined a more general model, where the cost of a bin is a monotone and concave function of the number of items in a bin. Let $f(j)$ define the cost of a bin that contains j items. The properties are defined as

Monotonicity. The cost of a bin does not decrease with the inclusion of additional items, i.e., if $j \le k$, then $f(j) \le f(k)$.

Concavity. The incremental cost (due to the addition of an item) to a set of items is no more than the incremental cost resulting from the addition of an item to a smaller set. Formally, for all $j \ge 1$, $f(j + 1) - f(j) \le f(j) - f(j - 1)$. We assume that $f(0) = 0$ as well.

The authors showed that the classical algorithms NF, FF, BF, FFD, and BFD have neither finite absolute worst-case ratios nor finite asymptotic worst-case ratios for the bin packing problem with general cost structure, where these ratios are defined in a similar way to those for the classical problem—just replace the number of bins by the sum of the cost of all bins used. They also proved that the absolute worst-case bound for the NFI (NEXT-FIT-INCREASING) algorithm is less than or equal to

$$\min\left\{1.75,\, 1.7 + \frac{2}{b_{OPT}(L)},\, 1.691\ldots + \frac{3}{b_{OPT}(L)}\right\}$$

where $b_{OPT}(L)$ denotes the optimal cost for the list L. This is the best known algorithm for this problem.

33.3 Bounds on the Number of Items per Bin

Krause et al. [3] investigated a task scheduling problem on a multiprogramming computer system. Here we suppose that we have a system with $k \ge 2$ processors that share a common memory of fixed capacity. A sequence of tasks with unit processing times have to be executed on these processors. Each task has a certain memory requirement. The goal here is to execute these tasks in the shortest possible time. We can represent the tasks by items and each unit of time by one bin. The memory requirements of the tasks are then the item sizes, and tasks that are performed at the same time correspond to items in the same bin. The size of the memory is the bin capacity. The schedule length will be the number of bins used in the packing. So they actually defined a bin packing problem with the restriction that no more than k items can be placed in one bin. Krause et al. at first investigated a suitable modification of the FF heuristic: use the FF rule with the additional constraint that we can place an item into a bin only if the number of items is not larger than k. Let us call this heuristic kFF. They proved that for each list L,

$$kFF(L) \leq \left(\frac{27}{10} - \frac{24}{10k}\right) OPT(L) + 2$$

and also gave examples (with arbitrarily large OPT(L)) such that

$$kFF(L) = \left(\frac{27}{10} - \left\lceil \frac{37}{10k} \right\rceil\right) OPT(L)$$

From this we have

$$\left(\frac{27}{10} - \left\lceil \frac{37}{10k} \right\rceil\right) \leq R^{\infty}_{kFF} \leq \left(\frac{27}{10} - \frac{24}{10k}\right)$$

where, in particular, $R^{\infty}_{2FF} \leq 1.5$ and $1.4666\ldots \leq R^{\infty}_{3FF} \leq 1.9$.

This is, of course, an online algorithm. They also offered better offline algorithms. The first is called the LARGEST MEMORY FIRST (LMF) algorithm, but it is actually a suitable modification of the First Fit Decreasing rule: first sort the items and then use the FFD rule. If a bin already has k items, it is closed. For this algorithm they proved that

$$R^{\infty}_{LMF} = 2 - \frac{2}{k}$$

if $k \geq 2$.

The second algorithm of Krause et al. is called the ITERATED WORST-FIT DECREASING (IWFD) rule. It starts by sorting the items in ascending order of size and then opens q empty bins, where

$$q = \left\lceil \max\left(\frac{n}{k}, \sum_{j=1}^{n} s(a_j)\right) \right\rceil$$

n being the number of items in our list. It is an obvious lower bound on $OPT(L)$. The IWFD rule uses the Largest Processing Time (LPT) rule to pack the list: put the next item into the bin with the lowest level. It breaks ties in favor of the highest index. The IWFD rule starts with q bins. If LPT does not pack all items into q bins, then this number is increased by 1. All bins are cleared and the procedure starts all over again. This is repeated until the whole list is packed. The number of bins used in the last step is defined as IWFD(L). It can be shown that for special lists the IWFD rule has good properties and for the general case

$$\frac{4}{3} \leq R^{\infty}_{IWFD} \leq 2$$

As the gap is quite large, the exact value remains an interesting open question. The authors put it at 4/3.

Babel et al. [16] returned to this bin packing problem. They presented two heuristics for the online version. Both heuristics better the previous best result by Krause et al. For increasing values of k, the asymptotic worst-case ratio tends to 2 for the first method, and it is 2 for the second algorithm. The chief feature of the first heuristic is that a new item can be packed into a bin only if the bin contains relatively few items or, if it does not, the bin together with this new item is sufficiently filled. The second algorithm defines three different bin types (depending on the bin level and the number of items already packed) and attempts to pack the next item first in the first, then in the second, and finally in the third type of bins. The authors also gave the best possible algorithm for $k = 2$ with an asymptotic worst-case ratio of $\sqrt{2}$. For $k = 3$ they offered a simple heuristic with worst-case ratio of 5/3 and showed that no online algorithm for this case can have worst-case ratio better than 3/2.

33.3.1 Online Bin Coloring

Shachnai and Tamir [17] defined a coloring problem, which is actually a generalization of bounds on the number of items per bin. In their version every item has the same (unit) size and a color. The number of different colors is M. The bins have a capacity B and c compartments. We need to fill the bins with items, subject to capacity constraints (such that items of different colors are placed in different compartments) so that each bin contains at most c different colors. The goal is to minimize the number of bins used. The absolute and asymptotic worst-case ratios are defined in a similar way to the classical problem. This variant is called the *Class-Constrained Bin Packing* (CCBP). Their first result is a tight bound of 2 on the competitive ratio of any online algorithm.

For special lists they obtained better results. Let $S_{c,B}(k, h)$ denote the set of all lists, where $kc < M \leq (k+1)c$ and $h \cdot B < n \leq (h+1) \cdot B$ (n is the number of items in the list). The competitive ratio of an algorithm A restricted to an input set S of lists will be denoted by $r_A(S)$. They showed that for any deterministic algorithm A, $1 < c < B$, $k \geq 0$ and $h \geq k - 1 + \max\{\lceil k/(c-1)\rceil, \lceil (kc+1)/B\rceil\}$,

$$r_A(S_{c,B}(k, h)) \leq 1 + \frac{k + 1 - \left\lceil \frac{kc+1}{B} \right\rceil}{h+1}$$

The authors showed that a variant of the FF rule achieves this bound. A greedy algorithm based on partitioning the items into color sets was shown to be efficient as well.

Krumke et al. [18] introduced a new variant of bin packing called *bin coloring*. Here we have unit size items where each item has a color, and we have to pack them into bins of size B (an integer). They considered an online, bounded-space problem, that is, one where we can use at most m open bins at the same time. A further restriction is that we can close a bin only when it is full, that is, after we have packed B items into it. The goal is to minimize the maximum number of different colors assigned to a bin. To measure the goodness of a heuristic algorithm they used the absolute worst-case ratio. They investigated two heuristic algorithms and gave some general bounds.

- The first method was the GREEDYFIT rule, which works as follows: if upon the arrival of item a_i the color of this item is already contained in one of the currently open bins, put it into this bin. (If the bin becomes full with this item, close it.) Otherwise, put the item into a bin that contains the least number of different colors (which means opening a new bin if currently fewer than m bins are partially filled). The competitive ratio of this method is at most $3m$ but not less than $2m$ (provided the capacity B is sufficiently large).
- The second method was the trivial algorithm ONEBIN, which is actually the Next Fit algorithm: the next item is packed into the (one) open bin. A new bin is opened only if the previous item closed the previous bin by filling it up completely. Quite surprisingly, this algorithm has a better competitive ratio than GREEDYFIT, it being $2m - 1$.

They also proved that no online algorithm can be substantially better than ONEBIN: no deterministic online algorithm can have a competitive ratio better than m. This bound holds for randomized algorithms too. Using resource augmentation, that is, allowing the online algorithm to use a fixed number of $m' \geq m$ open bins, the lower bound will still be $\Omega(m)$.

33.4 Dynamic Bin Packing

Coffman et al. [4] defined an interesting generalization of the classical problem. They added arrival and departure times to each item. These define the various time intervals during which items occupy bins. Compared with the classical "archival" model, this model is more realistic in certain applications, such as those relating to computer storage allocation.

The formal model is defined as follows. We are given a list $L = (p_1, p_2, \ldots, p_n)$. Each item p_i in L corresponds to a triple (a_i, d_i, s_i), where a_i is the arrival time for p_i, d_i its departure time, and s_i its size. The item p_i resides in the packing for the time interval $[a_i, d_i)$, and we assume that $d_i - a_i > 0$ for all i. We also assume that the items in L are ordered in such a way that $a_1 \leq a_2 \leq \cdots \leq a_n$.

Coffman et al. analyzed the FF method for dynamic bin packing. With this version, FF maintains two lists of bins: a list of currently empty bins and a list of currently occupied bins, with the latter ordered such that the times of the most recent transitions from empty to nonempty bins are nondecreasing. We use $B_1, B_2, \ldots$ to denote the bins in the occupied bins, in this order.

For each i, as in the classical version, the FF rule attempts to pack p_i into the first occupied bin (the one with the lowest index) that has sufficient available space for it. If no such occupied bin exists, p_i is put into an empty bin and this bin is appended to the list of occupied bins. The departure of p_i at time d_i simply causes an increase by s_i in the available space in the bin in which it was packed and, if the bin becomes empty at that time, it is moved to the list of empty bins.

Let $FF(L, t)$ denote the number of occupied bins in the FF packing of L at time t. The performance of FF applied to the list L is defined by

$$FF(L) = \max_{0 \le t \le a_n} FF(L, t)$$

This is the maximum number of occupied bins ever required by FF for processing L. This definition can be applied to an arbitrary packing algorithm A simply by replacing FF with A. We will apply this measure to two different ways of optimal packing depending on how the items in L can be packed. The first method, $OPT_R(L)$, is the maximum number of bins ever required in dynamically packing L when the current set of items is *repacked* into the minimum number of bins each time a new item arrives. The second, $OPT_{NR}(L)$, is the maximum number of bins ever required in dynamically packing L when *no rearrangement* of items is allowed, and otherwise packed optimally so as to achieve the least possible value of this maximum over all such packings of L, with L assumed to be fixed and known in advance. The performance ratio of an arbitrary packing algorithm A is now defined in the standard way. Let

$$W_{R,n}\left(A, \frac{1}{k}\right) = \sup_{|L|=n} \frac{A(L)}{OPT_R(L)}$$

where all item sizes are less than or equal to $1/k$. We then define

$$W_R^{\infty}\left(A, \frac{1}{k}\right) = \limsup_{n \to \infty} W_{R,n}\left(A, \frac{1}{k}\right)$$

Similar definitions apply to $W_{NR}^{\infty}(A)$. The authors gave the following bounds:

$$W_R^{\infty}\left(FF, \frac{1}{k}\right) \le \frac{k+1}{k} + \frac{1}{k-1} \log \frac{k^2}{k^2-k+1}, \quad k \ge 2$$

$$W_R^{\infty}(FF, 1) \le \frac{5}{2} + \frac{3}{2} \log \frac{\sqrt{13}-1}{2} \approx 2.897$$

They also gave a slightly improved FF version for which W_R^{∞} is bounded by 2.788.... In addition, they proved that

$$W_R^{\infty}\left(FF, \frac{1}{k}\right) \ge \frac{k+1}{k} + \frac{1}{k^2}, \quad k \ge 2$$

$$W_R^{\infty}(FF, 1) \ge \frac{11}{4} = 2.75$$

They derived a lower bound that holds for an *arbitrary* online algorithm A :

$$W_R^{\infty}\left(A, \frac{1}{k}\right) \ge W_{NR}^{\infty}\left(A, \frac{1}{k}\right) \ge \frac{k+1}{k} + \frac{1}{k(k+1)}, \quad k \ge 2$$

$$W_R^{\infty}(A, 1) \ge \frac{5}{2}$$

$$W_{NR}^{\infty}(A, 1) \ge \frac{43}{18} \sim 2.388\ldots.$$

We should note that the upper and lower bounds are quite close to each other. We have the largest gap for $W_R^\infty(FF, 1)$ for which

$$2.75 \le W_R^\infty(FF, 1) \le 2.897$$

33.5 Constraints on Data

33.5.1 Bin Packing Using Semi-Ordinal Data

Liu and Sidney [5] investigated the bin packing problem under the ordinal data scenario: the item sizes are not known, but the order of the weights is known, that is, $a_1 \ge a_2 \ge \cdots \ge a_n$. Specific sizes may be obtained, and the trade-off between the amount of information obtained versus the solution quality (performance ratio) is investigated.

If the only information available about L is the ordinal assumption, then we can place only one item per bin, since all items may be larger than 1/2. Even in this case the optimal solution may be 1 if $\sum a_i \le 1$. So we have a worst-case ratio of n. Suppose we could purchase perfect knowledge of k sizes, where we can specify the ranks (ordinal positions) of the desired sizes. Which ordinal positions should we choose to guarantee a good feasible solution that utilizes the knowledge of these sizes? Liu and Sidney proved that the worst-case ratio of an integer ρ can be achieved by at most

$$\lfloor \ln[n(\rho - 1) + 1]/\ln\,\rho \rfloor$$

exact observations, and that this worst-case performance cannot be achieved with fewer than

$$\left\lfloor \frac{\ln \frac{n(\rho-1)}{\rho^2-\rho+1}}{\ln\,\rho} \right\rfloor + 1$$

exact observations. They also gave a method for choosing a good set of indices.

33.5.2 Fragmentable Bin Packing

Mandal et al. [6] defined the following variant called *Fragmentable Object Bin Packing*: it is permissible to fragment the items while packing them into bins of fixed capacity. Fragmentation has an additional cost associated with it, leading to the consumption of additional bin capacity. They proved that this problem is NP-hard too. Unfortunately no heuristic was analyzed from the worst-case point of view.

Menakerman and Rom [19] tackled this problem further and defined two variants. The first variant is called BIN PACKING WITH SIZE-INCREASING FRAGMENTATION (BP-SIF). In this variant, when packing a fragment of an item, one unit of overhead is added to the size of every fragment. They supposed that the item sizes were integer-valued and that each bin size had an integer value U. An algorithm is said to prevent unnecessary fragmentation if it follows the following two rules:

- *No unnecessary fragmentation.* An item (or fragment of an item) is fragmented only if it is to be packed into a bin that cannot contain it. In this case the item is fragmented into two fragments. The first fragment must fill one of the bins, and the second fragment must be packed according to the packing rule of the algorithm.
- *No unnecessary bins.* An item is packed into a new bin only if it cannot fit in any of the open bins used by the algorithm (greedy).

They proved that for any algorithm that prevents unnecessary fragmentation the absolute worst-case bound is $\le \frac{U}{U-2}$. They also showed that the following variant of the NEXT FIT rule, called NF_f, achieves this bound. When an item does not fit in the open bin, it is fragmented into two parts. The first part or piece fills the open bin and the bin is closed. The second part or piece is packed into a new bin which becomes the open bin. The Next Fit Decreasing and the Next Fit Increasing rules have basically the same bound, for large enough U. Neither the First Fit Decreasing rule nor the following iterative variant of the

First Fit Decreasing rule improves the bound: we start with $m = \lceil s(L)/U \rceil$ bins and try to pack the items by the FFD rule. If every item has been packed then we stop. If some remain then m is increased by 1 and we start packing the whole list again. This is repeated until every item has been packed.

The second variant is BIN PACKING WITH SIZE-PRESERVING FRAGMENTATION (BP-SPF). In this version each item has a size and a cost. The items must be packed into m bins, where $s(L) \leq mU$. It is possible to fragment any item, in which case one unit is added to its cost while keeping the size fixed. The goal is to minimize the total cost. As every item must be packed and for the chosen m this is possible because the fragmentation does not increase the size we have a fixed cost for the whole list. The minimization of the cost is equivalent to the minimization of the number of fragmentations. The problem remains NP-hard. They proved that for any algorithm A that has no unnecessary fragmentations, the extra cost is bounded above by $m - 1$, and that NF_f achieves this bound. The appropriate variant of the FFD rule betters this bound only when U is small. If the bin size is unbounded, the worst-case behavior of the FFD rule is the maximum possible value.

33.5.3 Packing Nodes of Graphs

Jansen and Öhring [7] once looked at a constrained bin packing problem: in this case there is an undirected graph (*the conflict graph*) $G = (J, E)$ on the elements. The adjacent items $(a_i, a_j) \in E$ have to be packed into different bins, and the goal is to minimize the number of bins. Clearly, if E is an empty set, the problem is equivalent to the classical bin packing problem. In contrast, if $s(L) \leq 1$, then the problem is to compute the chromatic number $\chi(G)$ of the conflict graph. Both special cases are NP-complete. The authors used the absolute worst-case ratios and then proved that simply using the appropriate modifications of the classical algorithms NF, FF, and FFD will not yield a constant competitive ratio. (The appropriate modification simply means that we use the heuristic, but if the item to be packed has an adjacent item in the bin being packed, then we do not pack it into this bin.) Their other algorithms were based on the composition of two algorithms—a coloring algorithm and a bin packing heuristic.

The first algorithm of this type uses an optimal coloring, that is, it finds a minimum partition of L into independent sets $U_1, U_2, \ldots, U_{\chi(G)}$, and then applies one of the NF, FF, and FFD bin packing heuristics to each independent set. They proved that in this case NF has a competitive ratio of 3, FF of 2.7, and for the FFD the bound lies between 2.691 and 2.7.

The second algorithm of this type is based on a precoloring method. The main step is to compute a minimum coloring of the conflict graph where the large items are separated and colored differently. On the basis of this method, they obtained an approximation algorithm with competitive ratio of 5/2 for graphs such as interval graphs, split graphs, cographs, and other graphs. More involved coloring methods are used to obtain algorithms with worst-case bounds of 7/3, 11/5, and 15/7, respectively. The last of these methods is a general separation method that works for cographs and partial K-trees. Applying this separation method they obtained an approximation algorithm with worst-case ratio of $2 + \varepsilon$ for these two classes of graphs. This result implies an approximation with factor $2 + \varepsilon$ for any class of graphs with a constant upper bound on the treewidth (e.g., outerplanar graphs and series-parallel graphs).

Katona [20] investigated the edge disjoint polyp packing problem. A graph is called a *p-polyp* if it consists of p simple paths of the same length and one vertex of these paths is a common vertex. The polyp packing problem is a generalization of the classical bin packing problem: how does one pack a set of paths with different lengths into a set of disjoint polyps edges? Edge disjoint packing means that the embedded path may contain a vertex more than once, but each edge only once. Katona proved that this problem is NP-complete and that the appropriate modification of the FF rule has an asymptotic worst-case bound lying between 1.6904 and 1.7.

Codenetti et al. [21] have investigated the following variant: the items to be packed are structured as the leaves of a tree. They called this problem a hierarchically *structured bin packing problem* (SBPP). The goal is to pack the items while preserving some locality properties, that is, leaves whose lowest common ancestor has a low height should be packed into the same bin. This problem comes up in the area of document organization and retrieval where one is confronted with searching issues on very large structured, tree-like ontologies. The formal definition is given as follows. Given a tree $T = (V, E)$ and a vertex $v \in T$, $S_T(v)$ will denote the subtree rooted at v, $L_T(v)$ and $N_T(v)$ will denote the set of leaves and internal nodes of $S_T(v)$, respectively. Let $\mathcal{P}$ be a partition of $L_T(v)$. The *node dispersal number* for the node v of T with a given $\mathcal{P}$ is

$$\rho(v, \mathcal{P}) = | \{A \in \mathcal{P} \mid L_T(v) \cap A \neq \emptyset\} |$$

In other words, given a vertex v, $\rho(v, \mathcal{P})$ counts how many sets of $\mathcal{P}$ intersect $L_T(v)$. Now the SBPP is defined as follows. Given a tree T, a positive size function $s : L_T \rightarrow N^+$ and a positive integer (bin) capacity $c \leq \max_{v \in T} s(v)$, find a partition $\mathcal{P}$ of L_T such that

- for every set $A \in \mathcal{P}$ the total size of the leaves in A is bounded by c;
- the total node dispersal number $\rho(\mathcal{P}) = \sum_{v \in N_T} \rho(v, \mathcal{P})$ is minimum.

Informally, we start with a partition $\mathcal{P}$ of the leaves such that, in each subset, the total weight of the leaves is bounded by c (the bin capacity). Then for each internal node of the tree we define the node dispersal number, which is the number of subsets in $\mathcal{P}$ for which the node has a successor in the subset. The total node dispersal number is the sum of the node dispersal numbers for each internal node. In the SBPP we have to find a partition of leaves with the minimal total node dispersal number. The authors presented a heuristic with an asymptotic worst-case ratio of 2. For the special case where every item size is equal to 1 and the bin capacity is k, they found a heuristic with a worst-case bound of 3/2.

33.6 Changing the Bin Size

Azar and Regev [8] investigated the online version of a special case of this problem and called it bin stretching. They supposed that the optimal bin capacity is known and that the goal is to find a good heuristic, given this information. The supremum of the bin capacity ratio of an algorithm and the optimal value is called the stretching factor. They first proved that the stretching factor of any deterministic online algorithm is at least 4/3 for any number $m \geq 2$ of bins. They also gave two algorithms with a stretching factor of 5/3. To describe these algorithms we first need some additional notation. Let $c_j(B_i)$ denote the level of bin i after a_j was packed. Both algorithms use a parameter $\alpha > 0$ to classify the bins according to their levels. An appropriate choice of α will lead to an algorithm with a stretching factor of $1 + \alpha$. We will call a bin *short* if its level is at most α. Otherwise, it is *tall*. When item a_j arrives, $1 \leq j \leq n$, we define the following three disjoint sets of bins:

$$S_1^\alpha(j) = \left\{i \in M \mid c_{j-1}(B_i) + s(a_j) \leq \alpha\right\}$$
$$S_2^\alpha(j) = \left\{i \in M \mid c_{j-1}(B_i) \leq \alpha, \alpha < c_{j-1}(B_i) + s(a_j) \leq 1 + \alpha\right\}$$
$$S_3^\alpha(j) = \left\{i \in M \mid c_{j-1}(B_i) > \alpha, c_{j-1}(B_i) + s(a_j) \leq 1 + \alpha\right\}$$

The set S_1 consists of bins that are short and remain short if the current item is placed into them. The set S_2 contains bins that are short but become tall if the next item is packed. The last set S_3 consists of bins that are tall but remain below $1 + \alpha$ if the next item is packed. Note that there may be bins which are not in any of these three sets. Now the two algorithms are defined as follows:

$ALG1_\alpha$: when the next item a_j arrives

- Put the item into any bin belonging to the set S_3 or S_1, but not in an empty bin belonging to S_1 if there is a nonempty bin belonging to S_1.
- If $S_1 = S_3 = \emptyset$ then put the item into the bin belonging to S_2 with the least level.
- If $S_1 = S_2 = S_3 = \emptyset$ then report failure.

$ALG2_\alpha$: when the next item a_j arrives

- Put the item into any bin belonging to S_1.
- If $S_1 = \emptyset$ then put the item into any bin belonging to S_3.

- If $S_1 = S_3 = \emptyset$ then put the item into the bin with the least level.
- If $S_1 = S_2 = S_3 = \emptyset$ then report failure.

Note that both algorithms actually define a family of algorithms. Azar and Regev proved that both algorithms have a stretching factor of $5/3$ for the best possible choice of α (which is equal to $2/3$). They also presented an improved algorithm using five sets of bins. This has a stretching factor of $13/8$.

Kellerer et al. [22] showed that for two bins the List Scheduling algorithm has a stretching factor of 2.

Epstein [23] gave a tight analysis of bin stretching for two bins, where the items arrive sorted in nonincreasing size. She showed that the tight competitive ratio of this problem is 10/9 and gave a quite complicated algorithm that achieves this bound.

Speranza and Tuza [24] investigated a different problem. Suppose we have m bins of unit capacity and that the bin capacity can be exceeded. If the sum of the sizes of the items in the bin is greater than 1, then the cost of the bin will be this sum. Otherwise, the cost is equal to the capacity 1. The goal is to minimize the total cost of the bins. They investigated the online version of this problem. First they proved that every online algorithm has an absolute worst-case ratio of $7/6$. This can be demonstrated with two bins: simply make the first two elements equal to $1/3$, and for the sum of the next two items, let $a + b = 4/3$. Now, if both $1/3$ items are packed into the same bin, let $a = b = 2/3$. If they are packed into different bins, let $a = 1$ and $b = 1/3$. They proved as well that the List Scheduling algorithm has a tight bound of 5/4.

The above authors also presented an improved algorithm H_x. This depends on a parameter $x, 0 < x < 1$. The algorithm assigns an item to the bin with the highest level under the condition that after the assignment of the item to the bin the level of the bin does not exceed $1 + x$. If the item causes excess greater than x in each open bin, it is then assigned to an empty bin—if there is any—or to the bin with the lowest level. In case of ties, the bin with the lowest index is used. They proved that

$$\frac{H_x(L)}{\text{OPT}(L)} \leq \max\left(1 + \frac{x}{1+x}, \frac{5}{4} - \frac{x^2}{4}\right)$$

The right-hand side has a minimum at $x \approx 0.2956$, the minimum being ≈ 1.228. It is not known whether this bound is tight.

An $13/12$ algorithm is given by Dell'Olmo et al. [25].

Yang and Leung [26] introduced the *Ordered Open-end Bin Packing Problem* (OOBP). Here a bin can be filled to a level exceeding 1 so long as there is a designated last piece in the bin such that the removal of this piece brings the bin's level back to below 1. In this problem items of size 1 play a special role, and will be called 1-pieces. It is quite clear that a good algorithm for this problem will fill the majority of bins to levels no less than 1, while for any algorithm, no bin can be filled to a level more than 2. Hence, any good algorithm will have a worst-case ratio of no more than 2. The authors showed that for any online algorithm A, $R_A^{\infty} \geq 1.630297$ with the 1-pieces, and $R_A^{\infty} \geq 1.415715$ without the 1-pieces.

They then introduced two algorithms. The first is called MIXED FIT (MXF) and is defined as follows: we divide the items into four types according to their size. Type-1 items will have a size $0 < s(a_i) < 1/3$, type-2 items have size $1/3 \leq s(a_i) < 1/2$, type-3 items have size $1/2 \leq s(a_i) < 1$, and type-4 items have size 1. Accordingly, we define a type-1 open bin as an open bin containing a number of type-1 items, a type-2 open bin as a bin containing one or two type-2 items, and a type-3 open bin as a bin containing one type-3 item. We pack the items in order of their arrival. When the current item is of type-1, we pack it into the type-1 open bins using the FF rule without closing any bin. When the current item is of type-2, we pack it similarly into type-2 bins. Suppose the current item is of type-3 or type-4. We pack it into the first type-1 or type-2 open bin whose level is at least $2/3$ and close this bin. If there is no such bin, we pack the item into an open type-3 bin and then close it. If there is no such bin, we pack the item into a new bin and close it if the item is a type-4 item. The authors showed that with no 1-piece present,

$$R_{MXF}^{\infty} \leq 35/18 \approx 1.9444$$

and they also showed that regardless of the presence of the 1-pieces,

$$R_{MXF}^{\infty} \geq 25/13 \approx 1.9231$$

Their second algorithm is the GREEDY LOOK-AHEAD NEXT FIT (GLANF), which is an offline algorithm. With this algorithm there is one open bin at any given moment. GLANF keeps on filling the current bin with items in their original order unless the first piece is a 1-piece or the addition of the next piece will bring the bin's level to be at least 1. For the latter situation GLANF makes some greedy effort in filling the current open bin to the highest possible level. They proved that, without the 1-pieces,

$$\frac{27}{20} \le R^{\infty}_{GLANF} \le \frac{3}{2}$$

and with the 1-pieces,

$$R^{\infty}_{GLANF} \ge \frac{3}{2}$$

34.1 Introduction

In this chapter we continue our survey with a focus on two variants of the one-dimensional bin packing problem: the variable-sized bin packing problem and the bin covering problem. In Section 34.2, we survey algorithms for packing into bins of different sizes, a problem first studied by Friesen and Langston [1] in 1986. In Section 34.3, we survey the bin covering problem, which asks for a partition of a given set of items into a maximum number of subsets such that, in every subset, the total item size is always at least some lower bound. This problem was first studied by Assmann et al. [2] in 1984. Concluding remarks are given in Section 34.4.

34.2 Variable-Sized Bin Packing

In the classical bin packing problem the measure of a packing is the number of bins used. The wasted space in the packing is an equivalent measure; a packing that minimizes one of these measures minimizes the other. In what follows, we focus on the wasted-space measure.

Interesting results are available if we relax the condition of having bin sizes fixed in advance. In a problem posed by Friesen and Langston [3], the bin size, which must be the same for all bins, is part of the solution. What is a bin size α, and a packing into bins of this size, which minimizes the wasted space? If there were no bound on the maximum bin size, the problem would be trivial: use only one bin with a size equal to the total item size. But a maximum bin size is a constraint of the problem, and we normalize to one for convenience. The goal is to choose a number $\alpha \leq 1$, and produce a packing of a list $L = (a_1, a_2, \ldots, a_n)$ into N bins of size α such that

$$N\alpha - \sum_{i=1}^{n} s(a_i)$$

is as small as possible. The analysis compares the worst-case wasted space of approximation algorithms to OPT_{α_0}, the minimal space wasted using bin size $\alpha_0 \leq 1$. Friesen and Langston proved that if a bin packing algorithm A can guarantee a worst-case ratio R for the classical bin packing problem, then an iterated version of A can be used to achieve a bound as close to R as we would like. More precisely, if a bound of $R+\epsilon$ is sought, we can generate a sequence of sizes $\alpha_1, \alpha_2, \ldots, \alpha_k$ with $\alpha_{i+1} = \alpha_i R/(R+\epsilon)$ and prove that, if $\alpha_{i+1} < \alpha_0 \le \alpha_i$, then running algorithm A on bins of size α_i will ensure a wasted space $A_{\alpha_i}(L) < (R+\epsilon)OPT_{\alpha_0}(L)$.

The next step taken by Friesen and Langston [1] allowed more than one bin size for packing. They defined the variable-sized bin packing problem on a finite collection of k available bin sizes, $s_1 > s_2 > \cdots > s_k$, with an inexhaustible supply of each size. We adopt the normalization whereby the items $\{a_i\}$ and bins are such that the largest bin has size $s_1 = 1$ and $s(a_i) \le 1$ for all $1 \le i \le n$. The goal is to pack the items into bins so that the sum of the sizes of the bins used is minimum.

The variable-sized bin packing problem is NP-hard [1], so as usual, efficient algorithms that ensure near-optimal packings comprise the design goal. Let $s(A, L)$ denote the total size of the bins used by algorithm A to pack the items of L. Then

$$R_A^{\infty} = \limsup_{k\to\infty} \left\{ \max \frac{s(A, L)}{s(OPT, L)} : s(OPT, L) \ge k \right\}$$

is the asymptotic worst-case ratio of algorithm A.

Friesen and Langston presented three approximation algorithms, with asymptotic worst-case ratios of 2, 3/2, and 4/3, respectively. The first algorithm is a simple adaptation of the NEXT FIT (NF) rule. They called it NEXT FIT USING LARGEST BINS ONLY (NFL), that is, NF packing only into bins of size 1. The proof of $NFL(L) < 2 \cdot OPT(L) + 1$ for any list L is quite standard. Letting ϵ denote an arbitrarily small positive real value, any instance consisting of items of size $1/2+\epsilon$ and bins of sizes 1 and $1/2+\epsilon$ shows that 2 is a matching asymptotic lower bound.

The second algorithm is a variant of the FIRST FIT DECREASING (FFD) rule, called FIRST FIT DECREASING USING LARGEST BINS, THEN REPACK INTO SMALLEST POSSIBLE BINS (FFDLR); and it does what its name says: In the first round the elements are sorted in decreasing order and the items are packed into bins of size 1 by the FFD rule. In the second round it attempts to repack all used bins into the smallest possible bins, where only the full content of a bin can be repacked. This algorithm has an asymptotic worst-case bound of 3/2.

The third algorithm FFDLS (FIRST FIT DECREASING USING LARGEST BINS, BUT SHIFTING AS NECESSARY) uses two rounds as well but tries to repack the contents of certain bins even in the first round. It is a modification of the FFDLR rule in the sense that it uses the same method in both rounds, but in the first round when a_i is packed into bin B_j it checks whether B_j contains an item of size greater than 1/3. If so it repacks, where possible, all the items in B_j into the smallest empty bin $B_{j'}$ that will hold them, and for which $c(B_{j'}) \ge (3/4)c(B_j)$ holds. The second round of the FFDLS rule is the same as that for FFDLR. This algorithm has an asymptotic worst-case bound of 4/3.

Note that only the first of the three algorithms is online. Kinnersley and Langston [4] gave better online algorithms, as follows. First, they proved that two variants of FIRST FIT (FF) (FFL—FIRST FIT, USING LARGEST POSSIBLE BINS and FFS—FIRST FIT, USING SMALLEST POSSIBLE BINS) both have a worst-case bound of two. They observed that the FFL rule fails in its packing of "large" items (those with a size exceeding 1/2) and FFS fails in its packing of "small" items (those with size at most 1/2). So they focused on a hybrid approach that we denote by FFf. Let f denote a user-specified factor in the range $[1/2, 1]$. Suppose FFf has to start a new bin when it is packing a piece a_i. If a_i is a small piece, FFf starts a new bin of size 1. If a_i is a large piece, then it selects the smallest bin size in the range $[s(a_i), s(a_i)/f]$ if such a size exists, otherwise it will use bin size 1. Kinnersley and Langston proved that

$$FFf(L) \le \left(1.5 + \frac{f}{2}\right) OPT(L) + 2$$

for any list L. We should remark here that for the smallest possible f this gives an asymptotic upper bound of 1.75.

They also proved that for the parametric case, FFL gives the same performance as FF for the classical problem, if every item is at most 1/2. Later, Zhang [5] showed that the best possible FFf algorithm (with $f = 1/2$) has a tight bound of 17/10, the bound for FF in the classical bin packing problem.

Csirik [6] introduced a Harmonic type heuristic, VARIABLE HARMONIC M (VH_M) that is based on a harmonic subdivision of each bin size. Let $M > 1$ be a positive integer and let $M_j = \lceil M \cdot s(B_j) \rceil$ ($j = 1, 2, \ldots, k$). The algorithm is defined only for those M where $M_k \geq 2$. Let us divide the intervals $(0, s_j]$ ($j = 1, 2, \ldots, k$) into M_j parts according to the following harmonic partitioning:

$$I_{j,l} = \left(\frac{s_j}{l+1}, \frac{s_j}{l} \right], \quad j = 1, 2, \ldots, k; \; l = 1, 2, \ldots, M_j - 1$$

and

$$I_{j,*} = \left(0, \frac{s_j}{M_j} \right]$$

For each bin size s_j we define a weighting function as follows:

$$W_j(a_i) = \begin{cases} \frac{M_j}{M_j - 1} s(a_i) & \text{if } s(a_i) \in I_{j,*}, \\ \frac{s_j}{l} & \text{if } s(a_i) \in I_{j,l}, \; l = 1, 2, \ldots, M_j - 1, \\ \infty & \text{if } s(a_i) > s_j. \end{cases}$$

Let

$$W(a_i) = \min_{j=1,2,\ldots,k} W_j(a_i)$$

be the weight of a_i.

Now we can define the algorithm VH_M as follows.

Step 1. We assign to each item of the list a bin size; an item assigned to a bin of size s_j is called a type j item.

(a) $s_1 = 1$ is assigned to each element a_i with

$$W(a_i) = (M_1/(M_1 - 1)) \cdot s(a_i)$$

These items are called small items, and all others big items.

(b) A big item a_i will be a type-j element if j is the smallest integer such that $W(a_i) = W_j(a_i)$. A big element will be called an $I_{j,l}$ element if it is a type-j element and belongs to $I_{j,l}$.

Step 2. VH_M performs a harmonic fit type packing:

(a) Each big type-j element is packed by harmonic fit into bins of size s_j as follows. We classify these bins into $M_j - 1$ categories. Each category is designated to pack the same type of items. A bin of size s_j designated to pack $I_{j,l}$ items is called an $I_{j,l}$ bin. Clearly, each $I_{j,l}$ bin has room for exactly l items. We use a NF packing in all $I_{j,l}$ ($j = 1, 2, \ldots, k$; $l = 1, 2, \ldots, M_j - 1$) bins, that is, after packing l items into an $I_{j,l}$ bin, we close this bin and open a new $I_{j,l}$ bin.

(b) All small items are packed in bins of size 1 by NF.

Csirik proved that, using the sequence t_i defined in the harmonic algorithm, the following holds: If $t_{i(k)-1} < M_k \leq t_{i(k)}$, then

$$R_{VH_M} \leq \sum_{l=1}^{i(k)-1} \frac{1}{t_l - 1} + \frac{M_k}{(M_k - 1) t_{i(k)}}$$

He also considered the question of what performance can be achieved if we are free to choose the bin sizes. He proved that if we have just two bin sizes and the smaller bin size is optimally selected (this is 0.7) then the asymptotic worst-case ratio is 1.4.

Seiden [7] showed that variable harmonic is an optimal bounded-space algorithm. Seiden et al. [8] generalized the refined harmonic idea of the classical bin packing problem to the variable-sized problem with two bin sizes. Making use of refined harmonic they bettered the upper bound from 1.69103 to 1.63597. Seiden [9] once demonstrated that if we are allowed to choose the bin sizes then, with two bin sizes, the optimal performance ratio lies in the range [1.37530, 1.37532].

Epstein et al. [10] investigated in more detail the case of two different bin sizes. They presented two different algorithms for this case, both being combinations of harmonic and refined harmonic. They proved that the best of these two algorithms and the variable harmonic yields an upper bound of $373/227 < 1.63597$. They also gave the first lower bound for this problem, showing that for two bin sizes any online algorithm has an asymptotic performance ratio of at least 1.33561.

Burkard and Zhang [11] generalized the bounded space algorithm of Csirik and Johnson [12] so that it applied to the variable bin size problem. In the latter case we have to define the closing rule slightly differently because we may choose in between bin sizes too. Hence their closing rules are:

(1) *C-VF.* Close one active bin with size less than 1 if a such bin exists, otherwise use FF.
(2) *C-VB.* Close one active bin with size less than 1 if a such bin exists, otherwise use Best-Fit (BF).

They defined the opening rule in the following way: suppose a_i is a large item with size greater than 1/2. If it can be contained in a bin with size less than 1, it is called a B-item, otherwise it is called an L-item. The smallest bin that can contain a large item a_i is called an a_i-home-bin. Obviously, if a_i is an L-item, the size of the a_i-home-bin is 1. Their opening rule is, suppose the current item to be packed is a_i. If a_i is a B-item, open an a_i-home-bin and pack a_i into it. Otherwise, start a new bin of size 1 for a_i.

Burkard and Zhang proved that using this opening rule and the closing rule C-VB we will get a tight 1.7 performance bound for this algorithm for those cases where we have at least three open bins at the same time. This means that—taking into account Csirik and Johnson's result for classical bin packing—we need one more open bin for the variable-sized bin packing problem to have an algorithm with the same performance.

Chu and La [13] used a best-fit-like idea for variable-sized bin packing. They defined four algorithms: LARGEST OBJECT FIRST WITH LEAST ABSOLUTE WASTE (LFLAW), LARGEST OBJECT FIRST WITH LEAST RELATIVE WASTE (LRLRW), LEAST ABSOLUTE WASTE (LAW), and LEAST RELATIVE WASTE (LRW). Naturally, the first two are not online algorithms as they need a sorted list as input. They proved tight bounds for each algorithm, showing that

$$R^{\infty}_{LFLAW} = R^{\infty}_{LFLRW} = 2,\ R^{\infty}_{LAW} = 3 \text{ and } R^{\infty}_{LRW} = 2 + \ln 2$$

Zhang [14] introduced a relaxation on the online condition: Here we have all the information about the items, but we cannot preview the type of bin before it arrives. We must decide which items should be packed into the bin as it arrives. We will suppose that the largest item still fits in the smallest bin. In this case we have of course just one open bin, and we close it as we cannot pack more items into it. The goal is evidently to fill bins with the minimal total size. Zhang investigated the classical algorithms NF, FF, Next Fit Decreasing, and FFD and proved that each of them has an asymptotic worst-case ratio of 2. He also remarked that if there are at most l, $l \geq 1$, open bins at a time this ratio cannot be improved.

Dell'Olmo and Speranza [15] introduced a different relaxation on the variable-sized bin packing problem: They supposed that the bin sizes are extendible, that is, the total size of items packed into a single bin can exceed 1, if necessary. The goal is to minimize the total bin size, where the size of bin B_j is now given by $\max(c(B_j), s(B_j))$. The authors investigated two heuristics: Best Fit Decreasing (BFD) for the offline case and BF for the online case. They proved that BFD's performance bound is at most $2(2-\sqrt{2})$ and conjectured that the exact bound is 8/7. For the online case they proved a tight 5/4 bound for the BF algorithm and showed that no online algorithm can have better bound than 7/6.

Ye and Zhang [16] studied a similar problem. They supposed that we have m bins with different bin sizes. They called the set of bins a collection. We have to pack the items into these bins and overpacking is allowed. They distinguished two cases. In the first case, the largest item will fit into the smallest bin. They carefully analyzed the list scheduling algorithm and gave competitive ratios for each m and each collection. The ratios differ for an even number of bins and an odd number of bins. They were able to prove that

$$R_{LS}(m) = \begin{cases} 1 + \frac{m \cdot b_{\min}}{4\sum_{j=1}^{m} b_j} & \text{if } m \text{ is even} \\ 1 + \frac{(m^2-1)\cdot b_{\min}}{4m\sum_{j=1}^{m} b_j} & \text{if } m \text{ is odd} \end{cases}$$

where $b_{\min}$ is the smallest bin size. For equal bin size the ratio is 5/4 when m is even and $5/4 - 1/(4m^2)$ when m is odd. They presented an improved algorithm for $m = 2$ and $m = 3$.

In the second case, the largest item does not fit into the smallest bin. A lower bound for the overall competitive ratio is given for two bins.

Kang and Park [17] investigated the special case of variable-sized bin packing where we have (weak) divisibility conditions. Two types of conditions were looked at:

- where the sizes of the items are divisible,
- where the sizes of the bins are divisible, that is, $s(B_{j+1})$ exactly divides $s(B_j)$ for all $j = 1, 2, \ldots, k - 1$.

They also used a more general cost function: They assumed that the bin sizes are sorted in descending order, i.e., $b_1 \geq b_2 \geq \cdots \geq b_k$, and bins of size b_i have a cost c_i, where the unit size cost of each bin does not increase as the bin size increases, that is, the costs and the bin sizes satisfy $\frac{c_{i_1}}{b_{i_1}} \leq \frac{c_{i_2}}{b_{i_2}}$ for all $1 \leq i_1 \leq i_2 \leq k$. They studied iterative versions of the FFD and BFD rules. The ITERATIVE FIRST FIT DECREASING algorithm (IFFD) works as follows: We first pack all the items into the largest size bins using the FFD algorithm, and obtain a feasible solution. We then get another solution by repacking the items in the last bin of the solution into the next largest bin using the FFD rule. We obtain another feasible solution by continuing this procedure until we have repacked every item. In this way, we obtain feasible solutions for each type of bin. Then the best solution among them is selected as the final solution. The ITERATIVE BEST FIT DECREASING (IBFD) algorithm is similarly defined, using the BFD rule instead of the FFD rule in each step. They obtained a series of results for this algorithm:

- When L has divisible item sizes and bin sizes are divisible as well, there exists an optimal solution using k_1 or $k_1 - 1$ bins of type 1, where k_1 is the number of bins used in the first step of IFFD. This means that IFFD provides an optimal solution.
- For each L, if bin sizes are divisible, then $C(\mathit{IFFD}(L)) \leq \frac{11}{9} \cdot C(\mathit{OPT}(L)) + 5\frac{2}{9}$. Here $C(A(L))$ denotes the cost of packing list L by algorithm A. The bound of 11/9 is tight.
- The general case, that is, when we have no divisibility condition, for each L, $C(\mathit{IFFD}(L)) \leq \frac{3}{2} \cdot C(\mathit{OPT}(L)) + 1$. This bound is tight.

The same results apply to IBFD.

Xing [18] investigated a special case of variable-sized bin packing where we can have oversized items, that is, items with a size larger than the largest bin size. The bins cannot be overpacked, so we are free to divide up the oversized items such that the parts are no larger than the largest bin size. The problem is called *Bin Packing with Oversized Items,* (BPOS). Xing also defined a special objective function for this problem: If an item a_i is oversized and so packed into more than one bin, the extra bins do not contribute to the objective function. If we use bins $B_1, B_2, \ldots, B_m$ in the packing, then the objective function is

$$\sum_{i=1}^{m} s(B_i) - \sum_{i=1}^{n} (\lceil s(a_i) \rceil - 1)$$

Xing defined the following two-stage procedure: Let us delete size $\lfloor s(a_i) \rfloor$ from item a_i—now the size of the remaining part does not exceed the largest bin size. We can easily extend a heuristic algorithm of variable-sized bin packing to a heuristic of BPOS: first we pack $\lceil s(a_i) \rceil - 1$ unit-sized bins with unit parts of a_i and then the remaining part will be packed by the variable-sized bin packing heuristic. Let *TOPT(L)* denote the optimal value of the BPOS using a two-stage procedure. It can readily be seen that if there is only one bin size then *OPT*(L)=*TOPT*(L) for each list. If there are several bin sizes and the largest item is packed into l bins then

$$2 - \frac{1}{l+1} \leq R^{\infty}_{TOPT} \leq 2$$

and the ratio 2 is asymptotically tight.

Xing defined a modification of the FF algorithm for this problem and showed that its asymptotic worst-case ratio is 7/4. If there is a bin size between [2/3, 3/4], then the ratio is 3/2.

34.2.1 Number of Items

Langston [19] turned to the problem of maximizing the number of items packed into m available bins, where the bin sizes can be different. He analyzed the three heuristics given by Coffman et al. [20], and proved that both smallest-piece-first and first-fit-increasing have an asymptotic worst-case bound of 1/2. The best algorithm is the FFD* rule, for which Langston was able to prove that for all L and bin size-set B

$$n_{FFD} * (L, B) \geq \frac{2}{3} n_O(L, B) - \frac{2}{3}$$

He conjectured that the tight bound is 8/11—this is still an open question.

Friesen and Kuhl [21] gave the best known algorithm for maximizing the number of items in a given set of variable-sized bins. Their algorithm is an iterative version of the Best-2-Fit and FFD algorithms, and is similar to the compound algorithm given for the classical problem in Ref. [22]. This hybrid algorithm has a tight asymptotic worst-case ratio of 3/4.

Epstein and Favrholdt [23,24] investigated the online version of maximizing the number of items packed into variable-sized bins. They restricted the input sequences to be accommodating, that is, sequences that we know in advance every item can be packed by an optimal offline algorithm. They studied fair algorithms that reject an item only if the item does not fit in the empty space of any bin. They proved that any fair algorithm has a competitive ratio of at least 1/2, and BF has a performance bound of $n/(2n-1)$. They also showed that any fair, deterministic algorithm has a competitive ratio at most 2/3, and any fair, randomized algorithm has a competitive ratio at most 4/5.

34.3 Bin Covering

In the *packing* problems studied up to now, the goal was to partition a set of items into the *minimum* number of subsets such that, in every subset, the total size of the items does not exceed some upper bound. In a *covering* problem, the goal is to partition a set of items into the *maximum* number of subsets such that, in every subset, the total size of the items is always above some *lower* bound. Covering problems model a variety of situations encountered in business and in industry, from packing peach slices into tin cans so that each tin can contains at least its advertised net weight, to such complex problems as breaking up monopolies into smaller companies, each of which is large enough to be viable. Since covering problems can be viewed as a kind of inverse or dual version of the packing problem, they are sometimes called "dual-bin packing" problems in the literature. We note that the task of maximizing the number of items to be packed is sometimes also called dual-bin packing problem.

In the one-dimensional bin covering problem, the goal is to pack a list $L = (a_1, a_2, \ldots, a_n)$ into a maximum number of bins of size 1 such that the contents of each bin is at least one. Let R_A^∞ denote the asymptotic worst-case ratio of an approximation algorithm for bin covering ($A(L)$ and $OPT(L)$ denote the numbers of bins in the packing constructed by algorithm A and an optimization algorithm, respectively). It is defined by

$$R_A^n = \min\left\{ \frac{A(L)}{OPT(L)} \mid OPT(L) = n \right\}$$

and

$$R_A^\infty = \liminf_{n\to\infty} R_A^n$$

Since we are dealing with a maximization problem, the larger the worst-case ratio of an algorithm, the better the approximation algorithm will be. The bin covering problem was investigated for the first time in the Ph.D. thesis of Assmann [25] and in the journal article [2] by Assmann et al. [2]: They called it the *dual-bin packing problem.*

First of all one might adapt heuristics from the classical bin packing to the bin covering problem. This was indeed done by Assmann et al. [2]. They considered the following adaptation of NF, called DUAL NEXT FIT (DNF): DNF always has a single active bin. Newly arriving items a_i are packed into the active bin until the active bin is full (i.e., it has contents of at least one). Then the active bin is closed and another (empty) bin becomes the active bin. It is not difficult to show that DNF has performance

$$R^{\infty}_{DNF} = \frac{1}{2}$$

as all bins packed by DNF will have a content of less than 2, while for the lists

$$L_{4k} = \left(\underbrace{1-\varepsilon, \ldots, 1-\varepsilon}_{2k \text{ items}}, \underbrace{\varepsilon, \ldots, \varepsilon}_{2k \text{ items}} \right)$$

we get $\text{OPT}(L_{4k}) = 2k$ and $DNF(L_{4k}) = k$, if $\varepsilon < 1/2k$. Analogous modifications of FF, BF, and Harmonic *do not* improve this worst case ratio of 1/2 (e.g., modifying FF is useless, since after filling a bin, placing further items into it does not make sense). Actually, from the worst-case point of view, algorithm DNF is the best possible online bin covering algorithm, since Csirik and Totik [26] have proved that every online bin covering algorithm A satisfies the condition

$$R^{\infty}_{A} \leq \frac{1}{2}$$

A bettering of the performance ratio of 1/2 was achieved by Assmann et al. [2] by defining an *artificial upper bound* on the sum of the sizes of elements placed into the same bin. This upper bound can be regarded as the capacity of a bin and has some similarities with classical bin packing. However, after packing the items with a good heuristic for the classical bin packing problem, it might happen that in some of the bins the sum of item sizes is less than 1. Hence we have to use a second step to fill these bins. The algorithm based on the above observation is called FIRST FIT DECREASING WITH PARAMETER r (FFD_r) and proceeds as follows:

Phase I. ("Classical *FFD*")

(a) Presort the items in L such that $s(a_1) \geq s(a_2) \geq \cdots \geq s(a_n)$.
(b) While there is still an unpacked element, do the following: Let a_i be the first unpacked item and let B_j be the first (leftmost) unfilled bin with a current content less than or equal to $r - s(a_i)$. If such a bin exists, place a_i in B_j, otherwise open a new empty bin and pack a_i into this bin.

Phase II. (Repacking unfilled bins)

While there is more than one open nonfilled bin, remove an item from the rightmost such bin and add it to the leftmost one.

It is clear that after phase I there is no bin with content more than r. Furthermore, it follows from the definition in the first phase that adding an element from the rightmost open nonfilled bin will increase the total sum of sizes of elements in the leftmost bin to more than r. Lastly, the time complexity of FFD_r can be seen to be $O(n \log n)$. For this algorithm the following result holds [25]: for all r, $4/3 \leq r \leq 3/2$, and every lists L,

$$FFD_r(L) \geq \frac{2}{3}(OPT(L) - 1)$$

and the bound is tight.

Assmann et al. also suggested a further improvement by defining a pretty sophisticated algorithm called ITERATED LOWEST FIT DECREASING (ILFD). To define this heuristic we first consider the following problem: given the list L and a fixed number M of bins, what is the *maximum* possible value for the minimum bin level in a packing of L into M bins? From a good heuristic A for this problem we can derive a good approximation algorithm for the bin covering problem by iteratively applying this algorithm A. Let $A(L, M)$ stand for the minimum bin level in the packing of L generated by the heuristic A when the number of bins is fixed to be M. Now the algorithm iteratively applies A and proceeds as follows:

ITERATED "A"

Step 1. Let $UB = \left\lfloor \sum_{i=1}^{n} s(a_i) \right\rfloor$, $LB = 1$. (Clearly $LB \leq OPT(L) \leq UB$.)
Step 2. While $UB - LB > 1$ take $M = \lfloor (LB + UB)/2 \rfloor$ and apply heuristic A. If $A(L, M) > 1$ take $LB = M$, otherwise $UB = M$.

The resulting algorithm provides a feasible solution to the bin covering problem with *LB* bins. Clearly, the performance of this method depends on the choice of A. While the problem to be solved by A is closely related to multiprocessor scheduling problems, it seems natural to use for the heuristic A the Lowest Fit Decreasing (*LFD*) algorithm, as studied by Graham [27] and Deuermeyer et al. [28]. This algorithm proceeds as follows:

Step 1. Order L so that $s(a_1) \geq s(a_2) \geq \cdots \geq s(a_n)$ and start with M empty bins.
Step 2. While there is an unpacked item in L do the following: let a_i be the first unpacked item and let B_j be the bin with a minimum level (in case of ties, choose the rightmost one). Put a_i into B_j.

It is not difficult to verify that the time complexity of *ILFD* is $O(n \log^2 n)$. Furthermore, one can prove the following result [2]:

$$R^{\infty}_{ILFD} = \frac{3}{4}$$

Csirik et al. [29] achieved these bounds via simpler algorithms. Their first algorithm, called SIMPLE (SI), first sorts the items in descending order, and then packs the prefix of the list by NF into the next bin until the content becomes larger than 1 when the piece following the prefix is packed. It then fills the bin with a postfix, that is, packs the smallest items as long as the content of the bin is less than 1. For this algorithm

$$R^{\infty}_{SI} = \frac{2}{3}$$

The second algorithm, IMPROVED SIMPLE (ISI) is a bit more complicated. It divides the list L into three sublists:

- $s(a_1) \geq s(a_2) \geq \cdots \geq s(a_p) \geq 1/2$(X-sublist),
- $1/2 > s(a_{p+1}) \geq s(a_{p+2}) \geq \cdots \geq s(a_r) \geq 1/3$(Y-sublist),
- $s(a_{r+1}) \geq s(a_{r+2}) \geq \cdots \geq s(a_n)$(Z-sublist).

Now, ISI proceeds in two phases. In phase 1, if $s(a_1) \geq s(a_{p+1}) + s(a_{p+2})$, it then packs a_1 into an empty bin, otherwise packs a_{p+1} and a_{p+2}. Then it fills the just opened bin with elements from the end of the Z-sublist, that is, with $a_n, a_{n-1}, \ldots$ until the content of the bin is larger than 1, removes the packed elements, and then repeats the packing until $X \cup Y$ or Z is empty. In the second phase, if $X \cup Y$ is empty, it packs the remaining elements from the Z-sublist by NF. Otherwise, if Z is empty, it packs the remaining elements from the X-sublist by two, from the Y-sublist by three. The authors subsequently proved that

$$R^{\infty}_{ISI} = \frac{3}{4}$$

The time complexity of both algorithms here is $O(n \log n)$.

Coffman et al. [30] analyzed the bin covering problem when the list has divisible item sizes. They proved that the Next Fit Decreasing rule gives an optimal packing when the list is strongly divisible. They also proved that if the list is divisible, the Iterated Lowest Fit Decreasing rule gives an optimal packing as well.

Deuermeyer et al. [28] studied the problem of machine covering. Here we have m machines (bins) and we want to pack the list so as to maximize the minimum load for the machines. This means in bin covering terms that we would like to maximize the bin sizes such that the packing of the list will cover all the bins.

They investigated the performance of the Largest Processing Time (LPT) heuristic and proved that its performance is not larger than 3/4. The tight ratio of this method was found by Csirik et al. [31] to be $\frac{3m-1}{4m-2}$.

Azar and Epstein [32] investigated the online version of machine covering. They proved that there is a randomized $O(\sqrt{m}\log m)$ competitive algorithm, and any randomized algorithm is at least $\Omega(\sqrt{m})$ competitive. This is in marked contrast to the competitive ratio of the best possible deterministic algorithm, which is m. For the parametric version of this problem, where the sizes may vary up to a factor F they showed that there is a randomized $O(\log F)$ competitive algorithm. For the same problem where the optimal value is known in advance they offered a deterministic $2 - \frac{1}{m}$ competitive algorithm.

Woeginger and Zhang [33] considered bin covering with variable sized bins: there are several types $B_1, \dots, B_k$ of bins with sizes $1 = b_1 = s(B_1) > b_2 = s(B_2) > \cdots > b_k = s(B_k)$; there is an infinite supply of bins of each size. We will denote the set of feasible bin sizes here by **B** as well. The problem is to cover, with a given list of items $a_i \in [0, 1]$, a set of bins with the *largest total size*. Formally, let $OPT(L, \mathbf{B})$ and $A(L, \mathbf{B})$ denote, respectively, the total size of the bin cover produced by an optimum algorithm and the total size of the bin cover produced by an approximation algorithm A for an input list L and a set **B** of bin sizes. The asymptotic worst-case $R^{\infty}_{A,\mathbf{B}}$ of algorithm A for the set **B** is defined as

$$R^{\infty}_{A,\mathbf{B}} = \lim_{s\to\infty} \inf_{L} \left\{ \frac{A(L, \mathbf{B})}{OPT(L, \mathbf{B})} \mid OPT(L, \mathbf{B}) \geq s \right\}$$

Woeginger and Zhang [33] determined, for each finite set of bin sizes, the worst-case ratio of the best possible online covering algorithm. Let k_1 denote the number of bin sizes in **B** that are strictly greater than 1/2. Define

$$q(\mathbf{B}) = \max \left\{ \frac{b_j}{b_{j+1}} : 1 \leq j \leq k_1 - 1 \right\} \cup \{2b_{k_1}\}$$

Note that $q(\mathbf{B}) > 1$. Finally, define

$$r(\mathbf{B}) = \frac{1}{q(\mathbf{B})}$$

Woeginger and Zhang proved that for every set **B** of bin sizes, there exists an online approximation algorithm A for variable-sized bin covering with asymptotic worst-case ratio $r(\mathbf{B})$. For every set **B** this result is the best possible.

Epstein [34] gave similar results for the parametric case, that is, where each item size is less than or equal to $1/m$, where m is a positive integer. Similar to Ref. [33], she defined the number $r(\mathbf{B}, m)$ in the following way. For each $1 \leq i \leq k$, let $b_{i,j} = b_i/j$ and let $B_i(m)$ be the set of fractions of b_i between sizes $1/(2m)$ and 1/m, that is, $\mathbf{B}_i(m) = \{b_{i,j} \mid 1 \leq j \leq 2m\} \cap [1/(2m), 1/m]$. We define a new set of bins by $\mathbf{C}(m) = \cup_{1\leq i\leq k}\mathbf{B}_i(m)$. Enumerate the sizes of numbers in $\mathbf{C}(m)$, $\mathbf{C}(m) = \{c_1, \dots, c_l\}$, where $1/m = c_1 > c_2 > \cdots > c_l = 1/(2m)$. For every element in $\mathbf{C}(m)$, recall an original bin size that caused it to be inserted into $\mathbf{C}(m)$. For c_i, let $b(c_i)$ be the smallest b_j such that there exists an integer y that satisfies $yc_i = b_j$. Now define

$$q(\mathbf{B}, m) = \max \left\{ \frac{c_i}{c_{i+1}} \mid 1 \leq i \leq l - 1 \right\}$$

Note that $1 + 1/m \geq q(\mathbf{B}, m) > 1$. Finally, define

$$r(\mathbf{B}, m) = \frac{1}{q(\mathbf{B}, m)}$$

For every finite set of bins and integer $m \geq 1$, Epstein gave a deterministic algorithm with competitive ratio $r(\mathbf{B}, m)$. She also proved that this is the best possible for any online randomized algorithms.

Zhang [35] defined a special variable-sized bin covering problem which he called the *bin-batching* problem: in this problem, in addition to a list L, a parameter $0 \leq t \leq 1$ is also given. We are asked to group the item into batches. If a batch B has a total content $c(B)$, the gain of this batch is defined as

$$g(B) = \begin{cases} 0 & \text{if } c(B) < 1 - t \\ c(B) & \text{if } 1 - t \leq c(B) \leq 1 \\ 1 & \text{if } c(B) > 1 \end{cases}$$

The goal is to make the total gain as large as possible. We may note that this problem reduces to the bin covering problem when $t = 0$. In bin batching all bin sizes in $[1 - t, 1]$ are allowed, that is, we allow underpacking of bins up to a level of $1 - t$. It is clear that the problem is simple if $t \geq 1/2$, so we may assume $t < 1/2$. Zhang proved that every online algorithm for the bin-batching problem has an asymptotic worst-case ratio of at most $1/(2 - 2t)$, and that the following simple algorithm—called SA—will meet this bound: assume that the currently incoming item is a_i; if $s(a_i) \geq 1 - t$, put it into an empty bin with size $s(a_i)$ and close this bin immediately. If $s(a_i) < 1 - t$, we apply the NF algorithm with bin size 1.

Woeginger and Zhang [33] looked at the special problem of having only two different bin sizes (this was done by Csirik [6] for the classical variable-sized problem). They proved that, for a set $\mathbf{B} = \{1, b\}$ with two bin sizes, there exists an online approximation algorithm A for the bin covering problem with the best possible asymptotic worst-case ratio

$$R^{\infty}_{A,\mathbf{B}} = \begin{cases} \frac{1}{2} & \text{if } 0 < b \leq \frac{1}{2} \\ b & \text{if } \frac{1}{2} \leq b \leq \frac{1}{\sqrt{2}} \\ \frac{1}{2b} & \text{if } \frac{1}{\sqrt{2}} \leq b < 1 \end{cases}$$

For $\mathbf{B} = \{1, 1/\sqrt{2}\}$, the asymptotic worst-case ratio is $1/\sqrt{2}$. This is the best ratio that can be achieved with two bins.

34.4 Conclusion

In this chapter we conclude our survey of variants of the classical bin packing problem. The main topics covered include the variable-sized bin packing problem and the bin covering problem. Both problems have generated tremendous interests in the past and promise to have more results in the future.

Multidimensional Packing Problems

University of Karlsruhe

35.1 Introduction

There are several ways to generalize the bin packing problem to more dimensions. We consider two- and three-dimensional strip packing, and bin packing in dimensions two and higher. Finally we consider vector packing and several other variations.

In the most common two-dimensional version, the items are rectangles or squares, and the bins are unit squares. In the strip packing problem, instead of bins, we are given a strip of width 1 and unbounded height. In higher dimensions, the rectangles are replaced by boxes (or hyperboxes), the squares by cubes (or hypercubes), and the unit square by a unit cube (or hypercube of the relevant dimension). Strip packing becomes column packing.

A striking difference between one-dimensional bin packing and its multidimensional generalizations is that while for one-dimensional bin packing, offline algorithms clearly outperform online algorithms, this is not always the case in more dimensions. There are several cases where an online algorithm was at one point the best known approximation algorithm, or remains the best known approximation until today. Most likely, this simply reflects the fact that we do not understand the multidimensional case as well as the one-dimensional case. In contrast, some results simply cannot be generalized. For instance, we now know that there cannot be an asymptotic polynomial-time approximation scheme (APTAS) for two-dimensional bin packing [1], or for two-dimensional vector packing [2].

An important special case in multidimensional bin and strip packing is the case where (hyper)cubes need to be packed. For this case, better results are known than for the general case. In particular, the offline version of this problem admits an APTAS [1,3].

As is the case for one-dimensional bin packing, most attention has gone to the asymptotic worst-case ratio, but in the course of this chapter we will encounter some results on the absolute ratio as well.

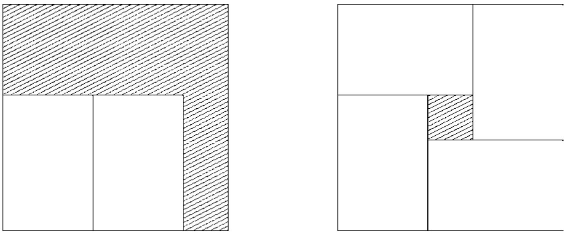

FIGURE 35.1 A comparison between the oriented and the rotatable models.

When packing of rectangle or boxes is considered, there are several ways to define the problem. In the oriented problem, items have a fixed orientation, and cannot be rotated. In the rotatable (or nonoriented) version, an item can be rotated and placed in any position such that its sides are parallel to the sides of the bin. Finally there are mixed versions where items can be rotated in certain directions, but not all directions. One such three-dimensional model where items can be rotated to the left or to the right but the top and bottom must remain such as the "z-oriented" packing studied by Miyazawa and Wakabayashi [4,5], also known as the "This Side Up" problem [6].

An illustration of the difference between the two problems is given in Figure 35.1. In this figure we see packings of rectangles of sides $\frac{3}{5}$ and $\frac{2}{5}$. If the rectangles are oriented so that their height is $\frac{3}{5}$ and cannot be rotated, we can pack at most two such items in one bin. However, if rotation is allowed, we can pack as much as four such rectangles together in one bin.

This chapter is organized as follows. We begin by presenting the algorithm Next Fit Decreasing Height, which is a fundamental algorithm for two-dimensional packing problems, in Section 35.2. We then discuss results on multidimensional packing problems, in order of increasing dimension. That is, we start with strip packing in Section 35.3 and move to two-dimensional bin packing in Section 35.4. We then discuss column packing in Section 35.5 and three- and more dimensional bin packing in Section 35.6. Finally, we mention results on vector packing in Section 35.7 and discuss several variations on multidimensional packing in Section 35.8.

35.2 Next Fit Decreasing Height

In 1968, Meir and Moser [7] introduced an algorithm for packing d-dimensional cubes into a d-dimensional hyperbox, which they called Next Fit Decreasing (NFD). This algorithm sorts the cubes by decreasing volume and packs them into layers. The authors show that if the sides of the cubes are denoted by $x_1, x_2, \ldots,$ and they are packed into a hyperbox of sides $a_1, \ldots, a_d$, where $x_1 \leq a_i$ for $i = 1, \ldots, d$, then the cubes can be packed into the hyperbox as long as their total volume is at most $x_1^d + \prod_{i=1}^{d}(a_i - x_1)$.

For $d = 2$ (packing squares into a rectangle), the algorithm works as follows. The largest square is put in the bottom left corner of the rectangle. The height of the first layer is equal to the side of this square. The next squares are put in this layer, next to each other and touching each other and the bottom of the layer, until one does not fit. At this point we define a new layer above the first layer, with height equal to the side of the first square packed into it. This continues until all squares are packed, or there is not enough room to pack some item (it does not fit into the current layer, and the last layer that is left is either empty or not high enough).

This algorithm (for two dimensions) was extended to an algorithm for packing rectangles into a rectangle (or a strip) by Coffman et al. [8], which was called Next Fit Decreasing Height (NFDH). It sorts the rectangles by decreasing height and then packs them as above. They showed that if this algorithm is applied to pack rectangles into a strip (of unbounded height), then the height used to pack the rectangles is at most twice the optimal height, plus an additive constant that is equal to the height of the highest rectangle. (Thus its absolute worst-case ratio is 3.)

The proof is quite straightforward. In each level, there may be wasted space to the right of the rightmost item, and above all items except the first. The height of a level is the height of the first item in it. This item did not fit on the previous level. This implies that the total area of the items in level i plus the first item in level $i + 1$ is at least the height of level $i + 1$ (since the width of the strip is 1). (If we move all items in level i up to level $i + 1$, and shift the first item in level $i + 1$ to the right, then level $i + 1$ is entirely covered by items.) Adding up the heights of all levels, this is upper bounded by twice the area of the packed items plus the height of the first level. This explains the performance bound including the additive constant, since the total area is an obvious lower bound for the optimal height.

This fundamental algorithm was used in many later papers as a subroutine. It works especially well when all rectangles are guaranteed to have a small width (relative to the width of the strip), and this property was, for instance, used by Kenyon and Rémila [9] in their approximation scheme for strip packing.

Meir and Moser [7] also showed the following important result in the same paper:

Theorem 35.1

Any set of rectangles with sides at most x and total area A can be packed into any rectangle of size $a \times b$ if $a \geq x$ and $ab \geq 2A + a^2/8$. This result is best possible.

For packing rectangles into a unit square, this result states that any set of rectangles of total area at most 7/16 (and sides not larger than 1) can be packed into a unit square.

35.3 Strip Packing

35.3.1 Online Results

Baker and Schwartz [10] were the first to study two-dimensional online strip packing. They introduced a class of algorithms called *shelf algorithms.* A shelf algorithm uses a one-dimensional bin packing algorithm A and a parameter $\alpha \in (0, 1)$. Items are classified by height: an item is in class s if its height is in the interval $(\alpha^{s-1}, \alpha^s]$. Each class is packed in separate *shelves*, where we use A to fill a shelf and open a new shelf when necessary. Note that the algorithm A is not necessarily online. See Figure 35.2 for an illustration of a shelf algorithm.

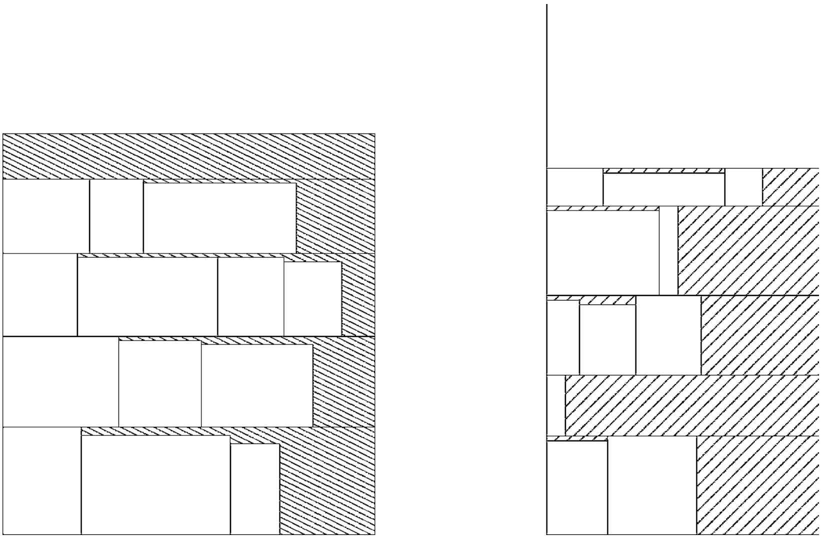

FIGURE 35.2 An illustration of a packing of NFDH (left) and of a shelf packing algorithm (right).

Baker and Schwartz showed that the algorithm FIRST FIT SHELF, which uses FIRST FIT as a subroutine, has an asymptotic performance ratio arbitrarily close to 1.7. Csirik and Woeginger [11] showed that by using HARMONIC as a subroutine, it is possible to achieve an asymptotic performance ratio arbitrarily close to $h_\infty \approx 1.69103$. Moreover, they show that any shelf algorithm, online or offline, has a performance ratio of at least h_∞. The idea of the lower bound is that items are given that could be combined nicely next to each other, but which end up in different height classes and are therefore packed in separate shelves. So basically, the best thing one can do is to use a bounded space algorithm (which has a constant number of simultaneously active bins) like HARMONIC as the subroutine. Finally, they mention that from the one-dimensional lower bound of van Vliet [12], together with the insights of Baker et al. [13], a general lower bound for online algorithms of 1.5401 is implied. It remains an open problem how to improve the upper bound of Csirik and Woeginger. It does not seem easy to find a good online algorithm that does not use shelves. As for the absolute performance ratio, Brown et al. [14] showed a lower bound of 2 for any algorithm. They also show some lower bounds for algorithms that may sort the items.

35.3.2 Offline Results

The strip packing problem was introduced in 1980 by Baker et al. [15]. They developed the first offline approximation algorithms for this problem, and give an upper bound of 3 on the absolute performance ratio. This bound was later improved to 2 independently by Schiermeyer [16] and by Steinberg [17], using different approaches. In the same issue of *SIAM Journal on Computing*, Coffman et al. [8] showed that NFDH has an asymptotic performance ratio of 2, First Fit Decreasing Height (FFDH) achieves a value of 1.7, and an algorithm called Split-Fit has 3/2. Also in 1980, Sleator [18] gave an algorithm with asymptotic performance ratio of 2.5, but absolute performance ratio of 2, which is better than that of Split-Fit, which has 3. In 1981, Baker et al. [13] gave an offline algorithm with asymptotic worst-case ratio of 5/4. Finally, Kenyon and Rémila [9] designed an asymptotic fully polynomial-time approximation scheme. This scheme uses some nice ideas, which we describe below.

Fractional strip packing. A fractional strip packing of L is a packing of any list L' obtained from L by subdividing some of its rectangles by horizontal cuts: each rectangle (w_i, h_i) is replaced by a sequence of rectangles $(w_i, h_i^1), (w_i, h_i^2), \ldots, (w_i, h_i^{k_i})$ such that $\sum_{j=1}^{k_i} h_i^j = h_i$.

In the case that L contains only items of m distinct widths in $(\varepsilon', 1]$, where $\varepsilon' > 0$ is some constant, it is possible to find a fractional strip packing of L that is within one of the optimal fractional strip packing $\textsc{fsp}(L)$ in polynomial time. Moreover, it is possible to turn this packing into a regular strip packing at the loss of only an additive constant $2m$. Denote the height of the optimal strip packing for L by $\textsc{opt}(L)$. We conclude that we found a packing with height at most $\textsc{fsp}(L) + 1 + 2m \leq \textsc{opt}(L) + 2m + 1$.

Modified NFDH. This is a method for adding narrow items (items of width at most ε') to a packing of wide items such as described above. Such a packing leaves empty rectangles on the right-hand side of the strip. Each of these rectangles is packed with narrow items using NFDH (starting with the highest narrow item in the first rectangle). When all rectangles have been used, the remaining items (if any) are packed above the packing using NFDH on the entire width of the strip.

Grouping and rounding. This method is a variation on the linear rounding defined by Fernandez de la Vega and Lueker [19]. It works as follows.

We stack up the rectangles of L by order of nonincreasing widths to obtain a left-justified stack of total height $h(L)$. We define $m-1$ threshold rectangles, where a rectangle is a threshold rectangle if its interior or lower boundary intersects some line $y = ih(L)/m$ for some $i \in \{1, \ldots, m-1\}$. We cut these threshold rectangles along the lines $y = ih(L)/m$. This creates m groups of items that have height exactly $h(L)/m$.

First, the widths of the rectangles in the first group are rounded up to 1, and the widths of the rectangles in each subsequent group are rounded up to the widest width in that group. This defines L_+.

Second, the widths of the rectangles in each group are rounded down to the widest width of the next group (down to 0 for the last group). This defines L_-.

It is easy to find a strip packing for L_- using a reduction to fractional strip packing. Moreover, it can be seen that the stack associated with L_+ is exactly the union of a bottom part of width 1 and height $h(L)/m$ and the stack associated with L_-. Thus $\text{FSP}(L) \leq \text{FSP}(L_+) = \text{FSP}(L_-) + h(L)/m$.

Partial ordering. We say that $L \leq L'$ if the stack associated to L (used for the grouping above), viewed as a region of the plane, is contained in the stack associated to L'. Note that $L \leq L'$ implies that $\text{FSP}(L) \leq \text{FSP}(L')$. As an example, in the grouping above we have $L_- \leq L \leq L_+$.

35.3.3 Rotations

The upper bound of 2 of NFDH and Bottom Leftmost Decreasing Width (BLDW) remain valid if orthogonal rotations are allowed, since the proofs use only area arguments. Miyazawa and Wakabayashi [5] presented an algorithm with asymptotic approximation ratio of 1.613. Epstein and van Stee [20] improved this to 3/2 using a simpler algorithm. This algorithm packs items that are wider and higher than 1/2 optimally, and packs remaining items first next to this packing (where possible) and finally on top of this packing. In this way, the resulting packing is either optimal, or almost all heights with a width of 2/3 is occupied by items. Finally, an asymptotic fully polynomial-time approximation scheme was given by Jansen and van Stee [21].

35.4 Two-Dimensional Bin Packing

We saw in section 35.3.1 that we can use a one-dimensional bin packing algorithm as a subroutine for a strip packing algorithm, basically without a loss in (asymptotic) performance ratio. Similarly, a two-dimensional bin packing algorithm can be used as a subroutine to create a three-dimensional strip packing algorithm, and this also holds for higher dimensions.

In contrast, a d-dimensional strip packing algorithm can also be used to create a d-dimensional bin packing algorithm at a cost of a factor of 2 in the performance ratio. The idea is to cut the packing generated by the strip packing algorithm into pieces of unit height. For each piece we do the following. Items that are completely contained in the piece are put together in one bin. Items that are partially in the next piece are put together in a second bin (see Figure 35.3).

Assume we have a guarantee of R on the asymptotic performance ratio of the strip packing algorithm. Then this method gives us $2R \cdot \text{OPT}(L) + C$ bins for an input L, where $\text{OPT}(L)$ is the height of the optimal

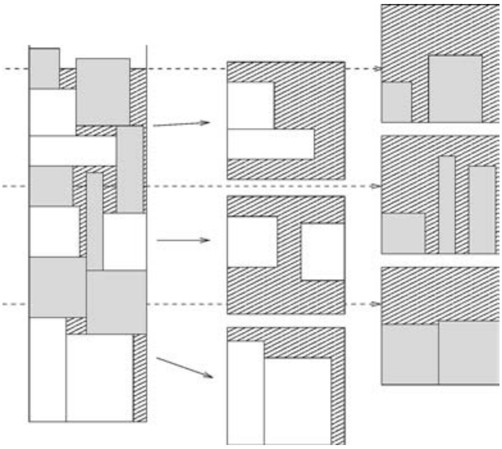

FIGURE 35.3 Converting a packing in a strip into a packing in bins.

strip packing. In contrast, there cannot be a *bin* packing into less than $\text{OPT}(L)$ bins, because this packing could be trivially turned into a strip packing of height less than $\text{OPT}(L)$. This explains the factor of two loss.

35.4.1 Online Results

Coppersmith and Raghavan [22] were the first to study the online version of this problem. They gave an online algorithm with asymptotic performance ratio of 3.25 for $d = 2$ (and 6.25 for $d = 3$). This result was improved by Csirik et al. [23], who presented an algorithm with performance ratio 3.0625. In the same year, Csirik and van Vliet [24] showed an online bin packing algorithm for arbitrary dimensions, which achieves a performance ratio of h_∞^d, where d is the dimension. Note that already for $d = 2$, this improves over the previous result, since $h_\infty^2 \approx 2.85958$ (see also Ref. [25] for $d = 2, 3$). Finally, Seiden and van Stee [26] gave an algorithm with ratio 2.66013 for two-dimensional bin packing.

Epstein and van Stee [20] introduced a new technique for packing small multidimensional items online, enabling them to achieve the asymptotic performance ratio of h_∞^d [24] using only bounded space.

Galambos [27] was the first to give a lower bound for this problem, which was higher than the best known lower bound for one-dimensional bin packing. His bound was 1.6. This was later successively improved to 1.808 by Galambos and van Vliet [28], 1.851 by van Vliet [29], and finally to 1.907 by Blitz et al. [30]. The gap between the upper and lower bounds remains relatively large to this day, and it is unclear how to improve either of them significantly.

An interesting special case is where all items are squares. Coppersmith and Raghavan [22] showed that their algorithm has an asymptotic performance ratio of 2.6875 for this case, and gave a lower bound of 4/3. This lower bound actually holds for the more general problem of packing hypercubes. Seiden and van Stee [26] showed that the algorithm HARMONIC × HARMONIC, which uses the HARMONIC algorithm to find slices for items and then uses the HARMONIC algorithm again to find bins for slices, has an asymptotic performance ratio of at most 2.43828. They gave a lower bound of 1.62176 for any online algorithm, and also showed a lower bound of 2.28229 for bounded space algorithms using the same instances.

Epstein and van Stee [31] give an algorithm with asymptotic performance ratio of at most 2.24437, and improved the lower bound to 1.6406. Here too, the gap between the lower and the upper bounds remains disappointingly large. Finally, the same authors [32] give bounds for the performance of their optimal bounded space algorithm from Ref. [20], showing that its performance ratio lies between 2.3638 and 2.3692.

35.4.2 Offline Results

As mentioned at the start of this chapter, Bansal and Sviridenko [1] proved that the two-dimensional bin packing problem is APX-hard. Thus, there cannot be an asymptotic polynomial-time approximation scheme for this problem.

Chung et al. [33] were the first to give an approximation algorithm for this problem. It has an asymptotic approximation ratio of 2.125. As mentioned above, the APTAS for strip packing by Kenyon and Rémila implies a $(2 + \varepsilon)$-approximation for any $\varepsilon > 0$. In 2002, Caprara [34] gave an h_∞-approximation.

Leung et al. [35] proved that the special case of packing squares into squares is still NP-hard (for general two-dimensional bin packing, this follows immediately from the one-dimensional case). Ferreira et al. [36] gave a 1.988-approximation for this problem, which uses as a subroutine an optimal algorithm for packing items with sides larger than 1/3. They conjecture that packing items with sides larger than 1/4 is already NP-hard. Independently of each other, Kohayakawa et al. [37] and Seiden and van Stee [26] gave a $(14/9 + \varepsilon)$-approximation $(1.5555\ldots + \varepsilon)$. However, the first result is more general in that it actually gives a $(2 - (2/3)^d + \varepsilon)$-approximation for packing d-dimensional hypercubes. The idea of both these algorithms is to find an optimal packing for large items (items with sides larger than ε) and to add the small items to this packing. Specifically, any bins in the optimal packing which contain only a single item with sides larger than 1/2 are filled with small items using the algorithm NFD from Meir and Moser (see Section 35.2). It is shown that all other bins are already "reasonably full," leading to the approximation guarantee.

In the same year, Caprara [34] gave an algorithm with performance ratio in the interval (1.490, 1.507) provided a certain conjecture holds. Two years later, Epstein and van Stee [38] gave a $(16/11 + \varepsilon)$-approximation $(1.4545 \ldots + \varepsilon)$. Simultaneously and independently of each other, Bansal and Sviridenko [1], and Correa and Kenyon [3] presented an asymptotic polynomial-time approximation scheme for this problem, which also works for the more general problem of packing hypercubes.

Recently, Bansal et al. [39] showed a special case which admits an APTAS. This is a rectangle packing, where the packing of each bin must be possible to achieve using guillotine cuts only. That is a sequence of edge to edge cuts, parallel to the edges of the bin. Even more special cases, where the number of stages in the sequence of guillotine cuts is limited, were studied by Caprara et al. [40]. They designed an APTAS for the two-stage problem. Note the shelf packing described above actually uses two stages of guillotine cuts. Kenyon and Rémila [9] point out that their approximation scheme uses five stages of guillotine cuts.

As regards the absolute performance ratio, Zhang [41] gave an approximation algorithm with absolute worst-case ratio of 3 for two-dimensional bin packing. Van Stee [42] gave an absolute 2-approximation for the special case where squares need to be packed, which is optimal by the result of Leung et al. [35].

35.4.3 Resource Augmentation

Since there cannot be an approximation scheme for general two-dimensional bin packing, several authors have looked at the possibility of resource augmentation, that is, giving the approximation algorithm slightly larger bins than the offline algorithm that it is compared with. Correa and Kenyon [3] give a dual polynomial-time approximation scheme. That is, they give a polynomial-time algorithm to pack rectangles into the k bins of size $1 + \varepsilon$, where these rectangles cannot be packed in less than k bins of size 1. Bansal and Sviridenko [43] showed that it is possible to achieve this even if the size of the bin is relaxed in one dimension only.

35.4.4 Rotations

For the case where rotations are allowed, Epstein [44] showed an online algorithm with asymptotic performance ratio of 2.45. The online problem was studied before by Fujita and Hada [45]. They presented two online algorithms and claimed asymptotic performance ratios of at most 2.6112 and 2.56411. Epstein [44] mentioned that the proof in Ref. [45] only shows that the first algorithm has an asymptotic performance ratio of at most 2.63889 and that the proof of the second algorithm is incomplete.

Two years later, Miyazawa and Wakabayashi [5] gave an offline algorithm with asymptotic performance ratio of 2.64. Epstein and van Stee [20] gave the best known result to date, an approximation algorithm with asymptotic performance ratio 2.25. It divides the items into types and combines them into bins such that in almost all bins, an area of 4/9 is occupied. Correa [46] adapted the dual polynomial-time approximation scheme from Ref. [3] to rotatable items.

35.5 Column (Three-Dimensional Strip) Packing

35.5.1 Online and Offline Results

Li and Cheng [47] were the first to consider this problem. In their paper [47] from 1990, they showed that three-dimensional versions of NFDH and FFDH have unbounded worst-case ratio. They gave several approximation algorithms, the best of which has an asymptotic performance ratio of 3.25. Their first algorithm sorts the items by height and then divides them into groups of area (in the first two dimensions) at most 7/16, so that they can be packed into a single layer by Theorem 35.1. They improve on this by classifying items with similar bottoms, and packing similar items together into layers. Two items have similar bottoms if both their length and their width fall into the same class when classified by the HARMONIC algorithm. For the case where all items have square bottoms, the ratio improves to 2.6875.

Two years later, the same authors [48] presented an online algorithm with asymptotic performance ratio arbitrarily close to $h_\infty^2 \approx 2.89$ for three-dimensional strip packing. At the time, there was no better *offline* approximation known. This algorithm uses the HARMONIC algorithm as a subroutine in both horizontal dimensions (i.e., to find a strip for a two-dimensional item, and a place inside a strip for a one-dimensional item), and a geometric rounding for the heights. The paper actually discusses several online algorithms for this problem and only mentions the use of HARMONIC in the summary section. The authors [47] note that the improvement in the asymptotic performance ratio compared with the approximation algorithm from their earlier paper only comes at the cost of a high additive constant.

In 1997, Miyazawa and Wakabayashi [49] improved the offline upper bound to 2.66994 (2.36 for items with square bottoms). This algorithm places columns of similar items next to each other in the strip, thus avoiding the layer structure of the previous algorithms. The algorithm is quite involved and its description takes three pages. This remains the best result to date.

35.5.2 Rotations

In the case where rotations are allowed, it becomes relevant what exactly the dimensions of the strip are. In two-dimensional strip packing, this does not really play a part, but in column packing, the base of the column might not be a square. However, if the base is not a square but may be an arbitrary rectangle, then having the ability to rotate items horizontally (leaving the top side unchanged) does not help, as was shown by Miyazawa and Wakabayashi [4]. The idea is that in this case it is possible to scale the input so that the smallest width of an item is still larger than the length of the base of the strip, so that no item can be rotated and still fit inside the strip. For this reason, in this section we focus on the case where the base of the strip is a square.

Epstein and van Stee [6] give an approximation algorithm with asymptotic worst-case ratio of $9/4 = 2.25$, improving on the upper bound of 2.76 by Miyazawa and Wakabayashi [5]. The special case where only rotations that leave the top side of items at the top are allowed has received more attention. It was introduced by Li and Cheng [50] as a model for a job scheduling problem in partitionable mesh connected systems. Here each job i is given by a triple (x_i, y_i, t_i), meaning that job i needs a submesh of dimensions $x_i \times y_i$ or $y_i \times x_i$ for t_i time units. They give an algorithm for minimizing the makespan (i.e., the height of the packing), which has asymptotic performance bound $4\frac{4}{7}$. This was improved to 2.543 by Miyazawa and Wakabayashi [5] and finally to 2.25 by Epstein and van Stee [6].

35.6 Three- and More Dimensional Bin Packing

At present, the online-bounded space algorithm from Epstein and van Stee [20] is the best (online or offline) algorithm for packing multidimensional items into bins for any dimension $d \geq 3$. Clearly, this problem is APX-hard as well since it includes the two-dimensional bin packing problem as a special case [1].

Blitz et al. [30] gave a lower bound of 2.111 for online algorithms for $d = 3$. However, there is no good lower bound known for larger dimensions: nothing above 3. It appears likely that the asymptotic performance bound of any online algorithm must grow with the dimension.

For the special case of packing hypercubes online in dimensions $d \geq 4$, there is no better lower bound than the 4/3 given by Coppersmith and Raghavan [22] (which works in any dimension $d \geq 2$).

The bounded space algorithm by Epstein and van Stee [20] for this problem has a performance ratio that is sublinear in d: it is $O(d/\log d)$ and $\Omega(\log d)$.

For $d = 3$ (online cube packing), Miyazawa and Wakabayashi [51] showed that the algorithm of Coppersmith and Raghavan [22] has an asymptotic performance bound of 3.954. Epstein and van Stee [31] give an algorithm with asymptotic performance ratio at most 2.9421, and a lower bound of 1.6680.

Furthermore, the same authors [32] give bounds for the performance of their bounded space algorithm from Ref. [20], showing that its performance ratio lies between 2.95642 and 3.0672.

As was seen in Section 35.4.2, we can do even better offline. Before Bansal and Sviridenko [1] and Correa and Kenyon [3] gave their asymptotic polynomial-time approximation scheme for any dimension $d \geq 2$, Miyazawa and Wakabayashi [51] gave two approximation algorithms, of which the best had an asymptotic performance ratio of 2.6681. Soon afterwards, Kohayakawa et al. [37] presented their paper which we discussed in Section 35.4.2 as well. For $d = 3$, its asymptotic performance bound is $46/27 + \varepsilon \approx 1.7037\ldots + \varepsilon$.

35.7 Vector Packing

In this section we discuss the nongeometric version of multidimensional bin packing. The d-dimensional "vector packing" or "vector bin packing" problem is defined as follows. The bins are instances of the "all-1" vector $(1, 1, \ldots, 1)$ of length d. Items are d-dimensional vectors, whose components are all in $[0, 1]$. A packing is valid if the vector sum of all items assigned to one bin does not exceed the capacity of the bin (i.e., 1) in any component. Since all bins are identical, the goal is to minimize the number of bins used.

The problem can be seen as a scheduling problem with limited resources. The machines (with correspond to bins) have fixed capacities of several resources as memory, running time, and access to other computers. The items in this case are jobs that need to be run, each job requires a certain amount of each resource. Another application arises from viewing the problem as a storage allocation problem. Each bin has several qualities as volume and weight. Each item requires a certain amount of each quality. Both applications are relevant to both offline and online environments.

For many years there were very few results on this problem. In the first paper which obtained an APTAS for classical bin packing, Fernandez de la Vega and Lueker [19] imply a $(d + \varepsilon)$-approximation for the vector packing problem. This improved very slightly on some online results. These results were an upper bound of $d + 1$ on the performance ratio of any algorithm of which the output never has two bins that can be combined, given by Kou and Markowsky [52], and a tight bound on the performance of First Fit of $d + \frac{7}{10}$, given by Garey et al. [53]. Note that this is a generalization of the tight bound of $\frac{17}{10}$ for First Fit in one dimension.

Since these results were obtained, for a while there was hope that an APTAS would be found for this problem. However, Woeginger [2] proved that unless $P = NP$, there cannot be such an APTAS, already for two-dimensional vectors. Clearly, more restricted classes of vectors may still admit an APTAS. One such type of input is one where there is a total order on all vectors. In [54], Caprara et al. showed that an APTAS for this problem indeed exists.

The offline result for the general case was finally improved by Chekuri and Khanna [55]. They designed an algorithm of asymptotic performance $1 + \varepsilon d + O(\ln \frac{1}{\varepsilon})$. If d is seen as a constant, the best ratio achieved in this way is $O(\ln d)$. They proved that for an arbitrary d, it is APX-hard to approximate the problem within a factor of $d^{\frac{1}{2}-\varepsilon}$ for every fixed positive ε. This was shown using a reduction from graph coloring.

The online result was not improved since 1976. Lower bounds on the performance ratio of online algorithms, which tend to 2 as d grows, were shown by Galambos et al. [56]. Improved lower bounds were given by Blitz et al. [30], but this construction also tends to 2 as d grows.

As for the absolute approximation ratio, Kellerer and Kotov [57] designed an algorithm for two-dimensional vector packing with absolute approximation ratio of at most 2. Recently, Erlebach [58] showed a nonconstant lower bound on the absolute performance ratio for this problem. Interestingly, the method is similar to the one used by Chekuri and Khanna to show the hardness of approximation. The lower bound holds for the asymptotic performance ratio if d is not seen as a constant, that is, for arbitrary d.

As for variable-sized packing, the online problem was studied by Epstein [59]. In this problem, the algorithm may use bins out of a given finite subset. This subset contains the standard "all-1" vector, and possibly other vectors. The cost of a bin is the sum of its components. She showed that there exists a finite set where an online algorithm can achieve a performance of ratio of $1 + \varepsilon$ (by defining the class of bins to be dense enough), whereas for another set (which contains except for the "all-1" bin only bins that have relatively small components), the ratio must be linear in the dimension. Clearly, no matter what the set is, there exists a simple algorithm with linear performance ratio.

Analogous to the bin covering problem, we can define the vector covering problem, where the vector sum of all vectors assigned to one bin is *at least* 1 in every component. This problem was studied by Alon et al. [60]. In this paper it was shown that the performance ratio of any online algorithm is at least $d + \frac{1}{2}$. A linear upper bound of $2d$ is achieved by an algorithm that partitions the input into classes. The same paper contains offline results as well. An algorithm of performance guarantee $O(\log d)$ is presented as well as a simple and fast 2-approximation for $d = 2$. In Ref. [61] some results on variable-sized vector covering are given. These results focus on cases where all bins are vectors of zeros and ones. The benefit of a covered bin is the sum of its nonzero components. The considered cases for the bin sets are as follows: a set which consists of a single type of bin, a set of all unit vectors (all components are zero except for one), unit prefix vectors (some prefix of the vector consists of ones only), and the set of all zero–one vectors.

35.8 Variations

35.8.1 Rectangle Stretching

Imreh [62] studied an oriented online strip packing problem where rectangles can be stretched in a way that results in a larger height but the original area. Note that allowing stretching that increases the width makes the problem trivial as all items would be stretched to have the same width as the bin. He showed that the offline problem is polynomially solvable, and that if the online problem is considered under the asymptotic performance ratio measure (and assuming an upper bound of 1 on the original height of any rectangle), then the performance ratio can be made arbitrarily close to 1. Therefore, the main results are for the absolute performance ratio. There are algorithms of performance ratios 6 and 4, and a lower bound of 1.73 on the performance ratio of any online algorithm.

35.8.2 Items Appear from the Top

A "Tetris-like" online model was studied in a few papers. This is similar to strip packing, however, in this model, a rectangle cannot be placed directly in its designated area, but it arrives from the top as in the Tetris game, and should be moved continuously around only in the free space until it reaches its place (see Figure 35.4), and then cannot be moved again.

In [63], the model was introduced by Azar and Epstein. In that paper, both the rotatable and the oriented models were studied. For the rotatable model, a 4-approximation algorithm was designed. The situation for the oriented problem is more difficult, as no algorithm with constant approximation ratio exists for

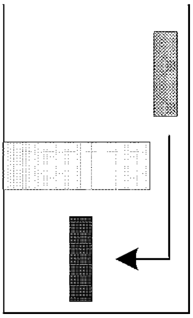

FIGURE 35.4 The process of packing an item in the "Tetris-like" model.

unrestricted inputs. If the width of all items is bounded below by ϵ and/or bounded above by $1 - \epsilon$, the authors showed a lower bound of $\Omega(\sqrt{\log \frac{1}{\epsilon}})$ on the performance ratio of any online algorithm for any deterministic or randomized algorithm. Restricting the width, they designed an $O(\log \frac{1}{\epsilon})$-approximation algorithm.

The oriented version of the problem was studied by Coffman et al. [64]. They assume a probabilistic model where item heights and widths are drawn from a uniform distribution on [0, 1]. They show that any online algorithm which packs n items has an asymptotic expected height of at least $0.313827n$ and design an algorithm of asymptotic expected height of $0.369764n$.

35.8.3 Dynamic Bin Packing

A multidimensional version of a dynamic bin packing model, which was introduced in Ref. [65] for the one-dimensional case, was studied recently by Epstein and Levy [66]. This is an online model where items do not only arrive but may also leave. Each event is an arrival or a departure of an item. Durations are not known in advance, that is, an algorithm is notified about the time that an item leaves only upon its departure. An algorithm may rearrange the locations inside bins, but the items may not migrate between bins. In Ref. [66], the same problem was studied in multiple dimensions.

In two dimensions, they designed a 4.25-approximation algorithm for dynamical packing of squares, and provided a lower bound of 2.2307 on the performance ratio. For rectangles the upper and lower bounds are 8.5754 and 3.7, respectively. For three-dimensional cubes they presented an algorithm which is a 5.37037-approximation, and a lower bound of 2.117. For three-dimensional boxes, they supplied a 35.346-approximation algorithm and a lower bound of 4.85383. For higher dimensions, they define and analyze the algorithm NFDH for the offline box packing problem. This algorithm was studied before for rectangle packing (two-dimensional only) [8], and for square and cube packing for any dimension [7,37], but not for box packing. For d-dimensional boxes they provided an upper bound of $2 \cdot 3.5^d$ and a lower bound of $d + 1$. Note that, as already mentioned in this survey, the best bound known for the regular offline multidimensional box packing problem is exponential as well. For d-dimensional cubes they provided an upper bound of $O\left(\frac{d}{\ln d}\right)$ and a lower bound of 2.

One earlier paper by Coffman and Gilbert [67] studies a related problem. In this problem, squares of a bounded size, which arrive and leave at various times, must be kept in a single bin. The paper gives lower bounds on the size of such a bin, so that all squares can fit. It is not allowed to rearrange the locations in the bin.

35.8.4 Packing Rectangles in a Single Rectangle

Another version is concerned with maximizing the number, area, or weight of a subset of the input rectangles that can be packed into a larger rectangle (of given height and width). The maximization problem with respect to the number of rectangles was studied already in 1983 by Baker et al. [68]. They designed an asymptotic $\frac{4}{3}$-approximation. This offline problem was recently studied by Jansen and Zhang [69,70]. The first paper considered the case of weighted rectangles and maximizing the total weight packed, whereas the second one considered unweighted rectangles and maximizing the number of packed rectangles. The problem is considered without rotation.

In [69], Jansen and Zhang proved that there exists an asymptotic FPTAS and an absolute PTAS, for packing squares into a rectangle. For rectangles they gave an approximation algorithm with asymptotic ratio of at most 2, and a simple one with an absolute ratio of $2 + \varepsilon$. In [70], Jansen and Zhang gave a more complicated algorithm for the weighted case with an absolute ratio of $2 + \varepsilon$. This algorithm has higher running time than the one for the unweighted problem. A special case of weights is simply the area of rectangles. The area maximization problem was studied by Caprara and Monaci [71]. They designed an algorithm with (absolute) approximation ratio of $3 + \varepsilon$.

An online version was studied by Han et al. [72]. In this version, we are given a unit square bin, rectangles arrive online, and the algorithm needs to decide whether to accept an arriving rectangle or not. The goal is again to maximize the packed area. They showed that if the algorithm is not allowed to remove rectangles accepted in the past, no algorithm with constant approximation ratio exists. This holds already for squares. It is easy to see that this holds with the following example. Take a first square which is very small and another one which fills the bin completely. An algorithm must accept the first square and therefore cannot accept the larger one. Next, they show that no algorithm with constant approximation ratio exists for rectangles, even if the algorithm is allowed to remove previously accepted rectangles. Therefore, the paper studies removable square packing. Before describing the results, we discuss a related paper that was used in this paper.

Januszewski and Lassak [73] studied a similar problem from the point of view of finding a threshold $\alpha \leq 1$ such that a set of squares of total area of at most α can be always packed online in a bin, without rearranging the contents of the bin. They showed that $\frac{5}{16}$ is lower bound on α. Moreover, they considered this problem for multidimensional cubes, and showed a lower bound of $\frac{1}{2^d-1}$ for $d \geq 5$. For the packing they used a nice tool which they called bricks. A brick is a rectangle, where the ratio of the maximum between height and width to the minimum between the two remains the same after cutting the rectangle into two identical parts. Clearly, this can work if the ratio is $\sqrt{2}$.

Han et al. [72] adopted this method. They showed that any algorithm has performance ratio of at least $\phi + 1 \approx 2.618$. They designed a matching algorithm for the case where rearranging is allowed, and a 3-approximation algorithm without rearranging. A direct consequence is that a lower bound on α for two dimensions is $\frac{1}{3}$.

Finally, another related problem is packing squares or rectangles into a square or rectangle of minimum size, where arbitrary rotations are allowed (not just over 90°). For example, five unit squares, can be packed inside a square with side $2 + \frac{1}{2}\sqrt{2}$, by placing four squares in the corners and one in the center at a 45° angle. For a survey on packing equal squares into a square; see for example, Ref. [74]. Novotný [75] showed that any set of squares with total area 1 can be packed in a rectangle of area at most 1.53 (without rotations).

36.1 Introduction

Cutting and packing problems consist of placing a given set of (small) items into one or more (larger) objects without overlap so as to minimize/maximize a given objective function. This is a combinatorial optimization problem with many important applications in the wood, glass, steel, and leather industries, as well as in Large Scale Integration (LSI) and Very Large Scale Integration (VLSI) design, newspaper paging, and container and truck loading. For several decades, cutting and packing has attracted the attention of researchers in various areas including operations research, computer science, manufacturing, etc.

Cutting and packing problems can be classified using different criteria. The dimensionality of a problem is one of such criteria, and most problems are defined over one, two, or three dimensions. In this chapter we consider two-dimensional problems. The next criterion to classify two-dimensional packing problems is the shape of items to pack. We focus on the *rectangle packing problem* in this chapter. This problem has been actively studied in the past few decades. When the shapes of the items to be packed are polygons or arbitrary shapes, the problem is called *irregular packing*. We also discuss in this chapter recent research in this area.

Almost all two-dimensional packing problems are known to be NP-hard, and hence it is impossible to solve them exactly in polynomial time unless P = NP. Therefore, heuristics and metaheuristics are very important to design practical algorithms for these problems. We survey practical algorithms for two-dimensional packing problems in this chapter. We also survey various schemes used to represent solutions to rectangle packing problem, and introduce algorithms based on these *coding schemes*.

The remainder of this chapter is organized as follows: Section 36.2 defines the rectangle packing problem and its variations. Section 36.3 introduces coding schemes for the rectangle packing problem, which are used to represent solutions. Section 36.4 presents heuristic algorithms, from the traditional to the latest ones, for the rectangle packing problem. Section 36.5 discusses practical algorithms based on metaheuristics. Sections 36.4 and 36.5 discuss computational results for the various algorithms on benchmark instances. Section 36.6 defines the irregular packing problem, and practical algorithms for this problem are presented.

36.2 Rectangle Packing Problem

We consider the following two-dimensional rectangle packing problem. We are given n items (small rectangles) $I = \{1, 2, \ldots, n\}$, each of which has width w_i and height h_i, and one or many large objects (rectangles). We are required to place the items orthogonally without any overlap (an edge of each item is parallel to an edge of the object) so as to minimize (or maximize) a given objective function. The rectangle packing problem arises in many industrial applications, often with slightly different constraints, and many variants of this problem have been considered in the literature. The following characteristics are important to classify the problems [1,2]: type of assignment, assortment of objects, and assortment of items. We will review some specific variations of the rectangle packing problem in this section. We should mention two more important constraints for the rectangle packing problem: orientation and guillotine cut constraint. As for the orientation of the items, we usually assume that "each rectangle has a given fixed orientation" or "each rectangle can be rotated by 90°." Rotation of items is not allowed in newspaper paging or when the items to be cut are decorated or corrugated, whereas orientation is free in the case of plain materials, and so on. Guillotine cut constraint signifies that the items must be obtained through a sequence of edge-to-edge cuts parallel to the edges of the large object (see Figure 36.1 for an example), which is usually imposed by technical limitations of the automated cutting machines or the material.

We introduce six types of rectangle packing problems that have been actively studied. For simplicity, we define the problems assuming that each item has a fixed orientation and the guillotine cut constraint is not imposed unless otherwise stated. It is straightforward to extend our definitions for other cases where each item can be rotated by 90° and/or the guillotine cut constraint is imposed. We first consider two types of typical rectangle packing problems with one large rectangular object, which may grow in one or two dimensions, where all the items are placed disjointly. The problems are called *strip packing* and *area minimization.*

Strip packing problem. We are given n items (small rectangles) each having width w_i and height h_i, and one large object (called a strip) whose width W is fixed, but its height H is variable. The objective is to minimize the height H of the strip such that all items can be packed into the strip.

Area minimization problem. We are given n items each having width w_i and height h_i, and one large rectangular object, where both its width W and height H are variables. The objective is to minimize the area WH of the object such that all items can be packed into the object.

In Sections 36.3–36.5, we focus mainly on the strip packing (and area minimization) problem, which is formally formulated as the following mathematical program:

$$\begin{array}{lll} \text{minimize} & \text{the height of the strip}\, H & \text{(or the area of the large object } WH) \\ \text{subject to} & 0 \le x_i \le W - w_i, & \text{for all } i \in I \qquad (36.1) \\ & 0 \le y_i \le H - h_i, & \text{for all } i \in I \qquad (36.2) \end{array}$$

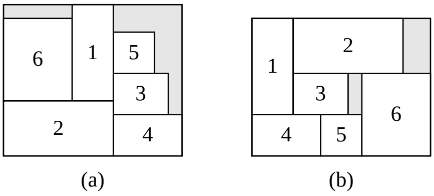

FIGURE 36.1 Examples of placements with/without guillotine cut constraint. (a) Guillotine cut; (b) nonguillotine.

At least one of the next four inequalities holds for every pair i and j:

$$x_i + w_i \leq x_j \tag{36.3}$$

$$x_j + w_j \leq x_i \tag{36.4}$$

$$y_i + h_i \leq y_j \tag{36.5}$$

$$y_j + h_j \leq y_i \tag{36.6}$$

where (x_i, y_i) is the coordinate of the lower left corner of an item i. Constraints (36.1) and (36.2) mean that all items must be placed into the large object, and Constraints (36.3)–(36.6) mean that no two items overlap (i.e., each inequality signifies one of the four relative locations: left-of, right-of, above, and below).

Two other rectangle packing problems are the *two-dimensional bin packing* and *knapsack* problems that have (many or one) fixed-sized objects.

Two-dimensional bin packing problem. We are given a set of items, where each item i has width w_i and height h_i, and an unlimited number of large objects (rectangular bins) having identical width W and height H. The objective is to minimize the number of rectangular bins used to place all the items.

Two-dimensional knapsack problem. We are given a set I of items, where each item $i \in I$ has width w_i, height h_i, and value c_i. We are also given a rectangular knapsack with fixed width W and height H. The objective is to find a subset $I' \subseteq I$ of items with the maximum total value $\sum_{i \in I'} c_i$ such that all items $i \in I'$ can be packed into the knapsack.

For the two-dimensional bin packing problem, Lodi et al. [3] proposed practical heuristic and metaheutistic algorithms and performed computational experiments on various benchmark instances. For the two-dimensional knapsack problem, Wu et al. [4] proposed heuristic algorithms that are effective for many test instances.

We should also mention the following two problems: *two-dimensional cutting stock* and *pallet loading.* For some industrial applications, such as mass production manufacturing, many small items of an identical shape or relatively few classes of shapes are packed into the objects. The following two problems are useful for modeling these situations.

Two-dimensional cutting stock problem. We are given a set of items each with width w_i, height h_i, and demand d_i. We are also given an unlimited number of objects having identical width W and height H. The objective is to minimize the number of objects used to place all the items (i.e., for each i, we place d_i copies of item i into the objects).

Pallet loading problem. We are given sufficiently large number of items with identical size (w, h), and one large rectangular object with size (W, H). The objective is to place the maximum number of items into the object, where each item can be rotated by 90°.

Note that the pallet loading problem with a fixed orientation of items is trivial to solve. Among many studies on the two-dimensional cutting stock problem, Gilmore and Gomory [5] provided one of the earliest solution methods. They proposed a column generation scheme in which new cutting patterns are produced by solving a generalized knapsack problem. Recently, some practical algorithms for the two-dimensional cutting stock problem have been proposed [6,7]. Morabito and Morales [8] proposed a simple but effective algorithm for the pallet loading problem.

The complexity of the pallet loading problem is open (this problem is not known to be in class NP, because of the compact input description), whereas the other problems we defined in this section are known to be NP-hard.

36.3 Coding Schemes for Rectangle Packing

In this section, we review coding schemes for rectangle packing problems. For simplicity, we focus on the strip packing problem. An effective search will be difficult if we search the x and y coordinates of each item directly, since the number of solutions is uncountable and eliminating the overlap between items is not easy. To overcome this difficulty, various coding schemes have been proposed and many algorithms for rectangle packing problems are based on some coding schemes.

A *coding scheme* consists of a set of coded solutions, a mapping from coded solutions to placements, and a *decoding algorithm* that computes for a given coded solution the corresponding placement using the mapping. (The mapping is sometimes defined by the decoding algorithm.) Properties of a coding scheme (and a decoding algorithm) are given below:

1. There exists a coded solution that corresponds to an optimal placement.
2. The number of all possible coded solutions is finite, where a small total number is preferable provided that property 1 is satisfied.
3. Every coded solution corresponds to a feasible placement.
4. Decoding is possible in polynomial time. Fast algorithms are more desirable.

Some of the coding schemes in the literature satisfy all of the above four properties, but others do not.

One of the most popular coding schemes is to represent a solution by a permutation of the n items, where a coded solution (i.e., a permutation of n items) specifies the placement order. The number of all possible coded solutions is $O(n!)$, which is smaller than other coding schemes in the literature, and every permutation corresponds to a placement without items overlapping. A decoding algorithm computes a placement from a given coded solution by specifying the locations of the items one by one, which defines the mapping from coded solutions to placements and is sometimes called a *placement rule*. The decoding time complexity and the existence of a coded solution that corresponds to an optimal placement depend on the decoding algorithms. In the literature, a number of decoding algorithms for permutation coding schemes have been proposed. We will explain some typical decoding algorithms in Section 36.4, and compare them theoretically and experimentally.

We now explain different types of coding schemes for rectangle packing problems. The schemes we explain hereafter specify the relative locations for each pair of items by a coded solution. In other words, for every pair of items, a coded solution determines one of the four inequalities (36.3)–(36.6), which must be satisfied to avoid item overlap. The placement corresponding to a coded solution is the best one among those that satisfy the relative locations specified by the coded solution.

One of the most popular coding schemes of this type is to represent a solution by an n-leaf binary tree [9]. This coding scheme can represent only slicing structures (in other words, each placement obtained by this representation always satisfies the guillotine cut constraint). The leaves of a binary tree correspond to items, and each internal node has a label "h" or "v," where h stands for horizontal and v for vertical. This coding scheme uses $O(n)$ space to represent a solution, and the number of all possible coded solutions is $O(n!2^{5n-3}/n^{1.5})$ [9]. In this scheme, one of the four relative locations is assigned for each pair i and j of items as follows: If i is a left descendant of an internal node u with "h" label and j is a right descendant of the same internal node u (i.e., u is the least common ancestor of i and j), then we must place i to the left of j (i.e., $x_i + w_i \leq x_j$). If the label of the least common ancestor is "v," then we place i below j (i.e., $y_i + h_i \leq y_j$). Figure 36.2 shows an example of a binary tree representation and a placement that satisfies these constraints. For example, in the figure, there is an internal node with "h" label for which the node for item 6 is a left descendant and the node for item 1 is a right descendant, and hence item 6 is placed to the left of item 1; the node for item 4 is a left descendant and the node for item 3 is a right descendant of the least common ancestor with "v" label, and hence item 4 is placed below item 3 and so forth. For a given binary tree τ, let Π_τ denote the set of all placements that satisfy the above horizontal–vertical constraints. The placement corresponding to a coded solution τ is one of the best (i.e., the most compact) placements in Π_τ. Though Π_τ contains infinitely many placements for any τ, natural decoding algorithms

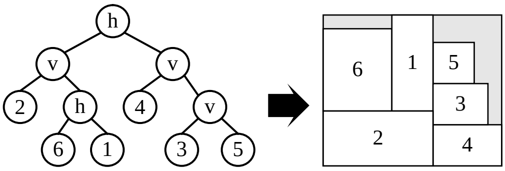

FIGURE 36.2 A binary tree representation τ and a solution $\pi \in \Pi_\tau$.

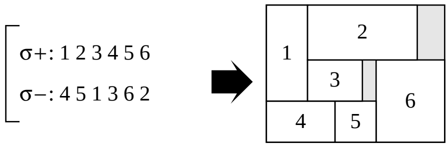

FIGURE 36.3 A sequence pair representation σ and a solution $\pi \in \Pi_\sigma$.

for this coding scheme run in linear time with respect to the number of items, and computes one of the best placements among Π_τ. Moreover, for any placement π that satisfy the guillotine cut constraint, there exists a binary tree τ that satisfies $\pi \in \Pi_\tau$. That is, the binary tree coding scheme satisfies all of the four desirable properties of a coding scheme if the guillotine cut constraint is imposed.

Murata et al. [10] proposed a coding scheme called *sequence pair*. For the sequence pair representation, a solution is represented by a pair of permutations $\sigma = (\sigma_+, \sigma_-)$ of the n items (see Figure 36.3 for an example). Based on this coded solution, we assign relative locations for each pair of items i and j as follows: If item i is before item j in both permutations σ_+ and σ_-, then item i must be placed to the left of j. If i is before j in σ_+ and after j in σ_-, then we place i above j. For example, in Figure 36.3, element 1 is before element 2 in both permutations, and hence item 1 is placed to the left of item 2; element 2 is before element 3 in permutation σ_+ and after element 3 in σ_-, and hence item 2 is placed above item 3 and so on. For a given pair of permutations $\sigma = (\sigma_+, \sigma_-)$, let Π_σ be the set of placements that satisfy the above constraints. The placement corresponding to a coded solution σ is one of the best placements in Π_σ. Murata et al. [10] proposed an $O(n^2)$ time decoding algorithm to obtain one of the best placements $\pi \in \Pi_\sigma$ for a given coded solution σ. Takahashi [11] improved the time complexity of the decoding algorithm to $O(n \log n)$; Tang et al. [12] further improved it to $O(n \log\log n)$. Moreover, for any feasible placement π, there exists a coded solution σ that satisfies $\pi \in \Pi_\sigma$ (such a pair of permutations σ can be computed in $O(n \log n)$ time [13]). That is, the sequence pair coding scheme satisfies all of the four desirable properties of a coding scheme.

Nakatake et al. [14] proposed a coding scheme called *bounded sliceline grid* (BSG). BSG consists of a set of small rooms that are separated by horizontal and vertical segments, where the number of rooms in the horizontal and vertical directions, denoted p and q, respectively, are parameters that satisfy $pq \geq n$ (see Figure 36.4[a] with $p = q = 6$). It introduces one of the four orthogonal relations (left-of, right-of, above, and below) uniquely for each pair of rooms (see Figure 36.4[b] and Figure 36.4[c]). In these figures,

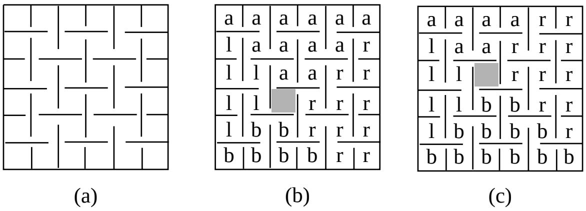

FIGURE 36.4 Rooms of bounded sliceline grid representation and relative locations.

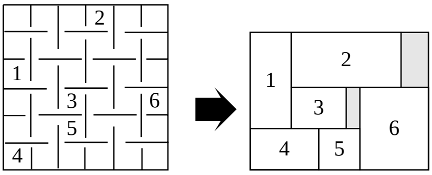

FIGURE 36.5 A bounded sliceline grid representation α and a solution $\pi \in \Pi_\alpha$.

a room with label l (resp., r, a, b) is left-of (resp., right-of, above, below) the shaded room. A solution is represented by an assignment of the items to rooms, where at most one item can be assigned to each room. The assigned items inherit the relations defined on the rooms. Figure 36.5 shows an example of an assignment of items to rooms and a placement that satisfy all specified constraints of relative locations. For example, in the figure, item 3 is placed to the right of item 1, item 3 is placed below item 2, item 3 is placed above item 4, and so forth. For a given assignment α, let Π_α be the set of all placements that satisfy the constraints given by α. The placement corresponding to a coded solution α is one of the best placements in Π_α. A decoding algorithm proposed by Nakatake et al. [14] runs in linear time with respect to the number of small rooms pq, and can find one of the best placements $\pi \in \Pi_\alpha$ for a given coded solution α. As for the existence of a coded solution that corresponds to an optimal placement, it is known that an assignment α such as $\pi \in \Pi_\alpha$ always exists for any placement π if and only if $p \geq n$ and $q \geq n$ hold. The BSG coding scheme with parameters $p \geq n$ and $q \geq n$ satisfies all of the four desirable properties of a coding scheme.

There are many other coding schemes that describe the relative locations for each pair of items. Guo et al. [15] proposed a tree representation called O-tree: Two ordered trees for the horizontal and vertical directions are used to represent a coded solution. This coding scheme can represent nonslicing structures and the number of all possible coded solutions is $O(n!2^{2n-2}/n^{1.5})$; this is smaller than the number of all coded solutions by the binary tree representation for slicing structures. There exists a coded solution corresponding to any placement π that satisfies the bottom left (BL) stability; that is, in the resulting placement, all items cannot be moved any further to the bottom or to the left. Chang et al. [16] extended the result of Guo et al. [15]. They proposed another tree representation called B*-tree; it is easy to implement this data structure and a decoding algorithm for B*-tree runs in linear time with respect to the number of items. Sakanushi et al. [17] proposed another coding scheme called quarter-state sequence: They utilized a string of items and labels to represent a solution and their decoding algorithm runs in linear time of the number of items.

36.4 Heuristics for Rectangle Packing

In this section, we describe heuristic algorithms for rectangle packing problems. We first explain some heuristic algorithms based on the permutation coding scheme. Those algorithms consist of two phases: (1) construct a permutation and (2) place the items one by one according to the permutation.

For the first phase, a standard strategy to construct a permutation is "a larger item has higher priority than a smaller one." To realize this, the items are sorted by some criteria, for example, decreasing height, decreasing width, or decreasing area. It is difficult to decide a priori which criterion is the best for numerous instances that arise in practice. Hence, many algorithms generate several permutations with different criteria, and apply a decoding algorithm to all such permutations.

Let us consider the second phase, that is, decoding algorithm for permutations. We first explain *level algorithms* in which the placement is obtained by placing items from left to right in rows forming levels (see Figure 36.6 for an example). The first level is the bottom of the object, and each subsequent level is along the horizontal line coinciding with the top of the tallest item packed on the level below.

The most popular level algorithms are the *next fit*, *first fit*, and *best fit* strategies, which are extended from the algorithms for the (one-dimensional) bin packing problem. Let i ($i = 1, 2, \ldots, n$) denote the

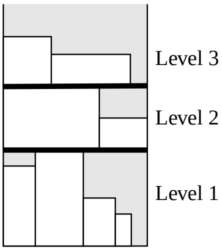

FIGURE 36.6 An example of level packing.

current item to be placed, and s be the level created most recently, where the bottom of the object is level 1 created at the beginning of an algorithm.

- *Next fit* strategy. Item i is packed on level s left justified (i.e., place it at the leftmost feasible position) if it fits. Otherwise, a new level ($s := s + 1$) is created and i is packed on it left justified.
- *First fit* strategy. We check whether or not item i fits from level 1 to level s, and pack it left justified on the first level where it fits. If no level can accommodate i, it is placed on a new level as in the next fit strategy.
- *Best fit* strategy. Item i is packed left justified on the level that minimizes the unused horizontal space among those where it fits. If no level can accommodate i, it is placed on a new level as in the next fit strategy.

Computation time of these algorithms is $O(n)$, $O(n \log n)$, and $O(n \log n)$, respectively, if appropriately implemented. The above strategies are illustrated by examples in Figure 36.7 (in this figure, items are sorted by decreasing height and are numbered accordingly). The resulting placements of these algorithms always satisfy the guillotine cut constraint. More precisely, they are the so-called two-stage guillotine placements in that they can be cut out in two stages: the first stage for horizontal cuts and the second stage for vertical cuts.

A different classical approach, and the most documented one, is the BL approach. The first algorithm of this type was proposed by Baker et al. [18] in 1980, and some variants of this method have been proposed in the last couple of decades. A common characteristic of this type of algorithms is to place items one by one at the BL stable positions; that is, in the resulting placement, all items cannot be moved any further to the bottom or to the left.

Baker et al. [18] used a BL rule that places each item at the leftmost point among the lowest possible positions. This approach is called *bottom left fill* (BLF) strategy in Refs. [19,20], which is illustrated by an example in Figure 36.8(a). The "x" marks in the figure show the BL stable positions. There are natural algorithms that require $O(n^3)$ time in the worst case for this strategy, and Hopper and Turton implemented one of them in their article [20]. Chazelle [21] devised an efficient algorithm that requires $O(n^2)$ time and $O(n)$ space in the worst case.

Jakobs [22] utilized another BL method: For each item, first place it at the top right location of the object and make successive sliding moves down and to the left alternately as far as possible (see an example

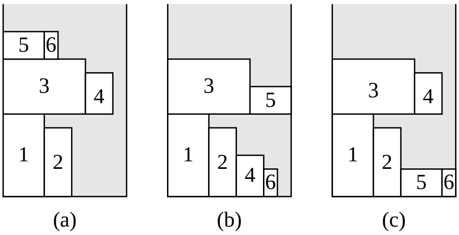

FIGURE 36.7 Three level algorithms for the strip packing problem: (a) next fit; (b) first fit; (c) best fit.

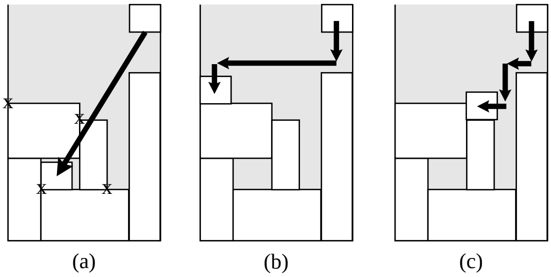

FIGURE 36.8 Three bottom left algorithms for the strip packing problem: (a) Baker et al.; (b) Jakobs; (c) Liu and Teng.

in Figure 36.8[b]). This strategy is called BL in Refs. [19,20] and it runs in $O(n^2)$ time, if appropriately implemented. We will see a comparison of BL and BLF algorithms through our computational experiments later on. Liu and Teng [23] developed another BL heuristics similar to Jakobs's algorithm. In their strategy, the downward movement has priority such that items slide leftward only if no downward movement is possible (see Figure 36.8[c]). This algorithm also runs in $O(n^2)$ time.

There are more algorithms which utilize the permutation to represent a solution. For example, Lodi et al. [3] proposed several decoding algorithms such as *floor ceiling, alternate directions,* and *touching perimeter,* and experimentally compared these algorithms with other decoding algorithms in the literature. Wu et al. [4] proposed complicated decoding algorithms, which runs in $O(n^4 \log n)$ or $O(n^5 \log n)$ time and has achieved certain computational success.

We discuss a different type of heuristic algorithm proposed by Burke et al. [19] in 2004. This method does not have a permutation of items to place, but dynamically decide the next item to place during the packing stage. More precisely, it finds the lowest available gap (LAG) within the large object and then places the item that best fits there (see Figure 36.9 for an example). This enables the algorithm to make informed decisions about which item should be packed next and where it should be placed. A natural implementation of this strategy runs in $O(n^2)$ time. We will also present experimental results for this algorithm.

At the end of this section, we compare typical heuristic algorithms through computational experiments. Test instances given by Hopper and Turton [20] were used for the experiments. There are seven different categories C1, C2, ..., C7 with the number of items ranging from 17 to 197, with each category having three instances. The optimal solution for all instances are known; these instances have placements without any dead space (in other words, these instances have perfect packings). The results of algorithms BL-R, BL-DW, BL-DH, BLF-R, BLF-DW, and BLF-DH are taken from Ref. [20], where BL (resp., BLF) means that items are placed with BL (resp., BLF) strategy into the object, and R, DW, and DH signify the types of permutations: R means random permutation and DW (resp., DH) means that items are sorted by decreasing width (resp., decreasing height). The results by Burke et al. reported in Ref. [19] algorithm (denoted BKW) are also shown.

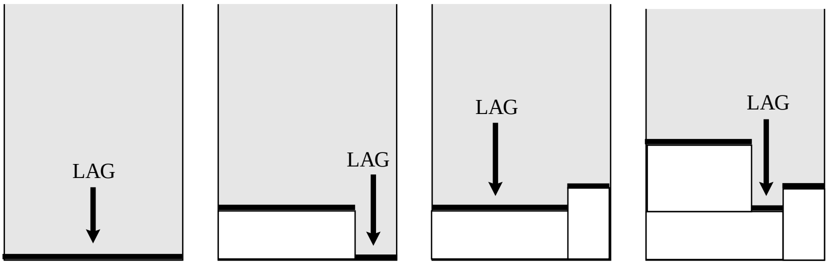

FIGURE 36.9 A heuristic algorithm for the strip packing by Burke et al. [19].

TABLE 36.1 Solution Quality of Heuristic Algorithms for the Strip Packing Problem

	C1	C2	C3	C4	C5	C6	C7
n	17	25	28	49	72	97	196
BL	25	39	33	33	31	34	41
BL-DH	17	68	27	21	18	19	31
BL-DW	18	31	24	18	22	21	29
BLF	14	20	17	15	11	12	10
BLF-DH	11	42	12	6	5	5	4
BLF-DW	11	12	12	5	5	5	5
BKW	12	7	10	4	3	2	2

Computational results are shown in Table 36.1. Each row corresponds to a heuristic algorithm and each column corresponds to a category of instances, where n is the number of items for each instance. In this table, the relative distances in percentage between the optimal and resulting solutions are reported. The computation time for each instance is within 1 second on a PC with an 850 MHz CPU (for BKW) or a 200 MHz CPU (for others). From Table 36.1, we can observe that BLF outperformed BL by up to 25% and that preordering the items by decreasing width or decreasing height for BL and BLF algorithms increased the packing quality by up to 10% compared to random permutations. Moreover, the algorithm by Burke et al. outperformed other algorithms, especially for large instances.

36.5 Metaheuristics for Rectangle Packing

In the last decade, many local search and metaheuristic algorithms for rectangle packing problems have been proposed. Dowsland [24] was one of the early researchers who implemented metaheuristics for rectangle packing problems. Her simulated annealing (SA) algorithm explores both feasible and infeasible (i.e., some items overlap) solutions. During the search, the objective is to reduce the overlapping area. Computational results for small problem instances are reported in Ref. [24].

Let us explain some metaheuristic algorithms based on the permutation coding scheme. These algorithms consist of two phases: (1) find a good permutation using metaheuristics and (2) the decoding algorithm places the items one by one following the permutation order. In Ref. [22], Jakobs proposed a metaheuristic algorithm for the strip packing problem. In this algorithm, he uses a genetic algorithm (GA) to find a good permutation, and places items by using the BL strategy explained in the previous section. He treats not only rectangle packing problems but also irregular packing problems, and reports several computational results. Liu and Teng [23] also proposed a GA algorithm using their BL type decoding algorithm.

In Ref. [20], Hopper and Turton compare the performance of various metaheuristics (multistart local search [MLS], SA, GA, and so on) with two decoding rules on small and large test instances. The computational results reported in Ref. [20] are shown in Table 36.2. The first decoding rule is the BL heuristic proposed by Jakobs [22], and the second one is the BLF strategy proposed by Baker et al. [18]. The stopping criterion for each algorithm is a fixed number of iterations, and the computation time for each instance is about 50,000 times as large as the simple heuristic algorithms (BL and BLF). The representation of this table is similar to that of Table 36.1. From this table, we observe that the performance of the hybrid

TABLE 36.2 Solution Quality of Metaheuristic Algorithms for the Strip Packing Problem

	C1	C2	C3	C4	C5	C6	C7
GA+BL	6	10	8	9	11	15	21
SA+BL	4	7	7	6	6	7	13
MLS+BL	9	18	11	14	14	20	25
GA+BLF	4	7	5	3	4	4	5
SA+BLF	4	6	5	3	3	3	4
MLS+BLF	7	10	7	7	6	7	7

algorithms is strongly dependent on the decoding rule and the instance size. Moreover, it is also reported that certain computation time is needed to attain better solutions with metaheuristics than the solutions obtained by well-designed heuristics such as BLF-DW and BLF-DH.

We now discuss metaheuristic algorithms based on other coding schemes. For the sequence pair representation, Murata et al. [10] proposed an SA algorithm and Imahori et al. [13] proposed an iterated local search (ILS) algorithm. They used metaheuristics to find a good coded solution where each coded solution is evaluated with its own decoding algorithms. Chang et al. [16] and Nakatake et al. [14] proposed SA algorithms using B*-trees and BSG, respectively. One of the advantages of the above algorithms is generality: Imahori et al. [13] incorporated "spatial cost functions" into their algorithms, which was used to handle various types of rectangle packing problems and scheduling problems. Chang et al. [16] and Nakatake et al. [14] designed algorithms that can treat the rectangle packing problem with additional constraints such as preplaced items and soft modules.

Recently, more effective algorithms for rectangle packing problems have been proposed. Lesh et al. [25] proposed a stochastic search variation of the bottom left heuristics for the strip packing problem. Their algorithm outperforms other heuristic and metaheuristic algorithms based on the BL strategy reported in the literature. Furthermore, they incorporated their algorithm in an interactive system that combines the advantages of computer speed and human reasoning. Using the interactive system, they succeeded in producing significantly better solutions than their original algorithm quickly.

Imahori et al. [26] proposed an improved metaheuristic algorithm based on sequence pair representation. Metaheuristic algorithms generate numerous number of coded solutions and evaluate all of them. Hence, the efficiency of metaheuristic algorithms strongly depends on the time complexity of decoding algorithms. Imahori et al. proposed new decoding algorithms to evaluate all coded solutions in various neighborhoods efficiently. As a result, they attained an amortized constant time to evaluate one coded solution in basic neighborhoods.

Bortfeldt [27] proposed a GA for the strip packing problem that works without any encoding of solutions. Instead of using a coding scheme, fully defined layouts are directly manipulated by specific genetic operators. He conducted thorough computational experiments using existing benchmark instances with up to 5000 rectangles, and compared his algorithm with 11 competing methods that were proposed in 1993–2004. He reported that his GA performed best among them.

For more information of the metaheuristic algorithms applied to rectangle packing problems, we refer the reader to articles by Hopper and Turton [20] and Bortfeldt [27].

36.6 Irregular Packing Problem

In this section, we consider the two-dimensional *irregular packing problem,* which has been actively studied in the last decade. The irregular packing problem has many practical applications, for example, the garment, shoe, and shipbuilding industries, and many variants of this problem have been considered in the literature. Among the numerous variants of this problem, the irregular strip packing problem has been studied extensively.

Irregular strip packing problem. We are given n items of arbitrary shapes, and one object (called a strip) with constant width W but variable height H. The objective is to minimize the height H of the strip such that all the items can be packed into the strip.

In this section, we mainly focus on fixed orientation packing. The problem in which items can be rotated (freely or by some fixed degrees) has also been studied in the literature. One of the main differences between rectangle and irregular packing problems is that the intersection test between irregular items is considerably more complex than the case with rectangular items. To overcome this difficulty, some approximation techniques and geometric algorithms have been incorporated into the packing algorithms.

One popular idea for speeding up the intersection test is to represent the items (irregular shapes) approximately. Oliveira and Ferreira [28] proposed two approaches to the irregular strip packing problem, and one of them uses this type of approach. Their approach is based on a raster representation (in other words, bitmap representation) of the irregular shapes to be placed. This approximation allows a quick test overlapping, but suffers from inaccuracy, caused by the approximation inherent in the raster representation. Their another approach uses a polygon-based representation that does not use any approximation technique. Both methods allow overlap in the solutions, and the extent of overlap is penalized by an evaluation function. They try to find a good solution via SA, where the algorithms aim to reduce the overlap to zero.

Okano [29] proposed a heuristic algorithm for the irregular two-dimensional bin packing problem using a scanline representation. He approximates a two-dimensional item with a set of parallel line segments. He also uses a clustering technique; some items are gathered and packed tightly, and then these items are treated as one new item. Okano designed his algorithm for the irregular two-dimensional bin packing problem; however, his technique is also useful for treating the irregular strip packing problem. He conducted computational experiments with real instances from a shipbuilding company, and reported that the quality of the resulting layouts was sufficiently high for practical use.

Jakobs [22] used another type of approximation scheme; for all irregular shapes, the minimum bounding rectangles of the given items are calculated and his algorithm treats these rectangles instead of the original shapes. For these shapes, a good placement is computed by his BL decoding algorithm and GA techniques. After finding a good placement for the rectangles, the algorithm replaces rectangles with the original irregular shapes, and computes a better placement of the irregular items. He reported computational results for this algorithm. Jakobs also discussed an idea of clustering several shapes, and finding the minimum bounding rectangle of several items.

Dighe and Jakiela [30] proposed an algorithm for the irregular strip packing problem, which is based on a clustering method with a tree structure. Their algorithm uses a tree structure to represent a solution: The leaves of a tree correspond to items, and clustering operations are applied to items from the leaves to the root of the tree. To find a good coded solution (i.e., tree), they utilized GA. Dighe and Jakiela created new test instances and conducted computational experiments on these instances.

One of the most popular geometric techniques used for the intersection test is *no-fit polygon*. The concept of no-fit polygon was introduced by Art [31] in 1966, who used the term "shape envelope" to describe the positions where two items can be placed without intersection. Albano and Sapuppo [32] proposed an algorithm to solve the irregular strip packing problem with this geometric technique. This was the first paper that used the term "no-fit polygon." This concept is also known as Minkowski sums, and is utilized in various fields such as motion planning for polygonal robots.

The no-fit polygon of item j relative to item i ($NFP_{i,j}$) is the set of all loci of the reference point of item j (denoted R_j) such that items i and j have a common point when the position of item i is fixed (each item is considered as the set of points on the boundary and inside it). If both items i and j are convex, the boundary of $NFP_{i,j}$ is the trace of R_j when item j slides along the boundary of item i. See Figure 36.10 for an example of the no-fit polygon $NFP_{i,j}$ of convex polygons i and j. From the definition of no-fit polygons, it follows that

- if the reference point R_j of item j is placed in the interior of $NFP_{i,j}$, then item j overlaps item i;
- if R_j is placed on the boundary of $NFP_{i,j}$, then item j touches item i;
- if R_j is placed in the exterior of $NFP_{i,j}$, then item j neither overlaps nor touches item i.

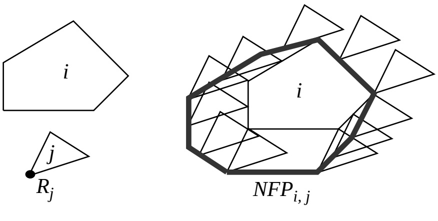

FIGURE 36.10 An example of the no-fit polygon $NFP_{i,j}$ of convex items i and j.

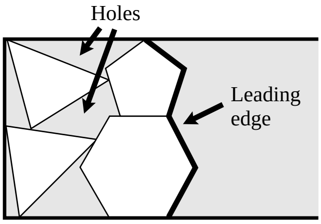

FIGURE 36.11 The leading edge and holes in a layout of irregular shapes.

The problem of finding the relative position of two polygons is transformed into a simpler problem of finding the relative position of one point and one polygon. To achieve a nonoverlapping compact layout, each item should have its reference point on the boundary of at least one no-fit polygon and in the exterior of all the other no-fit polygons.

Albano and Sapuppo [32] proposed an algorithm to solve the irregular strip packing problem using no-fit polygons. They approached the problem using a BL algorithm, which utilized the no-fit polygon to reduce the geometric complexity of the packing process. Their algorithm places each item one by one at the right frontier called the leading edge of the current layout only, that is, without hole filling capabilities. See Figure 36.11 for an example of the leading edge and holes in a layout. Blazewicz et al. [33] presented an extension of the work performed by Albano and Sapuppo [32]. Their method is an extension of the BLF algorithm; that is, their approach attempts to fill holes in the existing layout before attempting to place an item on the leading edge. Their algorithm utilizes the tabu search technique to produce moves from one solution to another.

Oliveira et al. [34] also tackled the irregular strip packing problem using no-fit polygons. Their algorithm places all small items one by one at a nonoverlapping position touching at least one item already placed. Several criteria to choose the next item to place and its orientation were proposed (in this article, they treated a problem such that each item can be rotated by some fixed degrees). Different evaluation functions were also proposed to evaluate partial solutions and to decide the position of each item. A total of 126 variants of the algorithm, generated by the complete set of combinations of criteria and evaluation functions, were computationally compared. In their computational experiments, they solved several types of test instances; test instances from a fabric cutting company and a test instance generated by Blazewicz et al. [33]. Oliveira et al. compared their results against an implementation of Albano and Sapuppo's algorithm [32], and against results from Blazewicz et al. [33]. In some cases, their new algorithm generated better solutions than the best known solutions in the literature; more precisely, their algorithm generated solutions that ranged from 6.2% better to 4% worse than the best known results.

Gomes and Oliveira [35] developed shape-ordering heuristics for an extended irregular packing algorithm similar to that given by Oliveira et al. [34]. The algorithm is improved by the introduction of the inner-fit rectangle, which is derived from the concept of no-fit polygon and represents the feasible set of points for placing a new polygon inside the object. In addition to this extension of geometric techniques, the paper introduces a 2-exchange heuristic for manipulating a permutation that specifies the order of placing items one by one. They generated some initial permutations with various criteria, for example, random, decreasing order of area, decreasing order of the longest length of items, and improved them using the 2-exchange heuristic over a number of iterations. In [35], they conducted thorough computational experiments and compared the proposed algorithm with existing algorithms. They improved almost all best known solutions for well-known benchmark instances (except for an instance called SHAPE0).

Gomes and Oliveira [36] also developed a hybrid algorithm of simulated annealing with linear programming (LP) technique to solve the irregular strip packing problem. In this algorithm, a neighborhood structure based on the exchange of items on the layout was used for SA. For a given layout (which is neither feasible nor tight), they solved LP to locally optimize the layout. Computational tests were conducted using 15 benchmark instances that are commonly used in the literature, and the best results published so far were improved for all instances by their new algorithm.

Burke et al. [37] proposed a heuristic algorithm for the irregular strip packing problem with new shape overlap resolution techniques applied to the given shapes directly (i.e., without reference to no-fit polygons). In this article, they treated not only polygons (i.e., shapes with line representation) but also shapes that incorporate circular arcs and holes, and proposed overlap resolution techniques for line & line, line & arc, and arc & arc. Items are placed one by one according to a permutation (coded solution) with the BLF strategy, and tabu search is used to find a good permutation. They conducted computational experiments on 26 existing benchmark instances and 10 new test instances with items having circular arcs and holes. Their technique produced 25 new best solutions for the 26 existing benchmark instances; most of them were found within 5 minutes on a PC with a 2 GHz CPU.

36.7 Conclusions

In this chapter, we surveyed practical algorithms for the two-dimensional rectangle packing problem and the irregular packing problem, both of which have many industrial applications. For the rectangle packing problem, we first introduced some coding schemes (in other words, how to represent a solution) such as permutation, binary tree, sequence pair, and BSG. We then explained various heuristic and metaheuristic algorithms, most of which are based on these coding schemes. For some representative algorithms, we reported computational results on benchmark instances and compared them. The irregular packing problem has also been studied extensively in the last decade. The main difference between rectangle and irregular packing problems is that the intersection test between irregular items is considerably more complex. To overcome this difficulty, some different types of methodologies have been proposed; no-fit polygon is one of the representative and effective ones. We explained some heuristic and metaheuristic algorithms based on these techniques for the irregular packing problem.

The survey in this chapter is by no means comprehensive, but we hope this gives valuable information to the readers who are interested in devising practical algorithms for cutting and packing problems. Fortunately, there have been many survey papers (30 or more in these 20 years) on cutting and packing problems; for example, Dyckhoff [1] and Wäscher et al. [2] presented typologies of cutting and packing problems and categorized existing literature, and Hopper and Turton [20] investigated heuristic and metaheuristic algorithms for the rectangle packing problem. Chapters 32–35, 78, and 79 of this handbook may also be useful for readers who are interested in related topics.

A Generic Primal-Dual Approximation Algorithm for an Interval Packing and Stabbing Problem

Sofia Kovaleva

Frits C. R. Spieksma
Catholic University of Leuven

37.1 Introduction

Packing and stabbing (or covering) problems are two basic problems in combinatorial optimization. Apart from the fact that they arise in many practical applications, investigating these problems improves our understanding of fundamental issues in combinatorial optimization. Admittedly, the generality of a packing or a stabbing problem has its price: When it comes to solving such a problem, and when one insists that an optimal solution is produced for all instances, one needs to accept that, for some instances, large running times are unavoidable. Moreover, when one restricts oneself to polynomial-time algorithms, only very weak statements concerning the quality of the solutions found can be made (see, e.g., Chapter 1, Ausiello et al. [1] or Vazirani [2] for an introduction and terminology).

Here, we focus on a special case of these two problems. On the one hand, by studying a (geometric) special case, we enter the world of polynomial-time algorithms that admit a constant performance guarantee; on the other, this special case is still general enough to admit a variety of applications.

As an appetizer, consider the following two questions dealing with intervals on the line. Imagine that n intervals $(l_i, r_i]$, $i = 1, \ldots, n$, etc. on the line are given; further, we say that two intervals are *disjoint* when their intersection is empty, interval i *contains* point p when $l_i < p \leq r_i$, and interval i is *stabbed* by point p when interval i contains p.

Question 1. Select as many pairwise disjoint intervals as possible.

Question 2. Stab every interval at least once using as few points as possible.

These two questions are, in fact, easy to answer. Indeed, it is well known that the following rule does the job. After sorting the intervals in nondecreasing order with respect to the r_i's, repeat the following instructions iteratively: (i) select the remaining interval with the smallest r_i, (ii) discard all intervals containing r_i, and (iii) add point r_i to the set of points. Essentially, this rule solves an independent set problem, and a clique cover problem, in an interval graph.

This chapter deals with generalizations of this setting. We consider the case when the set of intervals is partitioned into, say m, subsets such that at most one interval of a subset can be selected (while still requiring disjointness). Such a subset of intervals is sometimes referred to as a *job*. Even more generally, we consider the problems that arise when a given number of intervals from a subset can be selected, and when the disjointness restriction is replaced by allowing a given number of intervals to intersect each other. Also, weights for the intervals are considered.

In the sequel we formulate precisely the problems we consider, describe previous research, and explain the setup of this chapter. Our main focus is on the description of a generic primal-dual algorithm for a weighted set packing problem (WSP), and how this method works for our particular geometric setting. This chapter is based on a part of the Ph.D. thesis of Kovaleva [3].

Preliminaries

We use an underlying grid to formulate our problems. Given is a grid consisting of t columns, numbered consecutively from left to right, and m numbered rows. Furthermore, given is a set of intervals $I = \{1, 2, \ldots, n\}$ lying on the rows of the grid. An interval $i \in I$ is specified by the triple l_i, r_i, ρ_i, where l_i, r_i are the indices of the left- and the rightmost columns intersecting interval i and ρ_i is the index of the row where interval i lies. For each column c, row r, and interval i we are given positive integral parameters v_c, u_r, and p_i, respectively, referred to as the column, row, and interval capacities. For each interval i we are given a positive integral parameter w_i referred to as the interval demand. We assume that the intervals are ordered according to nondecreasing r_i. We refer to the family of inputs that arise in this way as Job Interval instances (JI). Thus, an instance $\mathcal{I}$ of JI can be seen as a collection of numbers t, m, for each $i \in I : l_i, r_i, \rho_i, p_i, w_i$, for each $c = 1, \ldots, t : v_c$, and for each $r = 1, \ldots, m : u_r$.

We use the following terminology in the sequel: Column c is said to *stab* interval i if column c intersects interval i, that is, $l_i \leq c \leq r_i$. Also, row ρ_i is said to *stab* interval i if interval i lies on row ρ_i.

For each instance $\mathcal{I}$ of JI we formulate the following two problems:

Job Interval Packing Problem (JIP)

For each interval $i \in I$ specify an integral multiplicity x_i such that

- *it does not exceed the interval capacity p_i,*
- *for each column c the sum of multiplicities of the intervals stabbed by column c does not exceed the column capacity v_c,*
- *for each row r the sum of multiplicities of the intervals stabbed by row r does not exceed the row capacity u_r,*
- *the total demand $\sum w_i x_i$ is maximized.*

Job Interval Stabbing Problem (JIS)

For each column c, row r, and interval i specify integral multiplicities y_c, z_r, and s_i respectively, such that

- *for each interval i the sum of the multiplicities of the columns stabbing interval i plus the multiplicity of the row stabbing interval i plus the multiplicity of interval i equals at least its demand w_i,*
- *the total capacity $\sum_{c=1}^{t} v_c y_c + \sum_{r=1}^{m} u_r z_r + \sum_{i=1}^{n} p_i s_i$ is minimized.*

One may interpret the interval demands w_i as interval weights in JIP and the column, row and interval capacities v_c, u_r, p_i as column, row, and interval weights in JIS. However, in this chapter we refer to these parameters as demands and capacities to keep the terminology uniform for both problems.

In this chapter we describe a generic primal-dual algorithm and show how it can be applied to two special cases of JIP and JIS. The first special case deals with instances where all the column, row, and interval capacities are unit, that is, $v_c = u_r = p_i = 1$, $\forall c, r, i$. We refer to the family of inputs satisfying this condition as *JI with unit capacities.* The second special case assumes that all the interval demands are unit, that is, $w_i = 1$, $\forall i = 1, \ldots, n$. The family of these inputs is referred to as *JI with unit demands.*

Below we give natural Integer Linear Programming (ILP) formulations of JIP and JIS:

$$\text{JIP: Maximize} \quad \sum_{i=1}^{n} w_i x_i \tag{37.1}$$

$$\text{subject to} \quad \sum_{i:\rho_i=r} x_i \le u_r \quad \forall r = 1, \ldots, m \tag{37.2}$$

$$\sum_{i:c\in[l_i,r_i]} x_i \le v_c \quad \forall c = 1, \ldots, t \tag{37.3}$$

$$x_i \le p_i \quad \forall i = 1, \ldots, n \tag{37.4}$$

$$x_i \in \mathbb{Z}_+^1 \quad \forall i = 1, \ldots, n \tag{37.5}$$

$$\text{JIS: Minimize} \quad \sum_{c=1}^{t} v_c y_c + \sum_{r=1}^{m} u_r z_r + \sum_{i=1}^{n} p_i s_i \tag{37.6}$$

$$\text{subject to} \quad z_{\rho_i} + \sum_{c\in[l_i,r_i]} y_c + s_i \ge w_i \quad \forall i = 1, \ldots, n \tag{37.7}$$

$$z_r, y_c, s_i \in \mathbb{Z}_+^1 \quad \forall r, c, i \tag{37.8}$$

Observe that for any instance $\mathcal{I}$ of JI the Linear Programming (LP) relaxations of these ILP formulations (which arise when we substitute the integrality constraints [37.5] and [37.8] by nonnegativity constraints $x_i \ge 0$, $\forall i = 1, \ldots, n$ and $z_r, y_c, s_i \ge 0, \forall r, c, i$, respectively) constitute a primal-dual pair of LP problems. It follows then from the strong duality theorem for linear programming that for any instance $\mathcal{I}$, the LP relaxations of JIP and JIS have the same optimum value, which we denote by $LP(\mathcal{I})$, and thus the following holds:

$$JIP(\mathcal{I}) \le LP(\mathcal{I}) \le JIS(\mathcal{I}) \tag{37.9}$$

where $JIP(\mathcal{I})$ and $JIS(\mathcal{I})$ are the optimum values of JIP and JIS for $\mathcal{I}$, respectively.

We say that problems JIP and JIS are weakly dually related and establish the following result:

Lemma 37.1 (Weak duality lemma for JIP and JIS)

For any instance $\mathcal{I}$ of JI, for any feasible solution to JIP with value $JIP^{feas}(\mathcal{I})$ and any feasible solution to JIS with value $JIS^{feas}(\mathcal{I})$ holds:

$$JIP^{feas}(\mathcal{I}) \le JIS^{feas}(\mathcal{I}).$$

Proof

Follows from (37.9). □

Previous Research

JIP and its special cases have received a great deal of attention in the literature. Its applications, mentioned by different authors, include printed circuit board assembly, combinatorial auctions, satellite photography, computational biology, throughput scheduling [4–7]. JIP is MAX SNP-hard even if all the parameters are unit ([7]; this implies that there is no polynomial-time approximation scheme for JIP unless $\mathcal{P} = \mathcal{NP}$). A greedy 1/2-approximation algorithm for JIP with unit capacities and demands (i.e., $u_r = v_c = p_i = w_i = 1$, $\forall c, r, i$) is described in Spieksma [7]. A better approximation guarantee for this case has been found by Chuzhoy et al. [8]. They present an algorithm with performance guarantee $(e-1)/e - \varepsilon \approx 0.63 - \varepsilon$, for any $\varepsilon > 0$, exploiting a sophisticated technique involving randomized LP-rounding. Bar-Noy et al. [6] describe a $(1/2 - \varepsilon)$-approximation algorithm for JIP with unit capacities (i.e., $u_r = v_c = p_i = 1$, $\forall c, r, i$) using an LP-rounding technique. One can easily generalize this algorithm to JIP (with arbitrary capacities and demands) and, using the ideas introduced by Calinescu et al. [9], improve the approximation factor to 1/2. The resulting 1/2-approximation algorithm (which involves solving an LP problem) has to our knowledge so far the highest approximation factor for JIP. Combinatorial 1/2-approximation algorithms for JIP with unit capacities are described by Berman and DasGupta [4] and Bar-Noy et al. [10]. In Ref. [5] the performance of greedy algorithms for JIP with constant column capacity and unit row capacity (i.e., $v_c = v,\ \forall c,\ u_r = 1,\ \forall r$) is investigated using competitive analysis.

So far JIS has not been as extensively studied as JIP. Applications of JIS that have been mentioned in the literature include military and medical applications [11]. JIS is also MAX SNP-hard even if all the parameters are unit [12]. Recently, Kovaleva and Spieksma [13] describe a $\frac{e}{e-1}$-approximation algorithm for JIS with unit demand. This algorithm is based on solving the linear programming relaxation of constraints (37.6)–(37.8), and rounding this solution to an integral one. Earlier work is described in Gaur et al. [14] who consider the so-called *rectangle stabbing* problem, which generalizes JIS with unit demands to the case where rectangles intersecting several rows of the grid are given instead of intervals; their work implies a 2-approximation for JIS with unit demand. Hassin and Megiddo [11] describe a combinatorial $2 - \frac{1}{K+1}$-approximation algorithm for the case of JIS with unit capacities and demands, where each interval is intersected by exactly K columns, and a 2-approximation for a slightly more general case, when each interval is intersected by the same number of columns.

Outline of the Chapter

Section 37.2 is devoted to JI with unit capacities. We first describe a generic primal-dual algorithm, called Local Covering, for the WSP (Section 37.2.1) and then specify a setup of Local Covering for JIP with unit capacities, yielding algorithm ALG1 (Section 37.2.2). We also give conditions which guarantee that a particular setup of Local Covering yields a constant factor approximation algorithm. This algorithm is in fact a primal-dual interpretation of the *Opportunity Cost* algorithm described by Akcoglu et al. in [15], which is in turn based on the local-ratio technique, introduced by Bar-Yehuda and Even [16] and later elaborated upon by Bar-Noy et al. [10].

A distinctive feature of the primal-dual algorithm ALG1 described in Section 37.2.2 is that it simultaneously delivers two feasible solutions, one for JIP and one for JIS with unit capacities. Moreover, we show that their values are within a factor of 2 of each other. The weak duality relation between JIP and JIS implies then that these solutions are respectively a 1/2-approximation for JIP with unit capacities and a 2-approximation for JIS with unit capacities. This analysis is tight, that is, the approximation guarantees cannot be improved by carrying out a better analysis of the algorithm.

Note that, when viewed as a 1/2-approximation algorithm for JIP, ALG1 behaves similar to the algorithms described previously by Berman and DasGupta [4] and Bar-Noy et al. [10].

In Section 37.3 we consider JI with unit demands. It is easy to see that JIS with unit demands is a special case of the the weighted hitting set problem. Following the framework of the generic *primal-dual algorithm with reverse delete step* described in Ref. [17] for the weighted hitting set problem, we develop a primal-dual approximation algorithm ALG2. Similar to ALG1 it returns two feasible solutions, one for JIS and the other for JIP with unit demands. Again, we show that their values are within a factor of 2 of each other. This makes ALG2 a 1/2-approximation algorithm for JIP and a 2-approximation algorithm to JIS with unit demands.

Note that the algorithms described here are combinatorial and do not require solving a linear program.

37.2 The Case of Unit Capacities

37.2.1 The Local Covering Algorithm for the Weighted Set Packing Problem

Consider the WSP: *given is a collection $\mathcal{S}$ of subsets of a finite ground set $\mathcal{E}$. For each subset $s \in \mathcal{S}$ a nonnegative weight w_s is given. Find a maximum-weight collection A of disjoint subsets from $\mathcal{S}$.*

Below we give a natural ILP formulation of WSP, where we use the characteristic vector of A, $\chi \in \{0, 1\}^{|\mathcal{S}|}$, as a vector of decision variables:

$$\text{WSP:} \quad \text{Maximize} \quad \sum_{s \in \mathcal{S}} w_s \chi_s \tag{37.10}$$

$$\text{subject to} \quad \sum_{s : e \in s} \chi_s \leq 1 \quad \forall e \in \mathcal{E} \tag{37.11}$$

$$\chi_s \in \{0, 1\} \quad \forall s \in \mathcal{S} \tag{37.12}$$

By substituting nonnegativity constraints $\chi_s \geq 0 \ \ \forall s \in \mathcal{S}$ for integrality constraints (37.12), we obtain the LP relaxation of this formulation.

Let us also introduce the dual linear problem to this LP relaxation (here we use $\gamma \in \mathbb{R}_+^{|\mathcal{E}|}$ for a vector of dual variables):

$$\text{Minimize} \quad \sum_{e \in \mathcal{E}} \gamma_e \tag{37.13}$$
