### 17.1 Introduction

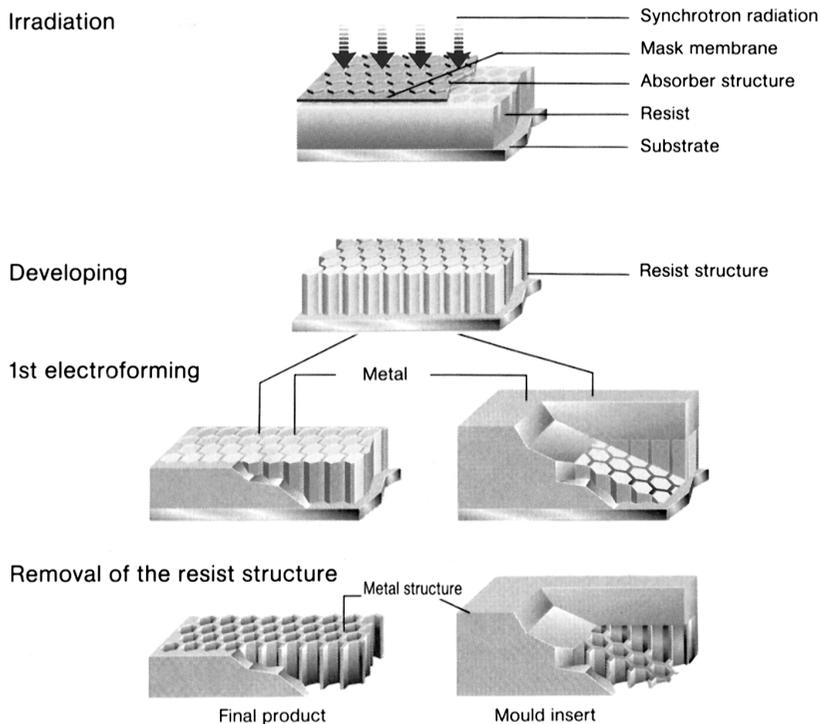

---

LIGA is the German acronym for X-ray lithography (X-ray lithographie), electrodeposition (galvanoformung), and molding (abformtechnik). The process involves a thick layer of X-ray resist—from microns to centimeters—and high-energy X-ray radiation exposure and development to arrive at a three-dimensional resist structure. Subsequent electrodeposition fills the resist mold with a metal and, after resist removal, a free standing metal structure results (see [Figure 17.1](#)) [IMM, 1995]. The metal shape may be a final product or serve as a mold insert for precision plastic injection molding. Injection-molded plastic parts may in turn be final products or lost molds. The plastic mold retains the same shape, size and form as the original resist structure but is produced quickly and inexpensively as part of an infinite loop. The plastic lost mold may generate metal parts in a second electroforming process or ceramic parts in a slip casting process.

Micromachining techniques are reshaping manufacturing approaches for a wide variety of small parts; frequently, IC-based, batch microfabrication methods are being considered for their fabrication together with more traditional, serial machining methods. LIGA, as a ‘handshake-technology’ between IC and classical manufacturing technologies, has the potential of speeding up this process. The method borrows lithography from the IC industry and electroplating and molding from classical manufacturing. The

---

<sup>1</sup>This chapter was originally published in Madou, M.J. (1997) “LIGA” (chap. 6), in *Fundamentals of Microfabrication*, CRC Press, Boca Raton, FL.

**FIGURE 17.1A** Basic LIGA process steps X-ray deep-etch lithography and 1st electroforming. (From Lehr, H. and M. Schmidt, *The LIGA Technique*, commercial brochure, IMM Institut für Mikrotechnik GmbH, Mainz-Hechtsheim, 1995. With permission.)

capacity of LIGA for creating a wide variety of shapes from different materials makes it akin to classical machining with the added benefit of unprecedented aspect ratios and absolute tolerances. The LIGA bandwidth of possible sizes in three dimensions makes it potentially useful, not only for microstructure manufacture itself (micron and submicron dimensions), but also for the manufacture of microstructure packages (millimeter and centimeter dimensions) as well as for connectors from those packages (electrical, e.g., through-vias or physical, e.g., gas in- and outlets) to the ‘macroworld.’

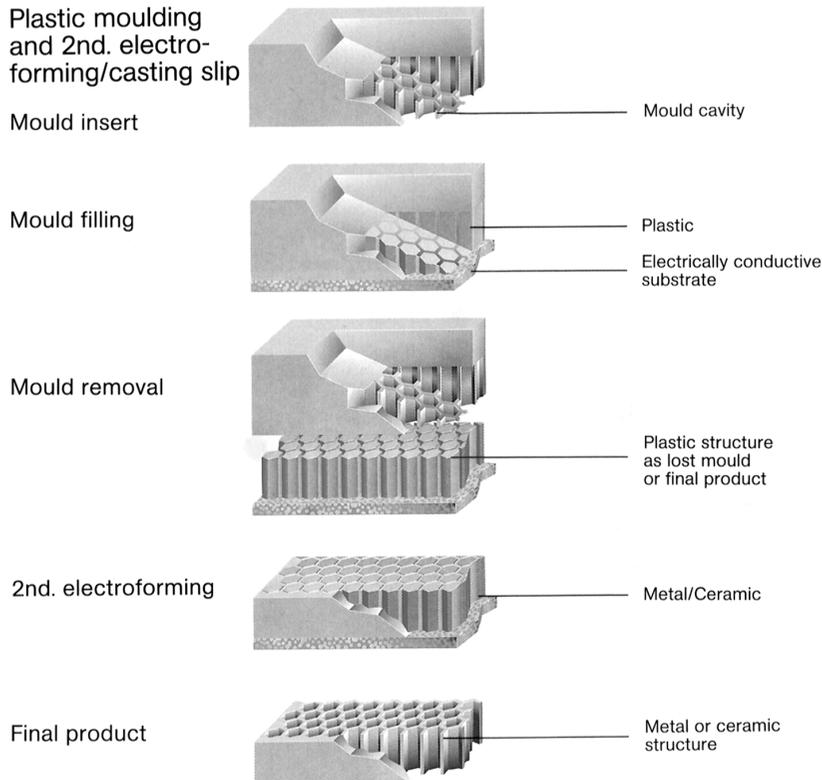

Given the cost of the LIGA equipment, various pseudo-LIGA processes are under development. They involve replication of molds created by alternate means such as deep, cryogenic dry etching and novel ultraviolet thick photoresists.

Some aspects of X-ray lithography for use in LIGA were explored in Madou (1997, chap. 1). After an historical introduction we will analyze all of the process steps depicted in [Figure 17.1](#) in detail, starting with a description of the different applications and technical characteristics of synchrotron radiation, followed by an introduction to the crucial issues involved in making X-ray masks optimized for LIGA. Alternative process sequences, popular in LIGA micromanufacturing today, will be reviewed as well. After an introduction to the technology we will review current and projected LIGA applications and discuss key technological barriers to be overcome and consider competing ‘LIGA-like’ processes.

## 17.2 LIGA Processes—Introduction to the Technology

### 17.2.1 History

LIGA combines the sacrificial wax molding method, known since the time of the Egyptians, with X-ray lithography and electrodeposition. Combining electrodeposition and X-ray lithography was first carried

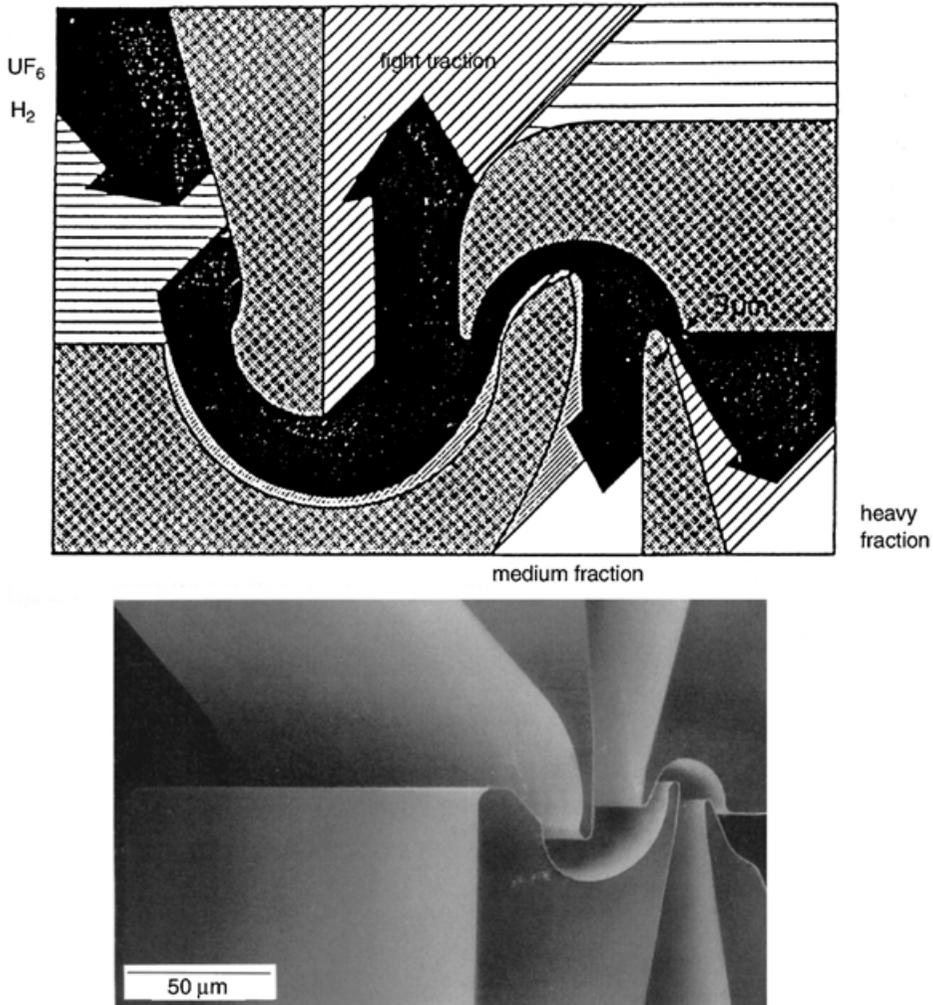

**FIGURE 17.1B** Plastic molding and 2nd electroforming/slip casting. (From Lehr, H. and M. Schmidt. The LGA Technique, commercial brochure, IMM Institut für Mikrotechnik GmbH, Mainz-Hechtsheim, 1995. With permission.)

out by Romankiw and co-workers at IBM in 1975 [Spiller et al., 1976]. These authors made high aspect ratio metal structures by plating gold in X-ray-defined resist patterns of up to 20  $\mu\text{m}$  thick. They had, in other words, already invented ‘LIG’; i.e., LIGA without the abformtech (molding) [Spiller et al., 1997]. This IBM work formed an extension to through-mask plating, also pioneered by Romankiw in 1969, geared toward the fabrication of thin-film magnetic recording heads [Romankiw et al., 1970]. The addition of molding to the lithography and plating process was realized by Ehrfeld et al. [Becker et al., 1982] at KfK in 1982. By adding molding, Ehrfeld and co-workers made the technology potentially low cost. These pioneers recognized the broader implications of LIGA as a new means of low-cost manufacturing of a wide variety of microparts previously impossible to batch fabricate [Becker et al., 1982]. In Germany, LIGA originally developed almost completely outside of the semiconductor industry. It was Guckel in the U.S. who repositioned the field in light of existing semiconductor capabilities and brought it closer to standard manufacturing processes.

The development of the LIGA process initiated by the Karlsruhe Nuclear Research Center (Kernforschungszentrum Karlsruhe, or KfK) was intended for the mass production of micron-sized nozzles for uranium-235 enrichment (see Figure 17.2) [Becker et al., 1982]. The German group used synchrotron radiation from a 2.5-GeV storage ring for the exposure of the poly(methylmethacrylate) (PMMA) resist.

Today LIGA is researched in many laboratories around the world. The technology has reinvigorated attempts at developing alternative micromolds for the large-scale production of precise micromachines. Mold inserts, depending on the dimensions of the microparts, the accuracy requirements and the fabrication costs are realized by e-beam writing, deep UV resists, excimer laser ablation, electrodischarge machining, laser cutting and X-ray lithography as involved in the LIGA technique.

### 17.2.2 Synchrotron Orbital Radiation—General Applications

Lithography based on synchrotron radiation, also called synchrotron orbital radiation (SOR), is primarily being developed with the aim of adopting the technology as an industrial tool for the eventual large-scale manufacture of microelectronic circuits with characteristic dimensions in the submicron range [Waldo and Yanof, 1991; Hill, 1991]. Synchrotron radiation sources outshine all other sources of X-rays. They emit a much higher flux of usable collimated X-rays, thereby allowing shorter exposure times and larger throughputs. Pros and cons of X-ray radiation for lithography in IC manufacture, identified in Madou (1997, chap. 1), are summarized in [Table 17.1](#).

Despite the many promising features of X-ray lithography, the technique lacks mainstream acceptance in the IC industry. Continued improvements in optical lithography outpace the industrial use of X-ray

TABLE 17.1 Pros and Cons of SOR X-Ray Lithography for IC Manufacture

Pros	Cons
Lithography process insensitive to resist thickness, exposure time, development time (large depth of focus)	Resist not very sensitive (not too important because of the intense light source)
Absence of backscattering results in insensitivity to substrate type, reflectivity and topography, pattern geometry and proximity, dust and contamination	Masks very difficult and expensive to make
High resolution < 0.2 $\mu\text{m}$	Very high start-up investment
High throughput	Not proven as a manufacturing system yet
	Radiation effects on $\text{SiO}_2$

lithography for IC applications. Its use for prototype development on a small scale will no doubt continue its course though. In 1991, experts projected that X-ray lithography could be in use by 1995 for 64 megabit DRAM manufacture, with critical dimensions (CDs) around 0.3 to 0.4  $\mu\text{m}$ . With more certainty, they projected that the transition to X-rays would occur with the 0.2- to 0.3- $\mu\text{m}$  CDs of 256 megabit DRAMs, expected to be in production by 1998 [Hill, 1991]. The first projected date has passed without materialization of the industrial use of X-rays; many are doubtful that the second prediction will be met [Stix, 1995].

In addition to the primary intended application—the production of the newest generation of DRAM chips—X-rays may also be used in the fabrication of microsensors and other microstructures, especially since the LIGA method enables the fabrication of high-aspect-ratio microstructures from a wide variety of materials. In LIGA, synchrotron radiation is used in the lithography step only. Other micromachining applications for SOR exist. Urisu and his colleagues, for example, explored the use of synchrotron radiation for radiation-excited chemical-vapor deposition and etching [Urisu and Kyuragi, 1987]. Micromachinists are well aware of the need to piggy-back X-ray lithography research and development efforts for the fabrication of micromachines onto major IC projects. The use of X-ray lithography for fabricating microdevices, other than integrated circuits, does not appear to present a large business opportunity yet. Not having a major IC product line associated with X-ray lithography makes it extra hard to justify the use of X-ray lithography for micromachining, especially since other, less expensive micromachining technologies have not yet opened up the type of mass markets one is used to in the IC world. The fact that the X-rays used in LIGA are shorter wavelength than in the IC application (2 to 10  $\text{\AA}$  vs. 20 to 50  $\text{\AA}$ ) also puts micromachinists at a disadvantage. For example, the soft X-rays in the IC industry may eventually be generated from a much less expensive source, such as a transition radiation source [Goedtkindt et al., 1991]. Also, nontraditional IC materials are frequently employed in LIGA. Fabricating X-ray masks pose more difficulties than masks for IC applications. Rotation and slanting of the X-ray masks may be required to craft nonvertical walls. All these factors make exploring LIGA in the current economic climate a major challenge. However, given sufficient research and development money, large markets are almost certain to emerge over the next 10 years. These markets may be found in the manufacture of devices with stringent requirements imposed on resolution, aspect ratio, structural height and parallelism of structural walls. Optical applications seem particularly important product targets. The commercial exploitation of LIGA is being aggressively pursued by two German companies: Microparts<sup>2</sup> (formed in 1990) and IMM<sup>3</sup> (formed in 1991).

So far, the research community has primarily benefited from the availability of SOR photon sources. With its continuously tunable radiation across a very wide photon range, also highly polarized and directed into a narrow beam, SOR provides a powerful probe of atomic and molecular resonances. Other types of photon sources prove unsatisfactory for these applications in terms of intensity or energy spread. As can be concluded from Table 17.2, applications of SOR beyond lithography range from structural and chemical analysis to microscopy, angiography and even to the preparation of new materials.

### 17.2.3 Synchrotron Radiation—Technical Aspects

Some important concepts associated with synchrotron radiation, such as the bending radius of the synchrotron magnet, magnetic field strength, beam current, critical wavelength and total radiated power, require introduction. Figure 17.3 presents a schematic of an X-ray exposure station. The cone of radiation in this figure is the electromagnetic radiation emitted by electrons due to the radial acceleration that keeps them in orbit in an electron synchrotron or storage ring. For high energy particle studies, this radiation, emitted tangential to the circular electron path, limits the maximum energy the electrons can attain. This so-called ‘Bremsstrahlung’ is a nuisance for studies of the composition of the atomic nucleus in which high energy particles are smashed into the nucleus. To minimize this problem, physicists desire ever bigger synchrotrons. For X-ray lithography applications, electrical engineers want to maximize the X-ray emission and build small synchrotrons instead (the radius of curvature for a compact, superconducting synchrotron, for example, is 2 m). The angular opening of the radiation cone in Figure 17.3 is determined by the electron energy,  $E$ , and is given by:

$$\theta \approx \frac{mc^2}{E} = \frac{0.5}{E(\text{GeV})} (\text{mrad}) \quad (17.1)$$

The X-ray light bundle with the cone opening,  $\theta$ , describes a horizontal line on an intersecting substrate as the X-ray bundle is tangent to the circular electron path. In the vertical direction, the intensity of the

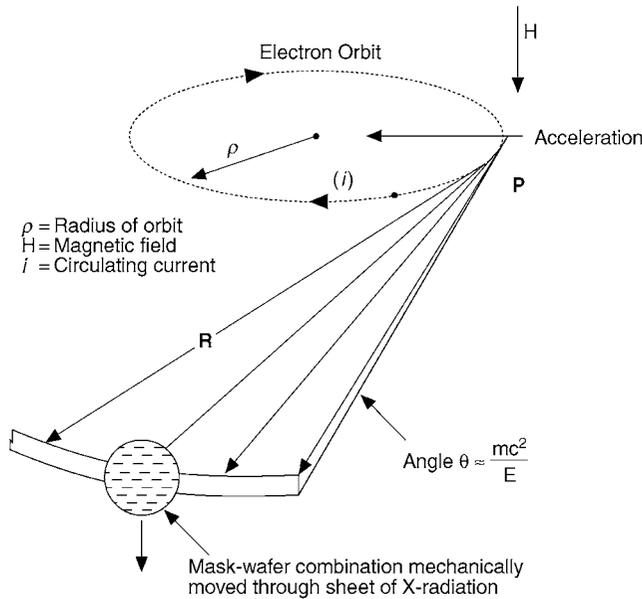

FIGURE 17.3 Schematic of an X-ray exposure station with a synchrotron radiation source. The X-ray radiation cone (opening,  $\theta$ ) is tangential to the electron's path, describing a line on an intersecting substrate.

beam exhibits a Gaussian distribution and the vertical exposed height on the intersecting substrate can be calculated knowing  $\theta$  and  $R$ , the distance from the radiation point,  $P$ , to the substrate. With  $E = 1$  GeV,  $\theta = 1$  mrad and  $R = 10$  m, the exposed area in the vertical direction measures about 0.5 cm. To expose a substrate homogeneously over a wider vertical range, the sample must be moved vertically through the irradiation band with a precision scanner (e.g., done at a speed of 10 mm/sec over a 100-mm scanning distance). Usually the substrate is stepped up and down repeatedly until the desired X-ray dose is obtained.

The electron energy  $E$  in Eq. (17.1) is given by:

$$E(\text{SeV}) = 0.29979 B (\text{Tesla}) \rho (\text{meters}) \quad (17.2)$$

with  $B$  the magnetic field and  $\rho$  the radius of the circular path of the electrons in the synchrotron.

The total radiated power can be calculated from the energy loss of the electrons per turn and is given by:

$$P(\text{kW}) = \frac{88.47 E^4 i}{\rho} \quad (17.3)$$

with  $i$  the beam current.

The spectral emission of the synchrotron electrons is a broad spectrum without characteristic peaks or line enhancements, and its distribution extends from the microwave region through the infrared, visible, ultraviolet and into the X-ray region. The critical wavelength,  $\lambda_c$ , is defined so that the total radiated power at lower wavelengths equals the radiated power at higher wavelengths, and is given by:

$$\lambda_c(\text{\AA}) = \frac{5.59 \rho(\text{m})}{E^3(\text{GeV})} \quad (17.4)$$

**TABLE 17.3** Access to Synchrotron Radiation Available at the Following Facilities in the U.S.

Facility	Institute	Contact (1997)

SURF	National Institute of Standards and Technology	Robert Madden
Synchrotron Radiation Center	University of Wisconsin-Madison	Pamela Layton
Center for Advanced Microdevices (CAMD)	Louisiana State University	Volker Saile
Advanced Light Source (ALS)	Lawrence Berkeley Laboratory	Alfred Schlachter

Equation 17.3 shows that the total radiated power increases with the fourth power of the electron energy. From Eq. (17.4) we appreciate that the spectrum shifts toward shorter wavelengths with the third power of the electron energy.

The dose variation absorbed in the top vs. the bottom of an X-ray resist should be kept small so that the top layer does not deteriorate before the bottom layers are sufficiently exposed. Since the depth of penetration increases with decreasing wavelength, synchrotron radiation of very short wavelength is needed to pattern thick resist layers. In order to obtain good aspect ratios in LIGA structures, the critical wavelength ideally should be 2 Å. Bley et al. (1992) at KfK designed a new synchrotron optimized for LIGA. They proposed a magnetic flux density,  $B$ , of 1.6285 T; a nominal energy,  $E$ , of 2.3923 GeV; and a bending radius,  $\rho$ , of 4.9 m. With those parameters, Eq. (17.4) results in the desired  $\lambda_c$  of 2 Å and an opening angle of radiation, based on Eq. (17.1), of 0.2 mrad (in practice this angle will be closer to 0.3 mrad due to electron beam emittance).

The X-rays from the ring to the sample site are held in a high vacuum. The sample itself is either kept in air or in a He atmosphere. The inert atmosphere prevents corrosion of the exposure chamber, mask and sample by reactive oxygen species, and removal of heat is much faster than in air (the heat conductivity of He is high compared to air). In He, the X-ray intensity loss is also 500 times less than in air. A beryllium window separates the high vacuum from the inert atmosphere. For wavelengths shorter than 1 nm, Be is very transparent—i.e., an excellent X-ray window.

### 17.2.4 Access to Technology

Unfortunately, the construction cost for a typical synchrotron today totals over \$30 million, restricting the access to LIGA dramatically. Obviously, one would like to find less expensive alternatives for generating intense X-rays. In Japan, companies such as Ishikawajima-Harima Heavy Industries (IHI) are building compact synchrotron X-ray sources (e.g., a 800-MeV synchrotron will be about 30 feet per side).

By the end of 1993, eight nonprivately owned synchrotrons were in use in the U.S. The first privately owned synchrotron was put into service in 1991 at IBM's Advanced Semiconductor Technology Center (ASTC) in East Fishkill, NY. Table 17.3 lists the eight U.S. synchrotron facilities.

Some of the facilities listed in Table 17.3 can perform micromachining work. For example, MCNC (Research Triangle Park, NC), in collaboration with the University of Wisconsin–Madison, announced its first multi-user LIGA process sponsored by ARPA in September 1993. CAMD at Louisiana State University has three beam lines on their synchrotron exclusively dedicated to micromachining work; ALS at Berkeley has one beam line available for micromachining.

Forschungszentrum Karlsruhe GmbH<sup>4</sup> also offers a multi-user LIGA service (LEMA, or LIGA-experiment for multiple applications).

## 17.2.5 X-Ray Masks

### 17.2.5.1 Introduction

A short introduction to X-ray masks was presented in Madou (1997, chap. 1 on lithography). X-ray masks should withstand many exposures without distortion, be alignable with respect to the sample and be rugged. A possible X-ray mask architecture and its assembly with a substrate in an X-ray scanner are shown in Figure 17.4. The mask shown here has three major components: an absorber, a membrane or mask blank, and a frame. The absorber contains the information to be imaged onto the resist. It is made up of a material with a high atomic number ( $Z$ ), often Au, patterned onto a membrane material with a low  $Z$ . The high- $Z$  material absorbs X-rays, whereas the low- $Z$  material transmits X-rays. The frame lends robustness to the membrane/absorber assembly so that the whole can be handled confidently.

The requirements for masks in LIGA differ substantially from those for the IC industry. A comparison is presented in Table 17.4 [Ehrfeld et al., 1986]. The main difference lies in the absorber thickness. In order to achieve a high contrast ( $>200$ ), very thick absorbers ( $>10\ \mu\text{m}$  vs.  $1\ \mu\text{m}$ ) and highly transparent mask blanks (transparency  $>80\%$ ) must be used because of the low resist sensitivity and the great depth of resist. Another difference focuses on the radiation stability of membrane and absorber. For conventional optical lithography, the supporting substrate is a relatively thick, near optically flat piece of glass or quartz highly transparent to optical wavelengths. It provides a highly stable ( $>10^6\ \mu\text{m}$ ) basis for the thin ( $0.1\ \mu\text{m}$ ) chrome absorber pattern. In contrast, the X-ray mask consists of a very thin membrane ( $2$  to  $4\ \mu\text{m}$ ) of

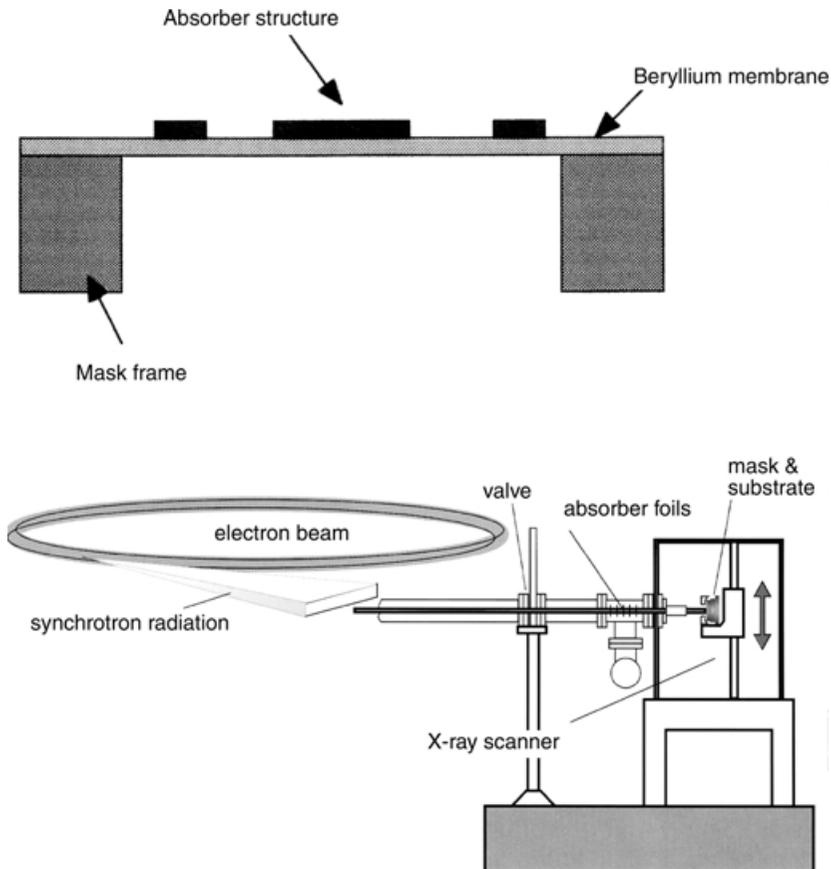

FIGURE 17.4 Schematic of a typical X-ray mask and mask and substrate assembly in an X-ray scanner. (The latter from IMM, 1995 Brochure. With permission.)

**TABLE 17.4** Comparison of Masks in LIGA and the IC Industry [Ehrfeld et al., 1986]

Attribute	Semiconductor	
	Lithography	LIGA Process
Transparency	≥50%	≥80%
Absorber thickness	±1 μm	10 μm or higher
Field size	50 × 50 mm <sup>2</sup>	100 × 100 mm <sup>2</sup>
Radiation resistance	= 1	= 100
Surface roughness	<0.1 μm	<0.5 μm
Waviness	< ±1 μm	< ±1 μm
Dimensional stability	<0.05 μm	<0.1–0.3 μm
Residual membrane stress	~10 <sup>8</sup> Pa	~10 <sup>8</sup> Pa

low-Z material carrying a high-Z thick absorber pattern [Lawes, 1989]. A single exposure in LIGA results in an exposure dose a hundred times higher than in the IC case.

We will look into these different mask aspects separately before detailing a process with the potential of obviating the need for a separate X-ray mask by using a so-called transfer mask.

### 17.2.5.2 X-Ray Membrane (Mask Blank)

The low-Z membrane material in an X-ray mask must have a transparency for rays with a critical wavelength,  $\lambda_c$ , from 0.2 to 0.6 nm of at least 80% and should not induce scattering of those rays. To avoid pattern distortion, the residual stress,  $\sigma_p$ , in the membrane should be less than 10<sup>8</sup> dyn/cm<sup>2</sup>. Mechanical stress in the absorber pattern can cause in-plane distortion of the supporting thin membrane, necessitating a high Young's modulus for the membrane material. Humidity or high deposited doses of X-ray might also distort the membrane. During one typical lithography step the masks may be exposed to 1 MJ/cm<sup>2</sup> of X-rays. Since most membranes must be very thin for optimum transparency, a compromise must be found between transparency, strength and form stability. Important X-ray membrane materials are listed in Table 17.5. The higher radiation dose in LIGA prevents the use of BN as well as compound mask blanks which incorporate a polyimide layer. Those mask blanks are perfectly appropriate for classical IC lithography work but will not do for LIGA work. Mask blanks of metals such as titanium (Ti) and beryllium (Be) were specifically developed for LIGA applications because of their radiation hardness [Ehrfeld et al., 1986; Schomburg et al., 1991]. In comparing titanium and beryllium membranes, beryllium can have a much greater membrane thickness,  $d$ , and still be adequately transparent. For example, a membrane transparency of 80%, essential for adequate exposure of a 500-μm-thick PMMA resist layer, can be achieved with a thin 2-μm titanium film, whereas with beryllium a thick 300-μm membrane must

**TABLE 17.5** Comparison of Membrane Materials for X-Ray Masks

Material	X-Ray Transparency	Nontoxicity	Dimensional Stability	Remark
Si	0	++	0	Single crystal Si, well developed, rad hard, stacking faults cause scattering, material is brittle
SiN <sub>x</sub>	0	++	0	Amorphous, well developed, rad hard if free of oxygen, resistant to breakage
SiC	+	++	++	Poly and amorphous, rad hard, some resistance to breakage
Diamond	+	++	++	Poly, research only, highest stiffness
BN	+	++	0	Not rad hard, i.e., not applicable for LIGA
Be	++	-	++	Research, especially suited for LIGA; even at 100 μm the transparency is good, 30 μm typical; difficult to electroplate; toxic material
Ti	-	++	0	Research, used for LIGA, not very transparent, films must not be more than 2 to 3 μm thick

**TABLE 17.6** Comparison of Absorber Materials for X-Ray Masks

Material	Remark
Gold	Not the best stability (grain growth), low stress, electroplating only, defects repairable
Tungsten	Refractory and stable; special care is needed for stress control; dry etchable; repairable
Tantalum	Refractory and stable; special care is needed for stress control; dry etchable; repairable
Alloys	Easier stress control, greater thickness required to obtain 10 db

be used. The beryllium membrane can thus be used at a thickness permitting easier processing and handling. In addition, beryllium has a greater Young's modulus  $E$  than titanium (330 vs. 140 kN/mm<sup>2</sup>) and, since it is the product of  $E \times d$  which determines the amount of mask distortion, distortions due to absorber stress should be much smaller for beryllium blanks [Schomburg et al., 1991; Hein et al., 1992]. Beryllium comes forward as an excellent membrane material for LIGA because of its high transparency and excellent damage resistance. Such a mask should be good for up to 10,000 exposures and may cost \$20 to 30 K (\$10 to 15 K in quantity). Stoichiometric silicon nitride (Si<sub>3</sub>N<sub>4</sub>) used in X-ray mask membranes may contain numerous oxygen impurities absorbing X-rays and thus producing heat. This heat often suffices to prevent the use of nitride as a good LIGA mask. Single crystal silicon masks have been made (1 cm<sup>2</sup> and 0.4 μm thick and 10 cm<sup>2</sup> and 2.5 μm thick) by electrochemical etching techniques. For Si and Si<sub>3</sub>N<sub>4</sub>, the Young's modulus is quite low compared to CVD-grown diamond and SiC films, which are as much as three times higher. These higher stiffness materials are more desirable because the internal stresses of the absorbers, which can distort mask patterns, are less of an issue.

### 17.2.5.3 Absorber

The requirements on the absorber are high attenuation (>10 db), stability under radiation over extended periods of time, negligible distortion (stress < 10<sup>8</sup> dyn/cm<sup>2</sup>), ease of patterning, repairable and low defect density. A listing of typical absorber materials is presented in Table 17.6. Gold is used most commonly. Several groups are looking at the viability of tungsten and other materials. In the IC industry an absorber thickness of 0.5 μm might suffice, whereas LIGA deals with thicker layers of resist requiring a thicker absorber to maintain the same resolution.

Figure 17.5 illustrates how X-rays, with a characteristic wavelength of 0.55 nm, are absorbed along their trajectory through a Kapton preabsorber filter, an X-ray mask and resist [Bley et al., 1991]. The low energy portion of the synchrotron radiation is absorbed mainly in the top portion of the resist layer, since absorption increases with increasing wavelength. The Kapton preabsorber filters out much of the low energy radiation in order to prevent overexposure of the top surface of the resist. The X-ray dose at which the resist gets damaged,  $D_{dm}$ , and the dose required for development of the resist,  $D_{dv}$ , as well as the 'threshold-dose' at which the resist starts dissolving in a developer,  $D_{th}$ , are all indicated in Figure 17.5. In the areas under the absorber pattern of the X-ray mask, the absorbed dose must stay below the 'threshold-dose',  $D_{th}$ ; otherwise, the structures partly dissolve, resulting in poor feature definition. From Figure 17.5 we can deduce that the height of the gold absorbers must exceed 6 μm to reduce the absorbed radiation dose of the resist under the gold pattern to below the threshold dose,  $D_{th}$ . In Figure 17.6, the necessary thickness of the gold absorber patterns of an X-ray mask is plotted as a function of the thickness of the resist to be patterned; the Au must be thicker for thicker resist layers and for shorter characteristic wavelengths,  $\lambda_c$ , of the X-ray radiation. In order to pattern a 500-μm high structure with a  $\lambda_c$  of 0.225 nm, the gold absorber must be more than 11 μm high.

Exposure of yet more extreme photoresist thicknesses is possible if proper X-ray photon energies are used. At 3000 eV, the absorption length in PMMA roughly measures 100 μm, which enables the above-mentioned 500-μm exposure depth [Guckel et al., 1994]. Using 20,000-eV photons results in absorption lengths of 1 cm. PMMA structures up to 10 cm (!) thick have been exposed this way [Siddons and Johnson, 1994]. A high energy mask used by Guckel for these high energy exposures has an Au absorber 50 μm thick and a blank membrane of 400-μm-thick Si. Guckel obtained an absorption contrast of 400 when exposing a 1000-μm-thick PMMA sheet with this mask. An advantage of being able to use these

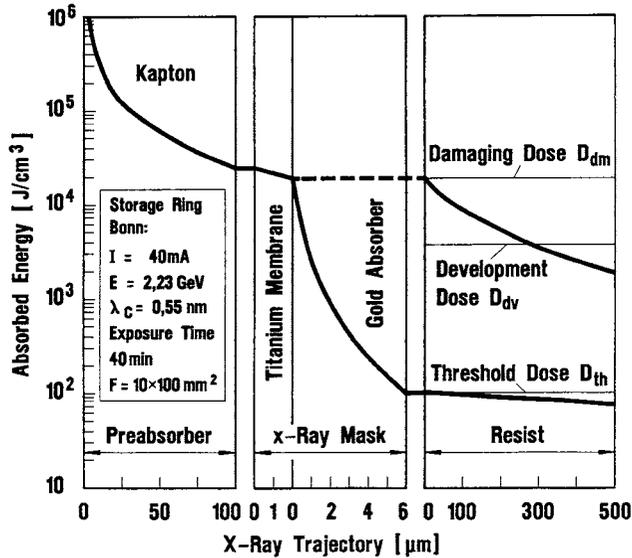

FIGURE 17.5 Absorbed energy along the X-ray trajectory including a 500- $\mu\text{m}$ -thick PMMA specimen, X-ray mask and a Kapton preabsorber. (From Bley, P. et al., Application of the LIGA Process in Fabrication of Three-Dimensional Mechanical Microstructures, presented at 1991 Int. Micro Process Conf. With permission.)

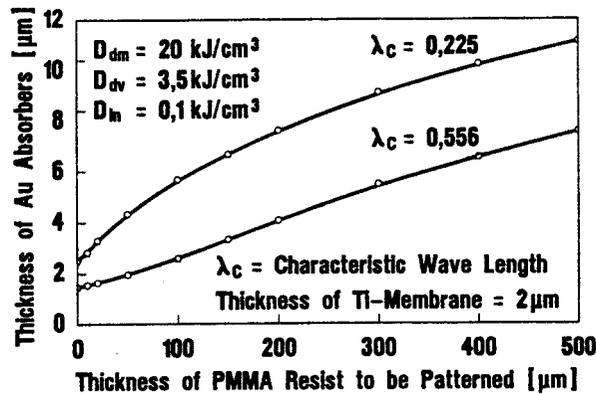

FIGURE 17.6 Necessary thickness of the gold absorbers of an X-ray mask. (From Bley, P. et al., Application of the LIGA Process in Fabrication of Three-Dimensional Mechanical Microstructures, presented at 1991 Int. Micro Process Conf. With permission.)

thick Si blank membranes is that larger resist areas can be exposed since one does not depend on a fragile membrane/absorber combination [Guckel, 1994].

#### 17.2.5.4 Thick Absorber Fabrication

To make a mask with gold absorber structures of a height above 10  $\mu\text{m}$ , one must first succeed in structuring a resist of that thickness. The height of the resist should in fact be a bit higher (say, 20%) than the absorber itself in order to accommodate the electrodeposited material fully in between the resist features. Currently, no means to structure a resist of that height with sufficient accuracy and perfect verticality of the walls exist, unless X-rays are used. Different procedures for producing X-ray masks with thicker absorber layers using a two-stage lithography process have been developed.

The KfK solution calls for first making an intermediate mask with photo or e-beam lithography. This intermediate mask starts with a 3- $\mu\text{m}$ -thick resist layer, in which case the needed accuracy and steepness of the walls of printed features can be obtained through several means. After gold plating in between the resist features and stripping of the resist, this intermediate mask is used to write a pattern with X-rays in a 20- $\mu\text{m}$ -thick resist. After electrodepositing and resist stripping, the latter will become the actual X-ray mask, i.e., the master mask.

Since hardly any accuracy is lost in the copying of the intermediate mask with X-rays to obtain the master mask, it is the intermediate mask quality that determines the ultimate quality of the LIGA-produced microstructures. The structuring of the resist in the intermediate mask is handled with optical techniques when the requirements on the LIGA structures are somewhat relaxed. The minimal lateral dimensions for optical lithography in a 3- $\mu\text{m}$ -thick resist typically measure about 2.5  $\mu\text{m}$ . Under optimum conditions, a wall angle of 88° is achievable. With electron-beam lithography, a minimum lateral dimension of 1  $\mu\text{m}$  is feasible. The most accurate pattern transfer is achieved through reactive ion etching of a tri-level resist system. In this approach, a 3- to 4- $\mu\text{m}$ -thick polyimide resist is first coated onto the titanium or beryllium membrane, followed by a coat of 10 to 15 nm titanium deposited with magnetron sputtering. The thin layer of titanium is an excellent etch mask for the polyimide; in an optimized oxygen plasma, the titanium etches 300 times slower than the polyimide. To structure the thin titanium layer itself, a 0.1- $\mu\text{m}$ -thick optical resist is used. Since this top resist layer is so thin, excellent lateral tolerances result. The thin Ti layer is patterned with optical photolithography and etched in an argon plasma. After etching the thin titanium layer, exposing the polyimide locally, an oxygen plasma helps to structure the polyimide down to the titanium or beryllium membrane. Lateral dimensions of 0.3  $\mu\text{m}$  can be obtained in this fashion. Patterning the top resist layer with an electron-beam increases the accuracy of the three-level resist method even further. Electrodeposition of gold on the titanium or beryllium membrane and stripping of the resist finishes the process of making the intermediate LIGA mask. To make a master mask, this intermediate mask is printed by X-ray radiation onto a PMMA resist coated master mask. The PMMA thickness corresponds to a bit more than the desired absorber thickness. Since the resist layer thickness is in the 10- to 20- $\mu\text{m}$  range, a synchrotron X-ray wavelength of 10 Å is adequate for the making of the master mask. A further improvement in LIGA mask making is to fabricate intermediate and master mask on the same substrate, greatly reducing the risk for deviations in dimensions caused, for example, by temperature variations during printing [Becker et al., 1986]. The ultimate achievement would be to create a one-step process to make the master mask. Along this line of work, Hein et al. (1992) have started an investigation in the direct patterning of 10- $\mu\text{m}$ -high resist layers with a 100-kV electron beam.

A completely different approach is suggested by Friedrich from the Institute of Manufacturing in Louisiana. He suggested the fabrication of an X-ray mask by traditional machining methods, such as micromilling, micro-EDM (electrodischarge machining) and lasers [Friedrich, 1994]. The advantages of this proposal are rapid turnaround (less than 1 day per mask), low cost and flexibility, as no intermediate steps interfere. Disadvantages are less dimensional edge acuity and nonsharp interior corners, as well as less absolute tolerance.

#### 17.2.5.5 Alignment of the X-Ray Mask to the Substrate

The mask and resist-coated substrate must be properly registered to each other before they are put in an X-ray scanner. Alignment of an X-ray mask to the substrate is problematic since no visible light can pass through most X-ray membranes. To solve this problem, Schomburg et al. (1991) etched windows in their Ti X-ray membrane. Diamond membranes have a potential advantage here, as they are optically transparent and enable easy alignment for multiple irradiations without a need for etched holes.

Figure 17.7 illustrates an alternative, innovative X-ray alignment system involving capacitive pickup between conductive metal fingers on the mask and ridges on a small substrate area; Si, in this case U.S. Patent 4,607,213 (1986) and 4,654,581 (1987). When using multiple groups of ridges and fingers, two axis lateral and rotational alignment become possible.

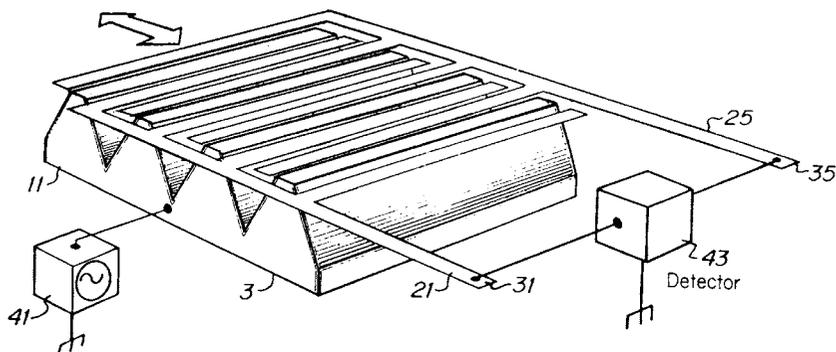

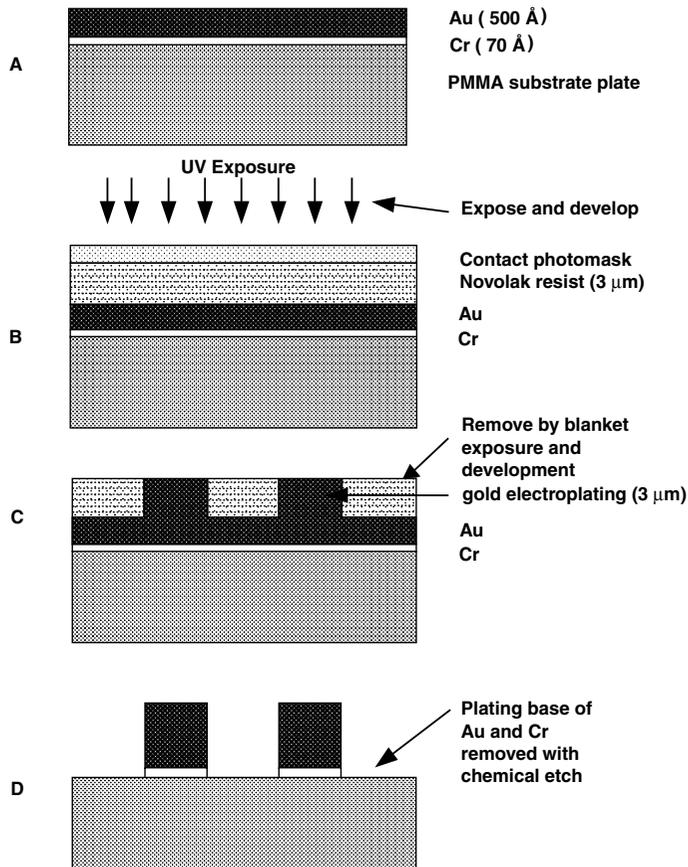

FIGURE 17.7 Mask alignment system in X-ray lithography. Conductive fingers on the mask and ridges on the Si are used for alignment. (From U.S. Patents 4,654,581, 1987 and 4,607,213, 1986.)

Another alternative may involve liquid nitrogen-cooled Si (Li) X-ray diodes as alignment detectors, eliminating the need for observation with visible light [Henck, 1984].

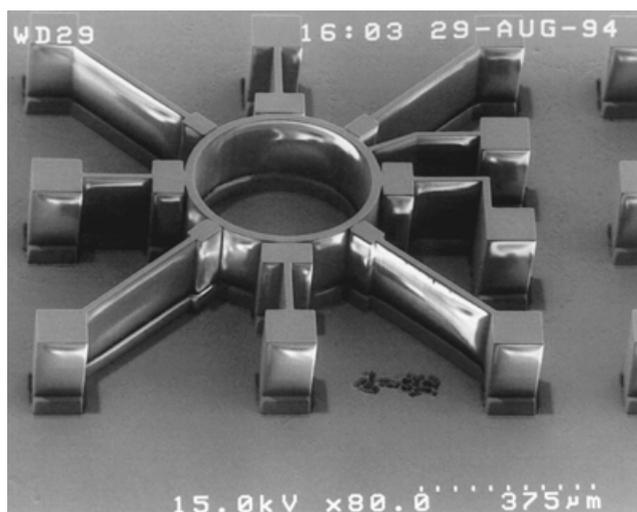

### 17.2.5.6 Transfer Mask for High Aspect Ratio Micro-Lithography

Recently Vladimirovsky et al. (1995) developed a procedure to eliminate the need for an X-ray mask membrane. Unlike conventional masks, the so-called 'X-ray transfer mask' does not treat a mask as an independent unit. The technique is based on forming an absorber pattern directly on the resist surface. An example process sequence is shown in Figure 17.8. In this process, a transfer mask plating base is first prepared on the PMMA substrate plate by evaporating 70 Å of chromium (as adhesion layer) followed by 500 Å of gold using an electron beam evaporator. A 3- $\mu\text{m}$ -thick layer of standard novolak-based AZ-type resist S1400-37 (Shipley Co.) is then applied over the plating base and exposed in contact mode through an optical mask using an ultraviolet exposure station. After development, the transfer mask is further completed by 3- $\mu\text{m}$  gold electroplating on the exposed plating base. The remaining resist is removed by a blanket exposure and subsequent development, and the 500 Å of Au plating base is dissolved by a dip of 20 to 30 sec in a solution of KI (5%) and I (1.25%) in water; the Cr adhesion layer is removed by a standard chromium etch (from KTI). Fabrication of the transfer mask can thus be performed using standard lithography equipment available at almost any lithography shop. Depending on the resolution required, the X-ray transfer mask can be fabricated using known photon, electron-beam or X-ray lithography techniques. New lithography and post lithography techniques, such as *in situ* development, etching and deposition, can now be realized by using a transfer mask. The presence of the membrane in a conventional mask practically precludes use of *in situ* development and is not compatible with etching and deposition due to physical obstruction and material resistance considerations. The patterning of the PMMA resist with a transfer mask can be accomplished in multiple steps of exposure and development. An example of a cylindrical resonator made this way is shown in Figure 17.9. Each exposure/development step involved an exposure dose of about 8 to 12 J/cm<sup>2</sup>. Subsequent 5-min development steps removed ~30  $\mu\text{m}$  of PMMA. With seven steps, a self-supporting 1.5-mm-thick PMMA resist was patterned to a depth of more than 200  $\mu\text{m}$ . The resist pattern shown in Figure 17.9 is 230  $\mu\text{m}$  thick and exhibits a 2- $\mu\text{m}$  gap between the inner cylinder and the pickup electrodes (aspect ratio is 100:1). The pattern was produced using soft (=10 Å) X-rays and a 3- $\mu\text{m}$ -thick Au absorber only.

Vladimirovsky et al. (1995) suggest that the forming of the transfer mask directly on the sample surface creates several additional new opportunities, besides the already mentioned *in situ* development, etching and deposition, these include exposure of samples with curved surfaces and dynamic deformation of a sample surface during the exposure (hemispherical structures would become possible this way). Elegant and cost-saving innovations like these could mainstream LIGA faster than currently believed.

## 17.2.6 LIGA Process Steps and Materials

### 17.2.6.1 Choice of Primary Substrate

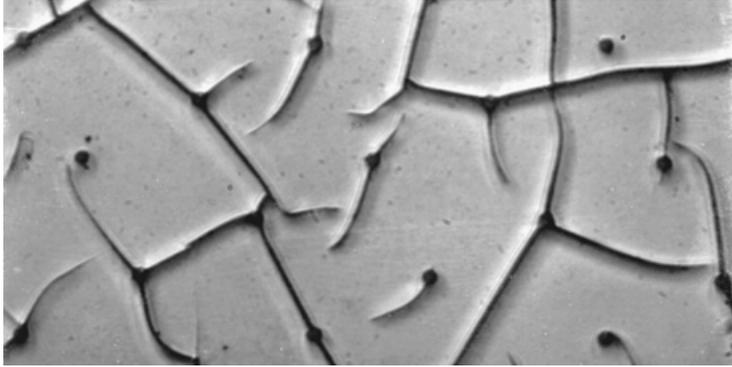

In the LIGA process, the primary substrate, or base plate, must be a conductor or an insulator coated with a conductive top layer. A conductor is required for subsequent electrodeposition. Some examples of primary substrates that have been used successfully are austenite steel plate, Si wafers with a thin Ti or Ag/Cr top layer [Michel et al., 1993], and copper plated with gold, titanium or nickel [Becker et al., 1986]. Other metal substrates as well as metal-plated ceramic, plastic and glass plates have been employed [Rogner et al., 1992]. It is important that the plating base provide good adhesion for the resist. For that purpose, prior to applying the X-ray resist on copper or steel, the surface sometimes is mechanically roughened by microgrit blasting with corundum. Microgrit blasting may lead to an average roughness,  $R_a$ , of 0.5  $\mu\text{m}$ , resulting in better physical anchoring of the microstructures to the substrate [Mohr et al., 1998]. In the case of a polished metal base, chemical preconditioning may be used to improve adhesion of the resist microstructures. During chemical preconditioning, a titanium layer, sputter-deposited onto the polished metal base plate (e.g., a Cu plate), is oxidized for a few minutes in a solution of 0.5 M NaOH and 0.2 M  $\text{H}_2\text{O}_2$  at 65°C. The oxide produced typically measures 30 nm thick and exhibits a microrough surface instrumental to better securing resist to the base plate. The Ti adhesion layer may further be covered with a thin nickel seed layer ( $\sim 150 \text{ \AA}$ ) for electroless or electroplating of nickel in-between the resist microstructures. When using a highly polished Si surface, adhesion promoters need to be added to the resist resin (see also Madou [1997, chap. 1] and Resist Adhesion farther below). A substrate of special interest is a processed silicon wafer with integrated circuits. Integrating the LIGA process with IC circuitry on the same wafer might greatly improve sensor applications.

Thick resist plates can act as plastic substrates themselves. For example, using 20,000-eV rather than the more typical 3000-eV radiation [Guckel et al., 1994; Siddons and Johnson, 1994], exposed plates of PMMA up to 10 cm thick.

### 17.2.6.2 Resist Requirements

An X-ray resist ideally should have high sensitivity to X-rays, high resolution, resistance to dry and wet etching, thermal stability of greater than 140°C and a matrix or resin absorption of less than  $0.35 \mu\text{m}^{-1}$  at the wavelength of interest [Madou, 1997, chap. 1; Moreau, 1988]. These requirements equal those for IC production with X-ray lithography [Lingnau et al., 1989]. To produce high-aspect-ratio microstructures with very tight lateral tolerances demands an additional set of requirements. The unexposed resist must be absolutely insoluble during development. This means that a high contrast ( $\gamma$ ) is required. The resist must also exhibit very good adhesion to the substrate and be compatible with the electroforming process. The latter imposes a resist glass transition temperature ( $T_g$ ) greater than the temperature of the electrolyte bath used to electrodeposit metals between the resist features remaining after development (say, at 60°C). To avoid mechanical damage to the microstructures induced by stress during development, the resist layers should exhibit low internal stresses [Mohr et al., 1989]. If the resist structure is the end product of the fabrication process, further specifications depend on the application itself, e.g., optical transparency and refractive index for optical components or large mechanical yield strength for load-bearing applications. For example, PMMA exhibits good optical properties in the visible and near-infrared range and lends itself to the making of all types of optical components [Gottert et al., 1991].

Due to excellent contrast and good process stability, known from electron-beam lithography, poly(methylmethacrylate) (PMMA) is the preferred resist for deep-etch synchrotron radiation lithography. Two major concerns with PMMA as a LIGA resist are a rather low lithographic sensitivity of about  $2 \text{ J/cm}^2$  at a wavelength  $\lambda_c$  of 8.34  $\text{\AA}$  and a susceptibility to stress cracking. For example, even at shorter wavelengths,  $\lambda_c = 5 \text{ \AA}$ , over 90 min of irradiation are required to structure a 500- $\mu\text{m}$ -thick resist layer with an average ring storage current of 40 mA and a power consumption of 2 MW at the 2.3-GeV ELSA synchrotron (Bonn, Germany) [Wollersheim et al., 1994]. The internal stress arising from the combination of a polymer and a metallic substrate can cause cracking in the microstructures during development, a phenomenon PMMA is especially prone to, as illustrated in the scanning electron microscope in [Figure 17.10](#).

**FIGURE 17.10** Cracking of PMMA resist. Method to test stress in thick resist layers. The onset of cracks in a pattern of holes with varying size (say, 1 to 4  $\mu\text{m}$ ) in a resist is shifted towards smaller hole diameter the lower the stress in the film. The SEM picture displays extensive cracking incurred during development of the image in a 5- $\mu\text{m}$ -thick PMMA layer on an Au-covered Si wafer. The 5- $\mu\text{m}$ -thick PMMA layer resulted from five separate spin coats. Annealing pushed the onset of cracking toward smaller holes until the right cycle was reached and no more cracks were visible [Madou and Murphy, 1995].

To make throughput for deep-etch lithography more acceptable to industry, several avenues to more sensitive X-ray resists have been pursued. For example, copolymers of PMMA were investigated: methylmethacrylate combined with methacrylates with longer ester side chains show sensitivity increases of up to 32% (with tertiary butylmethacrylate). Unfortunately, a deterioration in structure quality was observed [Mohr et al., 1988b]. Among the other possible approaches for making PMMA more X-ray sensitive we can count on the incorporation of X-ray absorbing high-atomic-number atoms or the use of chemically amplified photoresists [Madou, 1997, chap. 1]. X-ray resists explored more recently for LIGA applications are poly(lactides), e.g., poly(lactide-co-glycolide) (PLG), polymethacrylimide (PMI), polyoxymethylene (POM) and polyalkensulfone (PAS). Poly(lactide-co-glycolide) is a new positive resist developed by BASF AG, more sensitive to X-rays by a factor of 2 to 3 compared with PMMA. Its processing is less critical but it is not commercially available yet. From the comparison of different resists for deep X-ray lithography in Table 17.7, PLG emerges as the most promising LIGA resist. POM, a promising mechanical material, may also be suited for medical applications given its biocompatibility. All of the resists shown in Table 17.7 exhibit significantly enhanced sensitivity compared to PMMA, and most exhibit a reduced stress corrosion [Wollersheim et al., 1994]. Negative X-ray resists have inherently higher sensitivities compared to positive X-ray resists, although their resolution is limited by swelling. Poly(glycidylmethacrylate-co-ethyl acrylate) (PGMA), a negative electron-beam resist (not shown in Table 17.7), has also been used in X-ray

lithography. In general, resist materials sensitive to electron-beam exposure also display sensitivity to X-rays and function in the same fashion; materials positive in tone for electron-beam radiation typically are also positive in tone for X-ray radiation. A strong correlation exists between the resist sensitivities observed with these two radiation sources, suggesting that the reaction mechanisms might be similar for both types of irradiation (see Madou [1997, chap. 1]). IMM, in Germany, started developing a negative X-ray resist 20 times more sensitive than PMMA, but the exact chemistry has not been disclosed yet [IMM, 1995].

### 17.2.6.3 Resist Application

#### *Multiple Spin Coats*

Different methods to apply ultra-thick layers of PMMA have been studied. In the case of multilayer spin coating, high interfacial stresses between the layers can lead to extensive crack propagation upon developing the exposed resist. For example, in [Figure 17.10](#) we present an SEM picture of a 5- $\mu\text{m}$ -thick PMMA layer, deposited in five sequential spin coatings. Development resulted in the cracked riverbed mud appearance with the most intensive cracking propagating from the smallest resist features. The test pattern used to expose the resist consisted of arrays of holes ranging in size from 1 to 4  $\mu\text{m}$ . We found that annealing the PMMA films shifted the cracking toward holes with smaller diameter compared to the unannealed film shown in [Figure 17.10](#) [Madou and Murphy, 1995]. The described experiment might comprise a generic means of studying the stress in thick LIGA resist layers. It was found at CAMD that multiple spin coating can be used for up to 15- $\mu\text{m}$ -thick resist layers and that with applying the appropriate annealing and developer (see below) no cracking results [private communication, 1995]. Further on we will learn that a prerequisite for low stress and small lateral tolerances in PMMA films is a high mean molecular weight. The spin-coated resist films in [Figure 17.10](#) might not have a high enough molecular weight to lead to good enough selectivity between radiated and nonradiated PMMA during a long development process.

#### *Commercial PMMA Sheets*

High molecular weight PMMA is commercially available as prefabricated plate (e.g., GS 233; Rohm GmbH, Darmstadt, Germany) and several groups have employed free-standing or bonded PMMA resist sheets for producing LIGA structures [Guckel, 1994; Mohr et al., 1988]. After overcoming the initial problems encountered when attempting to glue PMMA foils to a metallic base plate with adhesives, this has become the preferred method [Mohr et al., 1988a]. Guckel used commercially available thick PMMA sheets (thickness > 3mm), XY-sized and solvent-bonded them to a substrate, and, after milling the sheet to the desired thickness, exposed the resist without cracking problems [Guckel, 1994].

#### *Casting of PMMA*

PMMA also can be purchased in the form of a casting resin, e.g., Plexit 60 (PMMA without added cross-linker) and Plexit 74 (PMMA with cross-linker added) from Rohm GmbH in Darmstadt, Germany. In a typical procedure, PMMA is *in situ* polymerized from a solution of 35 wt% PMMA of a mean molecular weight of anywhere from 100,000 g/mol up to  $10^6$  g/mol in methylmethacrylate (MMA). Polymerization at room temperature takes place with benzoyl peroxide (BPO) catalyst as the hardener (radical builder) and dimethylaniline (DMA) as the starter or initiator [Mohr et al., 1988a; 1988b]. The oxygen content in the resin, inhibiting polymerization, and gas bubbles, inducing mechanical defects, are reduced by degassing while mixing the components in a vacuum chamber at room temperature and at a pressure of 100 mbar for 2 to 3 min.

In a practical application, resin is then dispensed on a base plate provided with shims to define pattern and thickness and subsequently covered with a glass plate to avoid oxygen absorption. The principle of polymerization on a metal substrate is schematically represented in [Figure 17.11](#). Due to the hardener, polymerization starts within a few minutes after mixing of the components and comes to an end within 5 min. The glass cover plate is coated with an adhesion preventing layer (e.g., Lusin L39, Firma Lange u. Seidel, Nurnberg). After polymerization the anti-adhesion material is removed by diamond milling and a highly polished surface results. *In situ* polymerization and commercial-cast PMMA sheets top the list of thick resist options in LIGA today.

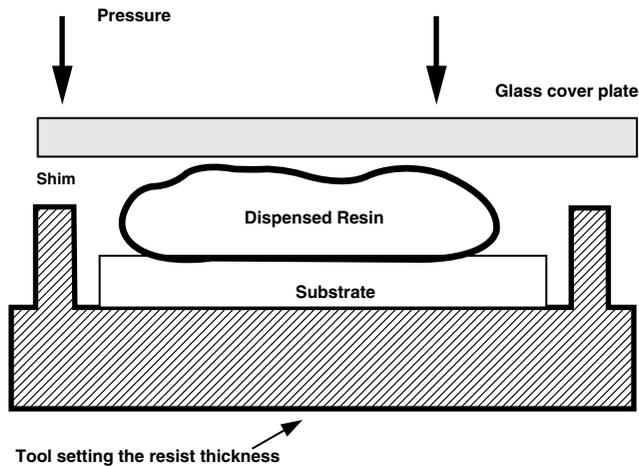

FIGURE 17.11 Principle of *in situ* polymerization of a thick resist layer on a metal substrate.

### Plasma Polymerized PMMA

Guckel et al. explored plasma-polymerized PMMA to make conformal coatings more than 100  $\mu\text{m}$  thick [Guckel et al., 1988]. As discussed in Madou (1997, chap. 3), plasma polymerization offers several advantages. Surprisingly, little work focuses on plasma polymerized X-ray resists.

#### 17.2.6.4 Resist Adhesion

Adhesion promotion by mechanically or chemically modifying the primary substrate was introduced above under Choice of Primary Substrate. Smooth surfaces such as Si wafers with an average roughness,  $R_a$ , smaller than 20 nm pose additional adhesion challenges often solved by modifying the resist itself. To promote adhesion of resist to polished untreated surfaces, such as a metal-coated Si wafers, coupling agents must be used to chemically attach the resist to the substrate. An example of such a coupling agent is methacryloxypropyl trimethoxy silane (MEMO). With 1 wt% of MEMO added to the casting resin, excellent adhesion results. The adherence is brought about by a siloxane bond between the silane and the hydrolyzed oxide layer of the metal. As illustrated in Figure 17.12, the integration of this coupling agent in the polymer matrix is achieved via the double bond of the methacryl group of MEMO [Mohr et al., 1988b].

Hydroxyethyl methacrylate (HEMA) can improve PMMA adhesion to smooth surfaces but higher concentrations are needed to obtain the same adhesion improvement. Silanization of polished surfaces prior to PMMA casting, instead of adding adhesion promoters to the resin, did not seem to improve the PMMA adhesion. In the case of PMMA sheets, as mentioned before, one option is solvent bonding of the layers to a substrate. In another approach Galhotra et al. (1996) simply mechanically clamped the exposed and developed self-supporting PMMA sheet onto a 1.0-mm-thick Ni sheet for subsequent Ni plating. Rogers et al. (1996) have shown that cyanoacrylate can be used to bond PMMA resist sheets to a Ni substrate and that it can be lithographically patterned using the same process sequence used to pattern PMMA. For a 300- $\mu\text{m}$ -thick PMMA sheet on a sputtered Ni coating on a silicon wafer a 10- $\mu\text{m}$ -thick cyanoacrylate bonding layer was used. Such a thick cyanoacrylate layer caused some problems for subsequent uniform electrodeposition of metal. The dissolution rate of the cyanoacrylate is faster than the PMMA resist, resulting in metal posts with a wide profile at the base.

#### 17.2.6.5 Stress-Induced Cracks in PMMA

The internal stress arising from the combination of a polymer on a metallic substrate can cause cracking in the microstructures during development. To reduce the number of stress-induced cracks (see Figure 17.10), both the PMMA resist and the development process must be optimized. Detailed measurements of the heat of reaction, the thermomechanical properties, the residual monomer content and the molecular weight distribution during polymerization and soft baking have shown the necessity to produce resist layers with

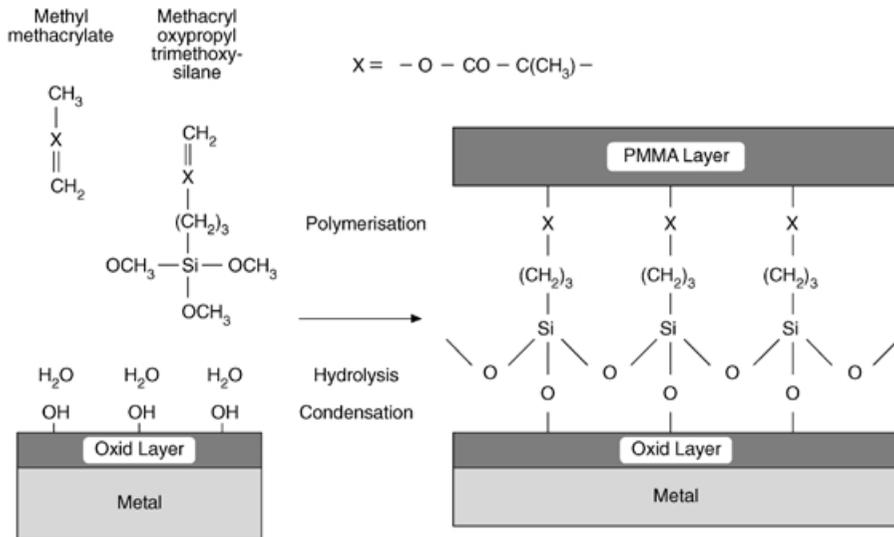

FIGURE 17.12 Schematic presentation of the adherence mechanism of methacryloxypropoyl trimethoxy silane (MEMO). (From Mohr, J. et al., *J. Vac. Sci. Technol.*, B6, 2264–2267, 1988. With permission.)

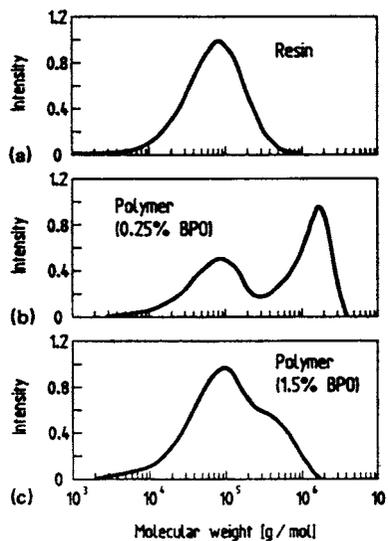

FIGURE 17.13 Molecular weight distribution of (a) the casting resin, (b) a resist layer polymerized at low hardener content, and (c) a resist layer polymerized at high hardener content determined by gel permeation chromatography. (From Mohr, J. et al., *J. Vac. Sci. Technol.*, B6, 2264–2267, 1988. With permission.)

a high molecular weight and with only a very small residual monomer content [Mohr et al., 1988a; 1988b]. Figure 17.13 compares the molecular weight distribution determined by gel permeation chromatography of a polymerized PMMA resist (two hardener concentrations were used) with the molecular weight distribution of the casting resin. The casting resin is unimodal, whereas the polymerized resist layer typically shows a bimodal distribution with peak molecular weights centered around 90,000 and 300,000 g/mol. The first low-molecular-weight peak belongs to the PMMA oligomer dissolved in the casting resin, and the second molecular weight peak results from the polymerization of the monomer. The molecular weight

distribution is constant across the total resist thickness, except for the boundary layer at the base plate, where the average molecular weight can be significantly higher (~450,000 g/mol) [Mohr et al., 1989].

The amount of the high molecular weight portion in the polymerized resist depends on the concentration of the hardener. A low hardener content leads to a high molecular weight dominance and vice versa (see [Figure 17.13](#)) [Mohr et al., 1988b]. Since high molecular weight is required for low stress, a hardener concentration of less than 1% BPO (benzoyl peroxide) must be used. Ideally, for a low stress resist, the residual monomer content should be less than 0.5%. The residual monomer content decreases with increasing hardener content, and >1% BPO is needed to reduce the residual monomer content below 0.5%. The problem resulting from these opposite needs can be overcome by the addition of 1% of a cross-linking dimethacrylate (triethylene glycol dimethacrylate, TEDMA) to the resin. In such cross-linked PMMA, a smaller amount of BPO suffices to suppress the residual monomer content; crack-free PMMA can be obtained with 0.8% of BPO [Mohr et al., 1988a].

For solvent removal and to further minimize the defects caused by stress, the polymerized resin is cured at 110°C for one hour (soft bake). The measurement of the reaction enthalpy shows that post-polymerization reactions occur at room temperature and during heating to the glass transition temperature [Mohr et al., 1988b]. The rate of heating up to that temperature is 20°C/hr; after curing, the samples are cooled down from 110°C to room temperature at a very low rate of 5 to 10°C/hr [Mohr et al., 1988a; 1988b]. The soft-bake temperature is slightly below the glass transition temperature measured to be 115°C.

Another important factor reducing stress in thick PMMA resist layers is the optimization of the developer. Stress-induced cracking can be minimized with solvent mixtures whose dissolution parameters lie near the boundary of the PMMA solubility range, i.e., a nonaggressive solvent is preferred. This is discussed in more detail below, under Development. Small amounts of additives such as described above for reducing stress or to promote adhesion do not influence the mechanical stability of the microstructures or the sensitivity of the resist.

### 17.2.6.6 Optimum Wavelength and Deposited Dose

#### *Optimum Wavelength*

For a given polymer, the lateral dimension variation in a LIGA microstructure could, in principle, result from the combined influence of several mechanisms, such as Fresnel diffraction, the range of high energy photoelectrons generated by the X-rays, the finite divergence of synchrotron radiation and the time evolution of the resist profiles during the development process. The theoretical manufacturing precision obtainable by deep X-ray lithography was investigated by means of computer simulation of both the irradiation step and the development step by Becker et al. (1984) and by Munchmeyer (1984), and further tested experimentally and confirmed by Mohr et al. (1988a). The theoretical results demonstrate that the effect of Fresnel diffraction (edge diffraction), which increases as the wavelength increases, and the effect of secondary electrons in PMMA, which increases as the wavelength decreases, lead to minimal structural deviations when the characteristic wavelength ranges between 0.2 and 0.3 nm (assuming an ideal development process and no X-ray divergence). To fully utilize the accuracy potential of a 0.2- to 0.3-nm wavelength, the local divergence of the synchrotron radiation at the sample site should be less than 0.1 mrad. Under these conditions, the variation in critical lateral dimensions likely to occur between the ends of a 500- $\mu\text{m}$ -high structure due to diffraction and secondary electrons are estimated to be 0.2  $\mu\text{m}$ . The estimated Fresnel diffraction and secondary electron scattering effects are shown as a function of characteristic wavelength in [Figure 17.14](#).

Using cross-linked PMMA, or linear PMMA with a unimodal and extremely high-molecular-weight distribution (peak molecular weight greater than 1,000,000 g/mol), the experimentally determined lateral tolerances on a test structure as shown in [Figure 17.15](#) are 0.055  $\mu\text{m}$  per 100  $\mu\text{m}$  resist thickness, in good agreement with the 0.2  $\mu\text{m}$  over 500  $\mu\text{m}$  expected on a theoretical basis [Mohr et al., 1988a]. These results are obtained only when a resist/developer system with a ratio of the dissolution rates in the exposed and unexposed areas of approximately 1000 is used.

The use of resist layers, not cross-linked and displaying a relatively low bimodal molecular-weight distribution, as well as the application of excessively strong solvents such as used to develop thin PMMA resist

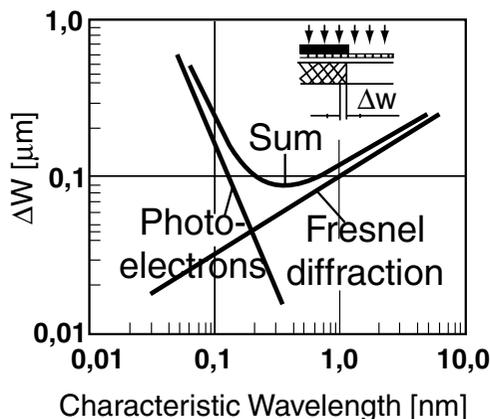

FIGURE 17.14 Fresnel diffraction and photoelectron generation as a function of characteristic wavelength,  $\lambda$ , and the resulting lateral dimension variation ( $\Delta W$ ). (After Menz, W.P., *Mikrosystemtechnik für Ingenieure*, VCH Publishers, Germany, 1993.)

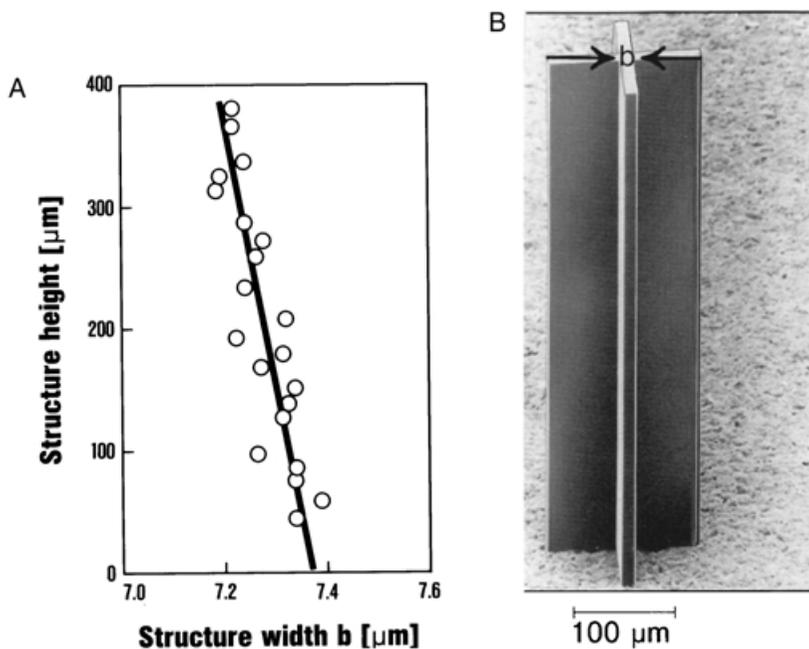

FIGURE 17.15 Structural tolerances. (A) SEM micrograph of a test structure to determine conical shape. (B) Structural dimensions as a function of structure height. The tolerances of the dimensions are within  $0.2 \mu\text{m}$  over the total structure height of  $400 \mu\text{m}$  [Mohr et al., 1988b]. (Courtesy of the Karlsruhe Nuclear Research Center.)

layers in the IC industry, lead to more pronounced conical shapes in the test structures of Figure 17.15. An illustration of the effect of molecular weight distribution on lateral geometric tolerances is that linear PMMA with a peak molecular weight below  $300,000 \text{ g/mol}$  shows structure tolerances of up to  $0.15 \mu\text{m}/100 \mu\text{m}$  [Mohr et al., 1988a]. To obtain the best tolerances necessitates a PMMA with a very high molecular weight, also a prerequisite for low stress in the developed resist. Finally, if the synchrotron beam is not parallel to the absorber wall but at an angle greater than  $50 \text{ mrad}$ , greater coning angles may also result [Mohr et al., 1988a].

### Deposited Dose

As shown in Figure 17.16, depicting the average molecular weight of PMMA as a function of radiation dose, the X-ray irradiation of PMMA reduces the average molecular weight [Menz and Bley, 1993]. For one-component positive resists, this lowering of the average molecular weight ( $M_n^*$ ; see Madou [1997, chap. 1, Eq. (1.7)]) causes the solubility of the resist in the developer to increase dramatically. The average molecular weight making dissolution possible is a sensitive function of the type of developer used and the development temperature. Interestingly, it can be observed from Figure 17.16 that above a certain dose (15 to 20  $\text{kJ}/\text{cm}^3$ ) the average molecular weight does not decrease any further. This can be understood by recalling the  $G(s)$  and  $G(x)$  values of a resist introduced in Madou (1997, chap. 1). These  $G$  values express the number of main chain scissions (in case of a positive resist), and cross-links (in case of a negative resist), respectively, per 100 eV of absorbed radiation energy. The average molecular weight decreases with radiation dose as long as  $G(s)$  is larger than  $G(x)$ . When the  $G$ -values are equal the average molecular weight does not change any further. Our example in Figure 17.16 shows this to occur at a radiation dose between 15 and 20  $\text{kJ}/\text{cm}^3$ .

The molecular weight distribution, measured after resist exposure, is unimodal with peak molecular weights ranging from 3000 to 18,000  $\text{g}/\text{mol}$ , dependent on the dose deposited during irradiation (see Figure 17.16). The peak molecular weight increases nearly linearly with increasing resist depth, i.e., decrease of the absorbed dose [Mohr et al., 1989]. At the bottom of the resist layer, the absorbed dose must be higher than the development dose,  $D_{dv}$ , while at the top of the resist the absorbed dose must be lower than the damaging dose,  $D_{dm}$ . In Figure 17.5, where the absorption of X-rays along the path from source to sample was illustrated, the exposure time and the preabsorber were chosen so that the bottom of a 500- $\mu\text{m}$ -thick PMMA layer received the necessary development dose  $D_{dv}$ , while the dose at the top of the layer stayed well below  $D_{dm}$ . Exposure of PMMA with longer wavelengths results in correspondingly longer exposure times and can lead to an overexposure of the top surface, where the lower energy radiation is mainly absorbed.

Menz and Bley (1993) describe the influence of the radiation dose on the quality of the resulting LIGA structures in a slightly different manner. Following their approach, Figure 17.17A illustrates a typical bimodal molecular weight distribution of PMMA before radiation, exhibiting an average molecular weight of 600,000. The gray region in this figure indicates the molecular weight region where PMMA readily dissolves, i.e., below the 20,000- $\text{g}/\text{mol}$  level for the temperature and developer used. Since the fraction of

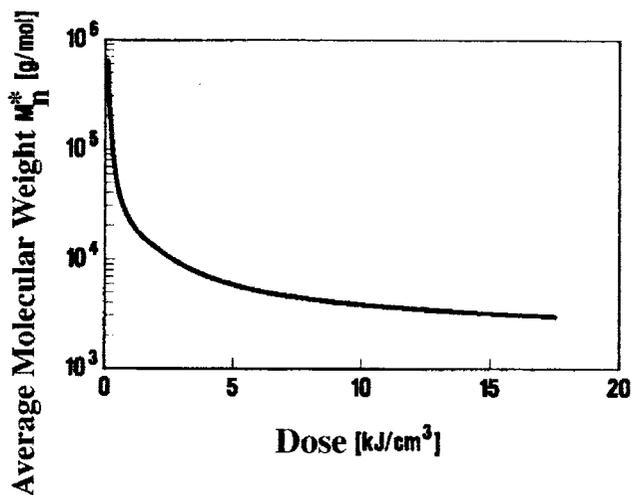

FIGURE 17.16 Average molecular weight  $M_n^*$  vs. X-ray radiation dose. (From Menz, W.P., *Mikrosystemtechnik fur Ingenieure*, VCH Publishers, Germany, 1993. With permission.)

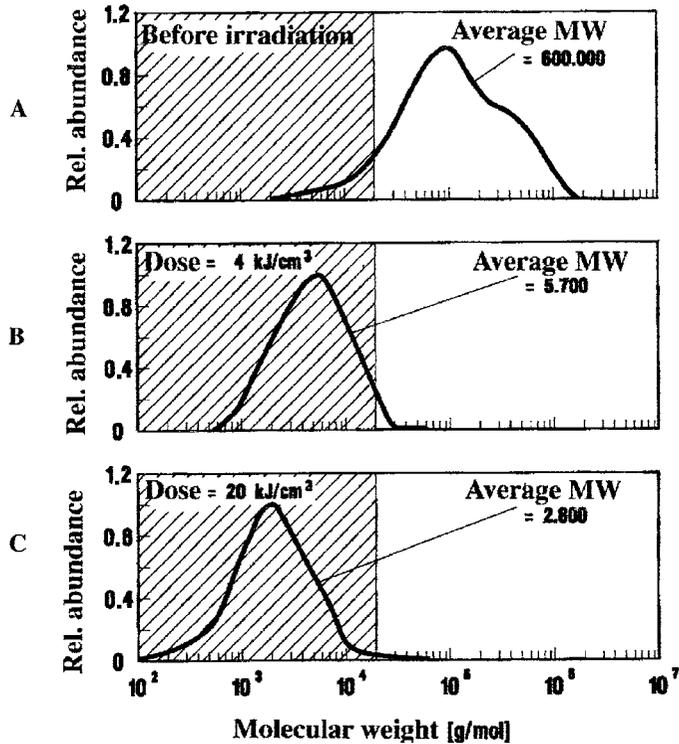

FIGURE 17.17 Molecular weight distribution of PMMA before (A) and after irradiation with 4 (B) to 20  $\text{kJ}/\text{cm}^3$  (C). The shaded areas indicate the domain in which PMMA is minimally 50% dissolved (at 38°C in the LIGA developer described in the text). (From Menz, W.P., *Mikrosystemtechnik fur Ingenieure*, VCH Publishers, Germany, 1993. With permission.)

PMMA with a 20,000 molecular weight is very small in nonirradiated PMMA, the developer hardly attacks the resist at all. After irradiation with a dose  $D_{ir}$  of 4  $\text{kJ}/\text{cm}^3$ , the average molecular weight becomes low enough to dissolve almost all of the resist (Figure 17.17B). With a dose  $D_{dm}$  of 20  $\text{kJ}/\text{cm}^3$ , all of the PMMA dissolves swiftly (Figure 17.17C). At a dose above  $D_{dm}$ , the microstructures are destroyed by the formation of bubbles. It follows that to dissolve PMMA completely and to make defect-free microstructures, the radiation dose for the specific type of PMMA used must lay between 4 and 20  $\text{kJ}/\text{cm}^3$ . These two numbers also lock in a maximum value of 5 for the ratio of the radiation dose at the top and bottom of a PMMA structure. To make this ratio as small as possible, the soft portion of the synchrotron radiation spectrum is usually filtered out by a preabsorber, e.g., a 100- $\mu\text{m}$ -thick polyimide foil (Kapton) in order to reduce differences in dose deposition in the resist.

X-ray exposure equipment developed by KfK has a vibration-free bedding; the exposure chamber is under thermostatic control ( $\pm 0.2^\circ\text{C}$ ) and includes a precision scanner for the periodic movement of the sample through the irradiation plane. The polyimide window isolates the vacuum of the accelerator from the helium atmosphere (200 mbar) which serves as coolant for substrate and mask in the irradiation chamber [Becker et al., 1986]. IMM in collaboration with Jenoptik GmbH developed an X-ray scanner for deep lithography, enabling irradiation of up to 1000- $\mu\text{m}$ -thick resist. A mask-to-resist registration within  $\pm 0.3 \mu\text{m}$  is claimed [Editorial, 1994c].

### 17.2.6.7 Development

X-ray radiation changes the polymer in the unmasked areas, and chemicals etch away the regions that have been exposed during development. To fully utilize the accuracy potential of synchrotron radiation lithography, it is essential that the resist/developer system has a ratio of dissolution rate in the exposed and

unexposed areas of approximately 1000 (see above). The developer empirically arrived at by KfK consists of a mixture of 20 vol% tetrahydro-1,4-oxazine (an azine), 5 vol% 2-aminoethanol-1 (a primary amine), 60 vol% 2-(2-butoxyethoxy)ethanol (a glycolic ether) and 15 vol% water [Mohr et al., 1988a; 1989; Ghica and Glashauser, 1982]. This developer causes an infinitely small dissolution of unexposed, high-molecular-weight, cross-linked PMMA and achieves a sufficient dissolution rate in the exposed area. It also exhibits much less stress-induced cracking than developers conventionally used for thin PMMA resists. During development the developing agent flows toward the resist surface being developed, circulates and is filtered continuously and the temperature remains controlled at 35°C. To stop development, less concentrated developer solutions are applied to prevent the precipitation of already dissolved resist.

Systematic investigation of different organic solvents and mixtures of the above developer systems showed that solvents with a solubility parameter at the periphery of the solubility range of PMMA dissolve exposed PMMA slowly but selectively and without stress-induced cracking or swelling of unexposed areas. Solvents with a solubility parameter close to those of MMA show a much higher dissolution rate, but cause serious problems related to cracking and swelling. As we saw before, the application of excessively strong solvents also led to more pronounced conical shapes in the test structures shown in [Figure 17.15](#). An improved developer found in the above systematic investigation is a mixture of tetrahydro-1,4-oxazine and 2-aminoethanol-1. Its sensitivity is 30% higher, but the process latitude is much narrower compared to the developer described above [Mohr et al., 1989].

At KfK, a dedicated machine was built for the development process, enabling the continuous and homogeneous transport of developing and rinsing agents into deep structure elements and the removal of the dissolved resist from these structures. Several substrates are arranged vertically on a rotor, with each structure surface facing to the outside. Three independent medium circuits are available for immersion and spraying processes [Becker et al, 1986].

After development the microstructures are rinsed with deionized water and dried in a vacuum. Alternatively, drying is done by spinning and blasting with dry nitrogen. At this stage the devices can be the final product, e.g., as micro-optical components, or they are used for subsequent metal deposition.

### 17.2.6.8 Electrodeposition/Electroless Deposition

#### *Electrodeposition*

**Overview.** In the electroforming of microdevices with LIGA (see [Figure 17.1](#)), a conductive substrate, carrying the resist structures, serves as the cathode. The metal layer growing on the substrate fills the gaps in the resist configuration, thus forming a complementary metal structure. The use of a solvent-containing development agent ensures a substrate surface completely free of grease and ready for plating. Most of the plating involves Ni. We will discuss Ni electroplating in detail and list some of the other materials that have been or could be plated.

The fabrication of metallic relief structures is a well-known art in the electroforming industry (see also Madou [1997, chaps. 3 and 7]). The technology is used, for example, to make the fabrication tools for records and videodiscs where structural details in the submicron range are transferred. Electrodeposition is a powerful tool for creating microstructures, not only in LIGA where resist molds are made by X-ray lithography, but also in combination with molds made by laser ablation, dry etching, Keller's polysilicon molding technique (see Chapter 16), bulk micromachining etc. Because of the extreme aspect ratio, several orders of magnitude larger than in the crafting of CDs, electroplating in LIGA poses new challenges. The near-ultimate in packing density, the extreme height-to-width aspect ratio and fidelity of reproduction of electrodeposition were first demonstrated in Romankiw's precursor work to LIGA in which gold was plated through polymeric masks generated by X-ray lithography. This author, using X-ray exposure, developed holes in PMMA resist features of 1- $\mu\text{m}$  width and depths of up to 20  $\mu\text{m}$  and electroplated gold in such features up to thicknesses of 8  $\mu\text{m}$  (see also Madou [1997, chap. 7]; Spiller et al. [1976]). By 1975, the same author and his team had used the electroplating approach to create microwires 300  $\times$  300 atoms in cross section [Romankiw, 1993].

**Nickel Electrodeposition.** The electrodeposition reaction of nickel on the cathode, i.e.,

competes with the hydrogen evolution reaction on the same electrode, i.e.,

The theoretical amount of Ni deposited from Reaction 17.1 can be calculated from Faraday's law (see Madou [1997, chap. 3, Eq. (3.29)]). Since some of the current goes into hydrogen evolution, the actual amount of Ni deposited usually is less than calculated from that equation. The electrodeposition yield,  $\eta$ , is then defined as the actual amount of deposited material,  $m_{\text{act}}$ , over the total calculated from Faraday's law,  $m_{\text{max}}$ , and can be calculated from [Romankiw, 1993]:

$$\eta[\%] = \frac{m_{\text{act}}}{m_{\text{max}}} \times 100 = \frac{m_{\text{act}}}{\frac{1}{z} i A t \frac{1}{F} M} \times 100 \quad (17.5)$$

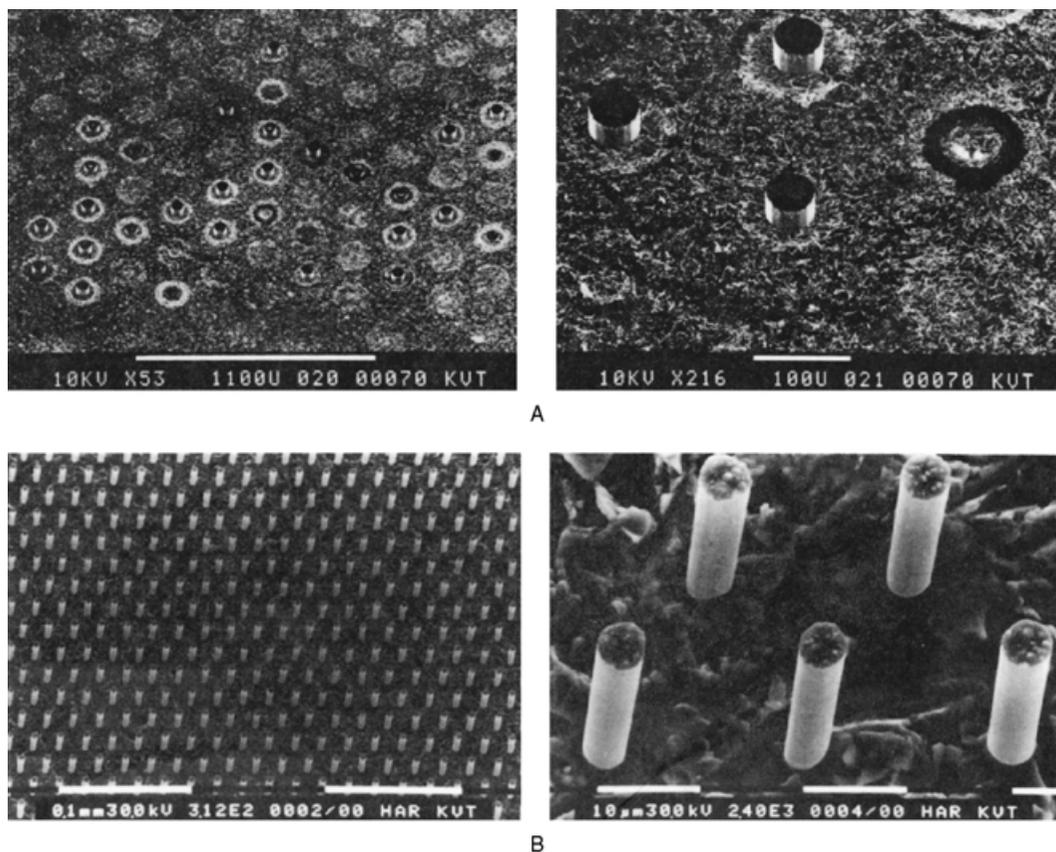

where

- $A$  = electrode surface
- $t$  = electrodeposition time
- $F$  = Faraday constant (96487 A/sec/mol)
- $i$  = current density
- $z$  = electrons involved in Reaction 17.1
- $M$  = atomic weight of Ni

The amount of hydrogen evolving and competing with Ni deposition depends on the pH, the temperature and the current density. Since one of the most important causes of defects in the metallic LIGA microstructures is the appearance of hydrogen bubbles, these three parameters need very precise control. Pollutants cause hydrogen bubbles to cling to the PMMA structures, resulting in pores in the nickel deposit, so the bath must be kept clean, e.g., by circulating through a membrane filter with 0.3- $\mu\text{m}$  pore openings [Harsch, 1988]. Besides typical impurities, such as airborne dust or dissolved anode material, the main impurities are nickel hydroxide formed at increased pH values in the cathode vicinity and organic decomposition products from the wetting agent. The latter two can be avoided to some degree by monitoring and controlling the pH and by adsorption of the organic decomposition products on activated carbon.

Another cause of defects in electroplating is an incomplete wetting of the microchannels in the resist structure. The contact angle between PMMA and the plating electrolyte at 50°C lies between 70 and 80°. A wetting agent is thus indispensable for wetting the surface of the plastic structures in order for the electrolyte to penetrate into the microchannels. With a wetting agent, the contact angle between PMMA and the plating electrolyte can be reduced from 80 to 5° [Harsch et al., 1988]. In the electroforming of microdevices, a much higher concentration of wetting agent is necessary than in conventional electroplating. A dramatic illustration of this wetting effect can be seen in [Figure 17.18A](#) and [B](#). In the set-up illustrated in [Figure 17.18A](#), where only 2.5 ml/l of a wetting agent is added to the sulfamate nickel deposition solution, nickel posts with a diameter of 50  $\mu\text{m}$  often fail to form. In the same experiment no posts with a diameter of 5 and 10  $\mu\text{m}$  form at all. Increasing the wetting agent concentration to 10 ml/l results in the perfectly formed nickel posts with a diameter of 5  $\mu\text{m}$  as shown in [Figure 17.18B](#).

A microelectrode of the same size or less than the diffusion layer thickness, as shown in [Figure 17.18B](#), could be expected to plate faster than a larger electrode because of the extra increment of current due to the nonlinear diffusion contribution [Madou, 1997, chap. 3, Eq. (3.53)]. On the other hand, as derived from Madou (1997, chap. 3, Eq. (3.55)), describing the current to a metal electrode recessed in a resist layer, we learned that the nonlinear diffusion contribution increases with decreasing radius  $r$  but decreases with increasing resist thickness,  $L$ . High-aspect-ratio features consequently will plate slower than low aspect ratio features. Moreover, the consumption of hydrogen ions in the high-aspect-ratio features causes

**FIGURE 17.18** Electrodeposition of nickel posts of varying diameter. (A) nickel posts with diameter of 50  $\mu\text{m}$ . Only 2.5 ml/l wetting agent added to the nickel sulfamate solution. Many 50- $\mu\text{m}$  posts are missing and posts with a diameter of 10 or 5  $\mu\text{m}$  do not even form. (B) Nickel posts with diameter of 5  $\mu\text{m}$ . 10 ml/l wetting agent was added; all posts developed perfectly. (Courtesy of the Karlsruhe Nuclear Research Center.)

the pH to locally increase. As no intense agitation is possible in these crevices, an isolating layer of nickel hydroxide might form, preventing further metal deposition. This all contributes to making the deposition rate, important for an economical production, much smaller than the rates expected from the linear diffusion model of current density in large, low-aspect-ratio structures.

A nickel sulfamate bath composition, optimized for Ni electrodeposition, is given in [Table 17.8](#). In addition to nickel sulfamate and boric acid as a buffer, a small quantity of an anion-active wetting agent

**TABLE 17.8** Composition and Operating Conditions of Nickel Sulfamate Bath

Parameter	Value
Nickel metal (as sulfamate)	76–90 g/l
Boric acid	40 g/l
Wetting agent	10 ml/l
Current density	1–10 A/dm <sup>2</sup>
Temperature	50–62°C
pH	3.5–4.0
Anodes	Sulfur depolarized

is added. Sulfur-depolarized nickel pellets are used as anode materials and are held in a titanium basket [Maner, 1988]. Table 17.8 also lists operational parameters. Nickel sulfamate baths produce low internal stress deposits without the need for additional agents avoiding a cause for more defects. The bath is operated at 50 to 62°C and at a pH value between 3.5 and 4.0. Metal deposition is carried out at current densities up to 10 A/dm<sup>2</sup>. Growth rates vary from 12 (at 1 A/dm<sup>2</sup>) to 120 μm/hr (at 10 A/dm<sup>2</sup>).

**Physical Properties of Electrodeposited Nickel.** The hardness of the Ni deposits can be adjusted from 200 to 350 Vickers by varying the operating conditions. The hardness decreases with increasing current density. To reach a high hardness of 350 Vickers, the electroforming must proceed at a reduced current of 1 A/dm<sup>2</sup>. Also, for low compressive stress of 20 N/mm<sup>2</sup> or less, a reduced current density must be used. Internal stress in the Ni deposits is not only influenced by current density but also by the layer thickness, pH, temperature and solution agitation. In the case of pulse plating (see below), pulse frequency has a distinct influence as well [Harsch et al., 1988]. From Figure 17.19 we can derive that for thin Ni deposits the stress is high and decreases very fast as a function of thickness. For thick Ni deposits (>30 μm), the stress as a function of thickness reaches a plateau. At a current density of 10 A/dm<sup>2</sup> these thick Ni films are under compressive stress; at 1 A/dm<sup>2</sup> they are under tensile stress; at 5 A/dm<sup>2</sup> the internal stress reduces to practically zero. Stirring of the plating solution reduces stress dramatically, indicating that mass transport to the cathode is an important factor in determining the ultimate internal stress. Consequently, since high-aspect-ratio features do not experience the same agitation of a stirred solution as bigger features do, this results in higher stress concentration in the smallest features of the electroplated structure. Since the stress is most severe in the thinnest Ni films, Harsch et al. (1988) undertook a separate study of internal stresses in 5-μm-thick Ni films. For three plating temperatures investigated (42°, 52° and 62°) 5-μm-thick films were found to exhibit minimal or no stress at a current density of 2 A/dm<sup>2</sup>. At 62°C, the 5-μm-thick films show no stress at 2 A/dm<sup>2</sup> and remain at a low compressive stress value of about 20 N/mm<sup>2</sup> for the whole current range (1 to 10 A/dm<sup>2</sup>). The internal stress at 2 A/dm<sup>2</sup> is minimal at a pH value between 3.5 and 4.5 of a sulfamate electrolyte (Table 17.8). Ni concentration (between 76 and 100 g/l) and wetting agent concentration do not seem to influence the internal stress. The higher the frequency of the pulse in pulse plating (see below), the smaller the internal stress.

The long-term mechanical stability of Ni LIGA structures was investigated by electromagnetic activation of Ni cantilever beams by Mohr et al. (1992). The number of stress cycles, *N*, necessary to destroy a mechanical structure depends on the stress amplitude, *S*, and is determined from fatigue curves or *S-N* curves (applied stress on the x-axis and number of cycles necessary to cause breakage on the y-axis). Experimental results show that for Ni cantilevers produced by LIGA the long-term stability reaches the range of comparable

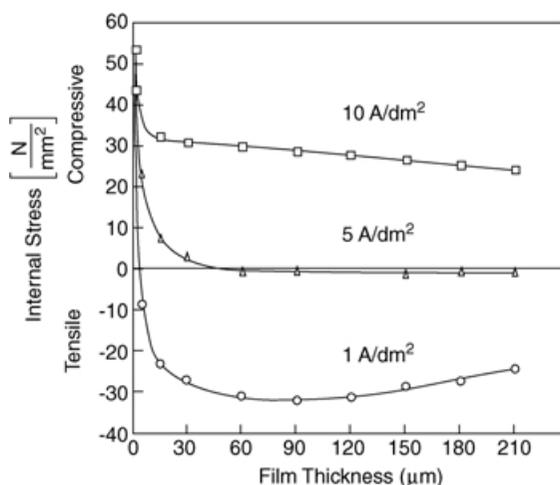

FIGURE 17.19 Influence of the nickel layer thickness on the internal stress. The electrolyte used is described in Table 17.5 (pH = 4; bath temperature = 52°C) [Harsch et al., 1998]. (Courtesy of the Karlsruhe Nuclear Research Center.)

literature data for bulk annealed and hardened nickel specimens. Usually, stress leads to crack initiation, which often starts at the surface of the structure. Since microstructures have a higher surface-to-volume ratio, one might have expected the S-N curves to differ from macroscopic structures, but so far this has not been observed. To the contrary, it seems that the smaller structures are more stable.

**Pulse Plating.** For the fabrication of microdevices with high deposition rates exceeding 120  $\mu\text{m/hr}$ , a reduction of the internal stress can occur only by raising the temperature of the bath or by using alternative electrodeposition methods. Raising of the bath temperature is not an attractive option, but using alternative electrochemical deposition techniques deserves further exploration. For example, using pulsed ( $\geq 500$  Hz) galvanic deposition instead of a DC method can be used to influence several important properties of the Ni deposit. Properties such as grain size, purity and porosity can be manipulated this way without the addition of organic additives [Harsch et al., 1988]. In pulse plating, the current pulse is characterized by three parameters: pulse current density,  $i_p$ ; pulse duration,  $t_d$ ; and pulse pause,  $t_p$ . These three independent variables determine the average current density,  $i_a$ , which is the important parameter influencing the deposit quality and is given by:

$$i_a = \frac{t_d}{t_d + t_p} * i_p \quad (17.6)$$

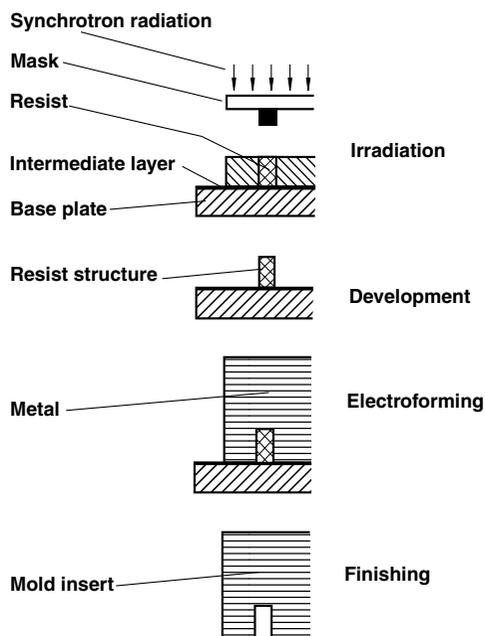

Pulse plating leads to smaller metal grain size and smaller porosity due to a higher deposition potential. Because each pulse pause allows some time for  $\text{Ni}^{2+}$  replenishment at the cathode ( $\text{Ni}^{2+}$  enrichment) and for diffusion away of undesirable reaction products which might otherwise get entrapped in the Ni deposit, a cleaner Ni deposit results. The higher frequency of the pulse leads to the smaller internal stress in the resulting metal deposit [Harsch et al., 1988].

Pulse plating represents only one of many emerging electrochemical plating techniques considered for microfabrication. For more background on techniques such as laser-enhanced plating, jet plating, laser-enhanced jet plating and ultrasonically enhanced plating, refer to the review of Romankiw and Palumbo (1987) and references therein, as well as Madou (1997, chaps. 3 and 7).

**Primary Metal Microstructure and Metal Mold Inserts.** The backside of electrodeposited microdevices attaches to the primary substrate but can be removed from the substrate if necessary. In the latter case, the substrate may be treated chemically or electrochemically to induce poor adhesion. Ideally, excellent adhesion exists between substrate and resist and poor adhesion exists between the electroplated structure and plating base. Achieving these two contradictory demands is one of the main challenges in LIGA.

Slight differences in metal layer thickness cannot be avoided in the electroforming process. Finish-grinding of the metal samples with diamond paste is used to even out microroughness and slight variations in structural height. Finally, the remaining resist is stripped out from between the metal features (see also under PMMA Stripping) and a primary metal microstructure results.

If the metal part needs to function as a mold insert, it can be left on the primary plating base or metal can be plated several millimeters beyond the front faces of the resist structures to produce a monolithic micromold (see [Figure 17.20](#)). In the latter case, to avoid damage to the mold insert when separating it from the plating base, an intermediate layer sometimes is deposited on the base plate, ensuring adhesion of the resist structures while facilitating the separation of the electroformed mold insert from its plating base. In addition, it helps to prevent burrs from forming at the front face of the mold insert as a result of underplating of the resist structures. Underplating can occur because the resist does not adhere well to the substrate, allowing electrolyte solution to penetrate between the two, or the plating solution might attack the substrate/resist interface. Finally, microcracks at the interface might contribute to underplating. Burrs are easily eliminated then by dissolving the thin auxiliary metal layer with a selective etchant, removing the mold without the need for a mechanical load. In view of the observed underplating problems it is surprising that Galhotra et al. (1996) did obtain good plating results when simply mechanically clamping the exposed and developed PMMA sheet to an Ni plating box.

**FIGURE 17.20** Fabrication of a LIGA mold insert. (From Haggmann, P. et al., *Fabrication of Microstructures with Extreme Structural Heights by Reaction Injection Molding*, presented at First Meeting of the European Polymer Federation, European Symp. on Polymeric Materials, Lyon, France, 1987. With permission.)

**Plating Automation.** An automated galvanofforming facility used by KfK is shown in [Figure 17.21](#) [GmbH, 1994]. This set-up includes provisions for on-line measurement of each electrolyte constituent in flow-through cells and concentration corrections when tolerance limits are exceeded. A computer-controlled transport system moves the individual plating racks, holding the microdevice substrates, through the process stages whereby the substrates are degreased, rinsed, pickled, electroplated and dried and are then returned to a magazine, which can accommodate up to seven racks. The facility is designed as cleanroom equipment, since contamination of the microstructures must be prevented [Maner et al., 1988]. An instrument as described here can be bought, for example, from Reinhard Kissler (the  $\mu$ GLAV 750) [GmbH, 1994]. Although this type of automation is a must for the eventual commercialization of the LIGA technique, it should be recognized that at this explanatory stage over-automatization may be counterproductive.

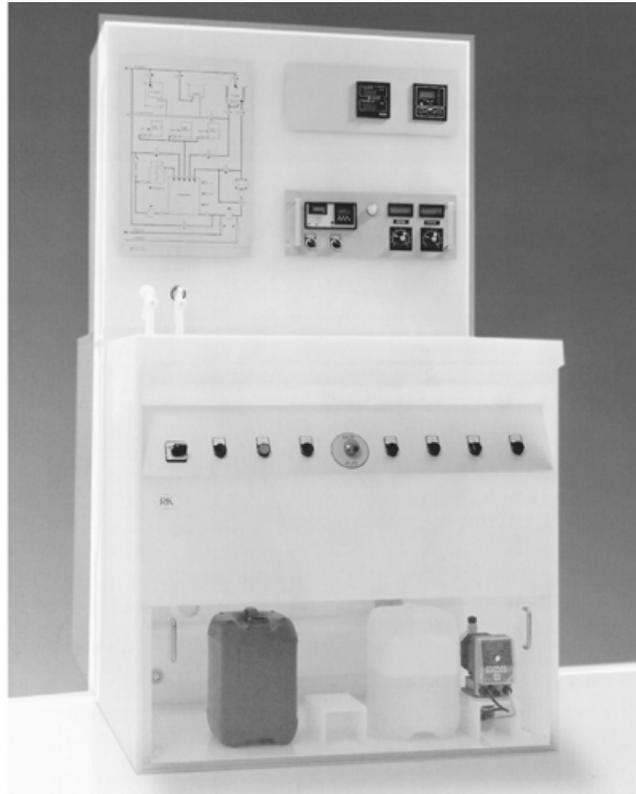

### Plating Issues

Two major sources of difficulty associated with plating of tall structures in photoresist molds are chemical and mechanical incompatibility. The chemical incompatibility means that the photoresist mask may be attacked by the plating solution, while the mechanical incompatibility is film stress in the plated layer which could cause the plated structure to lose adhesion to the substrate.

If the plating solution attacks the photoresist even slightly, considerable damage to the photoresist layer may have occurred by the time a 200- $\mu$ m-thick structure has been created. The limiting thickness of a plated structure due to a chemical interaction is therefore dependent on both the photoresist chemistry and the plating bath itself. In general, the plating bath must have a pH in the range of 3 to around 9.5 (acidic to mildly alkaline), a fairly wide range that can accommodate many of the commercially available photoresists. A surprising number of plating baths do not fall into that range though. Baths, either very strongly acidic or more than mildly alkaline, tend to attack and destroy photoresist.

The plated structure must have extremely low stress to avoid cracking or peeling during the plating process. In addition, if the structure contains narrow features, the stress must be tensile as any compressive stress would result in buckling of the structure. The primary concern with regard to stresses is the incorporation of 'brightening agents' into the plating solution. These can be selenium, arsenic, thallium and

A

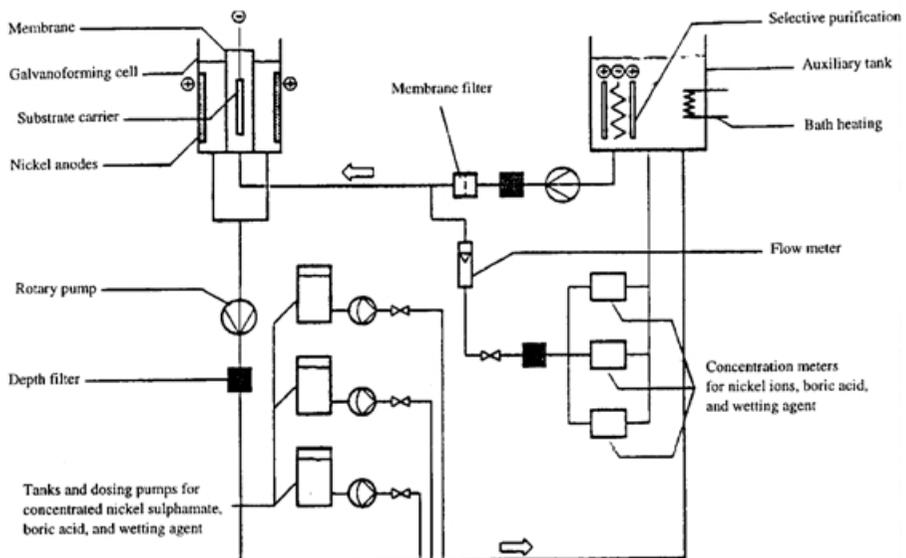

FIGURE 17.21 (A) The  $\mu$ GALV 750 comprises the galvanforming cell with nickel anodes and substrate carrier and an auxiliary tank incorporating heating and purification auxiliary equipment. Three concentration meters measure nickel ions, boric acid and the concentration of the wetting agent. The concentrations are adjusted automatically by adding via metering pumps [GmbH, 1984]. (With permission from Reinhard Kissler, GmbH, 1994.) (B) Schematic drawing of a galvanforming unit. (From Maner, A. et al., *Plating and Surf. Finishing*, 60–65, 1988. With permission.)

ammonium ions, as well as others. The brightening materials exhibit different atomic configurations and sizes compared to most materials which we would like to plate such as Cu, Au, Ni, FeNi, Pt, Ag, NiCo etc. This represents the source of a good deal of the stress intrinsic to the plating process. Ag and FeNi are notorious for their high stresses. The Ni-sulfamate bath, presently used extensively in LIGA, is used without brighteners, leading to Ni deposits with extremely low stress. Some other systems low in stress are the electroless plating baths (see section below). These auto-catalytic baths, such as Cu and Ni, coat indiscriminately, but have very low stress. They should be compatible with the LIGA process for certain applications, such as mold insert formation where significant overplating is required.

A third difficulty in finding plating baths compatible with LIGA is that most plating baths are not intended for use in the semiconductor industry. Information including normal deposition parameters, uniformity, stress, compatibility with various semiconductor processes and particulate contamination normally supplied by a vendor is not available. Since the majority of the semiconductor industry does not incorporate these kinds of “thin-film” processes, it may be difficult to determine whether a plating bath will be suitable simply from conversations with the vendor. In many instances, trial and error decide.

### ***Electroless Metal Deposition***

Electroless plating may be elected above electrodeposition due to the simplicity of the process since no special plating base is needed. This represents a major simplification for combining LIGA structures with active electronics where a plating base could short out the active electronics. Also, electroless Ni exhibits less stress than electrodeposited Ni, a fact of considerable importance in most mechanical structures. The major concern is the temperature of the electroless plating processes, which is often considerably higher than for electrochemical processes. Electroless deposition was reviewed in Madou (1997, chap. 3). Few studies of electroless plating in LIGA molds have been reported [Harsch et al., 1988]. We want to draw attention, though, to electroless plating applications with large market potential, i.e., the making of very high density read-write magnetic heads and vias and interconnects for three-dimensional ICs. It is interesting to note the similarity in traditional via plating efforts and making of magnetic read-write heads and the more recent LIGA work. Combining innovative plating techniques such as the ones pioneered by Romankiw (1984) and van der Putten and de Bakker (1993) with high-aspect-ratio LIGA molds will create many new opportunities for magnetic heads and vias and interconnects with unprecedented packing densities. Possibly, the progress made in LIGA microfabrication for these three-dimensional IC and magnetic head applications may pay off the most.

### **17.2.6.9 Summary of Electrochemical and Electroless Processes and Materials**

Figure 17.22 features a list of choices for material deposition employing electrochemical and electroless techniques [Ehrfeld, 1994]. The first metal LIGA structures consisted of nickel, copper or gold electrodeposited from suitable electrolytes [Maner, 1988]. Nickel-cobalt and nickel-iron alloys were also experimented with. A nickel-cobalt electrolyte for deposition of the corresponding alloys has been developed especially for the generation of microstructures with increased hardness (400 Vickers at 30% cobalt) and elastic limit [Harsch et al., 1991]. The nickel-iron alloys permit tuning of magnetic and thermal properties of the crafted structures [Harsch et al., 1991; Thomes et al., 1992]. From Figure 17.22 it is obvious that many more materials could be combined with LIGA molds.

Beyond the deposition of a wide variety of materials in LIGA molds, additional shaping and manipulation of the electroless or electrodeposited metals during or after deposition will bring a new degree of freedom to micromachinists. Of special interest in this respect is the ‘bevel plating’ from van der Putten and de Bakker (1993). With ‘bevel plating’ van der Putten introduced anisotropy in the electroless Ni plating process resulting in beveled Ni microstructures (see Madou [1997, chap. 7, Figure 7.10]). Combining van der Putten’s bevel plating with LIGA one can envision LIGA-produced contact leads with sharp contact points. In our own efforts we are attempting to make sharp Ni needles for use in scanning tunnelling microscopy work. A process to sharpen electrodeposited Ni posts is being developed by applying anodic potentials between an array of posts and a gate electrode, as shown in Madou (1997, chap. 1, Figure 1.8) [Madou, 1995; Akkaraju et al., 1996]. The anodic potentials force the posts to corrode in the electrolyte. Because of the concentric field

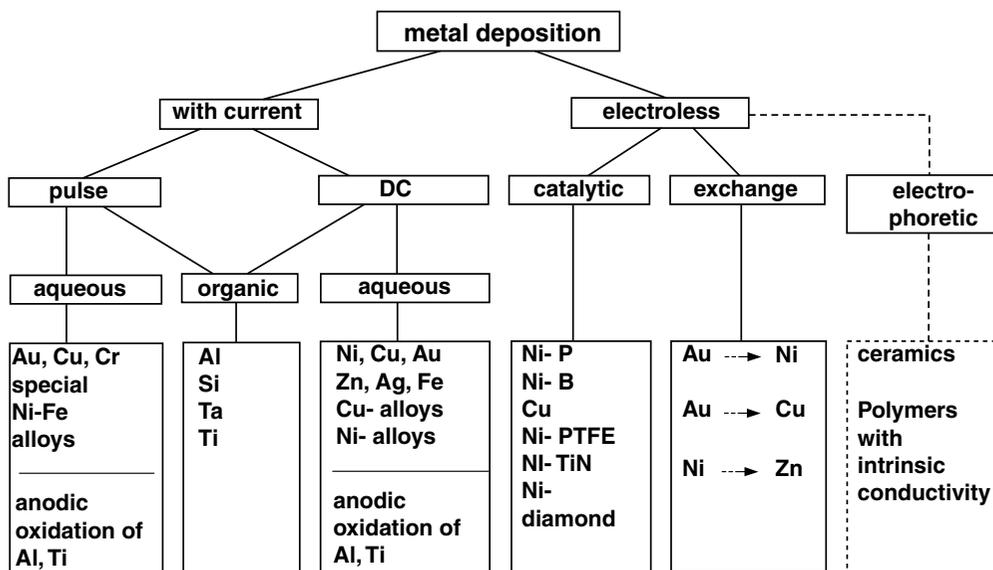

FIGURE 17.22 Processes and materials for electrochemical deposition of LIGA structures. (From Ehrfeld, W., *LIGA at IMM*, Banff, Canada, 1994. With permission.)

distribution between gate and posts, the corrosion works its way concentrically inward, leaving sharp tips. We believe that the only limitation in tip sharpness will be associated with the Ni crystal grain size which might be made very small by controlling the Ni deposition current density.

#### 17.2.6.10 PMMA Stripping

After finish grinding an electroplated LIGA work piece, a primary metal shape results from removing the photoresist by ashing in an oxygen plasma or stripping in a solvent. In the case of cross-linked PMMA, the resist is exposed again to synchrotron radiation, guaranteeing sufficient solubility before being stripped.

#### 17.2.6.11 Comparing Micromolds

LIGA PMMA features, as small as  $0.1\ \mu\text{m}$ , are replicated in the metal with almost no defects. When comparing mold inserts made by spark erosive cutting (see Madou [1997, chap. 7]) and by X-ray lithography combined with electroforming, the latter proves superior [Hagmann and Ehrfeld, 1988]. The electroformed structures have a superior surface quality with a surface roughness,  $R_{\text{max}}$  of less than  $0.02\ \mu\text{m}$  [Hagmann et al., 1987]. A significant application of LIGA might thus be the fabrication of those metal molds that cannot be accomplished with other techniques because of the tight wall roughness tolerances, small size and high aspect ratios. Discussions with classical electroforming industries might prove useful in determining the application shortcomings of their technology.

Micromolds may also be formed by such techniques as precision electro discharge machines (EDM), excimer layer ablation and e-beam writing. In Table 17.9 LIGA molds are compared with laser machined and precision engineered molds [Weber et al., 1996].

From the table it is obvious that LIGA micromolds excel both in very low surface roughness and excellent accuracy.

#### 17.2.6.12 Molding and Demolding

##### Overview

The previously described LIGA steps to produce primary PMMA structures or complementary primary metal mold inserts require intensive, slow and very costly labor. In order for LIGA to become an economically viable micromachining alternative, one needs to succeed in replicating microstructures

**TABLE 17.9** Comparison of Micromolds

Parameters	LIGA	LASER	EDM
Aspect ratio	10–50	<10	Up to 100 (related to dimensions)
Surface roughness	<50 nm	100 nm	0.3–1 μm
Accuracy	<1 μm	A few microns	Some microns
Mask needed?	Yes	No	No
Maximum height	Some microns	A few 100 μm	Microns to millimeters

From Weber, L., W. Ehrfeld, H. Freimuth, M. Lacher, H. Lehr, and P. Pech, *SPIE, Macromachining and Microfabrication Process Technology II*, Austin, Texas, 1996, pp. 156–167. With permission.

successively, in a so-called infinite loop, without having to remake the primary structures. In the plastic molding process illustrated in [Figure 17.1](#), a metal structure produced by electroforming serves as a mold insert used over and over without reverting back to X-ray exposure. For mass-produced plastic devices, one of the following molding techniques is suitable: reaction injection molding (RIM), thermoplastic injection molding and impression molding. As of the time of this writing, most of the plastic molding in LIGA has been executed in Germany with only some early efforts at CAMD in the U.S. [Galhotra et al., 1996; Rogers et al., 1996].

During reaction injection molding, the polymer components are mixed shortly before injection into the mold and the polymerization takes place in the mold itself (e.g., polyurethane and PMMA). Thermoplastic injection molding means heating the polymer above its glass transition temperature and introducing it in a more or less viscous form into the mold, where it hardens again by cooling—e.g., PVC (polyvinylchloride), PMMA and ABS (polyacrylonitrilbutadienestyrol). The pros and cons of these technologies are summarized in [Table 17.10](#). Compression molding means heating the mold material above its glass transition temperature and patterning it in vacuum by impression of the molding tool.

The high-aspect-ratio, electrodeposited metal mold inserts generate new problems compared to the molding and demolding processes for the production of records and videodiscs. Even high-aspect-ratio metal structures can be molded and demolded with polymers quite easily, as long as a polymer with a small adhesive power and rubber-elastic properties, such as silicone rubber, is used. However, rubber-like plastics have low shape stability and would not be adequate. Shape-preserving polymers, on the other hand, after hardening, require a mold with extremely smooth inner surfaces to prevent form-locking between the mold and the hardened polymer. A mold release agent may be required for demolding. Using external mold release agents may prove difficult because of the small dimensions of the microstructures to be molded, as typically they are sprayed onto the mold. Consequently, internal mold release compounds

**TABLE 17.10** A Comparison of Various Molding Techniques

	Injection Molding	Reaction Molding
Gas bubbles	Less of a problem	Reduced by evacuating the mold insert and the mold material; contributes to a high cost
Surface quality of mold insert	Less of an issue	Because of low viscosity demands on the surface quality of the mold, insert is very high
Chemicals	Easy to handle the molten plastic	Very reactive and explosive reagents
Reagent temperature (RT), form temperature (FT), and injection pressure (IP) of mold material	RT = 200°C, FT = 25°C, IP = 100 bar; temperature, time, and pressure need to be controlled very accurately	RT = 40°C FT = 70°C IP = 10–100 bar
Slow steps, cycle time	Injection time is long	Medium, with optimized release agent, 11.5 min cycle time
Viscosity of mold material	10 <sup>2</sup> –10 <sup>5</sup> Pa/sec	0.1–1 Pa/sec

need to be mixed with the polymer, without significantly changing the polymer characteristics. Given the early stage of development of molding and demolding plastic LIGA shapes in this country, we have analyzed the German plastic replication work in some detail.

### Reaction Injection Molding (RIM)

A laboratory-size reaction injection molding set-up, as shown in Figure 17.23, was used by the KfK group for their LIGA work [Hagmann and Ehrfeld, 1988]. The set-up consists of a container for mixing the various reactants, a vacuum chamber for evacuation of the mold cavity, the molding tool and a hydraulic clamping unit to open and close the vacuum chamber and the molding tool. After the vacuum chamber has been closed and evacuated, the tool is closed by the clamping unit. The mixed reagents are degassed in the materials container and, under a gas overpressure of up to 3 MPa, pushed through the opened inlet valve into the tool holding the evacuated insert mold. To compensate for shrinkage due to polymerization, an overpressure of up to 30 MPa can be applied during hardening of the casting resin. If the holding overpressure is too low, sunken spots appear in the plastic due to shrinkage of the polymer. For PMMA, the volume shrinkage is about 14%. If the mold material is not degassed and the mold cavity is not evacuated, bubbles develop in the molded piece, resulting in defects and possible partial filling of the mold. To harden the mold material and anneal material stress, the reaction injection molding machine can be operated at temperatures up to 150°C.

A variety of resins were tried to fabricate RIM products, including epoxy resins, silicone resins and acrylic resins. The most promising results are obtained with resins on a methacrylate base to which an internal mold release agent is added in order to reduce adhesion of the molded piece to the walls of the metal mold. The mold insert in the evacuated tool is covered by means of an electrically conductive perforated plate, i.e., the gate plate (Figure 17.24A). For filling the mold, injection holes are positioned above large, free spaces in the metal structure and the low-viscosity reactants fill the smaller sections laterally. After hardening of the molded polymer, a form-locking connection between the produced part and the gate plate is established at the injection holes, permitting the demolding of the part from the insert (Figure 17.24B). No damage to the mold insert is observed after up to 100 mold-demold cycles, even at the level of a scanning electron microscope picture. The secondary plastic structures formed are exact replicas of the original PMMA structures obtained after X-ray irradiation and development. If the

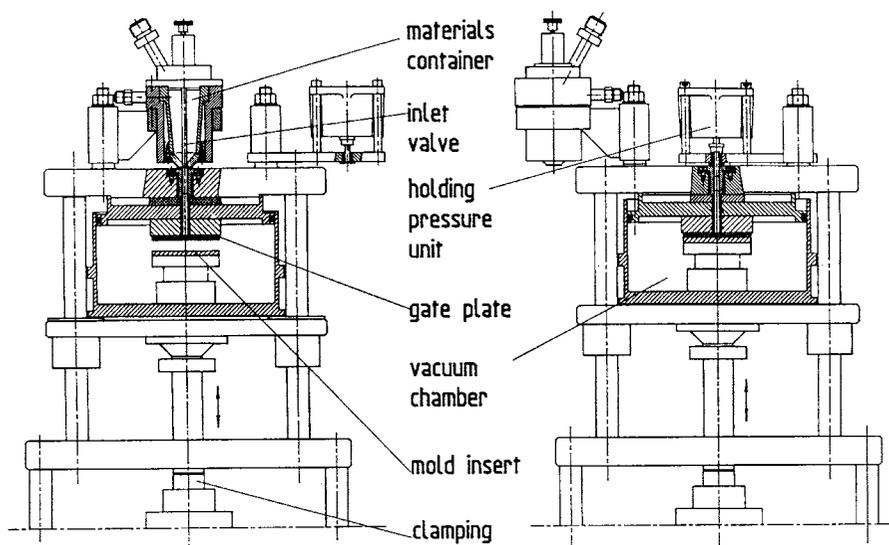

FIGURE 17.23 Schematic presentation of a vacuum molding set-up. With minor changes, this set-up can be used for reaction injection molding, thermoplastic injection molding and compression molding. (From Hagman, P.W., *J. Polymer Process. Soc.*, 4, 188–195, 1988. With permission.)

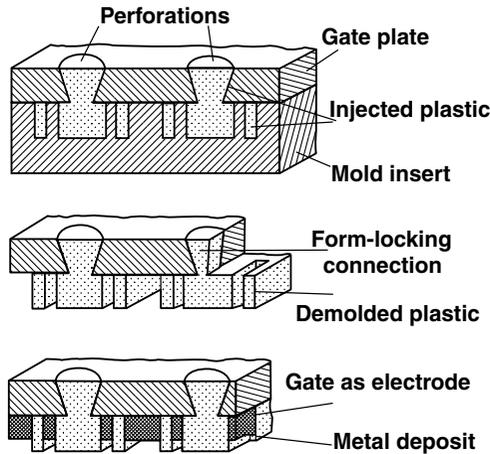

FIGURE 17.24 Molding process with a perforated gate plate. (A) Filling of the insert mold with plastic material. (B) Demolding. (C) Electrodeposition with the gate plate as plating base. (After Menz, W. and P. Bley, *Mikrosys-temtechnik fur Ingenieure*, VCH Publishers, Germany, 1993.)

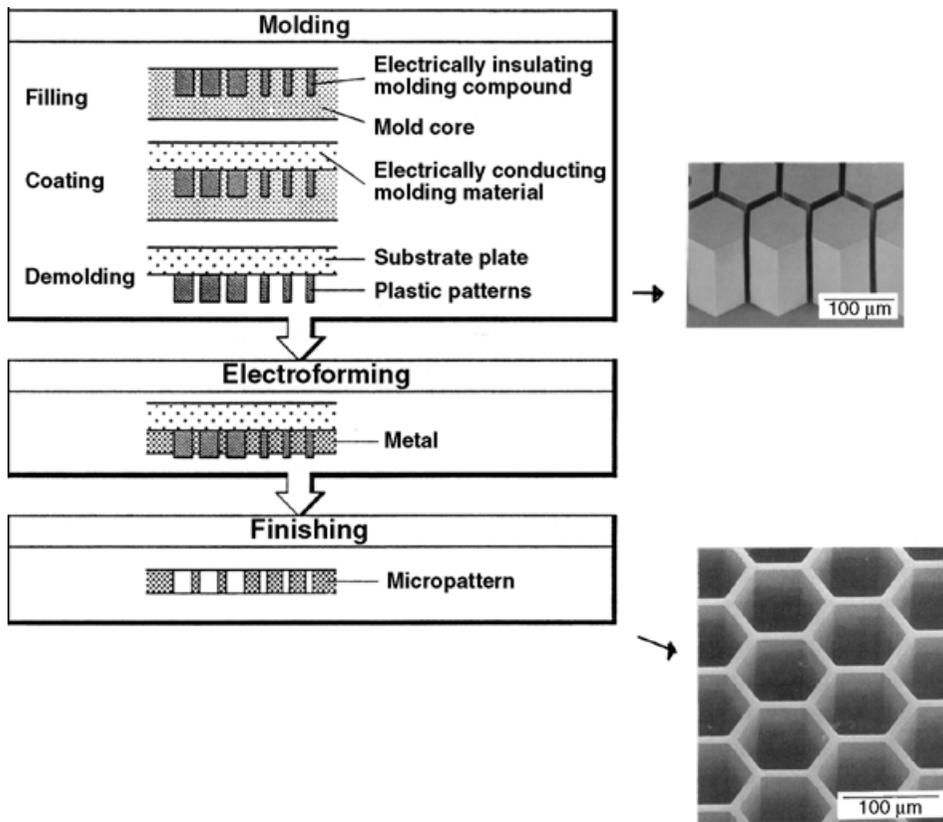

FIGURE 17.25 Ni honeycomb structure with cell diameter of  $80\ \mu\text{m}$ , wall thickness of  $8\ \mu\text{m}$ , and wall height of  $70\ \mu\text{m}$ . A structure like this could not be produced using a gate plate; a conductive plastic is used instead. The Ni plating occurs on the conductive plastic carrier pate, which is fused with the insulating plastic of the microstructure. (From Harmening, M. et al., *Makromol. Chem. Macromol. Symp.*, 50, 277–284, 1991. With permission.)

final product is plastic, the molding process can be simplified considerably by omitting the gate plate. The mold insert is then cast over with the molding polymer in a vacuum vessel, building a stable gate block over the mold insert after hardening. The polymeric gate block is used to demold the part from the insert.

The secondary plastic templates usually are not the final product but may be filled with a metal by electrodeposition as with the primary molds. In this case, the secondary plastic templates must be provided with an electrode or plating base. The gate plate can be used directly as the electrode for the deposition of metal in the secondary plastic templates (see [Figure 17.24C](#)). It is important that the mold insert is pressed tight against the gate plate so that no uniform isolating plastic film forms over the whole interface between the gate plate and the mold insert; otherwise, electrodeposition might be impossible. Safe sealing between mold insert and gate plate is achieved by use of soft-annealed aluminum gate plates into which the insert is pressed when closing the tool. It was found that the condition to be met for perfect deposition of metal does not require that the gate plate be entirely free of plastic [Hagmann and Ehrfeld, 1988]. It suffices that a number of electrical conducting points emerge from the plastic film. Transverse growth of the metal layer produced in electrodeposition allows a fault-free, continuous layer to be produced. The secondary metal microstructures are replicas of the primary metal structures and a comparison of, for example, a master separation nozzle mold insert with a secondary separation nozzle structure did not reveal any differences in quality. After the metal forming, the top surface must be polished and the plastic structures must be removed. Depending on the intended use of the secondary metal shape, one can leave it connected to the gate plate or the gate plate can be selectively dissolved or mechanically removed.

Gate plates can be applied only if the microstructures are interconnected by relatively large openings. The injection holes in the gate plate are produced by mechanical means with openings of about 1 mm in diameter and must be aligned with large openings in the mold insert. Many desirable microstructures cannot be built this way. For example, in [Figure 17.25](#) we show a Ni honeycomb structure with a cell diameter of 80  $\mu\text{m}$ , a wall thickness of 8  $\mu\text{m}$ , and a height of 70  $\mu\text{m}$  [Harmening et al., 1991]. The holes in a gate plate are too large to inject plastic into this structure and the interconnections in the honeycomb are too small to provide a good transverse movement of the polymerizing resin. Alternative approaches enabling the plating of any shape are discussed next.

**Electrically Conductive Plastic Plates as Carriers and Cathodes.** It is possible to use electrically conducting plastic as a starting layer for electrodeposition [Harmening et al., 1991]. In this process, illustrated in [Figure 17.25](#), the mold insert is filled initially with the electrically insulating, e.g., unfilled, casting resin. The surplus molding material is scraped off the front of the mold insert followed by covering of the mold insert with the electrically conducting carrier plate. While the casting resin cures, the carrier plate is forced against the front of the mold insert. In the curing process, the electrically insulating material in the honeycomb structures fuses with the carrier plate. After demolding one obtains insulating plastic structures firmly connected with the electrically conducting carrier plate. The conductive plastic is used for the electrodeposition between the insulating plastic features and, after removal of the plastic with a solvent, a plate with metal microstructures results. To achieve the desired conductivity in the plastic carrier plates one adds metal powders (e.g., copper, silver or gold) or carbon powders of an average grain diameter of less than 3  $\mu\text{m}$  to the cast resin. From the metallic powder additives, copper oxidizes too quickly, leading to a high resistivity composite material. Silver-filled resins, on the other hand, process easily and set into homogeneously conducting composites, i.e., free from bubbles and blisters. Carbon-filled resins only lead to homogeneous composite materials to a certain extent. At an Ag filler (Ag, Demetron type 6321-8000) content of 75 wt%, the PMMA attained a value of composite resistivity of  $2.4 \times 10^{-4} \Omega\text{cm}$ . The PMMA composite must also contain an internal mold release agent to make the release of the metal shapes easy (see Demolding). The addition of a demolding agent decreases the glass transition temperature ( $T_g$ ) and the temperature for the beginning of the softening process ( $T_s$ ) with respect to the values for pure PMMA, but both properties are practically independent of filler concentration. The thermal and mechanical properties of the composites are dependent on the filler content. With increasing filler content, the composite becomes stiffer, as indicated by an increasing Young's modulus and a drop of the maximum loss factor,  $\tan \delta$ , at the glass transition temperature. The coefficient of thermal expansion decreases with increase in filler content. To ensure high dimensional stability, both a high Young's modulus

and a low thermal expansion coefficient are beneficial. For uniform electrodeposition the composite material must also have a low, homogeneous resistivity. Metal deposition starts at the filler particles exposed at the surface. Those particles are connected to the bulk of the electrode by a network of conducting particles. Fault-free electroforming of patterns in the micrometer range requires a very small distance between the electrical points of contact, the starting points of electrodeposition, on the surface of the composite material. At a filler content of 75 wt%, the mean distance between the starting points of electrodeposition attained is 1.5  $\mu\text{m}$ .

The micro-pattern illustrated in [Figure 17.25](#) was made by molding electrically insulating micro-patterns of PMMA on the surface of substrate plates of PMMA filled with 75 wt% of silver. The pattern consists of a total of 74,400 single patterns on an area of 500  $\text{mm}^2$  and serves as an infrared high-pass filter [Harmening et al., 1991].

### ***Injection Molding***

Thermoplastic injection molding is the technique used to make compact discs involving features about 0.1  $\mu\text{m}$  high and minimum lateral dimensions of 0.6  $\mu\text{m}$ , i.e., an aspect ratio of 0.16. In LIGA, the aspect ratio easily can be 1000 times larger. Injection molding can work here as well, as long as the mold insert walls are kept at a uniform temperature above the glass transition temperature ( $T_g$ ) of the plastic material, so that the injected molten plastic mass does not harden prematurely. The latter requires a rather slow filling of the mold insert with the plastic mass. To be able to fill features with aspect ratios higher than 10, the temperature of the tool holding the insertion mold should be higher than what is typically used in more conventional PMMA injection molding applications. One should stay well below the PMMA melting temperature of 240°C (say, 70°C less), as the microstructure might show temperature-induced defects if one works at a temperature closer to the melting temperature [Eicher et al., 1992]. For injection molding, an apparatus very similar to the one shown in [Figure 17.23](#) can be used.

The mold insert must again have extremely smooth walls to be able to demold the structures. Walls with the required smoothness cannot be produced with a classical technique such as spark erosion. Because PMMA absorbs water in air (up to 0.3%), leading to poorer wall quality, the PMMA polymer flakes need to be dried for 4 to 6 hours at 70° before use in injection molding.

### ***Compression Molding (also Relief Printing or Hot Embossing)***

Compression molding or relief printing is the method of choice for incorporating LIGA structures on a processed Si wafer. Hot embossing takes place in a machine frame similar to that of a press. In this method, microstructures are generated by molding of a thermoplastic polymer (mold material) using a molding process as illustrated in [Figure 17.26](#). In a first step, the mold material is applied by polymerization onto the processed wafer with an electrically isolating layer and overlaid with a metal plating base ([Figure 17.26A](#)). At the glass transition temperature, the plastic is in a viscoelastic condition suitable for the impression molding step. Above this temperature (about 160°C for PMMA) the mold material is patterned in vacuum by impression with the molding tool. In order to avoid damaging the electronic circuits by contact with the molding tool, the mold material is not completely displaced during molding. A thin, electrically insulating residual layer is left between the molding tool and the plating base on the processed wafer ([Figure 17.26B](#)). The residual layer is removed by reactive ion etching (RIE) in an oxygen plasma etch ([Figure 17.26C](#)), freeing the plating base for subsequent electrodeposition. The oxygen RIE process is as anisotropic as possible, so that the sidewalls of the structures do not deteriorate and the amount of material removed from the top of the plastic microstructures is small compared to the total height. After electrodeposition on the plating base the metal microstructures are laid bare by dissolution of the mold material ([Figure 17.26D](#)). Finally, using argon sputtering or chemical etching, the plating base in between the metal microstructures is removed so that the metal parts do not short-circuit ([Figure 17.26E](#)). In the case of chemical etching, a very fast etch should be employed to avoid etching of the plating base from underneath the electrodeposited structures [Michel et al., 1993; Eicher et al., 1992].

At KfK, hot embossing is mainly used for small series production, whereas injection molding is applied to mass production. Both techniques are applied to amorphous (PMMA, PC, PSU) and semicrystalline

thermoplastics (POM, PA, PVDF, PFA). Reaction injection molding is used for molding of thermoplastics (PMMA, PA), duroplastics, (PMMA, epoxide) or elastomers (silicones) [Ruprecht et al., 1995].

### Demolding

The demolding step is carried out by means of a clamping unit at preset temperatures and rates (see Figure 17.23). Demolding is facilitated by an internal mold release agent such as PAT 665 (Wurtz GmbH, Germany), normally employed with polyester resins [Hagmann and Ehrfeld, 1988]. The optimum yield with this agent and Plexit M60 PMMA occurs at 3 to 6 wt%. The yield drops very fast below 3 wt% as adhesion between the molded piece and the mold insert becomes stronger. These adhesive forces are estimated by qualitatively determining the forces necessary to remove the plastic structures from the mold insert. An upper limit is 10 wt% where the MMA does not polymerize anymore. Above 5 wt%, the Young's modulus and, hence, the mechanical stability decrease, and above 6 wt%, pores start forming in the microstructures. The internal mold release agent also has a marked influence on the optimum demolding temperature. The demolding yield decreases quickly above 60°C for a 4 wt% PAT internal mold release agent. With 6 wt%, one can only obtain good yields at 20°C [Hagmann et al., 1987; Hagmann and Ehrfeld, 1988]. The molding process initially led to a production cycle time of 120 min. For a commercial process, much faster cycle times are needed, for instance, by optimizing the mold release agent. With that in mind, the KfK group started to work with a special salt of an organic acid leading to a 100% yield at a release agent content of 0.2 wt% only and a temperature of 40°C (at 0.05 wt% a 95% yield is still achieved). At 80°C, a 100% demolding yield was obtained and, significantly, a cycle time of 11.5 min was reached. During these experiments the mold was filled at 80°C and heated to 110°C within 7.5 min. As the curing occurs at 110°C, the material needs to be

cooled down to 80°C for demolding. Moreover, the 0.2 wt% of the ‘magic release agent’ did not impact the Young’s modulus and the glass transition temperature of Plexit M60 [Hagmann and Ehrfeld, 1988].

### 17.2.6.13 LIGA Extensions: Movable, Stepped, and Slanted Structures

Modifying the LIGA process enables movable microstructures and microstructures with different level heights, i.e., stepped and inclined sidewalls. These features often are essential for mechanical and optical devices [Mohr et al., 1992].

#### Movable Structures

As in surface micromachining (see Chapter 16), sacrificial layers make it possible to fabricate partially attached and freed metal structures in the primary mold process [Burbaum et al., 1991]. The ability to implement these features leads to assembled micromechanisms with submicron dimension accuracies, opening up many additional applications for LIGA, especially in the field of sensors and actuators. The sacrificial layer may be polyimide, silicon dioxide, polysilicon or some other metal [Guckel et al., 1991]. The sacrificial layer is patterned with photolithography and wet etching before polymerizing the resist layer over it. At KfK, a several-micron-thick titanium layer often acts as the sacrificial layer because it provides good adhesion of the polymer and it can be etched selectively against several other metals used in the process. If for exposure the X-ray mask is adjusted to the sacrificial layer, some parts of the microstructures will lie above the openings in the sacrificial layer, whereas other parts will be built up on it. These latter parts will be able to move after removal of the sacrificial layer [Mohr et al., 1990]. The fabrication of a movable LIGA structure is illustrated in Figure 17.27A.

#### Stepped Microstructures

In principle, stepped LIGA structures can be accomplished by means of X-ray lithography with a single mask with stepped absorber structures. In this manner, variable dose depositions can be achieved at the same resist heights. The variable dose results in different molecular weights and,

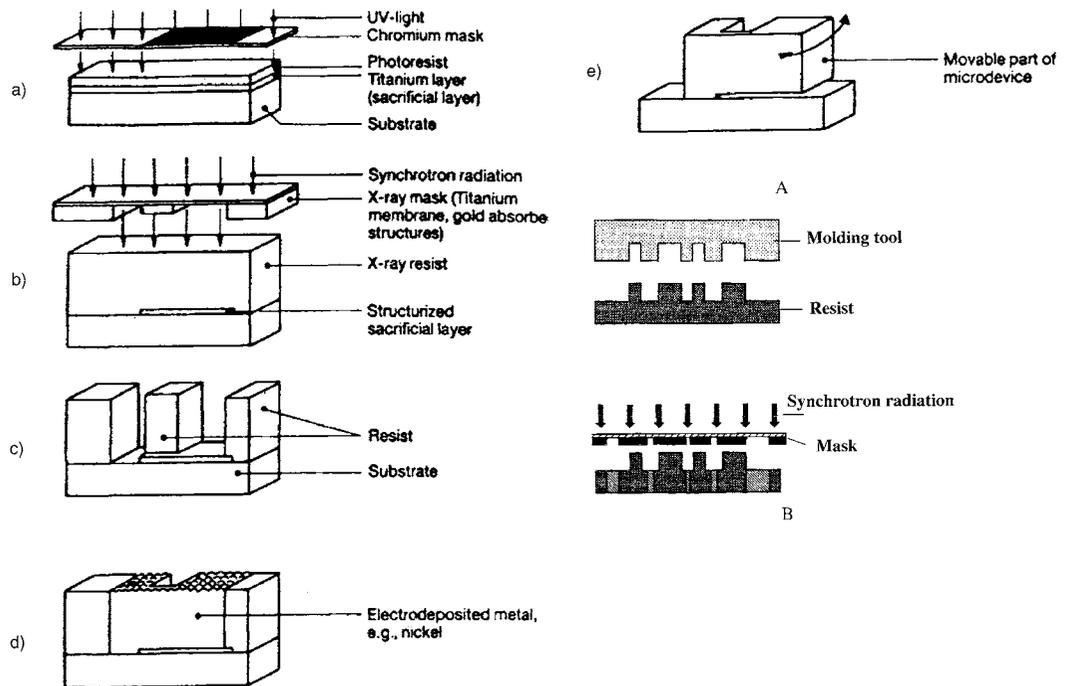

FIGURE 17.27 LIGA extensions. (A) Movable microstructures. (B) Stepped microstructures. (From Mohr et al. *Microsyst. Technol.* 90, Springer, Berlin, 1990. With permission.)

hence, in a different developing behavior. This technique unfortunately leads to rounded features and poor step-height control.

Alternatively, one can first relief print a PMMA layer, e.g., by using a Ni mold insert made from a first X-ray mask. Subsequently, the relief structure may be exposed to synchrotron radiation to further pattern the polymer layer through a precisely adjusted second X-ray mask. To carry out this process, a two-layer resist system needs to be developed consisting of a top PMMA layer which fulfills the requirement of the relief printing process, and a bottom layer which fulfills the requirements of the X-ray lithography [Harmening et al., 1992]. The bottom resist layer promotes high molecular weight and adhesion, while the top PMMA layer is of lower molecular weight and contains an internal mold-release agent. This process sequence combining plastic impression molding with X-ray lithography is illustrated in [Figure 17.27B](#). The two-step resist then facilitates the fabrication of a mold insert by electroforming, which can be used for the molding of two-step plastic structures. Extremely large structural heights can be obtained from the additive nature of the individual microstructure levels. Alternatively, to make stepped structures one can also employ multiple masks and irradiation steps. The latter method only requires one blend of PMMA resist.

### ***Slanted Microstructures***

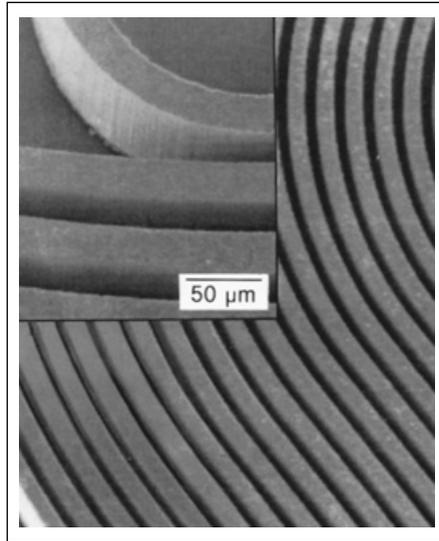

Changing the angle at which synchrotron radiation is incident upon the resist, usually  $90^\circ$ , enables the fabrication of microstructures with inclined sidewalls [Bley et al., 1991]. Slanted microstructures may be produced by a single oblique irradiation or by a swivel irradiation. One application of microstructures incorporating inclined sidewalls is the vertical coupling of light into waveguide structures using a  $45^\circ$  prism [Gottert et al., 1992]. Such optical devices must have a wall roughness of less than 50 nm. Due to the sharp decrease of the dose in the resist underneath the edge of the inclined absorber and because of the sharp decrease of the dissolution of the resist as a function of the molecular weight in the developer, usually no deviation of the inclination of the sidewall over the total height of the microstructure is found.

### **17.2.6.14 Alternative Materials in LIGA**

Alternative X-ray resist materials and a variety of other metals for electroplating besides Ni were discussed above. Following we will discuss some alternative molding materials. Besides PMMA and POM, used in a commercially available form, semicrystalline polyvinylidene fluoride (PVDF), a piezoelectric material, has been used to make polymeric microstructures [Harmening et al., 1992]. The optimum molding temperature of the PVDF was found to be  $180^\circ\text{C}$ . The PVDF structures could be molded without using mold release agents. Fluorinated polymers such as PVDF will also enable higher temperature applications than PMMA. Polycarbonate (PC), well known for molding compact discs, is under development and should perform well [Rogner et al., 1992].

Other materials that have the ability to flow or can be sintered, such as glasses and ceramics, can be incorporated in the LIGA process as well. In the case of ceramics, for example, the plastic microstructures are used as disposable or lost molds. The molds get filled with a slurry in a slip-casting process. Before sintering at high temperatures, the plastic mold and the organic slurry components are removed completely in a burnout process at lower temperatures. First results have been obtained for zirconium oxide and aluminum oxide. The process is illustrated in [Figure 17.1](#). An important application for ceramic microstructures is the fabrication of arrays of piezoceramic columns embedded in a plastic matrix. Since the performance of these actuators is linked to the height and width ratio of the individual ceramic columns, as well as the distance between the columns in the array, LIGA, with its tremendous capacity for tall, dense and high-aspect-ratio features is an ideal fabrication tool [Preu et al., 1991; Lubitz, 1989].

A very interesting method to make LIGA ceramic or glass structures in the future may be based on sol-gel technology. This technique involves relatively low temperatures and may enable LIGA products such as glass capillaries for gas chromatography (GC) or possibly even high-TC superconductor actuators. Sol-gel techniques should work well with LIGA-type molds if they are filled under a vacuum to eliminate trapped gas bubbles. In the sol-gel technique a solution is spun on a substrate which is then given an initial firing at around  $200^\circ\text{C}$ , driving off the solvent in the film. Subsequently, the

*Copper coil.* (Courtesy of IMM, Germany.)

substrate is given a high-temperature firing at 800 to 900°C to drive out the remaining solvents and crystallize the film. A major issue deals with the large shrinkage of the sol-gel films during the initial firing. For example, the maximum thickness of high-TC superconductor films currently achievable measures approximately 2  $\mu\text{m}$  due to the high stress in the film caused during shrinkage. The latter is related to the ceramic yield or the amount of ceramic in the sol-gel compared to the amount of solvent. The sol-gel technique, in general, suits the production of thicker films well, as long as high ceramic yield sol-gels are used. As LIGA-style films tend to be thick, a reduction in the amount of solvents to allow a high ceramic yield after firing would be in order to make sol-gel compatible with LIGA. This would require some development. Also lead zirconate titanate (PZT) devices could be made with sol-gel technology and LIGA, most likely by applying the metal plated structure rather than the direct PMMA template for the creation of the device, as PZT must be processed in several elevated temperature steps. The PZT sol-gel contains no particles that would prevent flow into small channels in a plated mold. The sol-gel contains high-molecular-weight polymer chains that hold the constituent metal salts, which are further processed into the final ceramic film. Thus, the sol-gel could be formed into the mold in a process much like reaction-injection molding, with the mold being filled with the chemistry under vacuum.

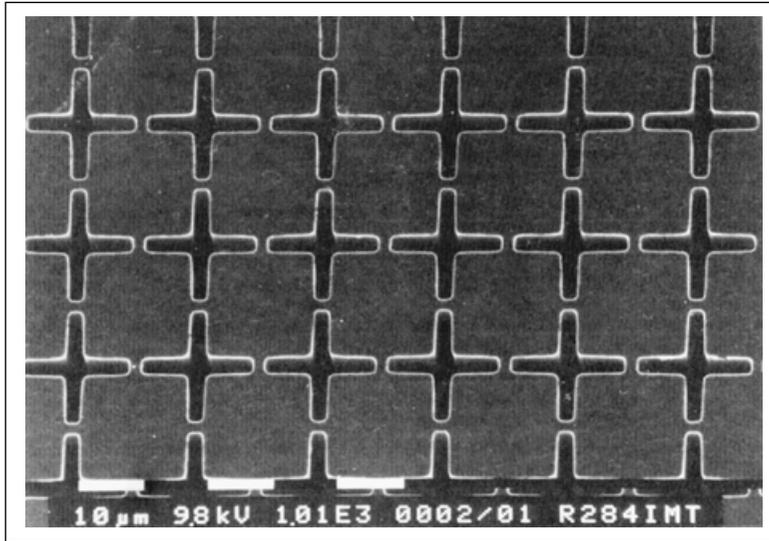

## 17.3 LIGA Applications

---

### 17.3.1 Introduction

A plethora of potential applications of LIGA have been investigated. Examples include a capacitive accelerometer, a *copper coil* for an inductive position sensor, a *resonant mesh infrared band pass filter* with a cross-shaped dipole pattern of 18.5- $\mu\text{m}$  slit length and 3- $\mu\text{m}$  slit width and a distance between two crosses of 1.5  $\mu\text{m}$ , electrical and optical interconnections, micron-sized nozzles, microfiltration membranes, spinneret plates for synthetic fiber production, microvalves, nozzles for fuel injection, ink-jet nozzles, microchannels and mixing elements. The economic and technical justification for applying LIGA for several of those applications requires further exploration. Nevertheless, these studies illustrate the potential of the method.

The following list of LIGA microstructures includes the more significant research devices realized as of this writing. The majority remain experimental and their performance cannot accurately be assessed yet, or they represent simple test structures designed to prove the feasibility of the process. Geometrical

*Resonant-mesh infrared band pass filter*—3  $\mu\text{m}$  slit width, 18.5  $\mu\text{m}$  slit length. (Courtesy of IMM, Germany.)

specifications of LIGA structures depend on the design, the fabrication process and the material. Typical values of LIGA features incorporated in the listed applications are [Rogner et al., 1992]:

- Structural height (typical): 20–500  $\mu\text{m}$
- Minimum dimension: 1–2  $\mu\text{m}$
- Smallest x, y surface detail: 0.25–0.5  $\mu\text{m}$
- Surface roughness: 0.03–0.05  $\mu\text{m}$  (max. peak to valley)
- Maximum x, y dimension: 20  $\times$  60 mm

The description of LIGA examples includes a discussion on the appropriateness of LIGA as a fabrication tool and complements the microfabrication applications discussed in Madou (1997, chap. 10).

## 17.3.2 Microfluidic Elements

### 17.3.2.1 Introduction

In fluid and gas dynamics a number of devices must have micrometer dimensions or have their efficiency and performance improved by miniaturization [Ehrfeld et al., 1987]. The impact of miniaturization in fluidics is discussed in detail in Madou (1997, chap. 9). Fluidic devices such as nozzles, valves, mixing chambers and pumps may at first glance appear good LIGA applications because both high aspect ratio and accuracy often drive the manufacturing choice. Moreover, the flexibility in the choice of materials and the wide dynamic range in size gives LIGA a significant advantage over bulk Si micromachining approaches. Surface micromachining in poly-Si does not suit microfluidics; the height of achievable structures is too low and the tendency of components to stick to each other would only be exacerbated when in contact with fluids. Fluidic devices (for example, fluidic logic devices) mostly made from photosensitive glass (see also Madou [1997, chap. 7]) reached their peak of popularity in the mid-1960s but lost out to electronic devices by the early 1970s. A new manufacturing technique will not revive fluidic logic; an approach proven noncompetitive. In the case of other fluidic devices, such as pneumatic sensors and analytical equipment incorporating fluidic elements, photosensitive glass again is an inexpensive alternative. LIGA might yet play an important role in those cases where tolerances are very tight, or extreme aspect ratios or very low wall roughness dominate. Examples include gas separation nozzles, spinneret nozzles and very sensitive flow meters.

### 17.3.2.2 Double Deflecting Gas Separation Nozzles for Uranium Enrichment

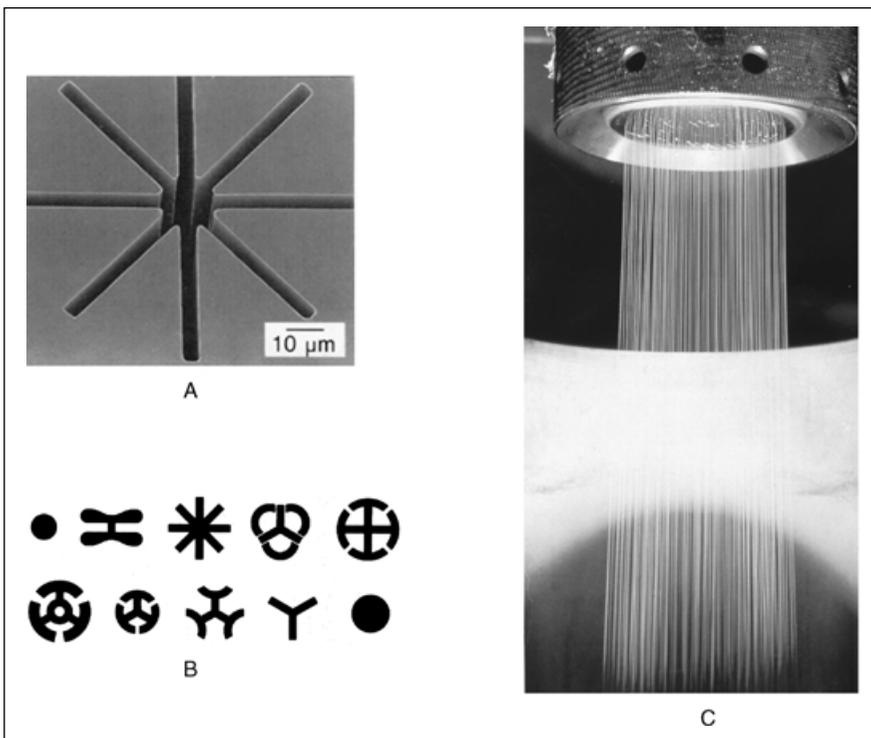

In separation nozzles, the optimum operating pressure is inversely proportional to the characteristic dimension of the flow; smaller nozzles make for an increased separation efficiency. The manufacture of tiny separation nozzles for separation of uranium isotopes at KfK [Becker et al., 1982; 1986] actually initiated the development work of LIGA (see Figure 17.2 for a picture of these micronozzles). In 1982, these nozzles were made by electroplating Ni in the primary resist structure; by 1985 they resulted from a combination of electroforming and plastic molding. The minimum slit width in the curved nozzle measures 3  $\mu\text{m}$ , and the slit length is about 300  $\mu\text{m}$ . Since a higher gas pressure results in a corresponding reduction of the compressor size and the piping system for a given throughput of a separation nozzle plant, the dimension reduction of the individual nozzles has a direct economic advantage [Ehrfeld et al., 1987].

The feasibility of the LIGA separation nozzles was demonstrated, but the parts were never implemented as government funding for the project stopped (the KfK work was carried out in Germany for the Brazilian government and the U.S. finally objected to the sale of the uranium separation system to Brazil). The accuracy and aspect ratio required for the reliable gas separation of uranium isotopes still make the gas separation nozzles one of the best demonstrations for the correct application of LIGA. No other technique can yet produce a mold insert with the required aspect ratios and tolerances (see also Spinneret Nozzles).

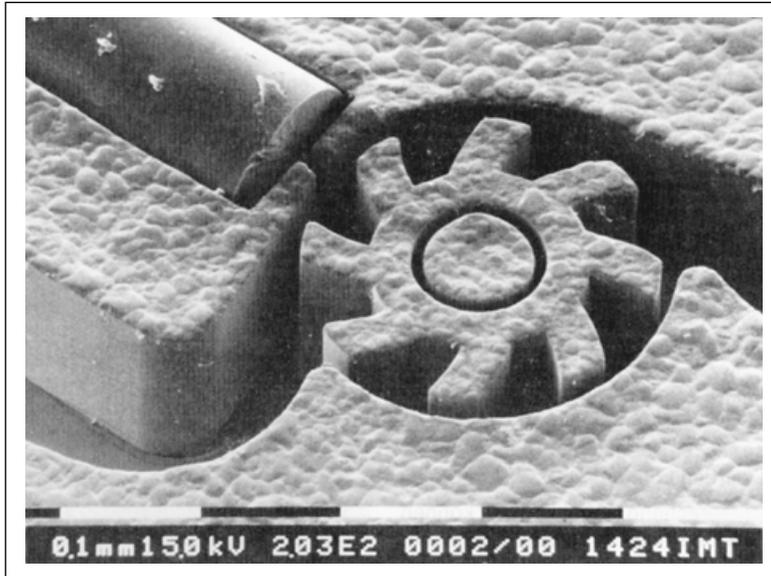

### 17.3.2.3 Spinneret Nozzles

Profiled capillaries (nozzles) in a *spinneret plate* for *spinning synthetic fibers* from a molten or dissolved polymer normally are produced by spark erosion (see Madou [1997, chap. 7]). This process establishes a practical lower limit of 20 to 50  $\mu\text{m}$  for the minimum characteristic dimension. Smaller, more precise nozzles can be produced by LIGA [Maner et al., 1987].

Spinneret nozzles lend themselves to LIGA from the technical point of view. Compared to fabrication by spark erosion, the minimum characteristic dimensions with LIGA can be reduced by an order of

(A) *Spinneret plate*; (B) *profiled spinneret nozzles*; (C) *spinning synthetic fiber*. (Courtesy of IMM, Germany.)

*Turbine rotor with integrated optical fiber.* (Courtesy KfK, Karlsruhe, Germany.)

magnitude, and a high capillary length with excellent surface finish can easily be obtained. Moreover, the LIGA process makes all the nozzles in parallel while the spark erosion operates as a serial technique. The market might focus on niche applications such as specialty, multilumen catheters. Also, medical use of atomizers for dispensing drugs is projected to increase dramatically in the coming years, this might cause a run for a wide variety of precise, inexpensive micronozzles.

#### 17.3.2.4 LIGA Turbine

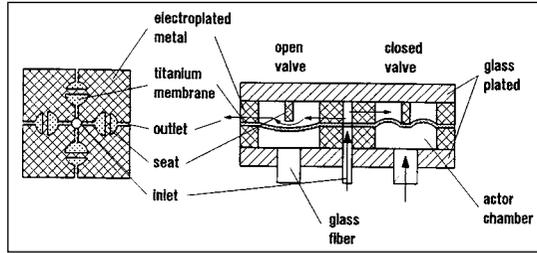

A small, released nickel *turbine rotor*, rotated by blowing gas through channels embedded in the surrounding structure, was produced using the LIGA technique. The turbine exemplifies one of the first movable LIGA structures. The axle, rotor and channels of the turbine are fabricated of plated nickel [Menz et al., 1991]. As the shaft and the gear are produced in one mask step, no alignment procedure of the finished components is necessary. Some data on the performance of the turbine were presented by Mohr et al. (1990; 1991). The maximum speed measured 2500 rotations per second, and a total of  $85 \times 10^6$  rotations on one turbine have been recorded. To make this turbine into a volumetric flow sensor requires a very tight packaging scheme. The packaging must minimize gas flow around the turbine and channel it all through the turbine. Another requirement is for very hard materials to enhance life-time. An integrated optical fiber measures rotation speed in the microturbine flow sensor. Flow rates from 10 to 50 sccm  $\text{min}^{-1}$  have been detected this way [Himmelhaus et al., 1992].

More materials-related development work is needed to further mature this application. For example, the bonding of a top layer to enclose LIGA structures is an area that still needs a good solution. In principle, flow sensors embody a good LIGA opportunity since they require both accuracy and a high aspect ratio. Improved fabrication accuracy may make for more uniformity of flow sensors from and between large batches. The high aspect ratio combined with high manufacturing accuracy will ensure more sensitive flow sensors for special applications.

#### 17.3.2.5 Microvalve

Microvalves represent one of the most eagerly pursued microdevices today, either as separate components or for integration in micromachined fluidic systems (pumps). No good solutions have been presented; valves are either too large or too expensive or they do not seal tightly enough.

Systems of *four LIGA microvalves* assembled from thin titanium membranes, an electroplated valve body in nickel or gold, and glass covers have been assembled [Schomburg et al., 1993]. The microvalves

**LIGA microvalves. Four valves connected to common inlet.** (From Schomburg et al., *J. Micromech. Microeng.*, 4, 186–191, 1994. With permission.)

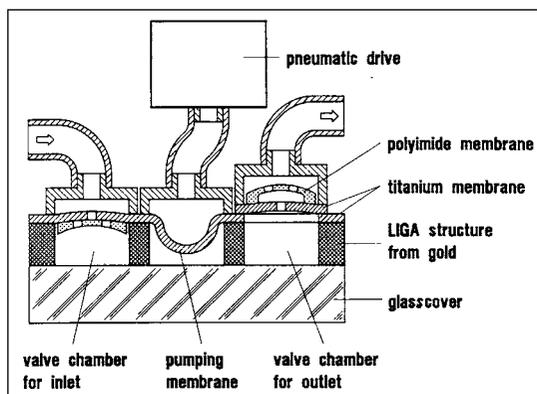

find a common support in the center of the four-valve system and can be actuated individually by an external pneumatic system. To close the flow channel, the 2.7- $\mu\text{m}$  thin titanium membrane is pressed pneumatically onto a valve seat dividing each valve chamber into two parts. If the membrane is not actuated, it is deflected off the valve seat by the pumped medium. Besides the lithography and plating of the valve body, no other LIGA steps are involved and the valve mechanism is completely traditional [Schomburg et al., 1994]. One wonders why the manufacture of the current microvalves did not follow the traditional thermoplastic molding method as in the case of the injection molded polysulfone pump discussed below.

The LIGA manufacturing technique introduced here does not improve upon the technological shortcomings of these types of valves, i.e., the high cost and poor valve sealing. Several commercially available non-LIGA micromachined valves are compared in Madou (1997, chap. 10).

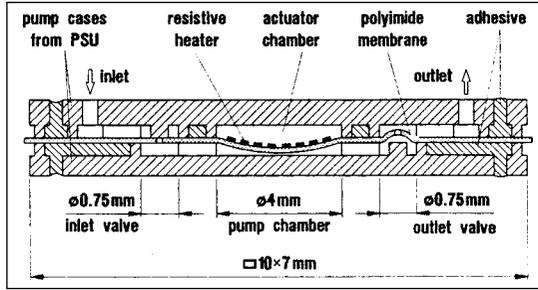

### 17.3.2.6 Micropump

For analysis and dosage of small amounts of liquids and gases, pumps capable of handling minute amounts of well-defined fluid quantities are needed. Many attempts to make such micropumps have been made but no clear solution yet stands out. Current micropumps are too expensive and, as we discussed above, do not have adequate valving systems. The following short history of LIGA pumps clearly illustrates that LIGA does not present the answer to every micromachining problem at hand.

The *first LIGA pump* for both water and air was a micromembrane pump with a case made of electroplated gold and incorporating a complex 1-mm-diameter valve consisting of a stiff titanium membrane working in tandem with a flexible polyimide membrane [Rapp et al., 1994]. The pump was manufactured by KfK using X-ray lithography to fabricate the gold pump case, photolithography for defining both the titanium and the polyimide membrane layers, and gluing on of a top glass plate. The LIGA pump was tested with an external pneumatic drive [Rapp et al., 1993; 1994]. The complexity of the first device led to the fabrication of a second *micro-pump* not involving any LIGA steps at all by the same KfK group. In this

**First LIGA pump.** (From Rapp et al., *Sensors and Actuators A*, A40, 57–61, 1994. With permission.)

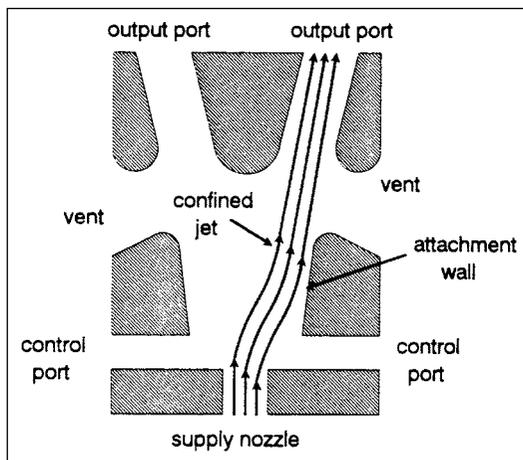

*Alternative non-LIGA pump.* (From Bustgens et al., Proceedings MEM '94, Oiso, Japan, 1994. With permission.)

case, the device was made by combining traditional thermoplastic molding with membrane techniques [Bustgens et al., 1994]. The pump case consisted of two pieces made by injection molding of polysulfone and had lateral dimensions of 7 by 10 mm. The depth and diameter of the pump chamber were 100  $\mu\text{m}$  and 4 mm, respectively, and the chamber was covered by a 2.5- $\mu\text{m}$ -thick polyimide membrane. The inlet and outlet valves were formed by orifices in the membrane positioned over a valve seat which is a part of the case. The membrane was driven in this case by an integrated thermopneumatic actuator.

The above short history of the LIGA pump demonstrates the fallacy of applying a new micromachining method to every micromachining issue without establishing a clear advantage beforehand. A new and expensive manufacturing technology should only be applied to a commercial need if it enables some new approaches (e.g., LIGA might provide much smoother valve seat surfaces to make a stronger actuator, etc.) or if it ultimately affords an old approach to be implemented more efficiently and at lower cost. In the case of the LIGA microvalves and micropumps, neither is the case and we are still struggling today to find a better, low-cost tightly closing microvalve. The micropump closest to market introduction is a bulk Si micromachined pump incorporating a piezoelectrically activated membrane developed by Debiotech (see Madou [1997, chap. 10]).

### 17.3.2.7 Fluidic Amplifiers

A LIGA *fluidic flip-flop*, also called a wall-attachment amplifier, is based on the Coanda effect. A jet emanating from a supply nozzle is attached to one of the two attachment walls. The jet can be switched from one position to the other by the temporary application of a small control pressure at the control port next to the attached jet. The jet reaching one of the two output ports builds up a pressure which

*Fluidic flip-flop.* Bistable wall attachment amplifier. (From Vollmer et al., *Sensors and Actuators A*, 43, 330–334, 1994. With permission.)

can be used, for example, to drive a microfluidic actuator. Using LIGA, bistable wall attachment amplifiers have been manufactured with heights up to 500  $\mu\text{m}$  [Vollmer et al., 1994a; 1994b].

The LIGA work from the early and mid-1990s as applied to fluidic amplifiers lacks originality. More sophisticated fluidic components providing functions such as flip-flops, logic elements such as OR-NOR gates and AND gates, proportional amplifiers and fluid resistors already existed in the 1960s. The fluidic components made in those days still provide an excellent demonstration for the capabilities of photofabrication with photosensitive glass (see Madou [1997, chap. 7] and Humphrey and Tarumoto [1965]). Humphrey and colleagues made detailed technical and economic comparisons of the different manufacturing options for fluidic elements before embarking upon photofabrication as the manufacturing choice, a practice every micromachinist should adapt. In the 1980s, Si micromachining was applied to make the same fluidic logic devices, as well as fluidic valves and analytical equipment (for a review of the more recent work, see Elwenspoek et al. [1994]). Despite these attempts, neither LIGA nor any of the Si microfluidics produced today surpass the degree of maturity achieved with the photofabrication method. The 'fluidic' logic elements could achieve many of the functions of an electronic circuit and were more robust, simpler and better able to operate in hostile environments. They reacted much slower (milliseconds instead of nanoseconds) and were larger than their electronic counterparts. The two latter factors added up to the eventual demise of microfluidics in the 1960s.

In view of the above, the use of LIGA micromachining for fluidic logic is hardly justifiable. If fluidic logic would, for some unforeseen reason, become competitive again with an electronic approach, the earlier photofabrication machining approach would still be the better approach for most applications since cost, not accuracy, is the major concern.

As demonstrated in the fabrication of some of the fluidic devices discussed so far, zero-basing the validity of a new approach to the micromanufacture of a microdevice at hand should be the first step in any micromachine design. This requires a thorough knowledge of the intended application, suppression of the urge to apply a new manufacturing tool to anything small, and a literature search stretching beyond the last 5 years. The role of LIGA in analytical instrumentation, especially equipment involving optics, may still represent an opportunity as tolerances on wall roughness and accuracy may be very stringent. Even in these latter applications, advantages over established techniques are not always self-evident.

### 17.3.2.8 Membrane Filters

A key component in all of today's filtration membranes is a microporous structure with uniform and well-defined pore sizes and a high overall porosity. Most current microfiltration membranes are characterized by a relatively broad distribution with respect to the size and position of the pores. When using membranes made by the nuclear track technique, isoporous membranes result. However, these type of filters suffer from limited porosity. The process to make LIGA membrane filters, on the other hand, allows the production of isoporous structures with a very high porosity [Becker et al., 1986]. Also, much smaller capillaries can be realized than when applying spark erosion. Since the membrane thickness may be some hundred micrometers, a high mechanical stability can be realized in combination with an extremely high transparency [Ehrfeld et al., 1988].

The porous membrane application makes a lot of sense for LIGA. This application would be of great interest, especially if we could make large sheets of the porous material in a continuous process. In principle, large primary molds could be manufactured by rolling long sheets of PMMA, in a continuous process, through the X-ray exposure zone. Table 17.11 presents a summary of the expected benefits of LIGA microfilters (MicroParts).

A *transverse flow microfilter* (cross-flow) with porous membrane built up by X-ray lithography is described in a 1989 patent by Ehrfeld et al. (U.S. Patent 4,797, 211).

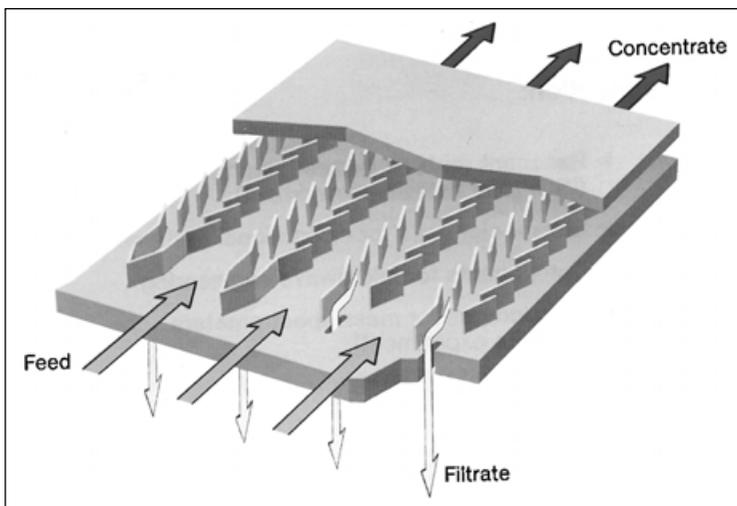

## 17.3.3 Electronic Microconnectors and Packages

The decrease in critical dimensions in ICs results in a corresponding demand for higher density electrical connections with subminiaturized dimensions. *Electrical multipin microconnectors* can be equipped with

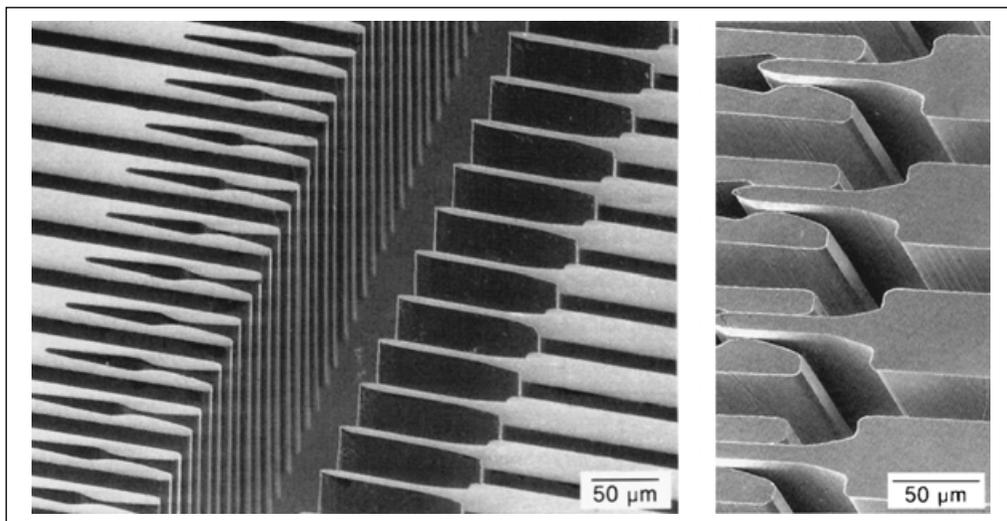

TABLE 17.11 LIGA Microfilter Characteristics

Uniform pore size	Sharp separation boundary
Extremely high porosity	High filtration flow
Designable pore shape	Optimized filtration characteristics
Constant channel cross-section	Ideal surface filter
Integrated supporting structures	High strength
Wide range of materials	Suitable for corrosive and high temperature media

*Electrical multipin microconnectors.* (From Ehrfeld, W., Proceedings, Micro System Technologies '90, Berlin, 521–528, 1990. With permission.)

precise guiding structures which allow multiple nondestructive insertions and separations [Ehrfeld, 1990]. Applications of these arrays include detachable interconnectors of high quality ICs or miniaturized multipin sensor heads [Ehrfeld, 1990]. The typical mating force of such a LIGA multipin electrical

connector is 2 and 15 cN/pin for the latching. The typical current capacity is 15 mA/pin and values up to 4 A before destruction have been observed.

Given that the required tolerances for microconnectors will become increasingly stringent, the electronic interconnect application does seem promising. Pseudo-LIGA techniques (for example, based on UV-sensitive polyimides) may prove more cost effective solutions for this application in the short run. But, further down the line, we may envision microconnectors being fabricated as part of the parallel batch IC process. LIGA with its wide dynamic range can cover the submicron dimensions of an IC as well as the millimeter dimensions of the connectors. Once the insertion point of X-ray lithography in the IC industry has become a fact, this 'integrated connector strategy' may become very important.

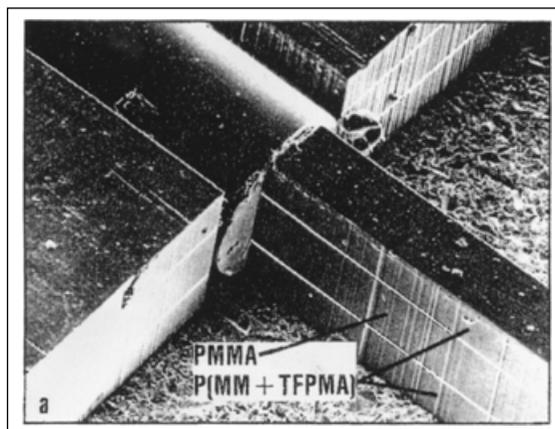

Most of the costs for producing an integrated chip relate to the package and introduction of the circuit into the package. Part of the cost differences follow from the vast difference between integrated circuit technology and packaging technology. In the future, we foresee packaging becoming more and more part of the IC process. The IC package, for example, could be replaced by a LIGA sealing wall around the edge of the chip and a seal of a metal diaphragm over the top. It may also be possible to plate completely over the top of the chip rather than sealing with a diaphragm. The leads to the chip would remain outside of the LIGA wall and the entire assembly could then be wire bonded to an inexpensive plastic package and still have the hermetic seal associated with more expensive packages. Additionally, this approach could be used for packaging of multi-chip modules. Other advantages would be built-in EMI (electromagnetic interference) protection and easy assembly of multi-chip modules, for instance, for stacking die vertically.

## 17.3.4 Micro-Optical Components

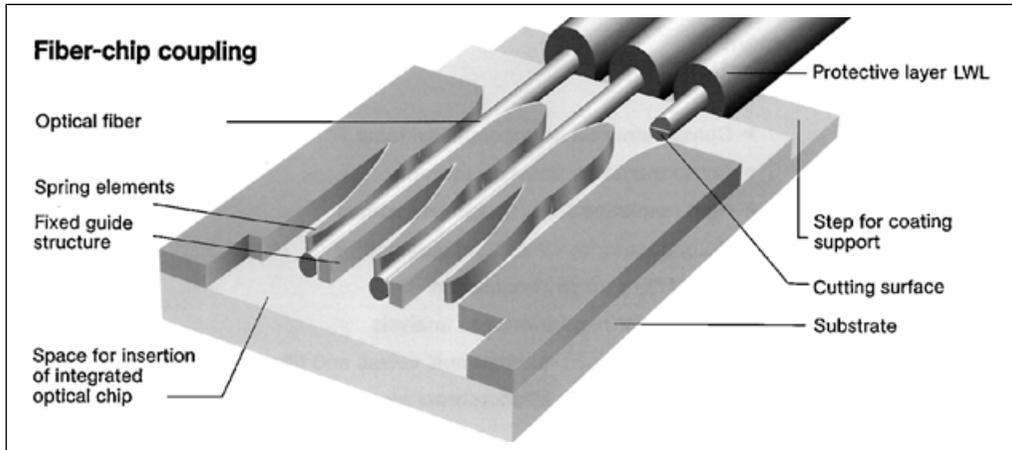

### 17.3.4.1 Introduction

Before LIGA, techniques suitable to micromanufacture micro-optical components such as prisms, lenses, beam splitters and optical couplings in a freely selectable configuration, material and structural size were hard to come by [Gottert et al., 1991]. LIGA enables the integrated fabrication of most of these components in a wide variety of materials and sizes. Micro-optics may develop into a significant LIGA application, especially for cases where cost can be overlooked. When very smooth vertical walls and high aspect ratio of the parts play a major role, LIGA may be the only available technique.

PMMA is transparent in the visible and near IR regions, making it a natural optical material. The simplest LIGA optical structure based on PMMA is a *multimode waveguide* of rectangular cross section consisting of a three-layer resist structure [Gottert et al., 1992]. To make such a planar waveguide, an epoxy phenolic resin substrate, insensitive to X-rays, is first coated with a cladding resist layer. A cladding material well-suited to X-ray patterning is a copolymer of PMMA (78%) and tetrafluoropropyl

*Multimode waveguide.* (From Gottert et al., Integrierte Optik und Mikrooptik mit Polymeren, Mainz, Germany, 1992. With permission).

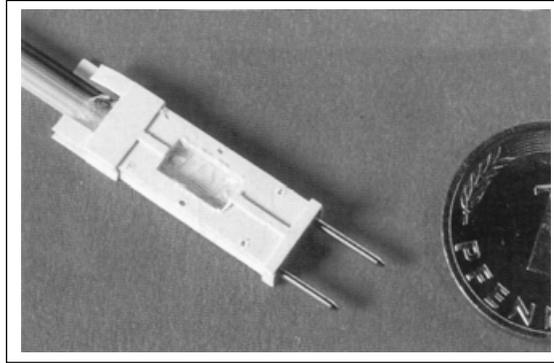

*Coupling for monomode fibers.* (Courtesy of IMM, Mainz, Germany.)

methacrylate (TFPMA) (22%) with a refractive index of 1.476. With this composition and a PMMA core layer (refractive index of 1.49), a numerical aperture of 0.2 is obtained. By varying the composition of the copolymer each refractive index between 1.49 and 1.425 can be obtained precisely, allowing the numerical aperture of the polymer waveguide to be fitted to the light-guiding fibers used to inject the light into the component. The planar cladding layer is milled down to a thickness corresponding to the thickness of a connecting optical fiber cladding. A foil of PMMA core material is then welded onto the first cladding layer and the core is milled down to the thickness of the same fiber core. Welding is performed slightly above the glass transition temperature and under pressure. The procedure causes only a small amount of interdiffusion of the two layers and a well-defined refractive index profile results; the variation of the refractive index between two successive layers takes place within an interface layer of less than 10  $\mu\text{m}$  thickness. A cover foil consisting of the same copolymer is finally welded and milled to cladding thickness on the PMMA core foil. Bulk PMMA specimens show a mean attenuation of 0.2 dB/cm in the 600- to 1300-nm wavelength range. At absorption peaks of 900 and 1180 nm, this value rises to 0.4 and 3 dB/cm, respectively. To manufacture low-loss PMMA material for the near-infrared region, deuterated PMMA may be used as a core material. This causes the absorption peak at about 900 nm, caused by C-H resonances, to be shifted to longer wavelengths. Attenuation of the deuterated material in the spectral range from 600 to 1300 nm is only about 0.1 dB/cm. For the described three-layer resist structure, the attenuation is somewhat larger than for the bulk PMMA specimens due to the relatively large roughness of the side walls of the thus fabricated waveguides and by defects in the three-resist layer [Mohr et al., 1991].

Although LIGA is producing projected features rather than three-dimensional true shapes (such as, say, in a contact lens), this technique has brought micromachinists much closer to the possible realization of a totally integrated micro-optical bench. The lithographic alignment of the separate optical components; the high, extremely smooth, vertical walls; and the excellent optical properties of one of the key LIGA resists, PMMA, all combine to propel LIGA as an ideal technique for micro-optical applications within reach of commercialization [Menz, 1995]. Micro-optical benches were attempted via polysilicon surface micromachining [Lin et al., 1995] and bulk micromachining techniques [Wolffenbuttel and Kwa, 1991]. In the former method, the very thin optical components had to be lifted from the surface and secured upright mechanically in a postfabrication assembly step (see Chapter 16). In the latter method, the proposed structures consisted of complex multi components. We suggest that given the required tolerances neither of these alternative optical benches will ever be manufactured outside a research laboratory.

#### 17.3.4.2 Fiberoptic Connectors

LIGA elements for *coupling monomode fibers* with integrated optical chips are under development. These prealignment arrays may utilize fixed nickel guiding structures in combination with leaf springs to ensure

**Pull-push LIGA connector.** (Courtesy, IMM, Mainz, Germany.)

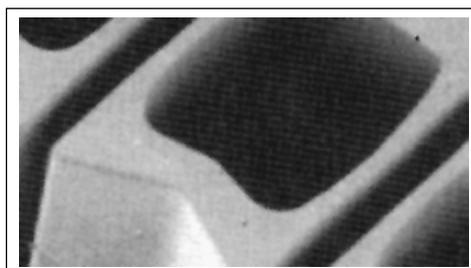

a precise alignment of the optical fibers relative to the optical chip with an accuracy in the submicron range. The thermal expansion coefficient of the substrate material is matched to the optical chip material—e.g., a glass substrate is used for coupling fibers to glass chips—and the use of spring elements simplifies the handling of the fibers [Rogner et al., 1991]. Alternatives involve the use of optical adhesives and the use of silicon V-groove arrays (see Chapter 16). Both technologies are more labor intensive and suffer from thermal expansion problems.

The use of microoptical LIGA components is especially attractive for the coupling of multimode fibers; here the capability of exact lithographic positioning of mechanical mounting supports is used advantageously to position the multimode fibers very precisely with respect to the micro-optical components without need for any additional adjusting operations [Gottert et al., 1992a; 1992b]

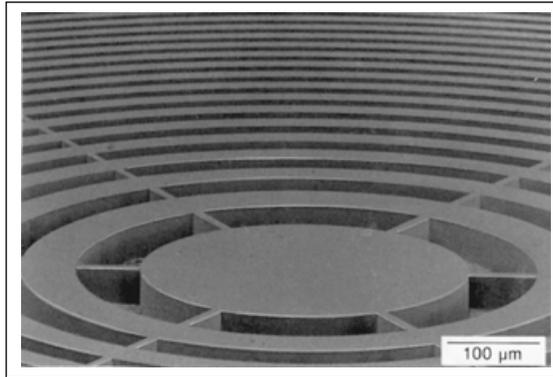

A **pull-push LIGA** connector for single-mode fiber ribbons, incorporating a set of **precision microsprings**, coupling up to 12 fibers spaced at 250  $\mu\text{m}$ , is close to commercial implementation and is one of the LIGA products with mass market appeal. To obtain good coupling efficiency, the fibers are positioned horizontally with a precision of 1  $\mu\text{m}$ . LIGA is an excellent method to provide that precision. These connectors are under development at IMM [Editorial, 1994a]. In line with the micromanufacturing philosophy presented in this book—to optimize the use of each micromachining technique for its optimum cost/performance application—those parts of the mold insert which do not require such high accuracy are fabricated using other methods of precision machining such as EDM (electro discharge machining) (see Madou [1997, chap. 7]).

#### 17.3.4.3 Fresnel Zone Plates

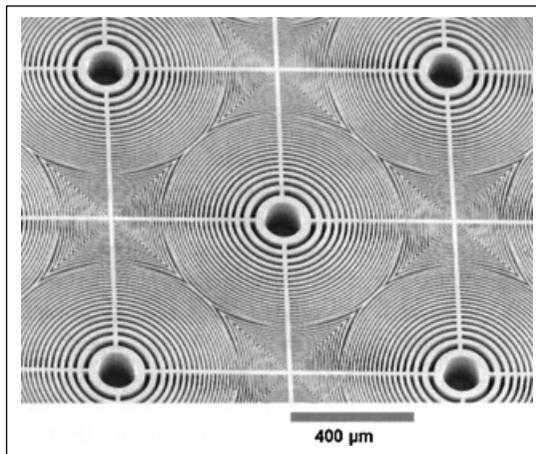

Self-supporting **Fresnel zone plates** have been made by LIGA [Munchmeyer and Ehrfeld, 1987]. One such lens was made of nickel with a distance between the rings of 74  $\mu\text{m}$  on the inner side, decreasing to 10  $\mu\text{m}$  on the external side. The width of the radial web was also 10  $\mu\text{m}$ . A **Fresnel zone plate array in PMMA** with a 10-mm focal length and a zone plate diameter of 10 mm was made as well [Editorial, 1994b]. In a similar way, self-supporting gratings or infrared polarizers might be fabricated.

#### 17.3.4.4 Planar Grating Spectrograph-Integrated Optical Bench

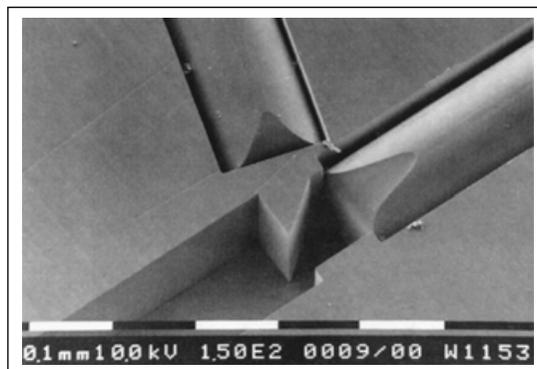

Using the above described planar polymer waveguide in combination with a self-focusing reflection grating, a *spectrometer*  $18 \times 6.4$  mm in size was developed [Anderer et al., 1988]. The polychromatic light, injected

into the waveguide by an optical fiber, is dispersed at a curved grating coated with a sputtered gold layer. The spectrally divided portions of the light are focused on ten optical fibers, or, alternatively, on an array of diodes positioned at the focal line. The intensity at the focal line is about 25% of the incoupled intensity, and the spectral resolution is 0.2 nm/ $\mu\text{m}$ . As the fiber grooves are aligned exactly to the grating, no adjustment is necessary to make the component work. The grating is designed to work in a spectral range between 720 and 900 nm and is blazed to diffract in the second order. The grating pitch (groove spacing) is 3.4  $\mu\text{m}$ , and the step of the groove is 0.5  $\mu\text{m}$  (more recently 0.25  $\mu\text{m}$  was realized), which is well within the accuracy of deep-etch X-ray lithography [Mohr et al., 1991]. Although the spectral resolution of this microspectrometer is relatively low, this type of grating can be used for optical analysis in the whole visible and near-IR-wavelength region (up to 1100 nm), e.g., for photometric analysis of gas mixtures, optical film thickness measurement and as a spectral detector in liquid chromatography [Staerk et al., 1996]. Another set of applications of the described microspectrometer is in the area of combining and separation of optical wavelengths. In this technology, signals of several different wavelengths are multiplexed on a single optical fiber. Multiplexer (MUX) and demultiplexer (DMUX) devices are required to combine and separate multichannel signals. Among the many proposed systems, the self-focusing concave reflection grating is the only one which can handle a large channel number ( $>5$ ) with good performance and without the need of additional reflecting and focusing elements [Anderer et al., 1988].

For operation at wavelengths greater than 1100 nm, air must be used as a transmission medium instead of a PMMA-based waveguide. At NASA Ames, we have embarked upon the development of a gas analysis spectrometer including the capability of CO<sub>2</sub> detection at 4.2  $\mu\text{m}$ . Instead of piping polychromatic light into the spectrometer on a multimode fiber, the intent here is to use a microfabricated heated filament integrated into the spectrometer. The microheater filament has already been realized by a combination of surface and bulk micromachining on an SOI substrate. Monochromatic light, at 4.2  $\mu\text{m}$ , will be isolated from the broad-band filament radiation by reflecting the light off a self-focusing grating and then bouncing the monochromatic light from several LIGA micromirrors in an absorption cell-type arrangement. A 10-cm light path is required for a 1-ppm CO<sub>2</sub> sensitivity, and we found that such a path length is easily designed by arranging the mirrors on a 1  $\times$  1-cm footprint. Crucial technical problems yet to be overcome are, first, the considerable self-diffraction of a small light beam at 4.2  $\mu\text{m}$  in air spreads the light spot quickly beyond the individual mirror size, and, second, the light emanating from the microfilament, fabricated in the substrate plane, must be brought from the vertical into a horizontal plane so it can be reflected off the vertical self-focusing grating and micromirrors. Finally, the integrity of the micro-optical components (e.g., reflectivity) must be preserved when exposed to a gaseous uncontrolled environment [Madou, 1997, chap. 10; Desta et al., 1995].

#### 17.3.4.5 Other Passive Optical Components

Other passive optical components that have been made using LIGA are Y-couplers [Rogner, 1992], cylindrical and prismatic lenses and beam splitters. The compact design of splitters and couplers with the light paths

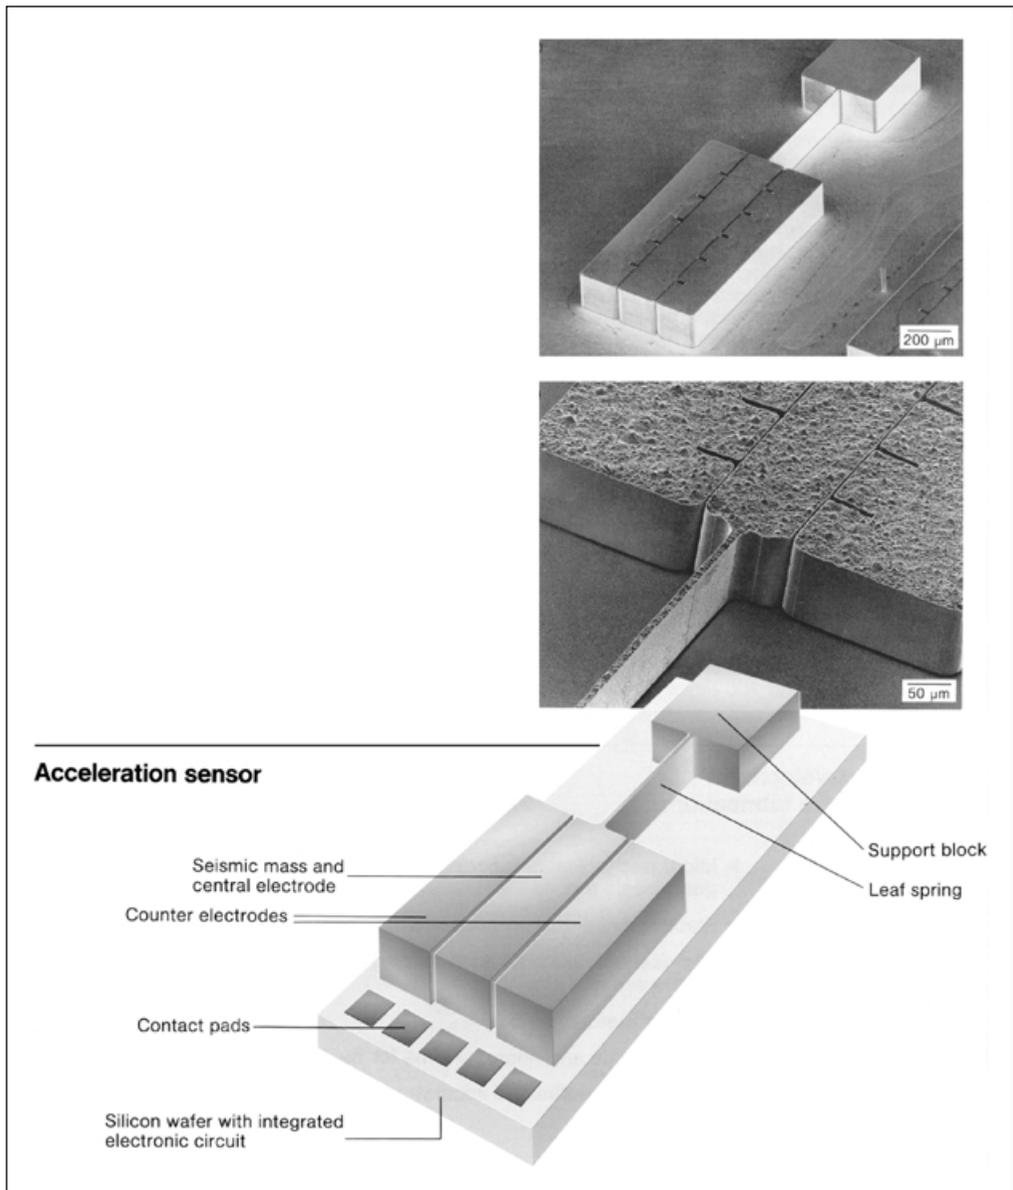

*Fiber coupling (1  $\times$  2 beam splitter).* (Courtesy, KfK, Karlsruhe, Germany.)

between two fiber ends in the range of the fiber diameter makes attenuation losses very small. For example, the excess loss of a *bidirectional fiber coupling element (1 × 2 beam splitter)* with 100/140 μm multimode fibers is less than 1 dB.

### 17.3.5 LIGA Accelerometer

The sacrificial layer technique was used to fabricate a LIGA *acceleration sensor* with a capacitive read-out. The width of the gap between stationary electrodes and a seismic mass (Ni in this case) changes when they are accelerated. The resulting change in capacity is what is measured. The advantage of a LIGA accelerometer over Si-technology is the material variety and therefore the choice of density of the seismic mass, as well as the choice of the Young's modulus of the bending beams. This flexibility could enable a

*Acceleration sensor with capacitive read-out.* (Courtesy, IMM, Mainz, Germany.)

family of accelerometers with a much wider g-range than bulk Si micromachined devices and definitely a wider range than poly-Si surface micromachined accelerometers which, due to the thin inertial mass, are limited in this respect. Also, the extreme aspect ratios attainable with LIGA bring about a better signal. The thickness of the sensor has no influence on the sensitivity, but it does affect the value of the absolute capacitance, which increases with greater thickness. A large sensor thickness also improves the stiffness of the cantilever which is advantageous to the cross-sensitivity. The width of the capacitor gap influences the sensitivity: the smaller the gap, the more sensitive the accelerometer. LIGA enables very narrow gaps and thick inertial plates. For example, the zero-point capacity given by a gap between the seismic mass and the electrodes of only 3 to 4  $\mu\text{m}$  at a structural height of 100  $\mu\text{m}$  is 0.7 pF. A sensor with this zero-point capacity was shown to have a sensitivity of 15% capacity change per g and a resonance frequency of 570 Hz. The temperature coefficient was found to be about  $0.5\% \text{ K}^{-1}$ . By optimized sensor design, the zero-point capacity and the temperature behavior can further be improved. Extremely temperature-resistant accelerometers were achieved by designing the sensor partly with a positive and partly with a negative temperature coefficient. In this way, a LIGA accelerometer for 1 g with a measured temperature coefficient of offset (TCO) of  $1.02 \times 10^{-4} \text{ g/K}$  in the temperature range  $-10$  to  $+100^\circ\text{C}$  was realized [Strohrmann et al., 1994]. For automotive applications a resonance frequency of more than 500 Hz is required, and for 1 g of acceleration the change in capacity should be larger than 20% [Burbaum et al., 1991]. In case the accelerometer is also electrostatically actuated, other benefits of using LIGA result as explained further below under electrostatic LIGA actuators.

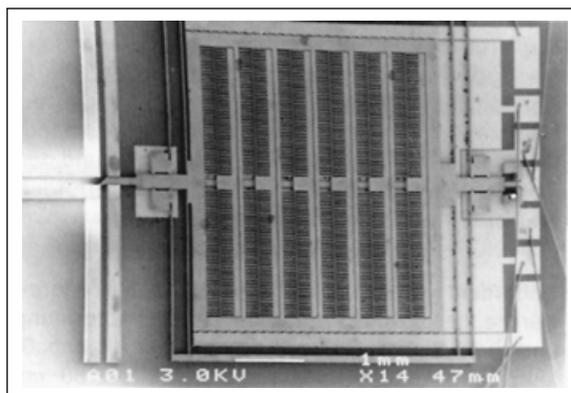

It has been shown that LIGA may be compatible with substrates containing active electronics, and in principle integrated LIGA accelerometers could represent a good business opportunity. On the other hand, there is more accessible bulk and surface micromachining technology available, which is now feeding most of the industrial needs.

### 17.3.6 Interlocking Gears

A series of interlocking gears was fabricated in one process sequence without assembly. The gears are free to rotate and could be used in watches or in audio, video and measuring technologies. The precision of the LIGA process allows the realization of gears with minimized backlash and friction [Rogner et al., 1992]. At this point, it is not clear if the accuracy demands in those different application fields really do require LIGA or if LIGA-like processes could fulfill those needs.

### 17.3.7 Electrostatic Actuators

For the fabrication of actuator elements, where free lateral patterning is required, one usually resorts to surface micromachining. With polysilicon surface micromachining, the thickness of actuator elements is usually limited to heights of a few micrometers, which is particularly disadvantageous in the case of

*Micro-optical switch with electrostatic comb-like structures.*

microactuators. This can be understood from our discussions on scaling laws in Madou (1997, chap. 9). In practical realizations, linear electrostatic microactuators often have two *comb-like structures*. By applying a voltage the movable part of the comb moves closer to the fixed part. For a rectangular design, the force and the microactuator displacement is proportional to the ratio of structure height,  $T$ , vs. separation gap,  $d$ , and the number of fingers,  $N$  (see also Madou [1997, chap. 9]):

$$F = -\frac{\epsilon_0 T V^2}{2d} N \quad (17.7)$$

An efficient comb drive can be thus achieved by designing many high comb fingers with narrow gaps. In surface micromachining, the thickness,  $T$ , is limited to about 2 to 3  $\mu\text{m}$ , whereas with LIGA several hundreds of microns are possible. Clearly, LIGA has the potential to produce better electrostatic actuators. Mohr et al. (1992) further showed that by making the comb fingers trapezoidal the maximum displacement of the interdigitated fingers can be further increased and smaller capacitor gaps are possible. For a more rigorous mathematical derivation of Eq. (17.7), we refer to the finite-element simulation of comb drives by Tang (1990). Muller and others have used LIGA electrostatic comb drives micromachined on top of a silicon wafer to fabricate micro-optical switches [Muller et al., 1993].

For better electrostatic actuators, LIGA will have to compete with surface micromachined structures on SOI wafers where the thickness of the epilayer can be much thicker than that of a poly-Si layer and where dry etching can also make good vertical walls and narrow gaps. But perhaps where ceramic actuators are involved, LIGA has a unique advantage.

### 17.3.8 LIGA Inductors

LIGA coils could find applications in inductive position or proximity sensing and all types of magnetic actuators. It is possible to achieve a high Q-factor as well as a high driving current as a result of the high aspect ratio and the high surface quality of the conductors. A very important application is to expand the work, initiated by Romankiw at IBM, to make finer and finer, batch-fabricated, thin-film magnetic recording heads (see Madou [1997, chap. 7, Figure 7.8]) [Romankiw, 1989]. Other applications of LIGA inductors are in RF oscillators or in inductive power transmission for rotating systems [Rogner et al., 1992]. Rogge et al. (1995) successfully demonstrated a fully batch-fabricated magnetic micro-actuator using a two-layer LIGA process. The contact forces at 1A for a permalloy relay made this way were well beyond those of miniaturized relays. Based on cost, only the most demanding applications such as the read-write heads might justify the use of LIGA; for most other applications LIGA-like methods will probably suffice.

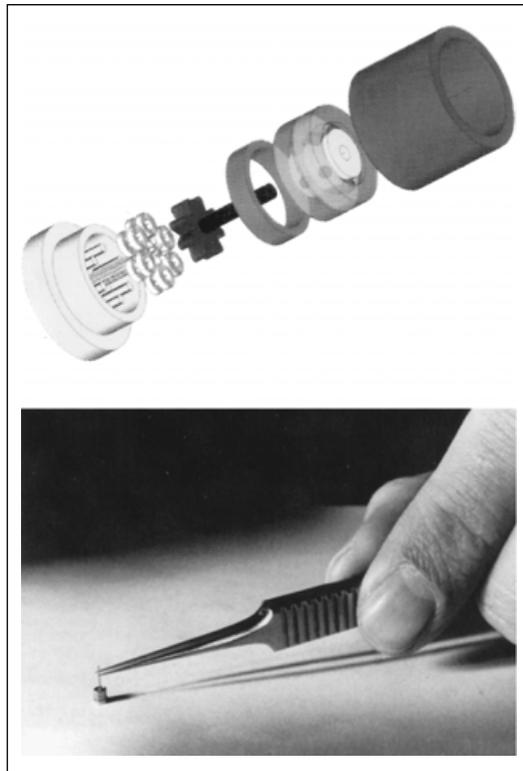

### 17.3.9 Electromagnetic Micromotor

We have shown already how LIGA makes better electrostatic actuators than other Si micromachining techniques; the same is true for electromagnetic actuators. In Madou (1997, chap. 9 on scaling laws), it is stated that most Si micromachined motors today are producing negligible amounts of torque. In practical situations, what is needed are actuators in the millimeter range delivering torques of  $10^{-6}$  to  $10^{-7}$  Nm. Such motors can be fabricated with classical precision engineering or a combination of LIGA and precision engineering.

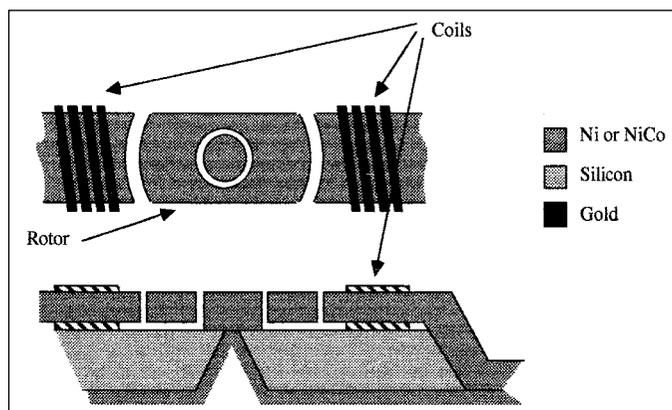

The performance with respect to torque and speed of a traditional miniature magnetic motor with a 1-mm diameter to 2-mm-long permanent magnetic rotor was demonstrated, in practice, to be incomparably better than the surface micromachined motors discussed in Chapter 16 [Goemans et al., 1993]. The small torque of the surface micromachined electrostatic motors is, to a large extent, due to the fact that they are so flat. The magnetic device made with conventional three-dimensional metal-working techniques has an expected maximum shaft torque of  $10^{-6}$  to  $10^{-7}$  Nm. The torque depends on the Maxwell shearing stress on the rotor surface integrated over the area of the latter; the longer magnetic rotor easily outstrips the flat electrostatic one with

the same rotor diameter [Goemans et al., 1993]. In both electric and magnetic microactuators, force production is proportional to changes in stored energy. The amount of force that may be generated per unit substrate area is proportional to the height of the actuator. Large-aspect-ratio structures are therefore preferred.

With LIGA techniques *large-aspect-ratio magnetic motors* can be built [Ehrfeld, 1994]. Essentially, a soft magnetic rotor follows a rotating magnetic field produced by the currents in the stator coils. The motor manufacture is an example of how micromachining and precision engineering can be complementary techniques for producing individual parts, which have to be assembled afterward. Only the components with the smallest features are produced by means of microfabrication techniques, whereas the other parts are produced by traditional precision mechanical methods.

*Large-aspect-ratio magnetic motor.* (Courtesy IMM, Mainz, Germany.)

*A LIGA-based micromotor with enveloping coils made of nickel and gold.*

A magnetic LIGA drive was also demonstrated by the Wisconsin team [Guckel et al., 1991] and consisted of a plated nickel rotor which was free to rotate about a fixed shaft. Large plated poles (stators) came close to the rotor. The rotor was turned by spinning a magnet beneath the substrate. Further work by the same group involved *enveloping coils*, to convert current to magnetic field *in situ* rather than externally [Guckel et al., 1992]. It is necessary to plate two different materials—a high-permeability material such as nickel and a good conductor such as gold—to accomplish this.

The motor can also be used as electrostatic motor. By applying voltages to the stator arms, the rotor (which is grounded through the post about which it rotates) is electrostatically attracted and, by poling the voltages, can be made to turn. Design rules and tests of electrostatic LIGA micromotors were presented by Wallrabe et al. (1994). Minimum driving voltages needed were measured to be about 60 V; optimized design torques of the order of some  $\mu\text{Nm}$  are expected. Cost of electromagnetic LIGA micromotors will often urge the investigation of LIGA-like technologies or hybrid approaches (LIGA combined with traditional machining) as more accessible and adequate machining alternatives.

### 17.3.10 Other Potential LIGA Applications

Besides the interconnect and packaging applications already mentioned, LIGA might have other applications in the microelectronics industry. Some of the circuit elements currently very expensive to fabricate on an integrated circuit could be replaced with LIGA circuit elements. The expense associated with large capacitors on an integrated circuit, for example, is due to the large amount of space they use. Shrinking capacitors to use less real estate is an area of great interest for research. A LIGA capacitor can be manufactured with tall, thin vertical plates to achieve a high capacitance without using a large amount of real estate.

An additional area of application would be the manufacture of supercapacitors, small devices with very large values of capacitance. These are used as discrete devices for a large range of applications, including the generation of extremely large current pulses (by trickle-charging the capacitor, then driving the capacitor plates together with explosive devices) for use in military equipment.

There are a number of methods for using LIGA as a means for creating much more precise and inexpensive optical components. Some possible applications, including a spectrograph for liquid and gas analysis, were mentioned already and some additional opportunities follow.

Presently, one of the largest areas for sensor research is in optical sensors. In general, an optical sensor is measuring a change in an optical property with the use of optical fibers. This change can be seen by measuring an amplitude change in light passing through or reflected off of some media or by a phase change resulting in interference patterns.

Different methods for connecting fiberoptic waveguides to sensor platforms, which can hold various chemistries or fluids or be inserted into a human body, still have not been satisfactorily developed. LIGA has a great deal of potential in this area, due to the ability to create both a fiberoptic connector and waveguide in one step. The waveguides can be of arbitrary shape, making it easy to include small cups to hold chemistries or to wrap extremely long waveguides into a small area. The number of ways which LIGA could be used for optical sensing is tremendous.

An additional item of note is that one of the limiting factors for the wide application of fiber optic sensors is the cost associated with connecting the sensor to a fiber with the required accuracy. This would not be a problem with LIGA-based sensor platforms. The optical applications of LIGA might have potential independent of developments in the IC industry as higher prices are often acceptable for precise optical components.

The use of LIGA as a method for creating on-chip waveguides would have a tremendous impact on the area of optical communication between chips. Presently, there is great interest in producing light-emitting diodes or semiconductor lasers on a silicon substrate by growing gallium arsenide (or other III-V semiconductors) directly on a silicon substrate and using this to create the light source. This source would then be used as a means of communication with the outside world, rather than electrical connections.

Coupling these light sources will require on-chip waveguides and a means for connecting the chips to optical fibers. LIGA is well suited to creating optical waveguides, as discussed above, and is an obvious and potentially inexpensive solution.

Micromanipulation is a field which is on the verge of explosive growth. The combination of techniques developed for use with integrated circuit lithography and probing completed microchips is also being applied to other areas of microelectronics—for instance, automated testing of wire bonds or failure analysis of integrated circuits.

Traditional micromanipulators are now quite large in size and movement compared to the devices they are to manipulate or probe. Not only can LIGA-based micromanipulator machines be built of extremely tiny LIGA parts, the actual microprobes can be manufactured by LIGA.

The ability to plate refractory materials such as rhenium, osmium and ruthenium would have use in the creation of incredibly precise two- and four-point probes for much higher accuracy in testing applications for integrated circuits. The relative precision with which a two- or four-point probe can test a substrate is related to how closely the probe points can be spaced. For two-point probes, the smallest spacing available is about 10  $\mu\text{m}$ , and this can only be achieved by hand assembly and grinding operations by a skilled technician. With LIGA, the probe points could easily be spaced as close as 0.5  $\mu\text{m}$ , perhaps as close as 0.2  $\mu\text{m}$ . The utility of this for probing silicon wafers during the manufacturing process would be very high.

An additional area for application would be the creation of LIGA probe cards for testing of integrated circuits. These probe cards are difficult to manufacture and expensive, and periodic realignment of the probe points is necessary due to wear and tear. A cheap, disposable LIGA probe card would be of great use for probing integrated circuit test patterns, which are increasingly complicated and decreasing remarkably in size. Many major integrated circuit manufacturers are relocating electrical test patterns into the scribe lines of silicon wafers to save on real estate. This necessitates a major size reduction in the contact pads that the probe card must contact. In the area of extremely precise probe cards, LIGA would have a definite advantage.

## 17.4 Technological Barriers and Competing Technologies

---

### 17.4.1 Insertion Point of X-Ray Lithography

The original work demonstrating the LIGA process was performed by a group of scientists led by Dr. E. W. Becker at Karlsruhe. Subsequently, a group led by Prof. Guckel replicated most of the aspects of this process and demonstrated some new technologies as well. This achievement was accomplished in a rather short amount of time, approximately 18 months. This was due to the extensive literature available on the topic (the Karlsruhe group has been very prolific in publishing on the various aspects of LIGA processing), but it also shows that LIGA is a technology which, in principle, is ready to be taken up by industry. Wider commercial acceptance of micromachining will be linked to cost/performance advantages and availability of the technique. The latter may well be dependent on the insertion point of X-ray lithography in the production of the next generation of industrial ICs. As pointed out earlier in this chapter and in Madou (1997, chap. 1), the X-ray lithography insertion point keeps on being postponed, possibly keeping LIGA a tool for the research community only.

### 17.4.2 Competing Technologies

Deep dry etching (often cryogenic) and thick UV-sensitive resists such as polyimides, AZ-4000 and SU-8 (see Madou [1997, chap. 1] and chap. 16, this book) are contenders for several of the applications for which LIGA is being promoted. With respect to dry etching, higher and higher aspect ratios are being achieved; especially when using highly anisotropic etching conditions and cryogenic cooling, remarkable results are being achieved (see Madou [1997, chap. 2]). With respect to photosensitive polyimides, 100- $\mu\text{m}$  high features can be accomplished readily, and minimum feature sizes of 2  $\mu\text{m}$  are possible (see Madou [1997, chap. 1]). Both competing techniques are more accessible than LIGA and will continue to improve, taking more opportunities away from LIGA. Like LIGA, both alternative techniques can be coupled with plating, but neither technique can yet achieve the extreme low surface roughness and vertical walls LIGA is capable of. The lesson is that more comparative studies of the different micromachining technologies should be undertaken before one is being decided upon.

Other less obvious competing technologies for LIGA-like applications are ion-beam milling, laser ablation methods and even ultra-precision machining (see Madou [1997, chap. 7]). The latter three are serial processes and rather slow, but if we are considering making a mold then these technologies might be competitive.

## 18.1 Introduction

---

Originally conceived for the fabrication of smaller microelectronic features, X-ray lithography has also proven to possess attributes of great utility in micromechanical fabrication. In contrast to the many micromachining processes that have been developed from microelectronic processing, however, X-ray-based approaches may be largely carried out independent of a tightly controlled clean-room environment. The mode of X-ray-based microfabrication most commonly used places this type of processing in the additive category where a sacrificial mold is used to define the desired structural material. As a result, this technique lends itself to a very rich and ever-expanding material base including a variety of plastics, metals and glasses, as well as ceramics and composites. The idea of using X-rays to define molds extends from the 1970s, when its precedent involved the definition of high-density coils for magnetic recording read/write heads and high-density magnetic bubble memory overlays when ultimately the use of X-rays for very large-scale integration (VLSI) lithography was initially investigated [Romankiw et al., 1970; Romankiw, 1995; Spiller et. al., 1976; Spears and Smith, 1972]. The distinction from VLSI X-ray lithography is that the mold or photoresist thickness for micromachining interests is generally much greater than 50  $\mu\text{m}$  and may be well over 1 mm. X-ray processing at these thicknesses has prompted the nomenclature *deep X-ray lithography* or DXRL-based microfabrication.

The primary utility of DXRL processing extends from its ability to precisely and accurately define a mold. Consequent component definition via mold filling is thus directly determined by mold acuity. Exceptional definition in this regard is possible with highly collimated X-rays that may be obtained via

synchrotron radiation from a storage ring. Such X-rays, in addition to possessing atomic rather than optical absorption character, thereby eliminating diffraction and standing wave effects, possess collimation on the order of 0.1 mrad. Combined with a developer that has high selectivity between unexposed and exposed photoresist, this exposure capability yields mold sidewall definition with less than 0.1  $\mu\text{m}$  run-out for several hundred micron thickness. This radical form of lithography has resulted in a new type of foundry service to provide synchrotron radiation access. In the U.S., for example, these services may be obtained from the facilities listed in Table 18.1. Many more facilities are actively engaged in this activity throughout the world.

Two distinct X-ray-based microfabrication philosophies exist. The realization that relatively thick ( $\gg 100 \mu\text{m}$ ) X-ray lithography was possible and could subsequently be applied to precision molding was first made by Ehrfeld for application to separation nozzle fabrication for uranium isotope enrichment [Becker et al., 1982; 1986; Ehrfeld et al., 1987; 1988a; 1988b]. The process was coined “LIGA,” a German acronym for the three basic processing steps of deep X-ray *lithography*, mold filling by *galvanoformung* or electroforming and injection molding replication or *abformung*. The approach defined by the LIGA process aims to become mostly independent from a synchrotron radiation X-ray exposure step by defining a master metal mold insert used to replicate numerous further plastic molds via plastic injection molding. Recently, improved storage ring access and the ability to expose multiple samples simultaneously have resulted in another option of using DXRL to form all sacrificial molds. The typical DXRL process sequence is outlined in Figure 18.1. With either case, the ultimate result is the ability to batch fabricate prismatically shaped components with nearly arbitrary in-plane geometry at thicknesses of several hundred microns to millimeters while maintaining submicron dimensional control. This result translates to 100-ppm accuracy for millimeter and submillimeter dimensions. Precision, or repeatability, is obtained by the batch nature of this lithographically based process.

The novel implications of this result are many-fold. For precision-engineered componentry, an increase in resolution is possible over such conventional machining techniques as stamping or fine blanking, or

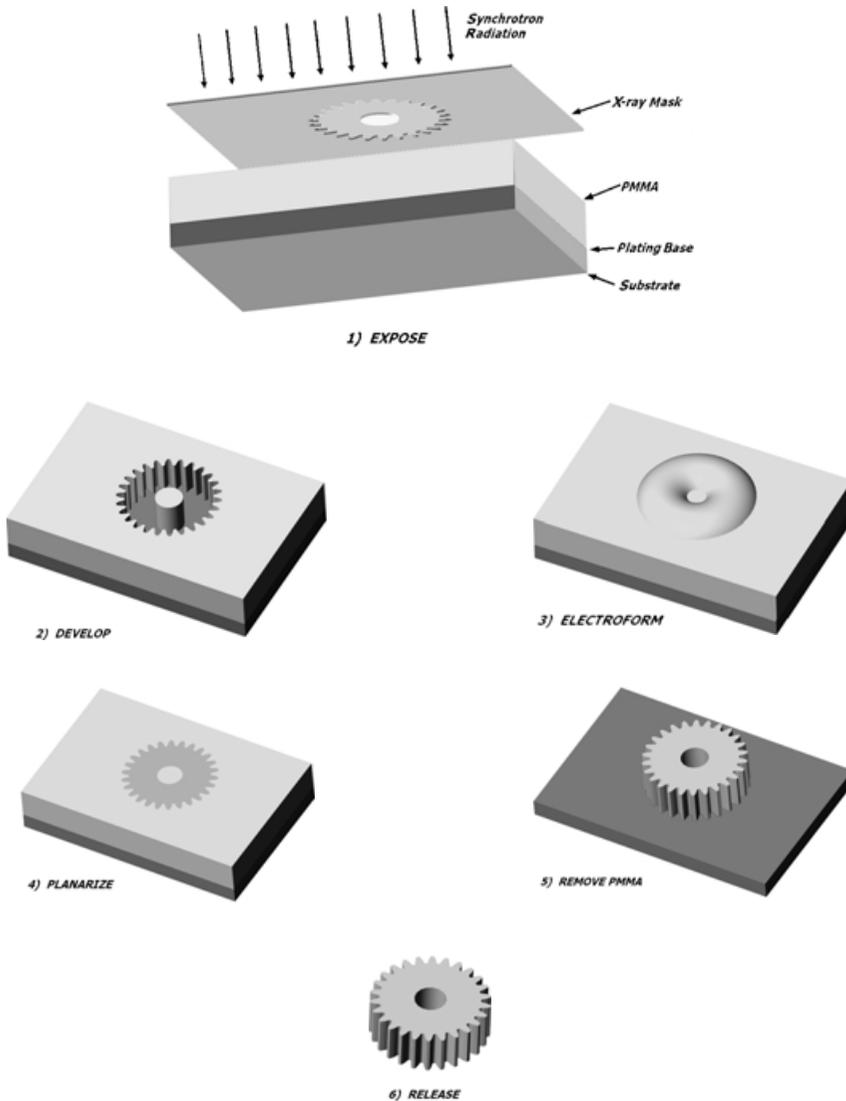

FIGURE 18.1 (Color figure follows p. 12-26.) DXRL-based (direct LIGA) microfabrication process.

electro-discharge machining (EDM), while the throughput associated with batch or parallel fabrication is acquired. Results of using DXRL-based molding for the fabrication of EDM electrodes have also shown that an arrayed type of tool may be used for batch plunge EDM of many precision parts in parallel. The conclusion is that DXRL-based processing is a tool appropriate for miniature precision piece-part component manufacture when material property requirements can be met through some additive deposition procedure or sequence of multiple molding steps. A fundamental issue for the fabrication of MEMS is the ability to batch fabricate complex three-dimensional mechanisms with appropriately scaled tolerances. The three-dimensional requirement is of particular concern for constructing microactuators where force output scales directly with the volume of stored energy as well as in micromachined sensors such as seismic sensors, for example, for the definition of inertial proof masses. Fabrication based on planar processing is immediately challenged in this regard and a so-called high-aspect-ratio (HAR) process is needed. Furthermore, the difficulty with process integration in realizing a microelectromechanical system

**TABLE 18.2** DXRL-Based Processing Attributes

Type of structural geometry accommodated	Prismatic with arbitrary two-dimensional shape and sidewall angle
Structural thickness	Commonly 200 to 800 $\mu\text{m}$ up to several millimeters (10 cm demonstrated)
Lateral run-out	<0.1 $\mu\text{m}$ per 100 $\mu\text{m}$ of vertical length
Minimum critical dimension	A few microns typical, function of photoresist stability
Surface roughness	10 to 20 nm RMS typical; as low as several nm
Thickness control	With conventional lapping: $\pm$ a few microns typical, as low as 0.5 $\mu\text{m}$ across 4-in. diameter
Materials (electroformable metals)	Ni, Cu, Au, Ag, NiFe, NiCo, NiFeCo etc.
Materials (pressed powders, embossed, hot forged)	Alumina, PZT, ferrites, NdFeB, SmCo, variety of plastics and glasses

(MEMS) is many times a result of temperature effects. Most additive mold-filling processing used in DXRL-based processing takes place at less than 100°C and is therefore appropriate for postprocessed components. By appropriately accommodating for possible semiconductor X-ray damage, the possibility of integrating microelectronics and microsensors with scaled precision metal mechanisms becomes particularly attractive.

The flexibility of the X-ray-based approach is also becoming apparent in its application to optical MEMS or micro opto electro mechanical systems (MOEMS). Exposures at arbitrary angles with the substrate are possible, and multiple-angled exposures can be accommodated, as has recently been demonstrated in photonic band gap (PBG) structure fabrication that uses three 120°-rotated exposures at 35.26° to form a diamond lattice structure [Feirtag et al., 1997a; Cuisin et al., 2000]. Table 18.2 provides a summary of DXRL processing attributes. The fundamental fabrication issues involved in DXRL processing center on X-ray mask fabrication, thick photoresist application, deep X-ray exposure and selective development. Subsequent process issues pertaining to typical device interests include mold filling, planarization, multilayer processing, assembly and mechanism construction and device integration. Applications arising from this fabrication technique are summarized in component, actuator and sensor categories.

## 18.2 DXRL Fundamentals

### 18.2.1 X-Ray Mask Fabrication

The fidelity of the X-ray mask pattern largely determines the results one will obtain with DXRL-assisted processing. There are two components to an X-ray mask: A supporting substrate or membrane with sufficient X-ray transparency is used in conjunction with an absorber layer patterned upon it. The required X-ray transmission character for the supporting mask substrate material may be found by considering the X-ray absorption behavior of the X-ray photoresist plotted in Figure 18.2 for poly(methyl methacrylate) (PMMA), the most commonly used X-ray photoresist. This plot conveys the X-ray photon energies required to practically expose a given thickness of PMMA to a dose needed to make it susceptible to dissolution by a suitable solvent, the developer. For typical DXRL layer thicknesses of 100  $\mu\text{m}$  to 1 mm, these energies range from 3.5 to 7 keV (or wavelength of from 3.5 to 1.7 Å). Possible mask substrates include Be, C and Si slices with thicknesses near 100  $\mu\text{m}$  and diamond, Si, SiC, SiN and Ti membranes with thicknesses of 1 to 2  $\mu\text{m}$  [Sekimoto et al., 1982; Visser et al., 1987; Guckel et al., 1989]. The transmission behavior for these mask substrates is plotted in Figure 18.3. What is practically desired is a mask substrate stable to large X-ray flux and with sufficient thickness or support to allow easy handling while maintaining the transmission required to readily achieve the required exposure dose, which, for PMMA, is near 3 kJ/cm<sup>3</sup>. A corresponding source of X-ray radiation is also required. The nearly ideal light source for this task is found in the synchrotron radiation (SR) that is emitted by charged-particle

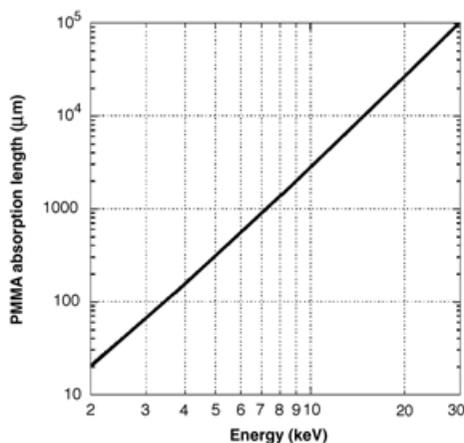

FIGURE 18.2 Absorption length of PMMA ( $C_5H_8O_2$ , density = 1.19 g/cc) as a function of X-ray photon energy.

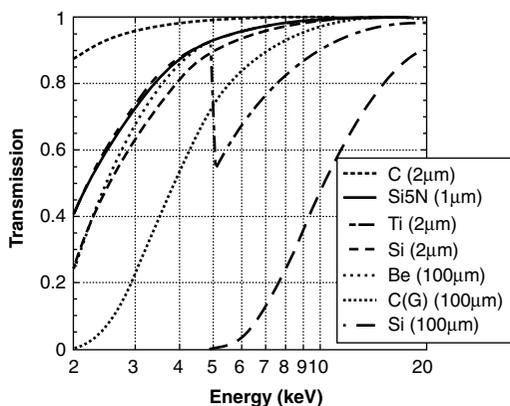

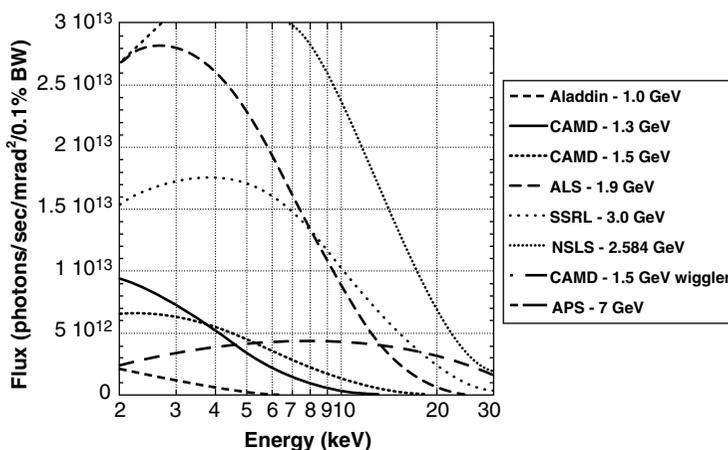

FIGURE 18.3 X-ray transmission of various X-ray mask substrates as a function of X-ray photon energy. The nonstoichiometric form of silicon nitride is a low-stress LPCVD (low-pressure chemical vapor deposition) form used in membrane fabrication. For the carbon mask at 100- $\mu\text{m}$  thickness, graphite with a density of 1.65 g/cc was used.

storage rings. The properties of this light source that result from accelerating charged particles at relativistic energies include highly intense radiation over a broad spectral range from ultraviolet (UV) to X-ray wavelengths and collimation of the order of 0.1 mrad. The SR beam is emitted in a narrow horizontal stripe of light through a vacuum line (*beamline*) extending from the storage ring, requiring the mask and photoresist combination to be scanned vertically through the beam which additionally determines a local dose rate in the photoresist. The SR spectra are plotted in Figure 18.4 for U.S. synchrotron radiation facilities. Frequently used SR equations are listed in Table 18.3 [Margaritondo, 1988]. Low-energy ( $<2$  keV) flux creates thermal problems generated by a locally peaked dose at the surface of the photoresist, requiring a filter to limit this dose to a value that avoids eventual photoresist damage found to occur in PMMA near a dose of  $20 \text{ kJ/cm}^3$  [Ehrfeld et al., 1988b]. Filtering is achieved with slices of lower atomic number materials inserted in the SR beamline, including a window that vacuum-isolates the storage ring from the exposure beamline. Thus, a mask substrate material with high thermal conductance is desired to assist in heat dissipation due to absorbed radiation by the mask substrate and absorber. The data in Figures 18.3 and 18.4 suggest that Be and C in the form of graphite can be used as X-ray mask substrates

**TABLE 18.3** Frequently Used Synchrotron Radiation Formulas

Wavelength/energy conversion	$\lambda(\text{\AA}) = \frac{12398.5}{h\nu(\text{eV})}$
Bending magnet radius	$\rho(m) \cong \frac{3.336E(\text{GeV})}{B(\text{T})}$
Critical wavelength	$\lambda_c(\text{\AA}) \cong \frac{18.64}{B(\text{T})E^2(\text{GeV})}$

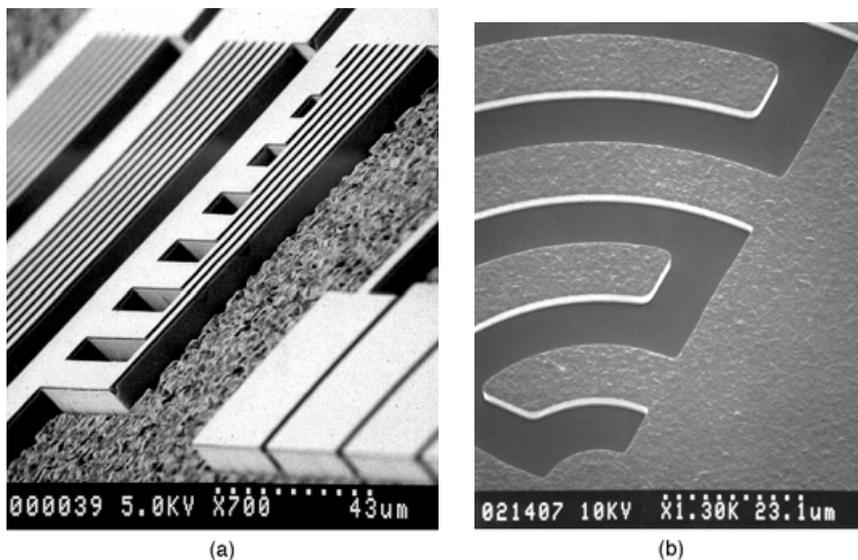

Note:  $h = 4.136(10)^{-15}$  eVs;  $\nu$  = frequency;  $E$  = energy of circulating charge particle;  $B$  = bending magnet field.

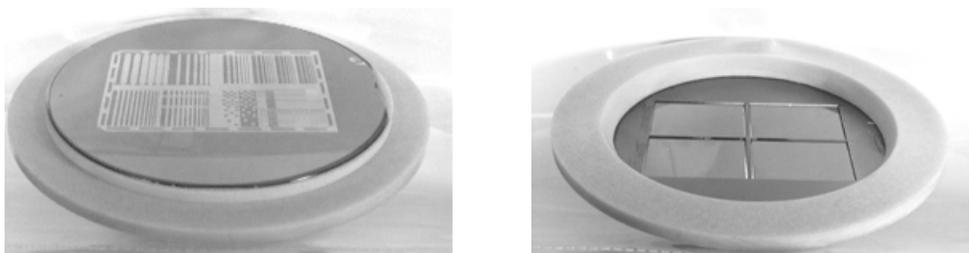

**FIGURE 18.4** Synchrotron radiation spectra for U.S. storage rings listed in Table 18.1. The spectral curve for the APS source which has a peak flux near  $1(10)^{14}$  photons/sec/mrad<sup>2</sup>/0.1 %BW at 16 keV does not appear on the graph.

at thicknesses of 100  $\mu\text{m}$  for all SR sources. The cost and hazards associated with Be processing make it less attractive, however, and graphite has proven to be a convenient mask material, particularly when its surface is treated in a manner that decreases roughness due to bulk porosity, thereby facilitating accurate lithography. Filling the porosity via a pyrolytic carbon coating, for example, and then subsequently polishing this surface layer may accomplish this.

Requirements for the X-ray absorber are set by the minimum required exposure contrast that may be defined as the exposure dose at the PMMA bottom surface in the mask transmission areas divided by the exposure dose delivered to the PMMA top surface under the absorber regions. Mask contrast is a function of the X-ray source, mask substrate and mask absorber and exposed photoresist thickness. The results reveal two categories of X-ray masks. One X-ray mask type is particularly well suited for low-energy exposures of PMMA up to several hundred micron thicknesses and requires a mask substrate with high transmission of flux near 4 keV such as membranes that are one to a few microns thick of strain-controlled silicon nitride, silicon carbide or silicon. Atomic number and density determine the figure of merit for an absorber material. Thus, materials such as platinum, tantalum, tungsten and gold are chosen, with gold being most prevalent as it is readily electroplated. The corresponding absorber for the low-energy mask is several microns of gold. For accurate dimensional control, this again leads to an additive technique in which a photoresist several micron thick is defined, usually via a UV optical microlithographic mask transfer, to provide for through-mask electroplating of gold. Vertical sidewall photoresist pattern transfer is essential to maintain accurate X-ray exposure definition, as an absorber sidewall taper leads to a sidewall taper that is X-ray exposed and developed and is the result of an insufficient absorber thickness. To achieve vertical photoresist patterns, a bi-layer deep UV (DUV) photoresist technique using spun-on PMMA has been implemented that takes advantage of the highly

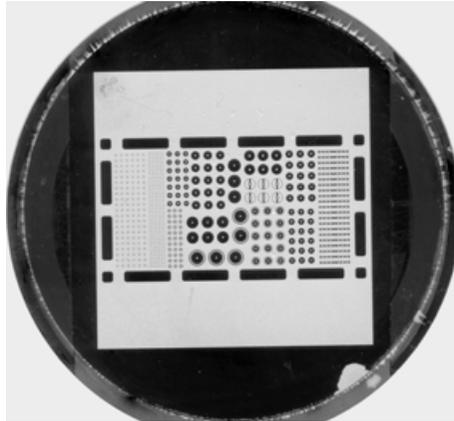

**FIGURE 18.5** (a) PMMA 8- $\mu\text{m}$  thick patterned with a conformal portable mask (CPM) or bi-layer process. A flood deep-UV source exposes the PMMA that was subsequently developed using G-G developing solution. (b) Resulting 6- $\mu\text{m}$ -thick gold absorber pattern after PMMA stripping.

**FIGURE 18.6** Frontside and backside view of 1- $\mu\text{m}$  thick silicon nitride membrane X-ray mask 5  $\times$  7 cm in area supported by a 4-in.-diameter silicon wafer with 8- $\mu\text{m}$ -thick patterned and electroplated gold absorber layer.

selective developing system used with DXRL PMMA exposures [Lin, 1975; Guckel et al., 1990]. Use of a bi-layer or CPM (conformal portable mask) technique minimizes out-gassing during exposure that is of particular concern for membrane contact lithography, whereby mask–membrane separation may consequently arise. A result is shown in Figure 18.5a, which reveals the vertical sidewalls of an 8- $\mu\text{m}$  thick PMMA layer. Subsequent gold electroplating and photoresist removal yields an absorber structure such as shown in Figure 18.5b. A number of recent commercial photoresist additions have also proven to be suitable for low-energy X-ray mask absorber definition, including Shipley SJR5740 and 220 developed for through-mask electroplating applications for magnetic read/write heads [Romankiw, 1995]. Thicker UV exposed photoresists have also been applied to through-mask plating for less critical applications [Allen, 1993; Loechel and Maciossek, 1995; Despont et al., 1997]. Figure 18.6 shows a typical membrane-type, low-energy X-ray mask.

Exposures of PMMA thicknesses of millimeters to over 1 cm entail substantially different X-ray masks. These exposures involve X-ray photon energies over 10 keV, and for sufficient contrast they require gold absorber thicknesses over 20  $\mu\text{m}$ . Because of the difficulty in precisely patterning this thickness of photoresist to submicron tolerances with UV lithography, a two-step mask fabrication sequence is commonly employed. Consequently, a low-energy X-ray mask with 2  $\mu\text{m}$  gold absorber is used to pattern

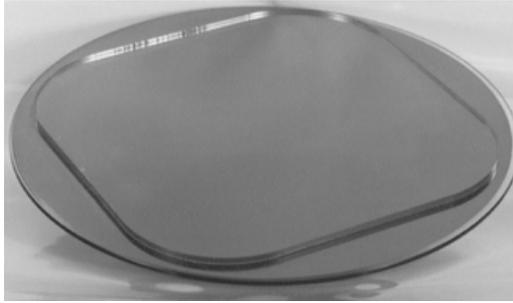

**FIGURE 18.7** X-ray mask patterned on a 3-in.-diameter graphite support 100  $\mu\text{m}$  thick with 20- $\mu\text{m}$ -thick gold absorber pattern.

several tens of microns of PMMA directly upon the high-energy X-ray mask substrate. Necessary soft X-ray filtering may then be transferred to the X-ray mask substrate due to the increased amount of filtering of softer X-rays required to maintain low surface doses with higher energy storage-ring spectra. Thus, the high-energy mask substrate may be a relatively thick layer of low Z material, such as 100- $\mu\text{m}$  thick silicon. Water cooling of the X-ray mask and exposure substrate also becomes a necessity with higher energy exposures due to an increased overall delivered power during exposure.

A mask manufacturability issue is evident which relates to the constraints of using a membrane-based, low-energy mask to achieve high-energy exposures. [Figure 18.3](#) reveals that carbon as graphite at 100- $\mu\text{m}$  thickness may serve both roles. The importance of graphite is apparent, as it possesses the qualities of being an inexpensive rugged mask substrate capable of being practically used for low- and high-energy DXRL exposures, having good thermal conductivity, and avoiding the hazards and expense of beryllium and other low-Z compounds and their associated processing. A carbon X-ray mask is depicted in [Figure 18.7](#).

### 18.2.2 Thick X-Ray Photoresist

High-aspect-ratio processing, as with many MEMS technologies, is particularly sensitive to internal and process-induced strain, as well as adhesion issues. The control of these two areas substantially determines DXRL-based manufacturability. The major issue of process stability in this regard concerns realization of thick, stress-free photoresist application with exceptional adherence to a metallized substrate for electrolytic deposition or other substrate material to facilitate further processing. The difficulty that arises in most photoresist application methods is avoiding large internal tensile stress, which can lead to crazing during development and subsequent processing. A number of X-ray photoresist materials suitable for thick application have been examined [Ehrfeld et al., 1997]. Because it possesses relatively good mechanical stability and uniquely high resolution, PMMA has been the primary X-ray photoresist of use. The application procedure initially conceived uses direct polymerization with a casting resin [Mohr et al., 1988]. A crosslinking agent is typically added in the process to further increase the yield strength, thereby providing additional resistance to crazing. To improve adhesion to a metallized substrate, an adhesion-promoting chemistry or intermediate layer may be used [Khan Malek et al., 1998; DeCarlo et al., 1998]. The volume contraction of 20%, resulting during polymerization, leads to a tensile-stressed film which may be partially alleviated with annealing but cannot be completely removed due to thermal mismatch with typical substrate materials that have lower thermal expansion coefficients. The consequences of residual photoresist stress are component geometry design rule constraints and limits on processing procedures.

**FIGURE 18.8** Bonded 1.5-mm-thick PMMA on 4-in.-diameter substrate.

An alternative approach makes use of precast, low-stress PMMA sheets [Guckel et al., 1996a]. In this method, a linear high-molecular-weight or crosslinked PMMA sheet is used to obtain PMMA plate cut-outs commensurate with a particular substrate geometry. Typical sheet thicknesses range from 500  $\mu\text{m}$  to 1 cm. A bonding technique providing for attachment of these sheet cut-outs to a metallized substrate without a significant temperature variation or induced chemical or mechanical perturbation is then implemented. A well-proven technique uses a thin prespun layer of high-molecular-weight (>1 million) PMMA combined with the use of the monomer, methyl methacrylate (MMA), as the bonding solvent. A plate of PMMA is placed on the desired substrate with a spun PMMA layer typically 1  $\mu\text{m}$  thick, and MMA is applied between the PMMA surfaces and wets the interface via capillary action. Because the diffusion of MMA through PMMA is extremely rapid even at room temperatures, curing may take place without a bake-out at elevated temperature. Figure 18.8 shows an example of the result, which is a highly repeatable procedure for obtaining thick low-stress PMMA films with arbitrary thickness. The bonded sheet may additionally be thinned via precision milling or flycutting. Use of a linear PMMA polymer allows dissolution of the PMMA subsequent to mold filling with a solvent such as methylene chloride.

The polymerization of organic vapors in a glow discharge is another method used to produce thin polymer films [Goodman, 1960; Biederman, 1987]. The use of MMA, in particular, has been studied for use as a plasma-deposited photoresist [Morita et al., 1980; Guckel et al., 1988]. The result is a highly conformal deposited film able to uniformly fill deep trenches with excellent adhesion to semiconductor materials. The plasma-polymerized MMA (PPMMA) film is highly crosslinked and has a stability dependence on reactor pressure, power and temperature. Practically, deposition rates as high as 140  $\text{\AA}/\text{min}$  may be achieved, and films as thick as 10  $\mu\text{m}$  have been deposited. Increased power levels result in further decomposition of MMA and films less like PMMA.

Another interesting X-ray resist candidate is provided by the negative-working SU-8 epoxy-based photoresist more typically used for e-beam or thick near-UV lithography [Lee et al., 1995; Khan Malek, 1998]. The resist is based on the EPON<sup>®</sup> resin SU-8 from Shell Chemical which possesses excellent high-temperature stability with a glass transition temperature of more than 200°C when crosslinked [Shaw et al., 1997]. This property is due to a high epoxide group functionality (with an average near eight) that also leads to an exceptionally high sensitivity as a photoresist. Deep X-ray lithography results indicate a sensitivity near 52  $\text{J}/\text{cm}^3$  [Bogdanov and Peredkov, 2000] or roughly 40 times greater than PMMA. The resulting crosslinked epoxy also possesses a high optical refractive index near 1.65 but is difficult to chemically dissolve in this state.

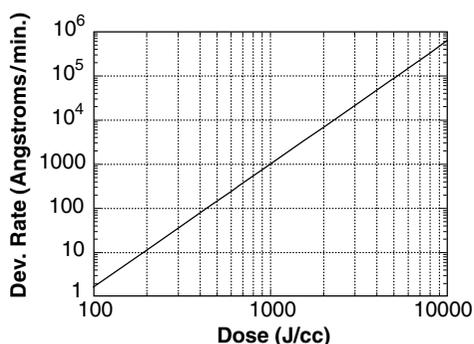

### 18.2.3 DXRL Exposure (Direct LIGA Approach)

With the ability to expose and apply PMMA layers over 1 cm in thickness while most applications being pursued require 150 to 500  $\mu\text{m}$  (10-cm exposures have been demonstrated [Siddons et al., 1994; Guckel, 1996]), the question of how to most beneficially use deep X-ray lithography arises. What becomes immediately apparent is that multiple sheets of PMMA may be stacked and exposed simultaneously

[Guckel, 1998; Guckel et al., 1999a; Siddons et al., 1997]. Accounting for the issues associated with the bonding or attachment of exposed PMMA sheets to a substrate accommodating development and mold filling, this procedure has significant throughput advantages. An examination of exposures obtained with the 7.5-Tesla wiggler insertion device [Manohara, 1998] at the Center for Advanced Microstructure Devices (CAMD), Louisiana State University, reveal these advantages. For a 1-cm-thick PMMA stack with a limited delivered top dose of  $10 \text{ kJ/cm}^3$  and bottom dose of  $3 \text{ kJ/cm}^3$ , an exposure time slightly greater than 4 hr results for an exposure area of  $12.5 \text{ cm} \times 5 \text{ cm}$ . This may be compared to the time (depending on storage-ring beam current) of roughly 20 to 30 min to perform the same area exposure at 250- $\mu\text{m}$  thickness using 1.5-GeV CAMD bending magnet radiation. The enhanced high-energy performance results in a throughput for a 250- $\mu\text{m}$  PMMA thickness of over 200 substrates per day with a total exposure cost of less than  $\$0.25/\text{cm}^2$ , or  $\$15$  per 4-in.-diameter equivalent substrate. The result reveals a potential approach for direct LIGA or using DXRL as the primary tool for precision mold fabrication.

## 18.2.4 Development

Although PMMA sensitivity, at roughly  $500 \text{ mJ/cm}^2$ , is much lower than other photoresists, the combination of high-intensity, well-collimated X-ray flux and the existence of a highly selective PMMA developing system facilitates exploitation of the high resolution of PMMA in a batch process for obtaining microminiature, ultra-precision molds. A developer composed of an aqueous mixture of solvents (80% diethylene glycol monobutyl ether, 20% morpholine, 5% ethanolamine, and 15% water), commonly referred to as the G–G developer after its patent holders, has been formulated to achieve very high contrast PMMA development [Ghica and Glashauser, 1983; Stutz, 1986]. The G–G developer is commonly used at a temperature of  $35^\circ\text{C}$  but may be also used successfully at lower temperatures down to  $15^\circ\text{C}$  with decreased development rates yet higher selectivity. The G–G developer solution also etches copper, which may require a protective layer if this material is desired as a plating base. Figure 18.9 shows development rate curves as a function of X-ray dose [McNamara, 1999]. Development rate temperature dependence has also been noted [Tan et al., 1998]. Additionally, the quality of PMMA definition has been found to be dependent on developer temperature and whether the PMMA is linear or crosslinked [Pantenburg et al., 1998]. Diffusion-limited development is another complicating factor, particularly for high-aspect-ratio features with critical dimensions of tens of microns and below. This issue has prompted the use of megasonic ( $\sim 600 \text{ kHz}$  to over  $1 \text{ MHz}$ ) agitation of the developing solution which additionally alleviates redeposition of dissolved yet marginally high-molecular-weight photoresist, thereby decreasing sidewall particulates and roughness.

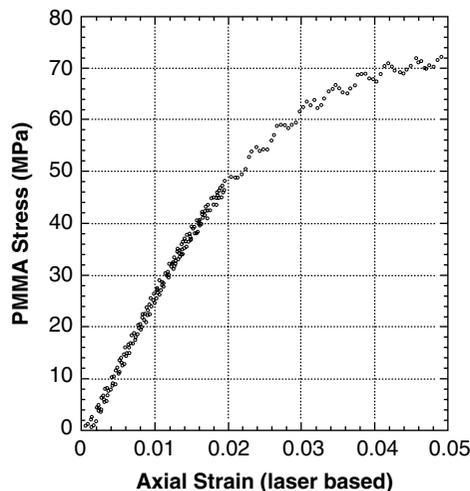

**FIGURE 18.9** PMMA development rate as a function of X-ray exposure dose for ICI CQ-grade PMMA with G–G developer at  $35^\circ\text{C}$ .

Detailed discussions of PMMA photochemistry and pattern limits exist in several references [Ouano, 1978; Mohr, 1986; Münchmeyer and Ehrfeld, 1987; Pantenburg and Mohr, 1995; Feiertag et al., 1997b]. Modeling of fluorescence radiation has revealed that a dose of magnitude 500 J/cc may be deposited underneath absorber regions at areas adjacent to the mask absorber edge and at the PMMA–substrate interface due to emission of fluorescence radiation at the substrate (in this case, titanium) surface [Feiertag et al., 1997c]. This behavior may readily lead to PMMA undercutting during development and ultimately PMMA adhesion loss. The consequence is the possibility of over development and a resulting defect “foot” in the electroform. Electroplating a few microns of sacrificial metal before the structural material can resolve this situation in some circumstances, although it is not an issue for freestanding PMMA exposures. Further study of G–G developer behavior has shown that this alkaline solvent mixture induces a chemical reaction with exposed PMMA prior to dissolution and additionally that there is a strong development dependence on PMMA stereochemistry [Schmalz et al., 1996]. Another related issue concerns the origins and tailoring of PMMA sidewall roughness, which has direct implications for optical components and tribological behavior. Results from CAMD exposures have shown PMMA sidewall roughnesses as high as 25 nm and as low as 5 nm RMS with typical results near 12 nm. This result concurs with the typical resolution quoted for PMMA of roughly 50 to 100 Å [Van der Gaag and Sherer, 1990].

### 18.2.5 PMMA Mechanical Properties

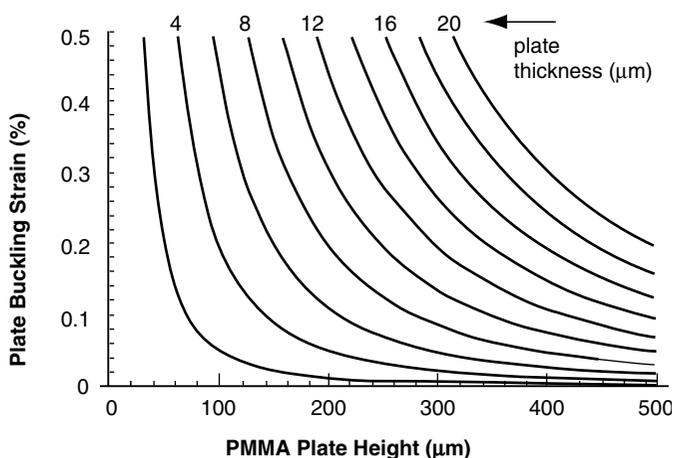

The origin of design rules in the DXRL-based molding process rests on the mechanical limitations of the mold material, PMMA. A tensile curve for a high-molecular-weight linear PMMA material is shown in Figure 18.10 and was measured with a milliscale tensile pulling technique. A summary of properties for PMMA is listed in Table 18.4. Many of these parameters are also dependent on the molecular weight or degree of crosslinking as well as additives that are commonly used for enhanced UV absorption and stabilization. The large thermal coefficient of expansion leads to significant concerns of geometry distortion and strain-induced buckling. As an example, for a PMMA sheet bonded to a silicon substrate, a 10°C temperature change leads to a 0.11% strain in the PMMA. This situation typically manifests itself via buckling of PMMA plates defined by three built-in edge conditions at the substrate interface and side edges and a free edge condition at the top edge. The solution for this plate-buckling problem may be to generate design curves indicating mechanically limiting regions of geometry and thereby establish minimum

**FIGURE 18.10** Tensile curve of PMMA (ICI CQ-grade) measured with load frame and laser extensometer system for a DXRL-patterned tensile coupon geometry with 750- $\mu\text{m}$  gauge width and 150- $\mu\text{m}$  thickness.

PMMA design rules [Christenson, 1995]. One such graph is provided in [Figure 18.11](#). The net effect is that this behavior constitutes the major restriction on aspect-ratio and process integration. This same effect, on the other hand, may be used to quantify residual PMMA strain.

### 18.3 Mold Filling

The material base that may be accessed largely defines application areas that may benefit from DXRL fabrication. PMMA mold forms produced by deep X-ray lithography are most commonly used to provide an electroforming mask, as depicted, for example, in [Figure 18.12](#). In the case of electroforming, the DXRL mold substrate must be provided with a plating base suitable for an electrolyte of interest. An example plating base is a three-layer film of Ti/Cu/Ti or Ti/Au/Ti in which the lower titanium layer

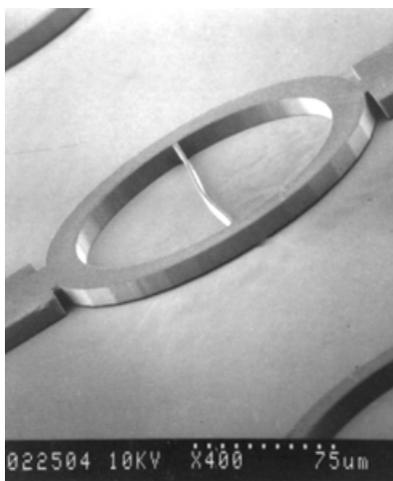

**FIGURE 18.12** DXRL-exposed and developed 200- $\mu\text{m}$ -thick PMMA mold form.

provides adhesion to a substrate such as silicon or glass and the top titanium layer provides for photoresist (PMMA) adhesion while also protecting the electroplating seed layer, which in this case is copper or gold. The top titanium layer may be removed after PMMA development with a dilute (100:1) hydrofluoric acid etch. Additional lower adhesion layer materials include Cr, V and Nb.

A large number of elemental metals and alloys may be electroplated, but this capability alone does not lead to their use as engineering or structural materials or allow electrodeposition into high-aspect-ratio mold forms. Many electroplating procedures, for example, require high temperatures or electrolytes that will dissolve or react chemically with PMMA molds, but the main hindrance to extending the use of electroplated materials to microelectroforming is internal strain. Electrodeposit strain can impart delamination stresses onto adjacent PMMA mold material and eventually lead to adhesion loss of the deposit itself. Geometry and process control cannot be attained without minimizing deposit stress to an acceptable level. An integrated means to obtain local measurement of internal electrodeposit stress may be accomplished with patterned beam structures as depicted in [Figure 18.13](#) [Guckel et al., 1992]. This approach employs arrays of clamped-clamped beams and ring-and-beam structures of various beam lengths that are sensitive to lateral buckling. The structures reveal internal strain levels by visual determination of a critical buckling beam length and are fabricated with the use of a lower sacrificial layer etched away to free the beam structure from the substrate. Considerable research directed to understand how stress arises during electrodeposition has been carried out [Marti, 1966; Weil, 1970; Harsch et al., 1988]. In the course of this research, certain electrolytes have proven to be particularly well suited for low-stress electroforming. The most notable of these is the sulfamate-based electroforming bath that has made intricate electroforming of nickel possible. This bath formulation, specified in [Table 18.5](#), is used for most LIGA electroforming due to the relative ease and rapidity with which thick low-stress electroforms may be obtained. Example resultant electroformed nickel structures subsequent to PMMA dissolution are shown in [Figure 18.14](#). Another material particularly convenient for electroforming is copper, for which the formulation listed in [Table 18.5](#) is particularly well suited for high-aspect-ratio electroforming. An increase in the ratio of sulfuric acid to copper has been identified as increasing plating solution conductivity and throwing power, which is advantageous for high-aspect-ratio geometry. Complications arising from electroforming through varied geometry and component dimensions arise due to

**TABLE 18.5** Common Electroforming Bath Compositions and Low Stress Plating Conditions

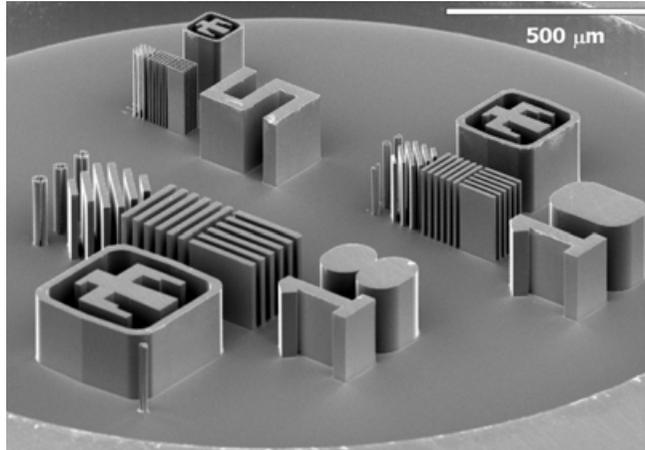

Nickel		Copper	
Ni(NH <sub>2</sub> SO <sub>3</sub> ) <sub>2</sub> · 4H <sub>2</sub> O	440 g/l	CuSO <sub>4</sub> · 5H <sub>2</sub> O	68 g/l

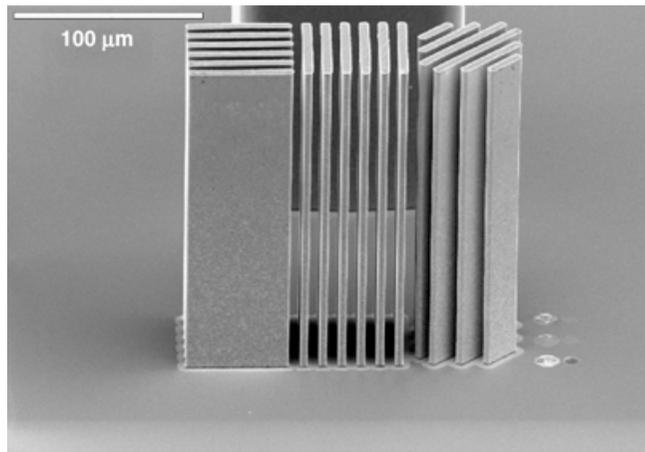

**FIGURE 18.13** DXRL-patterned and electroformed nickel ring and beam structure used to measure tensile internal strain via mechanical buckling. The beam cross member, 2  $\mu\text{m}$  wide and 18  $\mu\text{m}$  thick, was originally straight after electroforming and has now buckled after release via a sacrificial etch as a result of tensile internal strain. Together with the outer and inner ring radius of 100 and 80  $\mu\text{m}$ , respectively, the critical buckling geometry of this structure represents a 0.08% internal tensile strain.

locally varying current density as a result of current crowding and limited electrolyte conductivity, in addition to mass transport variation of the electrolyte to the electrodeposit surface [Mehdizadeh et al., 1993]. These issues may be partially alleviated with techniques such as pulse-plating and electrolyte agitation schemes, including jet or fountain plating and paddle cells [Andricacos et al., 1996]. What has been found is that extremely high-aspect-ratio cavities may be readily electroplated with high accuracy, as demonstrated by the structure in Figure 18.15. The electroform replication of the PMMA mold is also found to be essentially perfect to the subnanometer-length scale [Hall, 2000]. Other electroformable materials used with direct LIGA processing include gold, silver, indium, platinum, lead–tin and alloys of nickel, including nickel–iron and nickel–cobalt.

The ability to electroform ferromagnetic materials opens the possibility to implement a large class of magnetic devices. The nickel–iron alloy 78 Permalloy (78% Ni/ 22% Fe), for example, may be electroformed to 500- $\mu\text{m}$  thicknesses, as shown in Figure 18.16. This soft (low coercivity) ferromagnetic material has near zero magnetostriction and a B–H behavior, as shown in Figure 18.17. Because microactuator

(a)

(b)

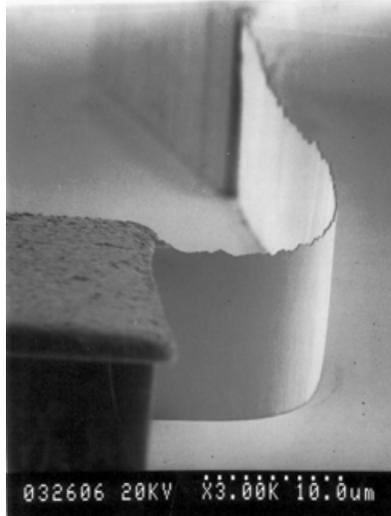

**FIGURE 18.14** (a) Electroformed nickel test structures 200  $\mu\text{m}$  tall; (b) close-up of 5- $\mu\text{m}$ -wide nickel lines and spaces.

force is developed from the equivalent mechanical pressure generated in a magnetic field as defined by Eq. (18.1):

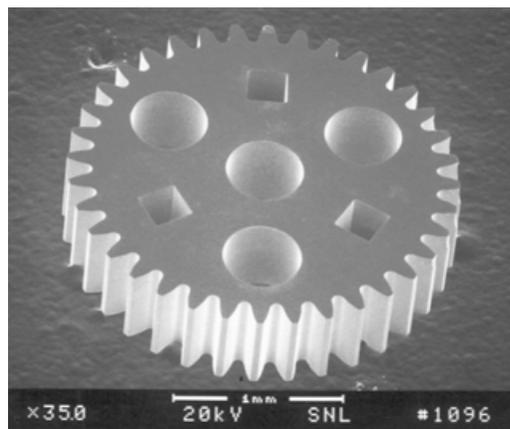

$$p_M = \frac{B^2}{2\mu_0} \text{ (Pa)} \quad (18.1)$$

where  $B$  is the magnetic flux density (T) and  $\mu_0$  is the permeability of free space ( $4\pi(10)^{-7}$  Hy/m), a need for soft ferromagnetic materials that can accommodate as large a  $B$  field as possible is evident. Recent work has demonstrated electroplated NiFeCo material with magnetic saturation flux density of 2.1 T [Osaka et al., 1998]. Such materials have great potential if they can be incorporated into DXRL processing.

Another area in magnetics requiring attention is identified by considering electromagnetic scaling issues for micromagnetic devices that show the advantage of using permanent magnets for efficient miniature electromagnetic transducers. Permanent magnets that possess the best qualities for microactuator applications are rare earth based and include the samarium cobalt (SmCo) and neodymium iron boron (NdFeB) families. These materials may be directly processed in a bonded form containing isotropic

**FIGURE 18.15** Electroplated nickel in PMMA craze resulting from PMMA stress concentration test structure. The resulting nickel wall is 20  $\mu\text{m}$  in height with a width of 0.12  $\mu\text{m}$ .

**FIGURE 18.16** Gear electroformed from 78/22 nickel/iron to a thickness of 500  $\mu\text{m}$ . This material, in addition to possessing desirable soft ferromagnetic response, has been found to perform well as part of mechanisms where tribology is of concern due to its high hardness and yield strength.

rare-earth-based powder mixed with a binder material such as epoxy. The figure of merit of interest, maximum energy product, varies for these types of magnets from 6 to 10 MGOe (mega-gauss-oersted; 1 MGOe =  $100/4\pi \text{ kJ/m}^3$ ) for bonded varieties to over 40 MGOe in fully dense anisotropic forms. Work with bonded rare-earth permanent magnet (REPM) material has demonstrated the direct molding of bonded REPM from DXRL PMMA mold forms [Christenson et al., 1999a]. The result is the batch fabrication of a multitude of prismatic REPM geometry with feature sizes as small as 5  $\mu\text{m}$  and dimensional tolerances of 1  $\mu\text{m}$ . The example of bonded permanent magnet geometry shown in Figure 18.18 was fabricated with the process outlined in Figure 18.19. An unmagnetized mixture of REPM powder and epoxy is applied to a substrate with a DXRL-defined PMMA mold while in a low-viscosity state by calendaring and pressing. After curing in a press at pressures near 10 ksi, the substrate with pressed composite is planarized. The entire substrate of permanent magnets is then subjected to a magnetizing

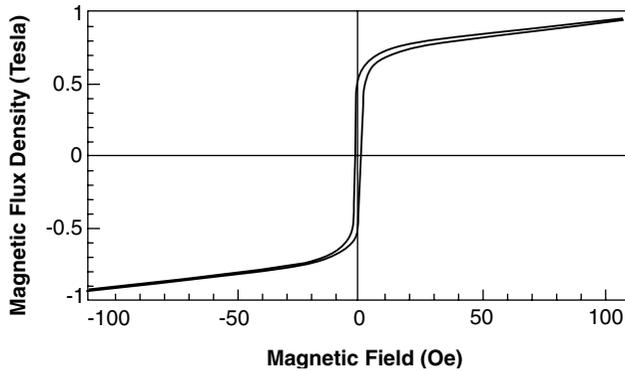

FIGURE 18.17 B–H response of an electroplated 78 Permalloy sample. The initial permeability is near 4000 and the magnetic saturation flux density is 1 T.

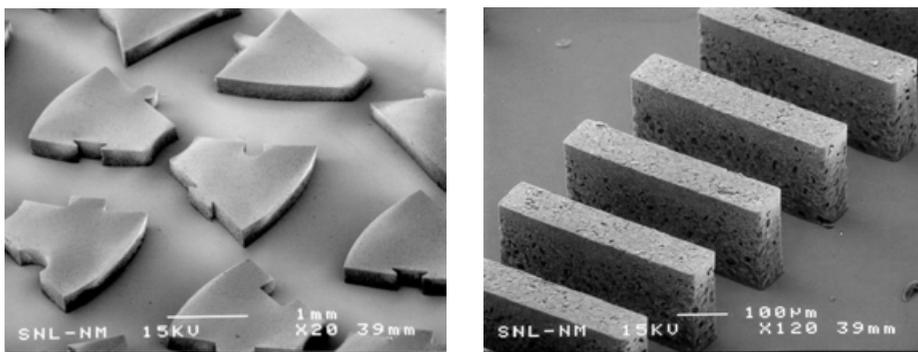

FIGURE 18.18 SEM photographs of bonded  $\text{Nd}_2\text{Fe}_{14}\text{B}$  permanent magnets formed with DXRL-defined PMMA molds. Powder particle size ranges from 1 to 5  $\mu\text{m}$ , and the binder is a methylene-chloride-resistant epoxy. These images show magnetized structures, thus mild distortion is present due to magnetic perturbations of the imaging electrons. Maximum energy products of 9 MGOe have been obtained with this process.

field of at least 35 kOe in the desired magnetization orientation and the magnets are subsequently released from the substrate by dissolving the PMMA and etching an underlying metal layer. A related result using a blended form of photoresist (epoxy-based SU-8) and  $\text{Sm}_2\text{Co}_{17}$  particle film uses direct UV lithography to pattern permanent magnets with 2.8-MGOe energy density [Dutoit et al., 1999].

Fabrication of REPM structures with a greater maximum energy product requires higher temperature processing, for which PMMA is not suited. An intermediate mold approach has therefore been examined. Direct slurry casting of alumina from PMMA mold forms has yielded replicated geometry with a minimum of distortion ( $<2 \mu\text{m}$ ) by careful firing sequences [Garino et al., 1998]. Figure 18.20 depicts example glass/alumina composite structures. Other ceramic materials have been demonstrated by this technique, including ferrites and PZT [Ritzhapat-Kleissl et al., 1996; Pieter et al., 1997]. The resulting alumina mold may be used to perform high-temperature processing with powder metals. The complications of anisotropic REPM powder processing have prompted an approach that does not involve powders [Christenson et al., 1999b]. In a manner similar to hot embossing, a bulk anisotropic slab of REPM material is placed over the alumina mold that is decorated with a copper release layer. By vacuum hot pressing at 700°C and 2000 psi, strain rates of 22% for die-upset  $\text{Nd}_2\text{Fe}_{14}\text{B}$  material are realized, thereby allowing filling of the alumina mold. Maximum energy products of 23 MGOe have been achieved in submillimeter permanent magnet shapes with this approach, with the test geometry results shown in Figure 18.21.

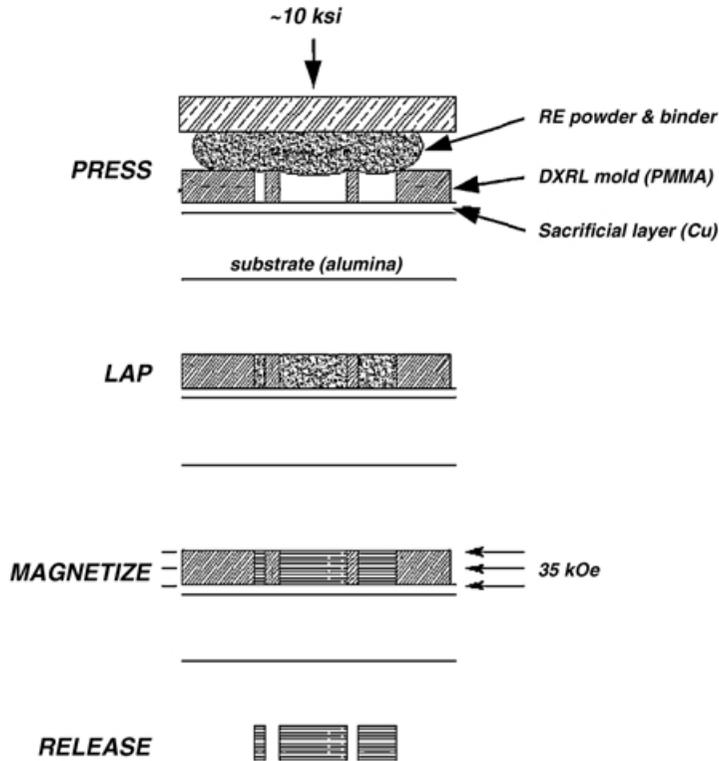

FIGURE 18.19 DXRL-based bonded REPM fabrication sequence.

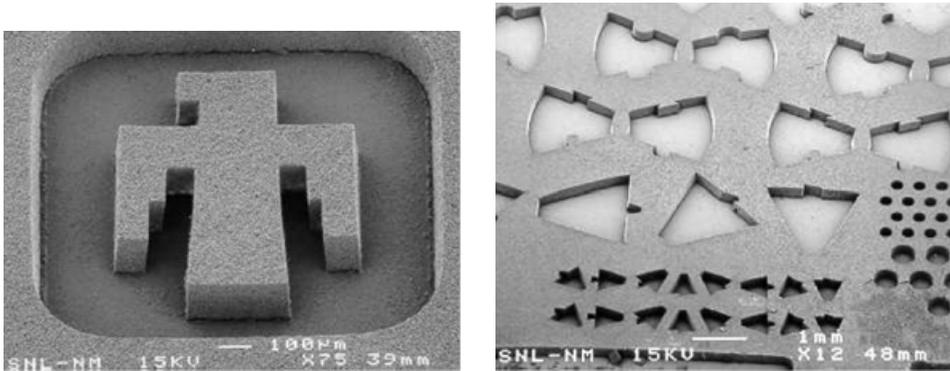

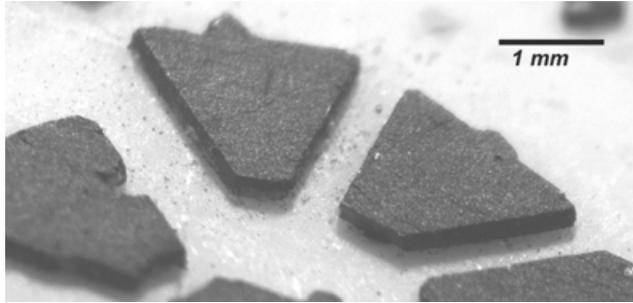

FIGURE 18.20 Alumina/glass structures created from DXRL-defined PMMA mold forms intended to be used for further high-temperature mold processing.

Further micromold filling techniques have been explored which involve approaches ranging from glass castings [Lee and Vasile, 1998] and embossing to flame spray [Christenson, 1998]. A promising batch microfabrication technique from the standpoint of dramatically widening the available material base is the use of DXRL-patterned electrodes for electro-discharge machining [Takahata et al., 1999]. The batch micro-EDM approach uses an electrode pattern defined with an array of components to simultaneously plunge cut a number of parts from a conductive material. Although currently not as accurate as electro-forming, these latter techniques may suit applications requiring batch microfabrication of a particular material.

**FIGURE 18.21** Hot-forged  $\text{Nd}_2\text{Fe}_{14}\text{B}$  permanent magnet test bars extracted from intermediate DXRL-formed alumina mold.

## 18.4 Material Characterization and Modification

Material properties possessed by DXRL-fabricated components are unique in the sense that they depend on the processing parameters used to fabricate them. Thus, a means of *in situ* metrology is needed to generate data reflecting lot-to-lot and intrasubstrate variation. This methodology is based on the drop-in test die approach used in integrated circuit planar processing. For ultra-precise, high-aspect-ratio, DXRL-defined components, commensurate routine dimensional metrology remains a challenge. Mechanical property measurement techniques are readily available, however, and have revealed material property deficiencies to which MEMS are particularly sensitive. Post-process treatments show some promise for ameliorating these deficiencies.

Strain diagnostic structures were previously mentioned. This procedure readily provides localized stress data as a function of process conditions as with current density during electroplating, for example. A measure of tensile mechanical behavior has been achieved with a milliscale torsion tester comprising a tabletop servohydraulic load frame instrumented with a laser displacement measurement system [Christenson et al., 1998a]. This system is compatible with common DXRL structural dimensions and accommodates the tensile specimen geometry depicted in Figure 18.22. The specimen has a gauge section roughly 3000  $\mu\text{m}$  long with a cross-section defined by a 762- $\mu\text{m}$  width and a height set by the electrodeposition thickness which may be from 50  $\mu\text{m}$  to 1 mm. Two pairs of extruding optical marker bars that are read by the laser displacement system define the gauge length. For these markers to negligibly interfere with the measurement and not rotate, a pair of spars 25  $\mu\text{m}$  wide are used to attach the marker to the gauge section. The specimen shape may be used as a drop-in test structure on any mask definition to allow tensile property measurement on every processed substrate.

The tensile testing procedure has aided in building a mechanical property database. Particularly useful information that has been extracted includes sensitivity to plating current density and temperature cycle effects. Data for nickel are listed in Figure 18.23 and Table 18.6 and copper results are given in Figure 18.24 and Table 18.7. Nickel-iron deposits are found to have substantially higher tensile strength as has been previously noted [Safranek, 1986]. Figure 18.25 shows the tensile data for 78/22 Ni-Fe deposited from a sulfate/citrate bath at room temperature and a pH of 4.8. The high yield strength of the Ni-Fe deposit that is also common to other electrodeposited alloys renders these materials well suited for use in spring fabrication.

A mechanical property complication in electroformed deposits is apparent, however, from deposit cross-section micrographs and grain-orientation distribution analyses. For direct current nickel deposits, for example, the initial deposit is found to have a fine grain structure which evolves into a coarser lenticular grain structure oriented parallel to the deposition direction. Figure 18.26 shows examples of this structure. Indentation data reveals corresponding anisotropic and varying elastic and hardness properties throughout the electrodeposited structure [Buchheit et al., 1998]. Another result of the morphology variation is an internal strain gradient through the thickness of the deposit with usually an initially compressive deposit [Harsch et al., 1988]. Means to resolve this nonuniformity include the use of pulse plating and bath chemical additions.

Because scaled micromechanisms fabricated with DXRL-based processing contain components with much larger ratios of surface area to volume, surface behavior may substantially affect or dominate mechanism dynamics. In the limiting case, situations of metal component surfaces in contact over a period of time can lead to a static friction situation that prohibits mechanism operation. As a result of these surface sensitivities and material base limitations, surface treatments that improve tribology and

**FIGURE 18.26** (a) Metallurgical cross-section photograph of electrodeposited nickel with deposition direction from left to right nucleating on an evaporated copper plating base; (b) nucleating surface; (c) top surface.

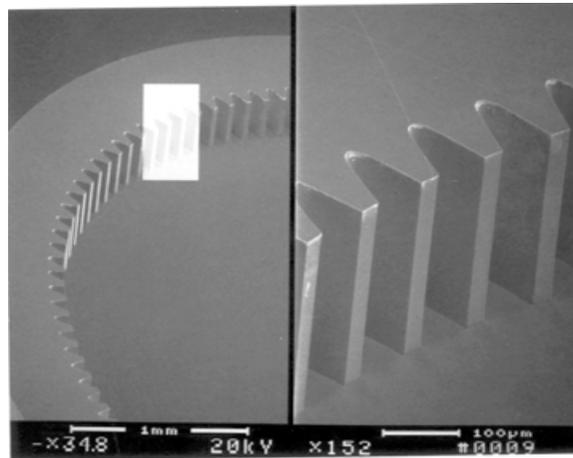

**FIGURE 18.27** Friction coefficients of electroformed nickel and comparison with (a) Ti/C treatment and (b) diamond-like carbon deposition. Data were obtained in laboratory ambient with unidirectional sliding against a 1.6-mm-radius 440C steel ball with 9-gf load.

wear for existing electrodeposited material have been explored. An important requirement for these treatments is that they do not substantially alter dimensional tolerances and that they do not introduce additional adhesion or shedding problems. A method that has been very successful in this regard that has been previously used for iron and steels is a dual implantation of titanium and carbon [Myers et al., 1997]. The procedure involves implanting Ti and C to a dose of  $2(10)^{17}/\text{cm}^2$  at respective energies of 180 and 45 keV. The result for electroplated nickel is found to be similar to iron and steel in that an amorphized region near the nickel surface is formed which possesses significantly enhanced mechanical properties. Table 18.8 shows a comparison summary of these properties. Furthermore, the implanted surface enhances tribological properties as Figure 18.27 explains. Fixturing to address the line-of-sight nature of the implant is needed to allow articulation of a substrate with attached DXRL components to yield an approximately even dose over all part topology while providing a batch wafer treatment.

Another approach to improving as-electroplated metal tribology has been explored with the use of diamond-like carbon coatings [Ager et al., 1998]. Experiments showed that carbon deposited via a pulsed vacuum-arc process has the advantage of providing partially conformal deposits. These films were deposited on nickel with thicknesses of 100 to 200 nm and possess hardnesses of over 30 GPa. The resulting coatings

**TABLE 18.8** Surface Mechanical Properties of Implanted Electrodeposited Nickel [Myers et al., 1997]

	As-Deposited Ni (GPa)	Ti-C Implanted (GPa)

provide enhancements in tribological performance similar to Ti/C implantation, as the test results in [Figure 18.27](#) show.

## 18.5 Planarization

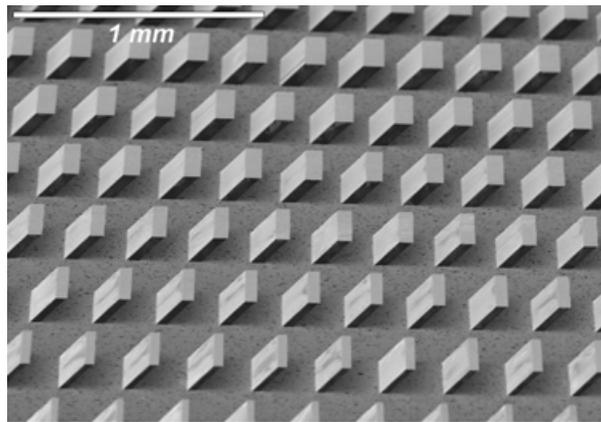

The demonstration of submicron in-plane tolerances for DXRL-fabricated components has resulted in similar requirements for thickness control for out-of-plane tolerances. Leveling during electroforming may be aided by bath composition, agitation and pulsed current techniques. Controlling electrodeposits several hundred microns thick to micron tolerances has proved impractical for the variety of component geometry of interest and in this case a concession is needed. An alternative approach is to let the electrodeposit form over the top of the photoresist mold and then planarize the plastic/metal geometry matrix to a desired thickness.

The planarization technique that has proven to be particularly appropriate for these materials is a diamond lapping procedure that has been referred to as “nano-grinding” [Christenson and Guckel, 1995; Gatzert et al., 1996]. Machining operations involving fly-cutting and milling are found to generate considerable impact loading and shear stress on microelectroformed parts. Standard lapping procedures involving loose alumina abrasive slurry on a glass plate, on the other hand, are found to preferentially remove the softer PMMA material, leaving a situation where the matrix metal is prone to smearing, resulting in loss of edge definition. A locally rounded metal surface is also a consequence of the rolling abrasive. In the nano-grinding approach, a diamond slurry is applied to a composite soft metal plate into which it is embedded via a conditioning plate or ring. The fixed diamond-loaded surface is then used as a grinding wheel to cut the metal/PMMA composite layer on a substrate held with a precision vacuum-mounted fixture. The metal plate flatness may be maintained to 0.0001 in. over a 15-in. diameter by the proper use of diamond cutting rings, thus a lapped surface can be held to a thickness within 1  $\mu\text{m}$  over a 3-in.-diameter substrate. Results are shown in [Figure 18.28](#) for a copper part. Nearly any material

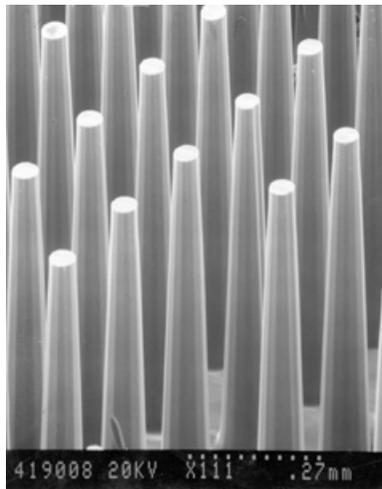

may be accommodated with this technique. These results are also a prerequisite for the precise incorporation of multiple layer processing.

## 18.6 Angled and Re-entrant Geometry

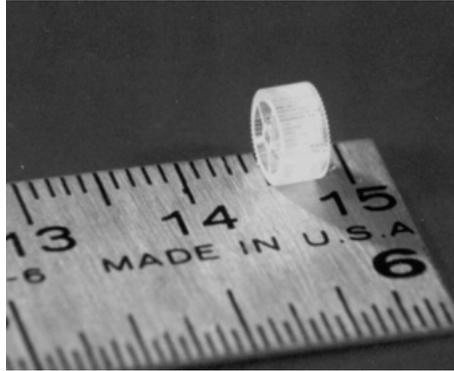

A large amount of flexibility of X-ray mask/substrate orientation relative to the SR beam is available due to the highly collimated beam as well as the absence of reflection outside the grazing incidence angles. The first straightforward result is a prismatic angled exposure as shown in Figure 18.29. In this case, both mask and substrate are oriented at an angle relative to the SR beam and scanned across the X-ray mask area. X-ray mask contrast potentially becomes a problem in this case at the edge of the absorber definition, where a gradient in contrast exists across the subtended length defined by the absorber thickness. Thus, for critical applications, the X-ray mask absorber may require patterning at the desired structure angle. A reduced mask contrast, however, may be useful in intentionally generating tapered geometry such as that shown in Figure 18.30 [Guckel, 1996]. The PMMA flank is generated by a partial exposure underneath the X-ray mask absorber region. For adjacent exposed areas with relatively much higher

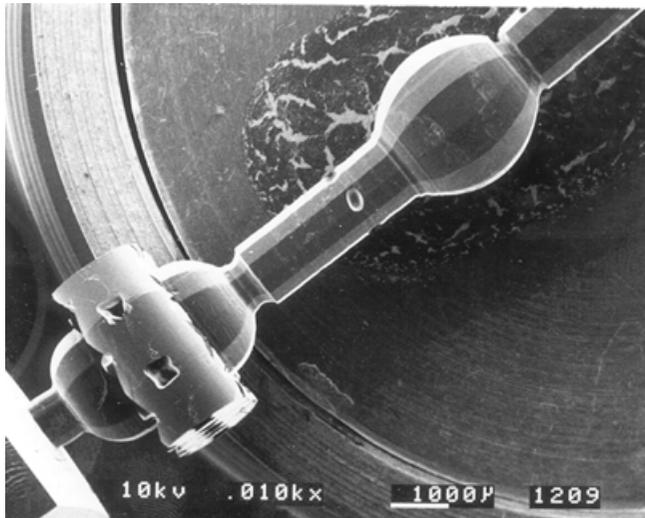

**FIGURE 18.29** Copper structures fabricated from a 45° DXRL exposure in PMMA. Metal thickness is 200  $\mu\text{m}$  normal to the substrate.

**FIGURE 18.30** Tapered PMMA test structures realized with a low-contrast X-ray mask and NSLS exposure. PMMA thickness is 1.5 mm.

**FIGURE 18.32** Re-entrant PMMA shape realized by rotation during X-ray exposure [Johnson, pers. comm.].

delivered dose, the flank profile is essentially constant. A transition to a parabolic flank dependence occurs in deeper regions of lower dose where diffusion-transport-limited development begins to contribute.

High-energy, ultra-deep X-ray exposures have yielded extremely thick photoresist exposures and structures [Siddons et al., 1997]. Results from the National Synchrotron Light Source (NSLS) depicted in [Figure 18.31](#) reveal over 3-mm-thick structures. Extending this effort still further, using 35-keV X-rays has enabled a 110-mm-deep lithography result [Siddons et al., 1994]. The ability of DXRL to precisely define nearly perfectly vertical sidewall definition has additionally suggested continuously rotating exposures of an X-ray mask aperture and PMMA substrate combination about an axis normal to the X-ray beam. The result is directly patterned re-entrant or undercut PMMA geometry. [Figure 18.32](#) shows an example. Using negative X-ray resist in this context also leads to additional novel microstructures [Ehrfeld and Schmidt, 1998].

## 18.7 Multilayer DXRL Processing

The use of multiple masks to form multilayer stepped prismatic structures makes possible such geometry as flow channels, stacked gears and gears with shafts, as well as integrated packaging structures. Several means have been explored to achieve a multilayer DXRL process. Direct plating has proven to be one viable approach with results depicted in [Figure 18.33](#) [Massoud-Ansari et al., 1996]. In this technique,

subsequent to planarization of the first layer, a second level of PMMA is bonded to the first composite metal/PMMA layer, X-ray exposed with an aligned X-ray mask, developed, electroformed and finally planarized. Consecutive layer geometry is typically restricted to be nonoverlapping with respect to previous geometry.

Another multilayer process has been demonstrated with the use of a batch diffusion bonding and release procedure [Christenson and Schmale, 1999]. The fabrication sequence is shown in cross section in Figure 18.34. Two planarized substrates decorated with DXRL patterned and electroformed layers and

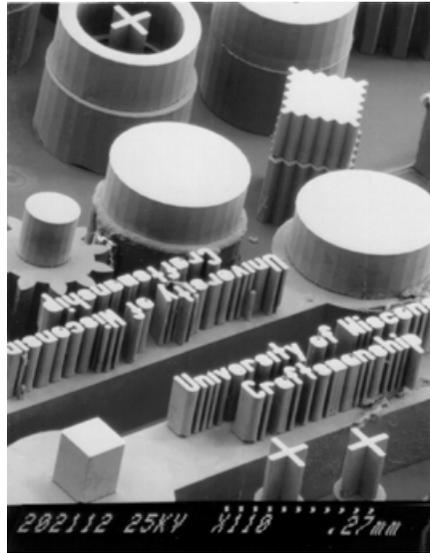

FIGURE 18.33 Two-level nickel DXRL-formed test structures produced via direct electroforming.

with PMMA removed are aligned face-to-face with gauge pins that are press-fit into complementing alignment structures. The substrates are joined in a vacuum hot press, and the sacrificial layer on one substrate is etched entirely away, leaving one layer bonded to the other. [Figure 18.35](#) reveals results for a test mask pattern. This procedure is compatible with arbitrary overlapping geometry and may be repeated indefinitely. Careful attention must be given to the temperature cycles that have the potential to degrade mechanical properties substantially. For this reason, a milliscale mechanical torsion tester suited for batch measurement of shear bond strength of high-aspect-ratio structures has been used to optimize diffusion bonding parameters [Christenson et al., 1998b]. Using this approach, a diffusion bond cycle of 450°C at 7 ksi for 4 hr with electrodeposited nickel was measured to yield a 130-MPa bond strength suitable for most applications. Alignment accuracy is measured with the vernier alignment structures shown in [Figure 18.36](#) which indicate a less than 1-µm alignment error over a 3-in.-diameter substrate.

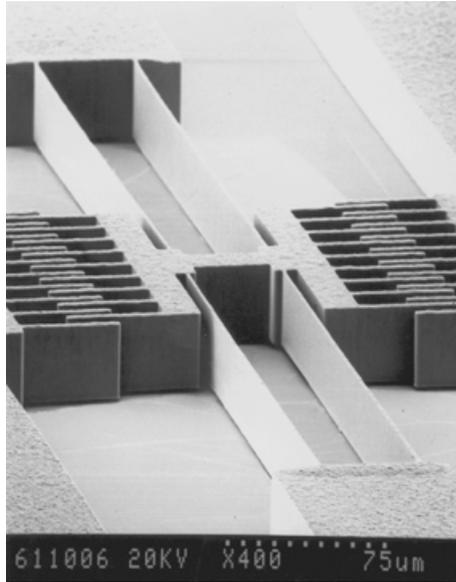

**FIGURE 18.36** Vernier indicators of two-level diffusion bonding alignment that reveal an alignment accuracy of less than 1  $\mu\text{m}$ . Each vernier mark indicates 0.5  $\mu\text{m}$  of misalignment.

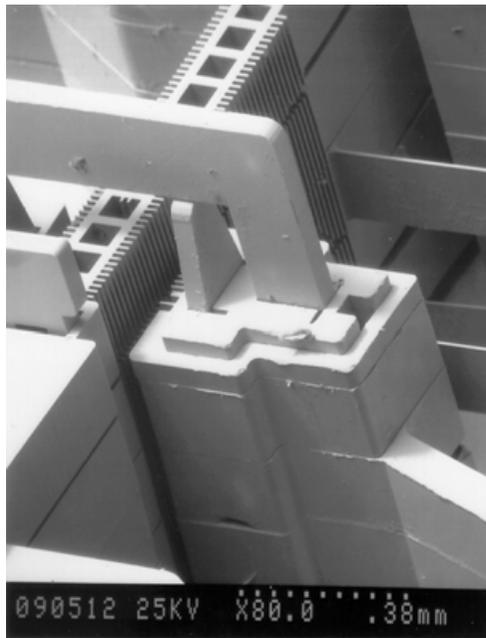

**FIGURE 18.37** Assembled nickel gear on nickel shaft and 10 $\times$  close-up showing 1- $\mu\text{m}$  journal bearing clearance at 120- $\mu\text{m}$  structural thickness.

## 18.8 Sacrificial Layers and Assembly

The multilayer fabrication schemes in the previous section aim to substantially alleviate the assembly burden. To date, however, most complex devices have required some form of micro-assembly. The reason for the reliance on assembly lies with the high-aspect-ratio nature of these types of components. Maintaining intercomponent tolerances of 1  $\mu\text{m}$  or less is not feasible directly at very high aspect ratios, thus assembly may be used to allow biasing of 1  $\mu\text{m}$  or less between two separately fabricated components which are then assembled to realize an acceptable precision fit. [Figure 18.37](#) is an image of a resulting combination. This micro-assembly sequence realizes released components via a sacrificial layer etch that may also be used to partially release structures such as the one in [Figure 18.38](#). The micro-assembly of DXRL-fabricated structures has been extended to more elaborate mechanisms via stacking ([Figure 18.39](#)) [Fischer and Guckel, 1998] and multistage element assembly ([Figure 18.40](#)) [Christenson, 1998]. The individual

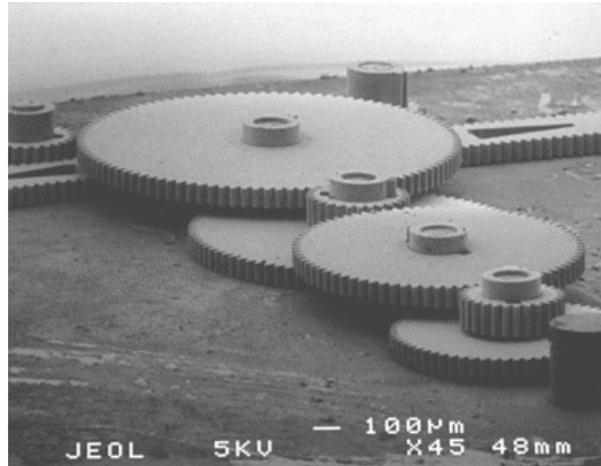

**FIGURE 18.38** Partially released nickel electrostatic comb drive.

**FIGURE 18.39** Five-layer stacked 78 Permalloy linear actuator mechanism over 1 mm in height.

microcomponent assembly techniques that have been employed include the use of magnetic probes for ferromagnetic materials and liquid surface tension to pick up certain geometry, as well as parallel robotic schemes [Feddema and Christenson, 1999]. Additive wafer transfer schemes such as batch processes incorporating wafer-scale component transfer with wafer-scale bonding and sacrificial layer-release sequences ultimately have the most appeal.

**FIGURE 18.40** Assembled two-layer gear train and rack mechanism fabricated from 78 Permalloy. The aluminum substrate was machined conventionally to accept press-fit tool steel gauge pins on which the keyed bushings and gears are assembled.

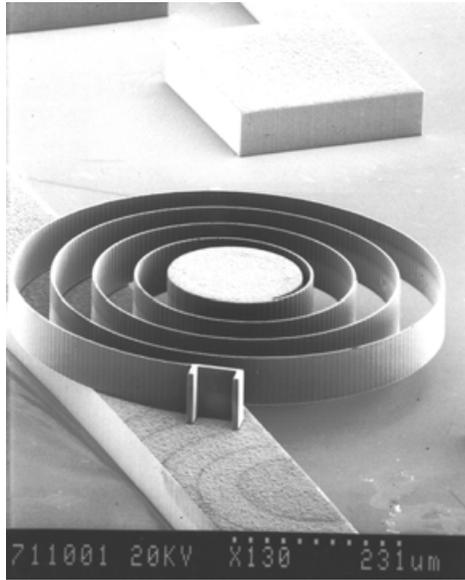

## 18.9 Applications

Two basic DXRL application areas will be discussed. One area includes the use of DXRL for the batch fabrication of precision-machined components requiring dimensional tolerances of  $1\ \mu\text{m}$  or less or those requiring a high aspect ratio with microscale critical dimensions. The other application area involves the use of the high-aspect-ratio nature of the process to generate increased actuation forces as well as increased inertial effects.

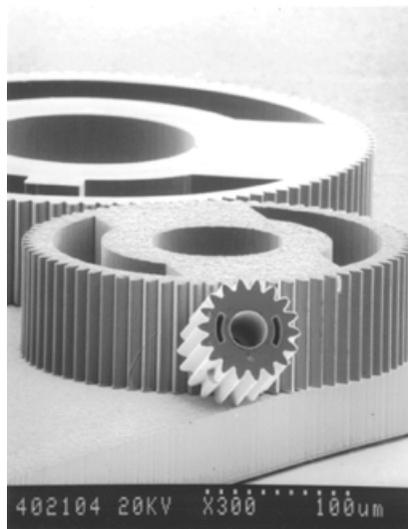

### 18.9.1 Precision Components

Devices in the precision component category range from mechanical elements such as springs that would require prohibitively difficult conventional machining approaches to precision alignment and optical structures. An example is shown in [Figure 18.41](#), where a compact flexure with a  $0.15\text{-N/m}$  lateral spring constant reveals the capability of realizing a power spring. The ability to pattern fine features within relatively large geometry allows accurate scaling of gears as depicted in [Figure 18.42](#). Arbitrary gear teeth profiles are possible, thus any pressure angle for an involute geometry, for example, may be accommodated. These components have been applied to a miniature precision planetary gear box construction, as shown in [Figure 18.43](#).

A large number of additional piece-part applications have centered around grid structures or arrayed apertures. The screen in [Figure 18.44](#) illustrates a typical example. This rather large nickel component contains  $50\text{-}\mu\text{m}$  wide spars with less than  $0.25\text{-}\mu\text{m}$  deviation through its thickness of  $150 \pm 1\ \mu\text{m}$ . In this case, repeatability is of prime importance for which the lithographic dimensional extension afforded by DXRL-based processing is well suited. A related structure is desired for use in a “lobster-eye” optic for X-ray astronomy [Peele, 1999]. The requirement is for an array of square apertures that reflect X-ray flux at a grazing angle off of their orthogonal sidewalls. These reflections are directed into a central focus area if the axis of each aperture is radial to the center of a sphere. A desired material for this X-ray optic structure is nickel with a figure of merit that is strongly dependent on sidewall surface roughness. An acceptable surface roughness for the X-ray wavelengths of interest is calculated to be a few nanometers. [Figure 18.45](#) depicts a test structure of the type needed for the optic element. Sidewall roughness for these structures is typically  $10\ \text{nm}$  and has been measured as low as  $7\ \text{nm RMS}$ . Methods to reduce this

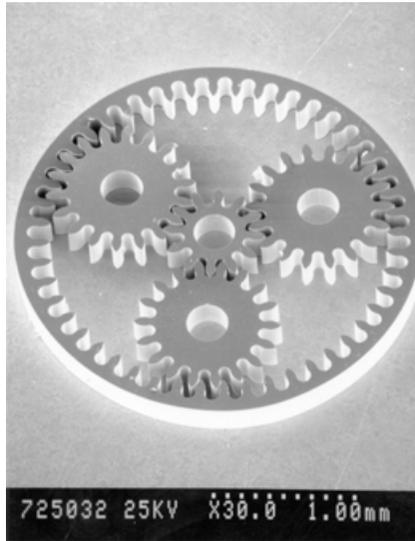

**FIGURE 18.41** Spiral spring with 3- $\mu\text{m}$ -wide flexural element and 100- $\mu\text{m}$  structural height fabricated from nickel.

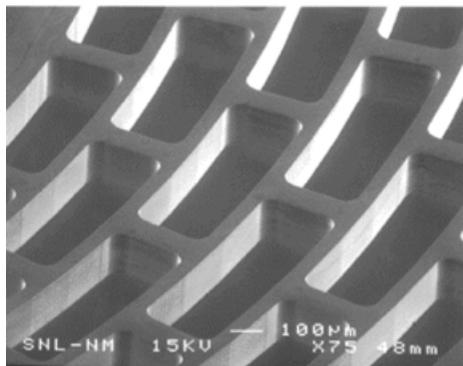

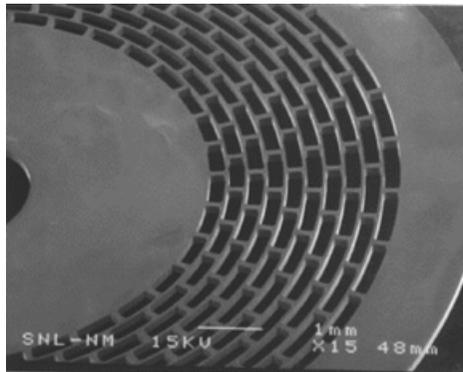

**FIGURE 18.42** Released nickel gears, 100  $\mu\text{m}$  thick, with 7- $\mu\text{m}$  involute gear tooth thickness.

value by roughly a factor of 5 are being investigated. The resulting screen would ultimately be deformed about a spherical mandrel.

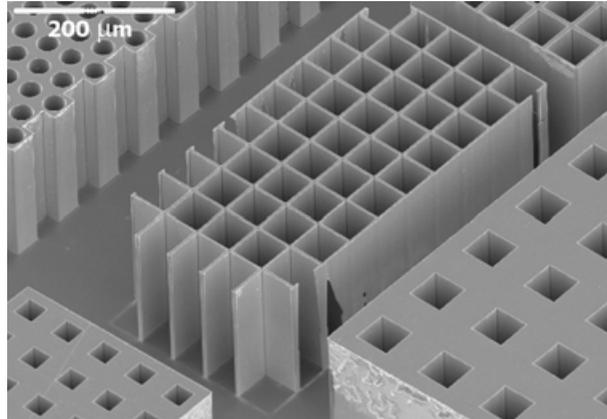

Another device category requiring arrayed channels concerns heat exchangers. Reduced heat exchanger dimensions of 100  $\mu\text{m}$  to 1 mm result in more effective heat transfer due to decreased thermal diffusion lengths. A DXRL-based fabrication method for cross-flow micro-heat exchangers has been realized [Harris et al., 2000]. The scheme uses a DXRL-patterned, two-layer nickel mold insert (Figure 18.46a) to hot emboss half of the heat exchanger panel (Figure 18.46b) [Despa et al., 1999]. Two panels are then placed face-to-face and bonded to realize the automobile-like radiator shown in Figure 18.46c. Estimated performance for this device realized in PMMA with an air pressure drop of 175 Pa and coolant pressure

**FIGURE 18.47** PMMA optical fiber alignment structure and focusing lens at 500- $\mu\text{m}$  thickness. This structure, which provides for a minimum-sized spot to optically monitor a moving surface, is press-fit over 200- $\mu\text{m}$ -diameter pins; subsequently, its two retaining breakable beams are detached, thereby providing a sprue function. The lens is a best-form aspheric designed for a 0.16-NA single-mode fiber at 632.8 nm with a center thickness of 200  $\mu\text{m}$ .

drop of 5 kPa is a heat dissipation of 6.0  $\text{W}/\text{cm}^2$  or 33.3  $\text{W}/\text{cm}^3$ , a substantial increase over larger, traditionally scaled devices.

The direct use of PMMA as a component material has also proven its utility for optical components. [Figure 18.47](#) reveals an integrated fiber alignment guide and prismatic focusing optic structure fabricated with PMMA [Holswade, 1999]. Two support sprues hold two components together and are removed after pin press-fit mounting. The structure accommodates input and output fibers oriented at 90° to each other. The light from one fiber is focused into a line across a reflective encoded surface that reflects a signal back into the receiving fiber.

## 18.9.2 Microactuators

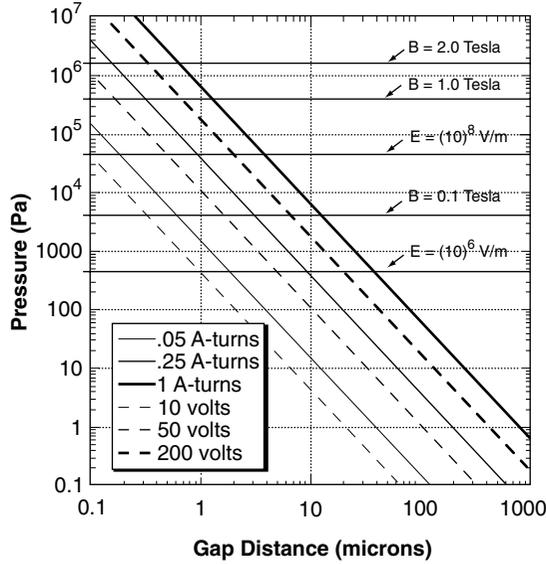

The ability to integrate magnetic material with batch DXRL-based microactuator fabrication has made possible high-pressure microactuators with low driving-point impedance. Both linear and rotary devices have profited in accord with a figure of merit for prismatic based actuators defined by the force generated in a working volume,

$$F_x = \rho_E h \frac{\partial A}{\partial x} \quad (18.2)$$

defined by a height  $h$  and area  $A$  tangent to the axis of motion in the  $x$  direction. The energy density multiplier,  $\rho_E$ , is limited for a magnetic actuator by the magnetic flux saturation density,  $B_{\text{sat}}$ , as was previously described, or for an electrostatic actuator by the electric breakdown field,  $E_{\text{bkdn}}$ , via:

$$\rho_{E_m}(\text{max}) = \frac{B_{\text{sat}}^2}{2\mu_o} \quad (18.3)$$

$$\rho_{E_e}(\text{max}) = \frac{1}{2}\epsilon_o E_{\text{bkdn}}^2 \quad (18.4)$$

**FIGURE 18.48** Plot of magnetic and electric pressure generated for various drive levels. Solid lines are magnetic with  $ni$  in ampere-turns and dashed lines are electric with  $V$  in volts as in Eqs. (18.5) and (18.6). Maximum pressures for limiting  $B$  and  $E$  fields are also indicated.

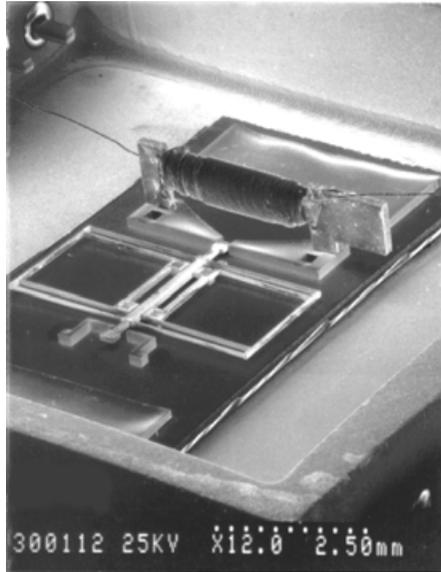

where  $\mu_o = 4\pi(10)^{-7}$  Hy/m and  $\epsilon_o = 8.854(10)^{-12}$  F/m are the vacuum permeability and permittivity, respectively. In terms of driving electrical parameters,  $ni$  (ampere-turns) for magnetics and  $V$  (volts) for electrostatics, and working volume air gap  $d$ , the relationships for actuator pressure become:

$$\rho_{E_m} = \frac{1}{2}\mu_o \left(\frac{ni}{d}\right)^2 \quad (18.5)$$

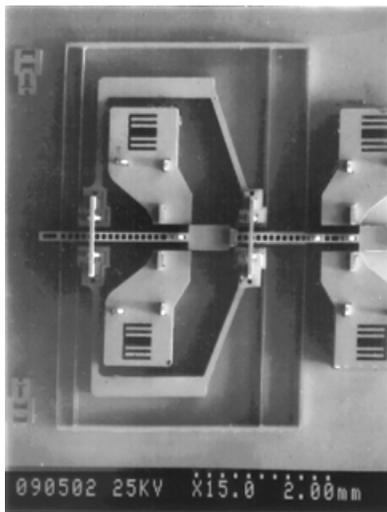

$$\rho_{E_e} = \frac{1}{2}\epsilon_o \left(\frac{V}{d}\right)^2 \quad (18.6)$$

The caveat in the magnetic case is that an efficient magnetic circuit is assumed with high permeability or soft ferromagnetic material. A plot of these equations in Figure 18.48 reveals the impedance–pressure trade-off for various working gaps.

Linear magnetic microactuators have been fabricated with three basic components. A movable plunger constrained by a folded spring flexure operates into a magnetic circuit portion that supports the transfer of flux to the working gap. Both components are fabricated from a soft ferromagnetic material such as 78/22 nickel/iron or 78 Permalloy. The third component, a coil, has been most effectively realized by conventional miniature coil winding techniques using a DXRL-defined mandrel that may be press-fit into the magnetic circuit. Figure 18.49 shows a typical construction for such a magnetic variable reluctance (VR) linear microactuator. Typical performance of this microactuator type at a structural thickness of 150  $\mu\text{m}$  is a force output in excess of 1 mN, with a stroke of 450  $\mu\text{m}$  for an input current of 40 mA and corresponding input power of 10 mW. The resonant characteristics include a resonant frequency near several hundred Hz and amplitude of  $\pm 200$   $\mu\text{m}$  at an input power of 200  $\mu\text{W}$  with a quality factor in air near 200. With an inductance change of 1  $\mu\text{Hy}/\mu\text{m}$ , the possibility of using inductance sensing to control microactuator position has been exploited [Guckel et al., 1996b; 1998; Stiers and Guckel, 1999]. The device depicted in Figure 18.50 uses a sense coil as part of an oscillator circuit whose resonant frequency is compared to an input frequency representing the desired actuator position. A phase detector

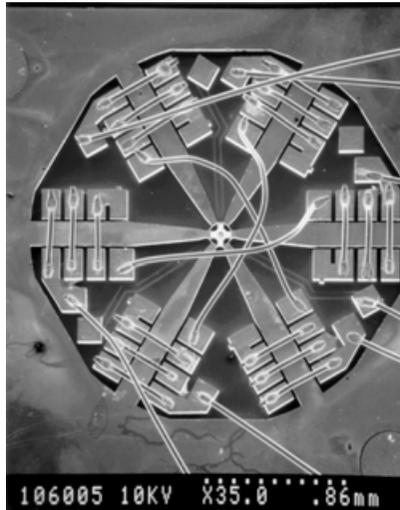

**FIGURE 18.49** Packaged VR linear microactuator.

**FIGURE 18.50** Linear magnetic microactuator with sensing for closed-loop control. All components are 78 Permalloy. Wound coil forms remain to be inserted into the serrated magnetic pad areas.

circuit that integrates the difference in drive frequency and sense frequency yields an effective phase-shift signal that constitutes a position error. Despite a significantly reduced electrical quality factor for microscale inductance-based oscillators, with the use of an integrating phase detection scheme a positional accuracy of 260 nm was realized with a settling time of roughly 100 ms.

Magnetic rotational microactuators have also been fabricated using a process similar to that of linear types, with the difference being the substitution of a rotor for the linear armature. [Figure 18.51](#) shows a rotational magnetic micromotor integrated with silicon-rotor-position-sensing p-n junction photodetectors, demonstrating the ability to readily post-fabricate DXRL-based structures on semiconductor substrates with microelectronics [Guckel et al., 1993]. Maximum achieved rotor speeds for 140- $\mu\text{m}$

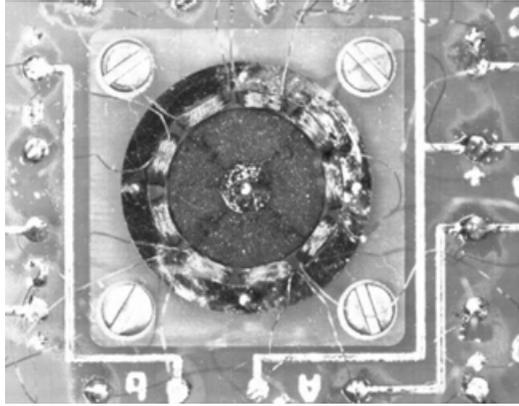

**FIGURE 18.51** DXRL-based VR stepping micromotor with integrated photodiode position sensors.

diameter rotors are 150,000 rpm for a closed-slot stator design that minimizes torque ripple in this variable reluctance design. These types of micromotors have been operated continuously for over three months at over  $10^{10}$  rotational cycles and reveal no change in operating characteristics, which for a journal bearing is quite acceptable. The low wear rate that is observed is suspected to be partially due to a vertical variable reluctance rotor suspension, a consequence of a thinner rotor than stator, that maintains rotor rotation off of the substrate. This category of micromotors with integrated wire-bonded coils is found to be rather inefficient, with output torques of the order of 10 nNm. A more efficient coil for rotational magnetic micromotors has been implemented with conventionally wound soft magnetic mandrels providing a large air gap flux and resulting in submillimeter-diameter, 200- $\mu\text{m}$ -thick rotors capable of providing 0.2  $\mu\text{Nm}$  of torque [Christenson et al., 1996].

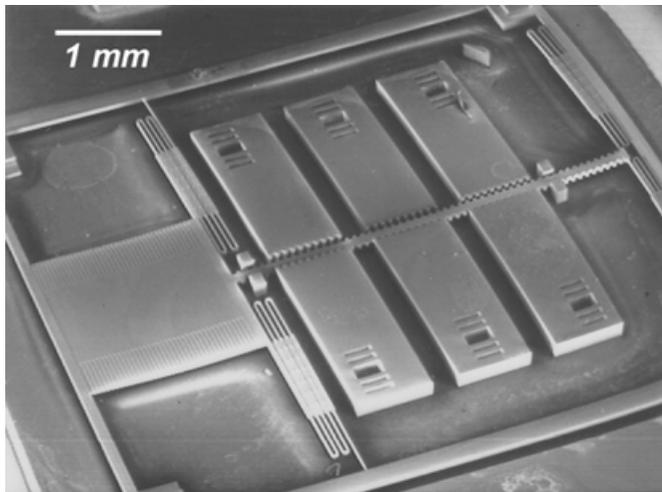

Much greater magnetic microactuator efficiency may be obtained by incorporating permanent magnets. The magnetization of permanent magnets is independent of scale which is an attribute making their use at the microscale much preferable to an electromagnet. An electromagnetic coil possesses a magnetic field production scaling dependence that is linear and brought about by current density constraints due to thermal and electromigration limitations. Coils utilizing superconductors share the same scaling relationship, which arises due to a similar critical current density limit. The use of rare-earth-based permanent magnets, in particular, is attractive due to their high magnetization and high demagnetization resistance making them amenable to a nearly arbitrary aspect ratio. The incorporation of DXRL-fabricated rare-earth permanent magnets has been demonstrated with a miniature brushless DC motor as depicted in [Figure 18.52](#) which shows a low profile brushless DC motor with a 5-mm-diameter, four-pole, radially anisotropic bonded  $\text{Nd}_2\text{Fe}_{14}\text{B}$  rotor [Christenson et al., 1999c]. The slotless four-pole, nine-slot configuration rotates at speeds of 15,000 rpm with 2-V, 5-mA, three-phase signals and generates a maximum torque near 10  $\mu\text{Nm}$  at 300- $\mu\text{m}$  rotor thickness. The planar configuration of this motor is suitable for tasks that are present in low-profile, miniature hard-disk drives, for example.

### 18.9.3 Magnetic Microactuator Applications

Magnetic linear actuators fabricated via DXRL approaches have found many uses for optical devices. A spectrometer application, for example, uses a three-phase, magnetic, VR, linear stepping motor to stretch and compress a tunable infrared (IR) filter for miniaturized gas analyzers and multispectral IR systems [Ohnstein et al., 1995; 1996]. [Figure 18.53](#) depicts an overview of the device that includes a

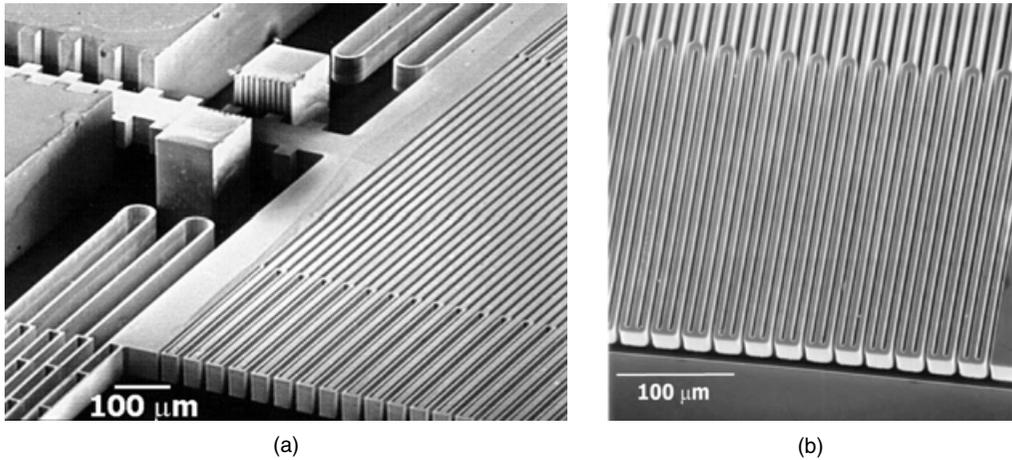

**FIGURE 18.52** Brushless DC motor with 5-mm-diameter four-pole rotor fabricated with DXRL-formed bonded  $\text{Nd}_2\text{Fe}_{14}\text{B}$  magnets. The rotor is mounted on a 320-mm-diameter shaft that extends into a 1.6-mm-diameter ball bearing residing under the rotor. The outer magnetic return path is 78 Permalloy with an 8-mm outer diameter. Nine coils with 120 windings per slot are arranged on a DXRL-defined PMMA coil form.

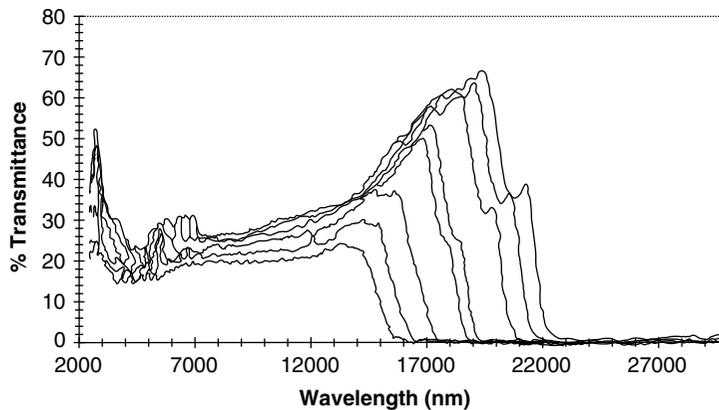

**FIGURE 18.53** Overview of tunable IR filter with integrated three-phase magnetic VR stepping linear microactuator. The IR filter is seen on the left with a  $2.5 \times 2.5$ -mm area and is supported by a frame surrounding the device. Three coils are assembled into the stator forms located to the right [Ohnstein, 1996].

DXRL- fabricated wire grid IR filter that is also part of a distributed flexure attached to an armature of a linear stepping motor. All components are fabricated from electroplated 78 Permalloy. The IR filters, shown in detail in [Figure 18.54](#), have an active area ranging from  $1 \text{ mm} \times 1 \text{ mm}$  to  $2.5 \text{ mm} \times 2.5 \text{ mm}$ , commensurate with an IR focal plane array and a wire spacing that may be deformed to yield cut-off between wavelengths of 8 and  $32 \mu\text{m}$ . The variable filter response is shown in [Figure 18.55](#). Total filter displacements of 1.7 mm were achieved with a stepping actuator, providing an average force of 2.4 mN/step at a drive current of 45 mA, which is more than sufficient for the filter spring constants at roughly 1 mN/mm.

A fiberoptic switching device has also been developed with a magnetic VR linear microactuator. A  $1 \times 2$  single-mode fiber switch consisting of a two-phase VR linear spring constrained microactuator is depicted in [Figure 18.56](#) [Guckel et al., 1999b]. Switch performance for a 125- $\mu\text{m}$ -diameter fiber with 8- $\mu\text{m}$  core

**FIGURE 18.54** (a) IR wire filter shown connected to linear stepping microactuator armature; (b) close-up of Ni/Fe IR wire filter.

**FIGURE 18.55** Transmission curves of the tunable IR filter.

includes a switching speed under 1 ms at a power dissipation of below 20 mW with as low as 0.5-dB insertion loss in air. Index matching fluids may also be used with this switch that may additionally incorporate permanent magnets for a latched state with zero power dissipation.

### 18.9.4 Other Applications

Deep X-ray lithography fabricated gears have been used to realize a miniature in-line gear pump [Deng et al., 1998]. A magnetic coupling consisting of a 78 Permalloy bar embedded in a 1.5-mm-diameter PMMA gear driven with an external motor and permanent magnet drives two counter-rotating gears in a PMMA cavity. Via a maximum calculated coupling torque of 12.4  $\mu\text{Nm}$  and a rotation speed of 3500 rpm with 200- $\mu\text{m}$ -thick gears, pumping rates of 70  $\mu\text{l}/\text{min}$  were achieved through 696- $\mu\text{m}$ -diameter inlet and outlet ports. Such a pump is self-priming and in this case was able to pull a maximum of 45 mm of water.

By combining the high density of electroplated materials such as gold with high-aspect-ratio DXRL structures, two main issues for miniaturized inertial sensors are addressed. Figure 18.57 reveals an additional possibility of integrating mechanical damping to provide an acceleration-time response [Polosky et al., 1999]. In this device, a proof-mass with extended rack feature when accelerated is driven into a

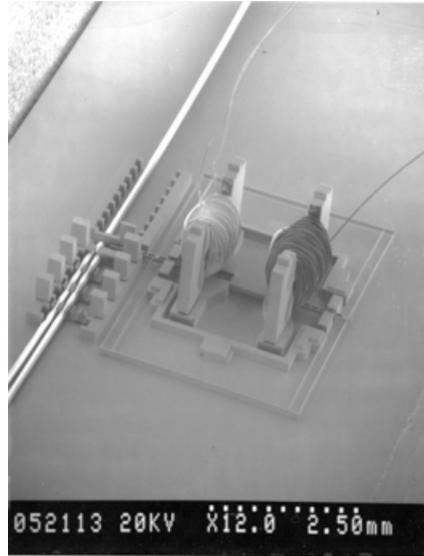

FIGURE 18.56 Assembled single-mode  $1 \times 2$  optical fiber switch.

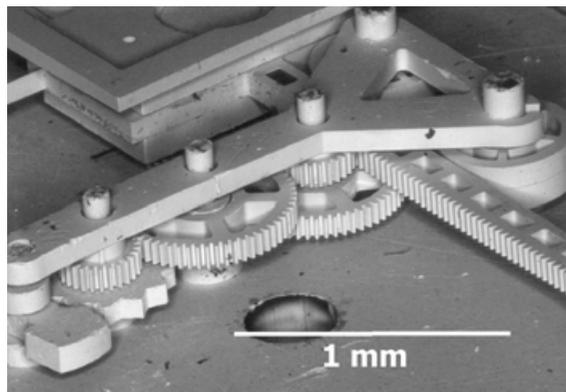

FIGURE 18.57 Assembled escapement mechanism used to provide damping for a spring-mass accelerometer structure via a rack-and-pinion coupling.

step-up gear train that drives an escapement and consequently provides damping. The resulting integrating accelerometer with total dimensions of  $4 \times 6$  mm is capable of sensing 4- to 8-g accelerations.

## 18.10 Conclusions

Tools for the microfabrication of mechanical structures continue to be aided by advancing microelectronic concerns. Many applications of micromechanics in turn ultimately depend on its integration with microelectronics. A key aspect of micromachining is achieving precision at the submillimeter scale. Highly collimated X-rays enable commensurate lithographic precision at this scale while providing a unique high-aspect-ratio capability. The utility of this batch fabrication approach is additionally enhanced by the additive nature of mold-based processing that lends itself to accommodating a large material base. The result is a generalized prismatic-based microfabrication tool set able to realize many useful microelectromechanical components and ultimately devices through repeated additive batch microfabrication steps. Consequent microsystem integration and packaging remain a challenge that this technology is well

positioned to address via its low-temperature character. Access to appropriate synchrotron radiation sources continues to improve as applications demanding high microscale precision and accuracy become more prevalent. The impending technological impact of these applications with entirely new characteristics looms large.

## Defining Terms

**Aspect ratio:** Most commonly defined as the ratio of structure height to structure width; another use is as the sidewall slope expressed as a vertical to horizontal run-out ratio.

**Beamline:** A unidirectional vacuum line extending from a storage ring that captures a segment of synchrotron radiation and transfers it to an “end-station” where the radiation is used for X-ray exposure, for example.

**Deep X-ray lithography (DXRL):** The use of X-rays to pattern photoresist at large thicknesses ( $>100\ \mu\text{m}$ ) for substantially micromechanical uses; additionally results in particularly high-aspect-ratio microstructures.

**LIGA:** A German acronym representing three fundamental processing steps: *lithographie*, deep X-ray lithography (see DXRL); *galvanoformung*, electroforming (electroplating into a mold); *abformung*, injection molding replication.

**Storage ring:** A roughly circular structure where either highly relativistic electrons or protons may be stored in a circular path for many hours; the source of synchrotron radiation.

**Synchrotron radiation:** The radiation emitted by a charged particle traveling in a circular arc as a consequence of its radial acceleration. This radiation is highly intense and directional when electrons traveling at close to the speed of light are bent in a magnetic field.

**X-ray mask:** The structure that defines the pattern during X-ray lithography. This structure must accommodate atomic absorption effects at these wavelengths and thus requires a relatively thin low atomic number carrier (the equivalent of a glass plate in UV microlithography) as well as a relatively thick high atomic number absorber (the equivalent of chromium in UV microlithography).

## For Further Information

International workshops devoted to high-aspect-ratio microstructure technology (HARMST) were first held in 1995 with a particular emphasis on DXRL processing and LIGA technique. The meetings are held directly following the international Transducers conference every other year. HARMST '95 was held in Karlsruhe, Germany; HARMST '97, in Madison, WI; HARMST '99, in Kisarazu, Japan; HARMST '01, in Baden-Baden, Germany. A book of abstracts is published with the workshop and selected papers from the workshop are published in the *Microsystem Technologies* research journal published by Springer.

Information on VLSI X-ray lithography with some DXRL subject matter is covered by the international conference on Electron, Ion and Photon Beam Technology and Nanofabrication (EIPBN), with papers published in the *Journal of Vacuum Science and Technology B*.

Book chapters devoted to the topic of LIGA may be found in *Fundamentals of Microfabrication* (M. Madou, CRC Press, 1997) and *Handbook of Microlithography, Micromachining, and Microfabrication*, Vol. 2: *Micromachining and Microfabrication* (P. Rai-Choudhury, Ed., SPIE Press, 1997; see chapters "Plating Techniques" and "High Aspect Ratio Processing"). Volume 1 also contains a comprehensive review chapter on "X-Ray Lithography."

Many LIGA-related journal articles may be found in the IoP *Journal of Micromechanics and Microengineering: Structures, Devices, and Systems*.

### 19.1 Introduction

---

Electrochemical fabrication (EFAB<sup>TM</sup>) is an emerging micromachining technology invented at the University of Southern California and licensed to MEMGen Corporation [Cohen, 1998; 1999; Tseng et al., 1999]. It is based on multilayer electrodeposition of material using a new selective deposition technique called Instant Masking<sup>TM</sup> which provides a simpler, faster and readily automated alternative to through-mask electroplating. EFAB is based on the paradigm of solid freeform fabrication (SFF), rather than the semiconductor clean-room fabrication paradigm on which conventional micromachining is based. The technology is targeted at prototyping and volume production of functional microscale components, devices and systems.

## 19.2 Background

---

### 19.2.1 Solid Freeform Fabrication

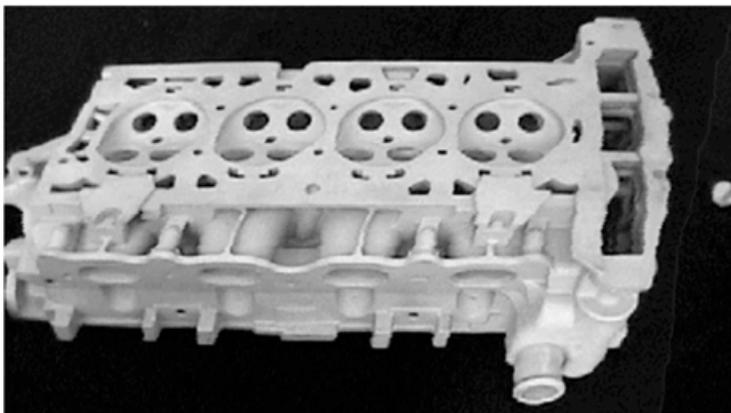

Since the late 1980s, there has been a great deal of commercial and research activity in the field known as solid freeform fabrication, also known as rapid prototyping. Generally speaking, SFF is an approach to fabricating mechanical components that is additive vs. subtractive (such as with machining). In SFF, multiple layers of material, each representing a cross section of a desired three-dimensional structure, are deposited one at a time to form a laminated stack. By using hundreds or even thousands of such layers, extremely complex, freeform, three-dimensional shapes can be produced. SFF technologies in commercial use include stereolithography, three-dimensional printing, fused deposition modeling and laminated object manufacturing.

Solid freeform fabrication technologies are characterized by a number of significant features. First, they are extremely versatile, producing extremely complex shapes (including shapes having internal features that would be impossible to produce by subtractive methods). Second, they typically involve a fixed process with just a few simple process steps repeated again and again to form each layer, and so can easily be implemented in a single process tool and automated (indeed, SFF processes almost universally run unattended). Third, they are driven in a top-down fashion by a three-dimensional CAD model of the desired structure.

Until recently, SFF has been applied primarily to the fabrication of models and prototypes of macroscale mechanical parts (e.g., the automotive part shown in [Figure 19.1](#)), and to making tooling for volume production of these parts. However, there is now growing interest in applying the SFF paradigm to micromachining, and it is this approach that is taken by EFAB.

### 19.2.2 SFF for Microfabrication

At first glance, the idea of bridging the worlds of SFF and micromachining seems dubious, and, indeed, as may be seen from [Table 19.1](#), conventional approaches to microfabrication are radically different in most ways from the approach used in SFF. Yet, if applying SFF principles to micromachining could be accomplished, it could offer a valuable alternative to conventional processes and help to make micromachining more versatile, rapid and cost-effective. SFF has the potential to offer microdevices virtually arbitrary three-dimensional geometry and thus a major increase in versatility and functionality; reduced lead times; fully automated, repeatable, unattended processing in a single, self-contained process tool;

**FIGURE 19.1** A part fabricated using macroscale solid freeform fabrication; in this case, a full-size aluminum cylinder head casting for an internal combustion engine. (Courtesy of Soligen, Inc.)

**TABLE 19.1** Conventional Microfabrication Compared with SFF

Characteristic	Conventional Microfabrication	SFF
Where device is manufactured	Clean room	Self-contained process tool in office or lab
Part complexity/number of structural layers	Up to 4 (to date)	Up to 1000s (highly complex three-dimensional shapes)
How device is manufactured	Mixture of manual and automated processing	Nearly total automation
Equipment required	Multiple process tools, each performing a different process	One process tool to build device (sometimes one other for post-processing)
CAD design level	Typically two dimensional (individual mask levels)	Three dimensional (solid model)
Steps required per layer	Many, usually different for each layer	Few, identical for each layer
Throughput	Fairly low (hours or days per layer)	High (minutes per layer)
Knowledge/skill level needed to design device	Rather high (commonly doctoral level)	Moderate (Bachelor's degree)
Knowledge/skill level needed to fabricate device	Rather high	Low (technician)
Capital expenditure required to produce devices	\$5–100s of millions	\$50–500,000

low-cost prototyping and manufacturing infrastructure with minimal need for a clean room; and easier design of devices.

### 19.3 A New SFF Process

While it is desirable to apply the principles of SFF to microscale manufacturing, the specific SFF technologies that have been developed for making macroscale models and prototypes do not readily lend themselves to this task. For example, most SFF processes cannot produce minimum features less than 75 to 100  $\mu\text{m}$  wide, yet microscale devices may require minimum features in the range of 10 to 25  $\mu\text{m}$  or smaller (e.g., for electrostatic actuators). Also, most SFF processes cannot produce layers thinner than about 75 to 150  $\mu\text{m}$ , yet the overall height of many microdevices ranges from several microns to several hundred microns. Therefore, much thinner layers (e.g., a few microns) are required to define a multilayer three-dimensional geometry that minimizes dimensional distortions and “stairsteps” on curved or oblique surfaces.

While the costs of traditional SFF are acceptable on the macroscale as a means of making prototypes, for micromanufacturing one requires a method that is suitable for both prototyping *and* volume production, as there is no other means of fabricating large quantities of functional devices. This means that a viable microscale SFF process needs to both be economically scaleable and work with functional engineering materials. Unfortunately, virtually all SFF processes are not batch processes and generate a layer serially (i.e., one volume element at a time), so are too slow and costly for quantity production. Also, SFF processes typically are based on materials whose physical properties leave something to be desired in terms of their functionality. For example, they tend to suffer from low strength, low ductility and low temperature resistance, either due to the intrinsic properties of the material or the presence of pores.

A further problem with some conventional SFF processes for micromanufacturing is that they do not produce net-shape structures, but instead require that support structures—in effect, “scaffolding”—be fabricated along with the desired structure. When these supports are made of the same material as the desired structure they must be removed manually. This is difficult and quite costly if the structure is very small and is clearly not viable for large-volume production. Finally, some macroscale SFF processes produce structures that are shrunken or distorted with respect to the CAD design, usually due to phase changes of the material or thermal effects during processing.

Several teams have been working to develop microscale versions of one SFF process—stereolithography [e.g., Zhang et al., 1998]—which have succeeded admirably in generating interesting structures having small features and thin layers. However, most “microstereolithography” processes are (as on the macro-scale) still serial<sup>1</sup> and require support structures for most geometries. Also, the materials used are still photopolymers, which do not offer the mechanical, electrical, thermal and optical properties desired for many microscale applications.

Given these issues with pre-existing SFF processes, it was determined necessary to develop a new SFF process suitable for microscale applications. The resulting new process is based on electrodeposition.

### 19.3.1 Why Use Electrodeposition?

Electrodeposition is a tremendously important industrial process used to finish metal parts (in the case of electroplating) and to manufacture metal parts by depositing metal over pre-formed mandrels (in the case of electroforming). Electrodeposition is carried out in an electrochemical cell comprising two electrodes—an anode and a cathode—and an electrodeposition bath. When depositing metals, the workpiece or mandrel serves as the cathode. When a current is applied, metal ions in solution migrate to the cathode where they become neutralized to form metal atoms which coat the cathode as a metallic deposit. In many plating processes, the anode also dissolves, producing metal ions that replenish those being deposited.

Compared with the additive processes on which most SFF processes are based, electrodeposition offers functional engineering materials such as metals and alloys that provide highly desirable properties. Moreover, electrodeposition allows material to be deposited on a very fine scale: essentially atom-by-atom (vs. particle-by-particle, drop-by-drop or sheet-by-sheet as in other SFF processes). This allows extremely thin, dense deposits to be produced with good material properties. Furthermore, with electrodeposition, material may be deposited over an entire layer (which may contain hundreds or thousands of devices) simultaneously, enabling batch processing. As a low-temperature process (i.e., 20 to 90°C), electrodeposition can achieve functional metal structures that exhibit low residual stress and no shrinkage. Finally, because more than one material can be readily deposited on a single layer, support structures formed from a different material than the structural material can be easily removed using an automated, batch process.

### 19.3.2 Selective Electrodeposition

A further key benefit of electrodeposition is that it can be used to define very small features. Some techniques for accomplishing selective electrodeposition are as follows.

#### 19.3.2.1 Through-Mask Plating

Through-mask plating is the standard technique for high-precision selective electrodeposition. It is used in the manufacture of read/write heads for hard disk drives and serves as the basis of the LIGA process. The technique can be used to create features down to 1 μm or smaller. Initially it might appear that through-mask plating provides a suitable patterning method for an SFF-type process. Indeed, a patent [Guckel, 1993] describes a multilayer electrodeposition process that relies on this approach to define each layer. With through-mask plating, a metal substrate is cleaned, photoresist is applied and exposed through a photomask, the resist is developed and often descummed, the substrate is plated through apertures in the resist, and, finally, the resist is chemically stripped. The entire process involves a large number of distinct steps, the use of several different pieces of equipment, often located in a cleanroom, and the application of or immersion in multiple liquids. Though it is of course possible to automate all these steps, the result would be a process tool of high complexity and cost. Furthermore, total cycle time for

---

<sup>1</sup>Some work in this area uses an electronically addressable mask and illuminates the entire substrate simultaneously; however, there is a trade-off between resolution and substrate area.

through-mask plating is on the order of several hours, so repeating all these steps hundreds or thousands of times to fabricate a complex 3-D microstructure would seem impractical.

### 19.3.2.2 Other Conventional Approaches

Other approaches to selective electrodeposition are brush plating, in which an electrodeposition bath is applied locally to a substrate using a brush-type electrode, and laser-enhanced plating, in which the electrodeposition rate is locally accelerated by the rise in temperature due to absorbed laser radiation. These processes have difficulty producing very small, well-defined features and tend to be slow, as they are essentially serial.

### 19.3.2.3 Sharp Anode

Some work on fabricating microstructures using selective electrodeposition was performed at MIT in which an anode with a very sharp tip was moved in a three-dimensional path [Madden and Hunter, 1996]. Deposition was observed to occur preferentially in a localized volume due to the high current density near the tip, and spline-like structures such as springs were produced in metals such as nickel. As attractive as this process is in terms of its ability to fabricate structures directly from CAD design data, it would have difficulty generating arbitrary three-dimensional shapes (e.g., structures with overhangs), as it lacks a support material, and the features created are rather imprecisely defined. Also, even if the process were to incorporate multiple anodes, it would appear to be somewhat slow for mass production.

Given these limitations of known methods for selective electrodeposition, it was necessary to develop a new technique on which to base a viable SFF-based micromachining technology.

## 19.4 Instant Masking

---

This new technique goes by the name of Instant Masking<sup>TM</sup>. It is similar to through-mask plating in that it uses photolithography to create a mask that defines the desired pattern of deposition and also allows material to be deposited simultaneously over an entire layer. Yet, unlike through-mask plating, Instant Masking: (1) allows the photolithographic processing to be performed completely *separate* from the device-building process; (2) allows all of the necessary masks to be produced as a batch, *prior* to part generation rather than *during* part generation; and (3) potentially allows the mask to be re-used.<sup>2</sup> By eliminating the need to repeat the photoresist processing inherent in through-mask plating over and over again for every layer, Instant Masking provides the enabling technology for a simple, low-cost, automated, self-contained SFF process tool that builds microdevices. Although the photolithographic steps required to generate micron-scale features may still need to be performed in a traditional clean room, the separation of mask fabrication from device fabrication allows for much-improved speed, efficiency and cost effectiveness. For example, the owner of the process tool does not need to spend millions of dollars to establish a clean room, as the Instant Mask<sup>TM</sup> can be purchased from an outside source, much like a printing plate, a photomask or an injection molding die is purchased now.

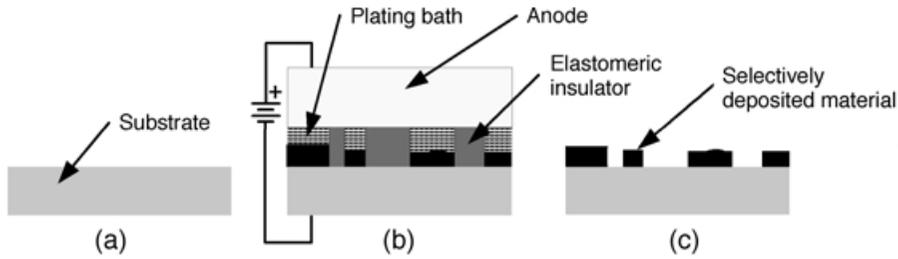

### 19.4.1 A Printing Plate for Metal

Instant Masking as a process is somewhat analogous to printing of ink on paper. With the latter process, a printing plate is fabricated which has a surface pattern that is the mirror image of the desired distribution of ink on paper. The plate is inked and pressed against the paper, then removed, resulting in a patterned deposit of ink. With Instant Masking, an Instant Mask is fabricated which has a surface pattern that is the mirror image of the desired distribution of metal on a substrate.<sup>3</sup> The Instant Mask is immersed in

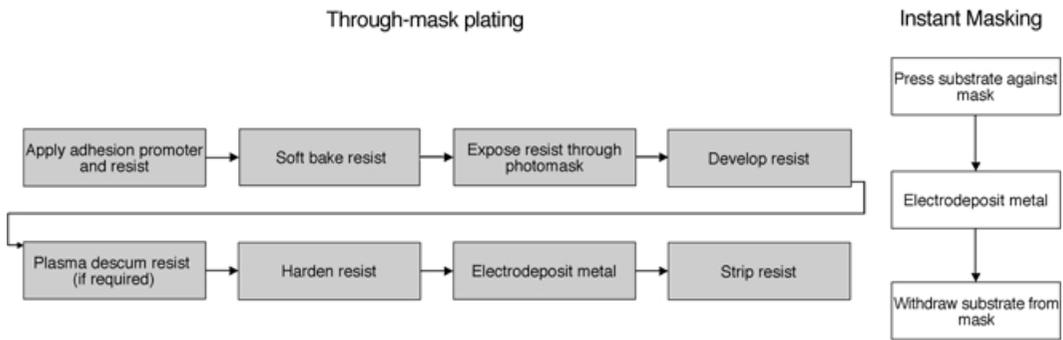

---

<sup>2</sup>Compared with the patterned photoresist used in through-mask plating, which is chemically removed and disposed of after electrodeposition.

<sup>3</sup>The term *substrate* signifies either the actual substrate upon which a microstructure is fabricated or, equivalently, the previous layer of a multilayer structure which itself behaves as a substrate for the next layer.

**FIGURE 19.2** The Instant Masking process: (a) bare substrate; (b) during deposition, with the substrate and Instant Mask in intimate contact; (c) the resulting patterned deposit.

**FIGURE 19.3** Instant Masking greatly reduces the number of steps required by conventional through-mask plating.

an electrodeposition bath and pressed against the substrate, current is applied and the mask is then removed to produce a micropatterned deposit of metal (Figure 19.2). Figure 19.3 compares the steps required for Instant Masking with those that may be required for through-mask plating, suggesting that simplification and improved speed are possible by bypassing the need for photoresist processing.

The Instant Mask is a two-component device, consisting of a layer of an insulating elastomeric mask material that is patterned with apertures and attached to an anode (Figure 19.2b). The elastomeric mask, having a typical hardness in the range of 5 to 300 Shore A, conforms to the topography of the substrate and prevents deposition of material other than within the region of the apertures. The anode serves its usual role in an electrodeposition cell but also provides mechanical support for the elastomer layer. Because the goal is to build nearly arbitrary three-dimensional structures, it is necessary to pattern nearly arbitrary two-dimensional cross sections, often with complex topology. Isolated “islands” of mask material are maintained in precise alignment by being attached to, and supported by, the anode.

### 19.4.2 Instant Masking Performance

The key performance issues with Instant Masking are (1) how selective the deposition process really is (i.e., is there any extraneous deposit, “flash,” in the masked areas); (2) how small a feature can be patterned with sharply defined edges and without flash; and (3) how thick a deposit can be obtained (too thin a layer is not acceptable, as layers in the range of 2 to 10  $\mu\text{m}$  would normally be desired for micromachining). Investigation of these issues was initially performed using the simple “printing press” apparatus shown schematically in Figure 19.4.

At the bottom of the apparatus, immersed in an electroplating bath, is an Instant Mask, with the patterned mask material facing upward. Located above the mask is a planarized metal substrate, mounted

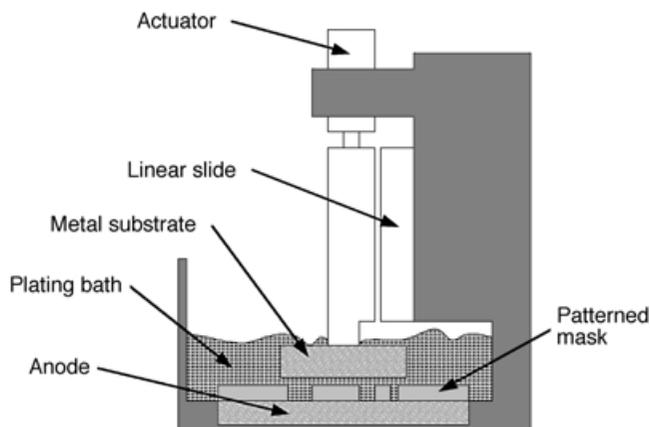

FIGURE 19.4 “Printing press” type of apparatus used to test Instant Masking.

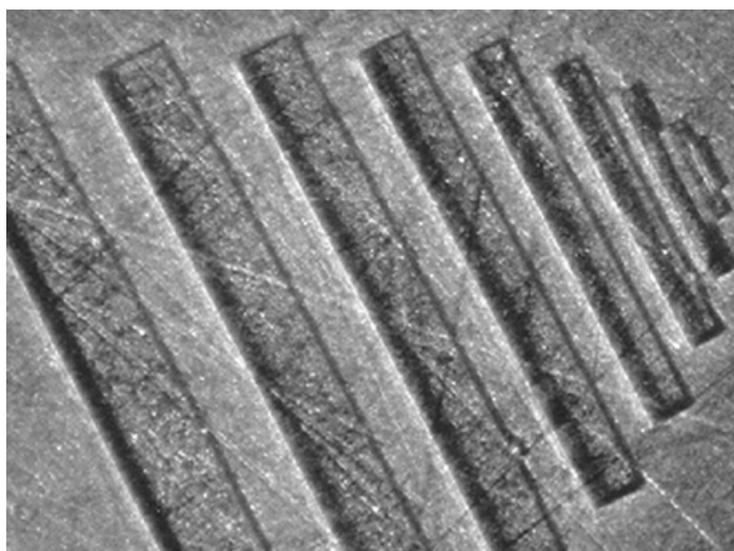

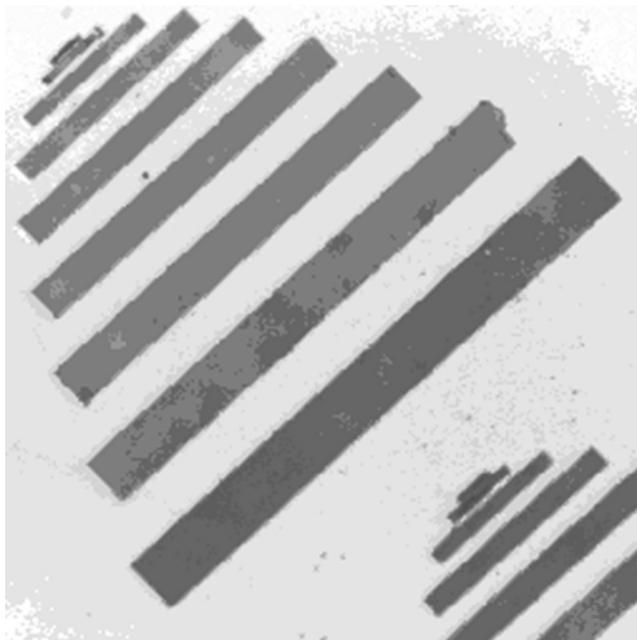

FIGURE 19.5 An Instant Mask featuring a resolution test pattern. The largest bar is 200  $\mu\text{m}$  wide and the smallest is 12  $\mu\text{m}$  wide.

on a linear slide that enables it to be pressed against the mask. Figure 19.5 shows a typical Instant Mask, in this case, one having a resolution test pattern in which the smallest bar is 12  $\mu\text{m}$  wide (along the short axis) and the largest is 200  $\mu\text{m}$  wide. Experiments using this and other apparatus and masks have shown very good definition of the plated deposit, as long as the substrate is reasonably flat, smooth and parallel to the mask. For example, as shown in Figure 19.6, the edges of the deposit are sharp and show virtually no flash<sup>4</sup> on bars down to 25  $\mu\text{m}$  in width, although 12- $\mu\text{m}$  bars showed some definition problems.

Instant Masking involves conditions very different from those in standard electroplating baths, in which a large volume of bath is available. Indeed, a solid understanding of the electrochemical phenomena under these conditions is not yet available. An immediate concern one might have is deposit thickness, as during Instant Masking there is a very small volume (as little as tens of picoliters) of electrodeposition

<sup>4</sup>Traces of electrolyte remain on the substrate in this photograph.

**FIGURE 19.6** A deposit of Cu on Ni produced with the mask of [Figure 19.5](#).

bath within the electrochemical cell formed by the anode, cathode and patterned elastomer. This tiny volume is capable of supplying only enough ions to deposit a few nanometers of material. Fortunately, this problem can be solved if the Instant Mask anode is made from a metal that is electrochemically dissolved during deposition so as to provide “feedstock.” Thus, Instant Mask anodes are normally made of the same metal that is to be deposited and normally erode several microns while depositing a layer. This erosion cannot be allowed to continue too long, as it can undercut and potentially delaminate the elastomer; however, to allow re-use of masks, it is believed that Instant Masks could be regenerated by plating metal back into the apertures to replace metal that has been lost (with the already-patterned elastomer serving as a mask).<sup>5</sup> [Figure 19.7](#) is a micrograph of an Instant Mask used to create the thick (approximately 13  $\mu\text{m}$ ) deposit shown in [Figure 19.8](#).

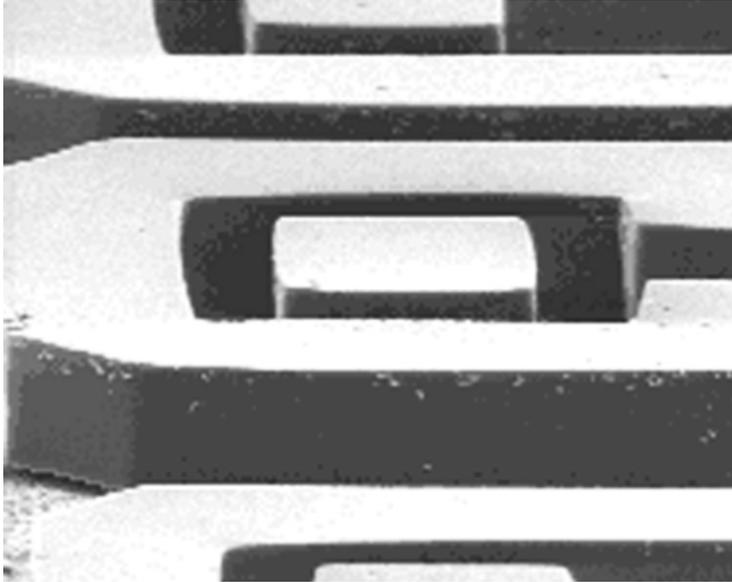

Other aspects of Instant Masking as a new method of electrodeposition still require further investigation. For example, chemical changes in the trapped volumes of the electrodeposition bath may occur during deposition. Also, because hydrogen is evolved when depositing materials with low current efficiency, deposition of these materials using Instant Masking may be problematic, as there is no escape route for these gasses. Difficulties with such materials have not been verified; however, efforts to date have focused on depositing metals such as copper having very high current efficiency. The strategy is generally to deposit the sacrificial material using Instant Masking and use conventional (i.e., open bath) plating methods to deposit the structural material, thus allowing for a considerable variety of structural materials without any of the constraints that Instant Masking might impose.

## 19.5 EFAB

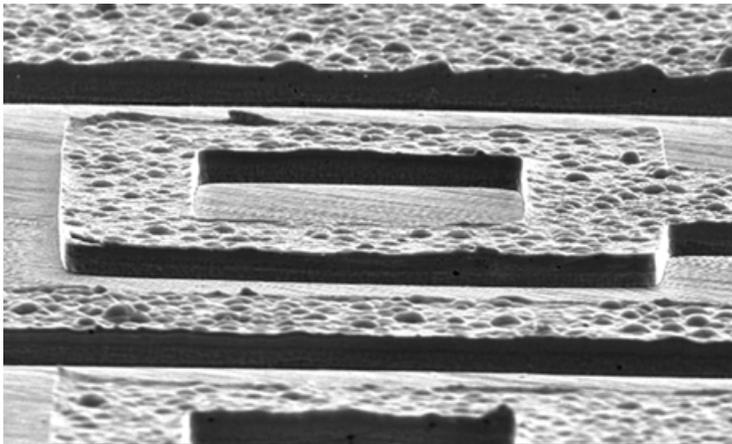

---

Having demonstrated the ability of Instant Masking to selectively deposit material in a simple, fast and easily automated manner, a new SFF process based on it was developed called EFAB.

<sup>5</sup>This process has not yet been developed.

**FIGURE 19.7** An Instant Mask used to pattern material for a single layer of a microstructure. The mask thickness (vertical dimension) is approximately 60  $\mu\text{m}$ .

**FIGURE 19.8** A thick ( $\sim 13 \mu\text{m}$ ) copper deposit produced with the Instant Mask of [Figure 19.8](#).

### 19.5.1 Multiple-Material Layers

A completed layer produced with EFAB consists of both a structural and a sacrificial material, as illustrated in [Figure 19.9](#). The sacrificial material in which EFAB-built devices are temporarily embedded serves the same purpose as sacrificial material in surface micromachining: mechanical support of structural material. This eliminates virtually all restrictions on microstructure geometry,<sup>6</sup> allowing the structural material on a layer to overhang—and even be disconnected from—that of the previous layer. [Figure 19.10h](#) shows a geometry that would suffer from a disconnected “island” on the fourth layer (right side) were there no

<sup>6</sup>The only restriction relates to the removal of sacrificial material: A hollow structure with no access to the interior cannot be fabricated, and certain geometries may include gaps, holes and slots that are difficult to clear of sacrificial material, especially if these features are long and narrow.

FIGURE 19.9 Plane view of a typical layer in EFAB, depicting structural material and surrounding sacrificial material.

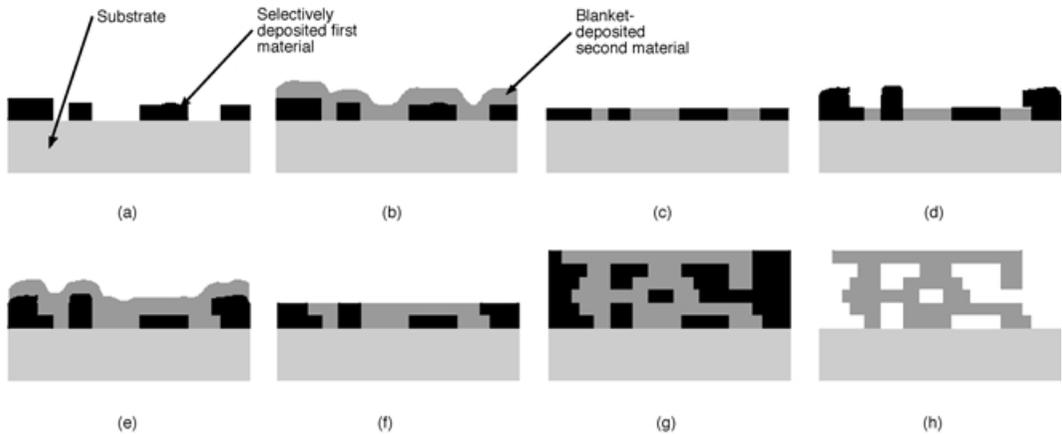

FIGURE 19.10 Steps in the EFAB process, as detailed in the text.

sacrificial material on the third layer. Such geometrical freedom also makes possible monolithically fabricated “assemblies” of discrete, interconnected parts (e.g., a gear train) without the need for actual assembly. The placement of the sacrificial material, and its ultimate removal in an automated batch process, is not geometry-specific (avoiding the need for explicit design and manual removal of support structures).

In EFAB, both the structural and the sacrificial materials are normally electrodeposited. For example, nickel can serve as the structural material, with copper as the sacrificial material. It is very important that both materials be conductive, as a conductive substrate is required for electrodeposition, and the goal is to allow layers to be deposited over one another regardless of the particular cross-sectional geometry of either layer.

## 19.5.2 Process Steps

Once Instant Masks representing each unique cross section of the desired microstructure and a suitable substrate have been prepared, the EFAB process can commence. This consists of the following three basic steps, repeated the same way for every layer: (1) selectively deposit a first material, (2) blanket deposit a second material and (3) planarize. The process flow is depicted in Figure 19.10 for a simple six-layer structure. In Figure 19.10a, the first material (here, the sacrificial material) has been selectively deposited onto a substrate using Instant Masking to yield a (partial) first layer. In Figure 19.10b, the second material (here, the structural material) has been blanket-deposited over this, contacting the substrate in those areas not covered with the first material. Then, as in Figure 19.10c, the entire two-material layer has been planarized to achieve precise layer thickness, smoothness and planarity. In Figure 19.10d, the first material has been selectively deposited for the second layer, while in Figure 19.10e the second material has been blanket-deposited over this. Figure 19.10f shows the second layer after planarization. After repeating these three steps for the remaining layers, the result is the embedded structure of Figure 19.10g. This is then etched to remove the sacrificial material, yielding the desired structure (Figure 19.10h).

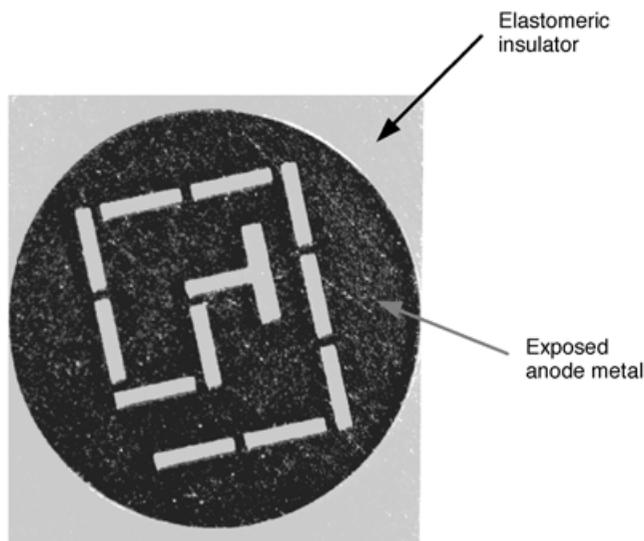

## 19.6 Detailed Process Flow

### 19.6.1 Mask Making

All SFF processes require software to generate cross-sectional layer geometry from three-dimensional CAD geometry. With EFAB, one or more standard photomasks must be prepared which include the geometry of all the cross sections of the device. Specialized Microsoft Windows<sup>®</sup>-based software called Layerize<sup>™</sup> has been developed which imports three-dimensional CAD geometry in a format that virtually all three-dimensional CAD systems can export (the SFF industry standard .STL file) and exports a two-dimensional file in a format accepted by commercial photomask pattern generators (e.g., a CIF or GDSII file). Layerize also takes as its inputs a set of rarely changed parameters located in an editable parameter file and a set of frequently changed parameters input by the user. It calculates the cross sections for each layer of the desired structure, formats them appropriately, and lays them out across the available photomask area. In a planned future version of Layerize, the geometries of cross sections will be compared and multiple layers will be assigned to a single mask, to reduce the total number of masks required.

For making prototype quantities of microdevices, the substrate is usually much smaller in area than the Instant Mask. Thus, the file that Layerize generates contains multiple smaller masks, or *submasks* (an example of which is shown in Figure 19.11), all of which are patterned on a common anode to form a single, easy-to-handle mask (Figure 19.12). One advantage of this approach is that all the submasks on the Instant Mask are patterned from the same photomask and are thus mutually aligned with the precision intrinsic to the photomask; this facilitates mask–substrate alignment later. Layerize also outputs a file that can control an automated EFAB process tool (e.g., instructing it which mask to use for each layer). Figure 19.13 illustrates the inputs and outputs of Layerize.

Once a photomask is produced (typically in two to four days), it is then used to fabricate the Instant Mask. One method of fabricating Instant Masks is based on micromolding. For example, the photomask can be used to expose a layer of thick photoresist deposited on a substrate, which when developed yields a two-level mold corresponding to the photomask geometry. A liquid elastomer can then be applied to the mold and a metal anode is then placed in contact with the elastomer and pressed to squeeze out

**FIGURE 19.11** A single submask of an Instant Mask used to define a single cross section. The circle is approximately 1.7 mm in diameter.

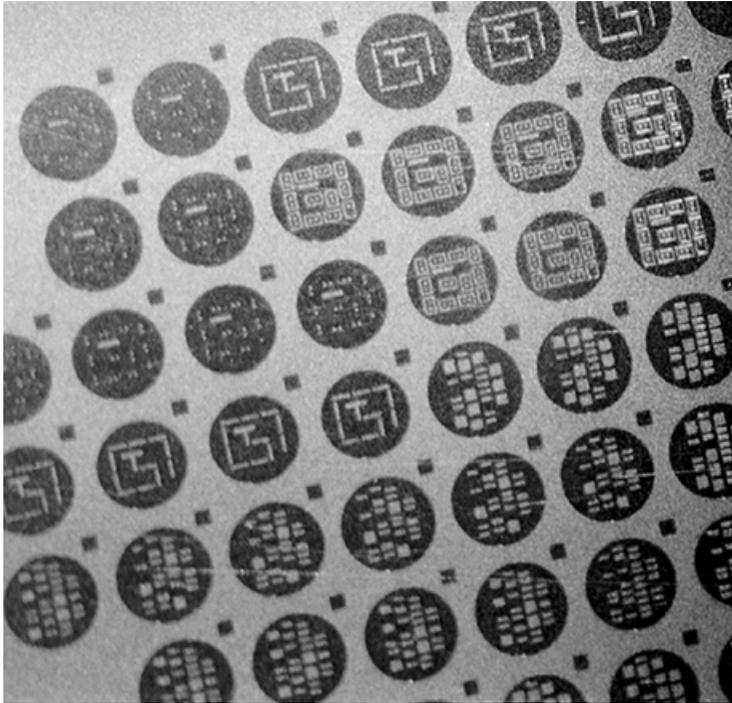

FIGURE 19.12 An Instant Mask comprising multiple submasks.

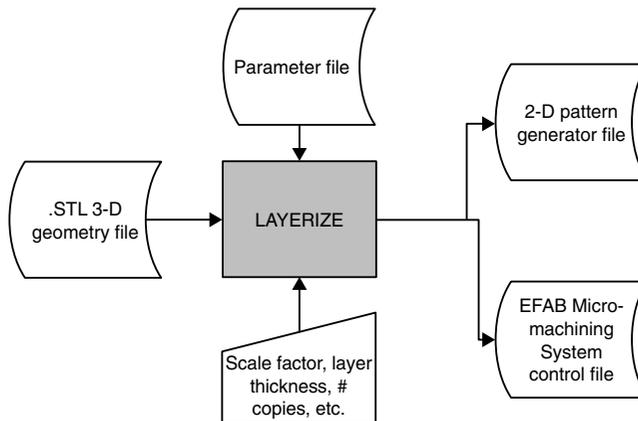

FIGURE 19.13 Inputs and outputs of Layerize software used for EFAB.

excess material. The elastomer can thereafter be hardened, after which it can be de-molded. Using this method, Instant Masks can be fabricated for all the required masks from a photomask within two days and then installed in the EFAB process tool.

### 19.6.2 Substrate Preparation

A conductive material to which the deposited materials are capable of adhering is needed as the substrate for the EFAB process. Typically, this is a metal plate, which is initially planarized before being installed in the EFAB process tool (it may alternatively be planarized online within the system), to provide a relatively flat, smooth starting surface for Instant Masking deposition.

### 19.6.3 EFAB Layer Cycle

The three steps performed on each layer in EFAB are described more fully as follows, with reference to [Figure 19.14](#), which depicts the configuration and operation of the tabletop, manually operated EFAB process tool shown in [Figure 19.15](#). The system consists of several subsystems: The first, a substrate fixture, includes a substrate onto which the layers are deposited, a linear slide to move the substrate up and down (to mate and unmate with the mask, to accommodate the addition of layers and to allow for motion during planarization) and a linear actuator. A second subsystem, for selective deposition, includes an Instant Mask (such as that shown in [Figure 19.12](#)) having multiple submasks, repeatable  $x$ - and  $y$ -travel stages, and a tank to contain the electrodeposition bath. A third subsystem, for blanket deposition, includes an anode and a tank containing an electrodeposition bath. Finally, a fourth subsystem is used for planarization—in this case, lapping (in the following, it is assumed that the substrate is already planarized before the first layer is created).

#### 19.6.3.1 Selective Deposition

An Instant Mask is mounted within the tank of the selective deposition subsystem; the  $x$ - and  $y$ -coordinates of each submask are measured using a microscope and recorded. Then the substrate is immersed in an electrodeposition bath for the first material to be deposited. A substrate is mounted in the substrate fixture, which is then lowered on top of the selective deposition subsystem and aligned manually by mechanical means. The mask is positioned using the  $x$ - and  $y$ -stages to locate the submask for the current layer in the correct position below the substrate ([Figure 19.14a](#)), according to the recorded coordinates. The actuator then lowers the substrate onto the mask. Once the substrate and mask are mated, an electric current of a magnitude calculated to provide the desired current density is passed between the substrate and the anode of the mask for a time calculated to selectively deposit the desired thickness of the first material.

#### 19.6.3.2 Blanket Deposition

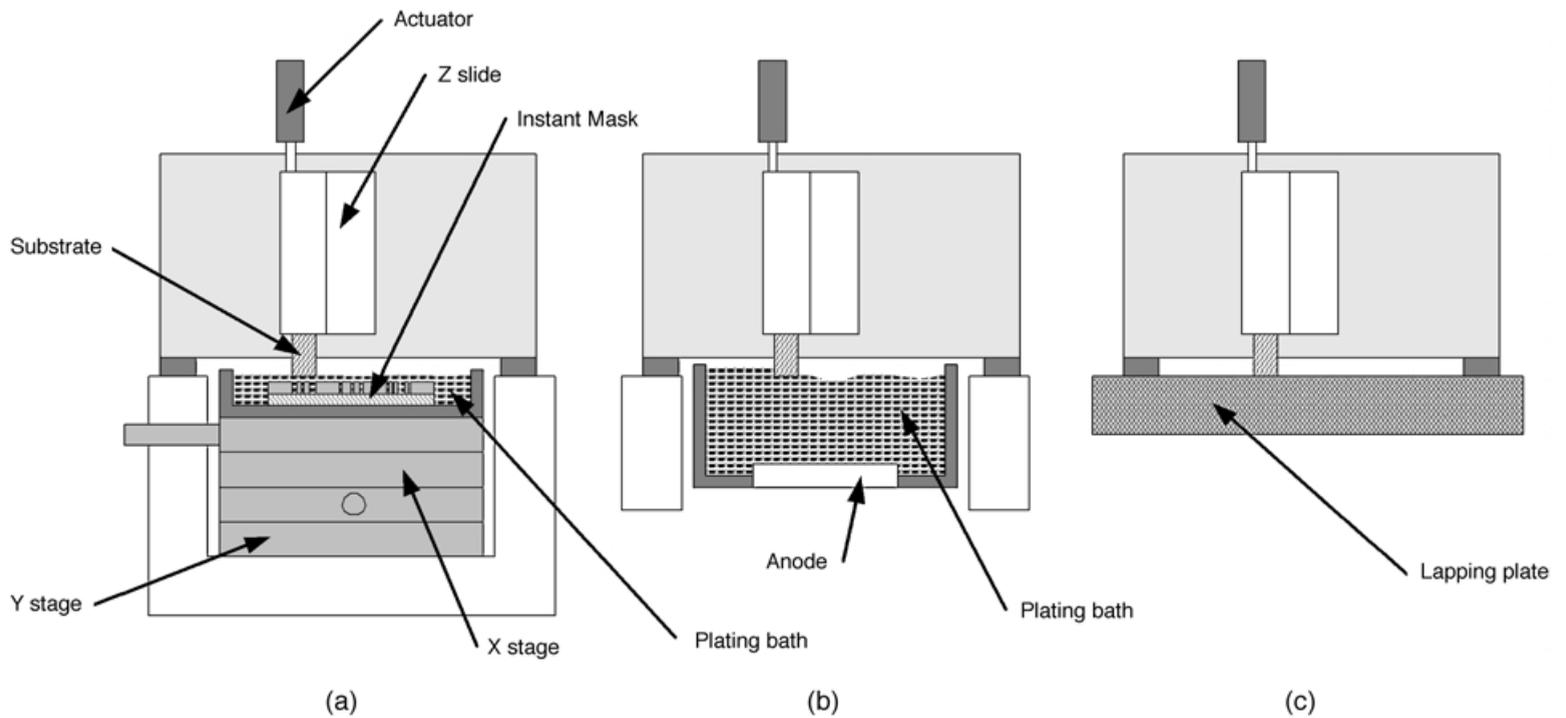

The substrate fixture is placed on top of the blanket deposition subsystem ([Figure 19.14b](#)), and the substrate is lowered into an electrodeposition bath for the second material. An electric current is passed between the anode of the third subsystem and the substrate. The current is turned off after a time calculated to deposit the desired thickness of the second material over the first material (typically the same thickness as the first material).

#### 19.6.3.3 Planarization

The substrate fixture is placed on top of a lapping plate ([Figure 19.14c](#)), and the two deposited materials are lapped until: (1) the second material no longer overlies the first, (2) the layer is reasonably flat and smooth and (3) the correct layer thickness is obtained. Electrodeposited materials are normally deposited with nonuniformities in thickness. By plating to a minimum thickness greater than that of the final layer thickness desired and then planarizing, such variations can easily be tolerated. Experience to date indicates that thickness nonuniformities are not excessive (e.g., [Figure 19.8](#)).

While it may be possible to selectively deposit both structural and sacrificial materials using Instant Masking, planarization is preferred for several reasons. For example, planarization (1) allows the use of blanket deposition of one material, thus requiring only half the masks and avoiding the need to align masks for one material with those for another; (2) avoids the need for either material to be deposited uniformly enough (e.g., due to pattern-dependent effects) to obtain a surface sufficiently planar and smooth to achieve good masking for the next layer; and (3) allows accuracy along the Z (vertical) axis to be precisely controlled.

Lapping and/or polishing may be performed using a variety of lapping plate and/or polishing pad materials and a variety of slurries, including those containing alumina, diamond and silicon carbide. Other lapping parameters include pressure and speed of the pad or plate. A means of endpoint detection must also be provided, so that lapping can be stopped when the layer is the proper thickness. Depending on the lapping materials and parameters used, surface roughnesses can be obtained on the order of 100 nm rms or smaller with very good planarity (e.g.,  $<1 \mu\text{m}$  over several centimeters). Polishing can yield even

**FIGURE 19.14** A schematic of a manually operated tabletop system used for EFAB, as described in the text.

FIGURE 19.15 The actual system shown in illustration in [Figure 19.14](#).

FIGURE 19.16 Some five-layer nickel structures measuring  $\sim 40 \mu\text{m}$  high.

smoother surfaces, when required by some applications (e.g., optical mirrors or valve seats). Certain combinations of materials may exhibit differential planarization rates, causing one material to become recessed below the surface of the other, although no such effect has been measured, for example, with copper and nickel. By proper selection of planarization materials and parameters, these effects should be largely controllable.

#### 19.6.4 Post-Processing

Once the above three steps have been repeated for all layers required, the sacrificial material is removed, typically by chemical etching. With copper as the sacrificial material, etching rates of several hundred microns per hour can be obtained. Material can be removed from fairly high aspect ratios; for example, copper has been etched from a volume with an exposed cross section of  $25 \times 300 \mu\text{m}$  to a depth of 3 mm.

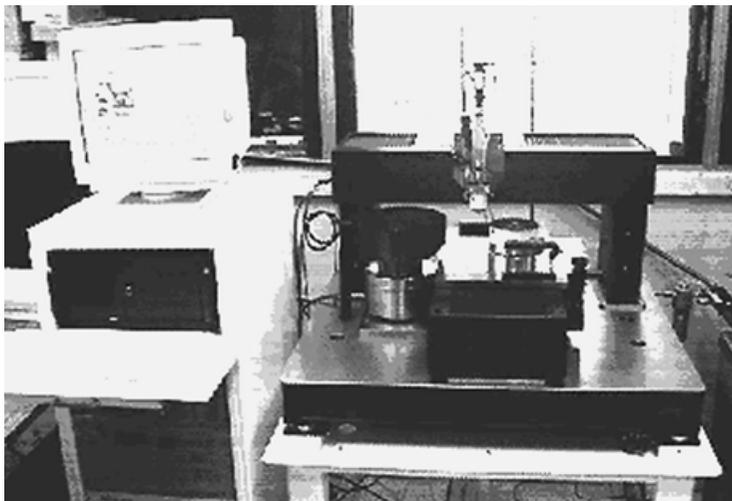

### 19.7 Microfabricated Structures

---

As of this writing, EFAB has fabricated several fairly simple nickel structures such as the five-layer structure shown in [Figure 19.16](#), whose overall height is  $\sim 40 \mu\text{m}$ . The 12-layer microchain shown in [Figure 19.17](#) has links of  $\sim 290 \mu\text{m}$ . The horizontal links are free to move, while the vertical links are in this case attached to the substrate. However, by simply including a sacrificial layer beneath these, the entire chain

**FIGURE 19.17** A 12-layer microchain fabricated in nickel using EFAB, without assembly. Overall height is  $\sim 100\ \mu\text{m}$  and the width of a chain link is  $\sim 290\ \mu\text{m}$ . All horizontal links are free to move.

**FIGURE 19.18** A prototype automated EFAB process tool, partly assembled.

could be released from the substrate. The entire chain is fabricated in a pre-assembled state, without the need for actual assembly. All structures were built using the tabletop EFAB process tool shown in [Figure 19.15](#), located in a room that is anything but clean! Far more complex structures with many more layers are planned for the next-generation automated EFAB process tool.

## 19.8 Automated EFAB Process Tool

[Figure 19.18](#) shows a partially assembled prototype of an automated process tool for EFAB, designated the EMS-Alpha (for EFAB Micromachining System). The system consists of two modules: (1) a cabinet housing a PC, motor drivers and other electronics and (2) a frame on which is mounted subsystems that perform the EFAB process (motorized motion stages, a planarization system etc.), as well as support subsystems

such as electrodeposition bath pumps and filters. The footprint of the entire system when completed will be about  $2.0 \times 2.0$  m. The system—and future commercial systems like it—could be installed in any reasonable lab space or shop floor and used to produce prototype quantities of microdevices—only compressed air and electricity vs. a clean room are required.

Whereas the manual tabletop system of [Figure 19.15](#) has a throughput of about two completed, planarized, two-material, 8- $\mu\text{m}$ -thick layers per day (in a single shift), the throughput of the EMS-Alpha is projected to be over 30 such layers per day (in three shifts). The system is designed for fully automated, unattended operation under the control of specialized software. The substrate is sized for prototyping purposes, measuring initially about 8 mm in diameter, though larger substrates can be accommodated. The system can handle several 100- $\mu\text{m}$  Instant Masks, allowing structures with hundreds of unique cross sections to be fabricated. In summary, the EMS-Alpha, when completed, will be similar in operation to commercial solid freeform fabrication systems. As of this writing, the hardware and software are being debugged and operating parameters are being established.

## 19.9 Materials for EFAB

---

EFAB can be used to form microstructures from many materials that can be deposited by electrolytic or electroless deposition from aqueous solutions at temperatures ranging from 20 to 90°C. Such materials include many pure metals (e.g., nickel, copper, gold, silver, lead, zinc, iron, cobalt), a variety of metal alloys (e.g., nickel phosphorous, tin–lead solder), certain semiconductors (e.g., lead sulfide, bismuth telluride), composites (e.g., Ni-Teflon<sup>®</sup>, Ni-diamond) and even conductive polymers as well [Schlesinger and Paunovic, 2000]. A constraint is that there must be a depositable sacrificial material available that can be selectively removed (e.g., by etching) after all layers are formed. The material system that has received the greatest attention so far is nickel and copper, with copper as the sacrificial material.<sup>7</sup> Nickel has good strength and good temperature and corrosion resistance, while copper can be selectively etched with respect to nickel fairly easily. Other structural materials compatible with copper as the sacrificial material include nickel alloys, gold, platinum, iron, tin–lead solders and nickel composites.

## 19.10 EFAB Performance

---

Primary issues with any manufacturing process for mechanical structures are geometric accuracy and materials properties. The following issues are known as of this writing.

### 19.10.1 Accuracy

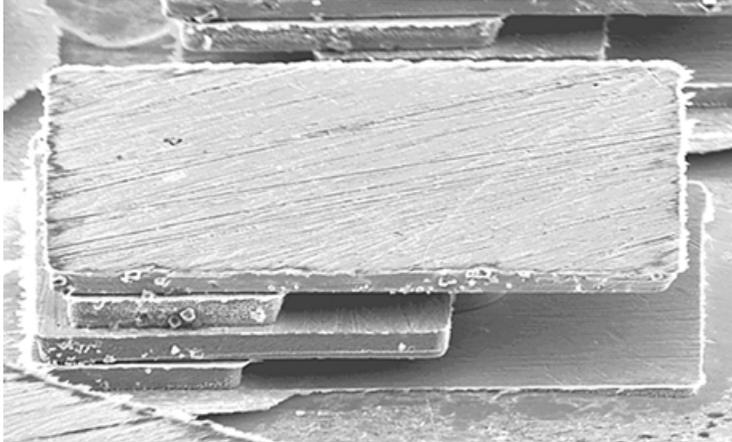

#### 19.10.1.1 *x*–*y* Accuracy

Accuracy in the plane of the layers (defined as the *x*–*y* plane) is affected by multiple factors. The width of deposited metal features is determined by the width of the corresponding features in the Instant Mask during deposition. These in turn are the result of pattern transfer distortions with respect to the photo-mask associated with fabrication of the Instant Mask and possible mask distortion due to the mating pressure of mask and substrate. However, it is believed that, once characterized, both effects can be minimized using compensation algorithms built into Layerize software to yield a feature width accuracy of approximately  $\pm 1$   $\mu\text{m}$ . Mask–substrate misalignments can cause a shift in the relative position of layers, an effect that can be observed quite easily in [Figure 19.19](#), where a five-layer, letter “E” shape<sup>8</sup> exhibits layers that are misregistered by as much as  $\pm 8$   $\mu\text{m}$ . Here, the problem was caused in part by a subsequently fixed defect in the manual EFAB system, but also by the nature of this apparatus: It uses mechanical, operator-dependent methods for registration. The EMS-Alpha, in contrast, uses precision, high repeatability

---

<sup>7</sup>This can be reversed, such that the nickel is etched and the copper is left behind.

<sup>8</sup>The bottom layer is still embedded in sacrificial material, as the etching was stopped prematurely for this structure.

**FIGURE 19.19** A Ni microletter “E,” illustrating some manufacturing artifacts. Overall height is  $\sim 40\ \mu\text{m}$ .

motion stages to achieve an expected layer-to-layer alignment of about  $\pm 1\ \mu\text{m}$ . The misalignment error will not accumulate from layer to layer, as all layers are aligned with respect to the substrate, rather than the previous layer.

Another alignment issue is *layer skew*, a problem caused by nonorthogonality between the  $z$ -travel of the substrate and the plane of the layers. Layer skew would cause a “vertical” wall formed by multiple layers that should be precisely  $90^\circ$  from the layer plane to lie at some other angle. By proper design and calibration of the system, this effect can be reduced to a few minutes of arc or better. A final  $x$ - $y$  accuracy issue is *smearing*, an artifact of the planarization process which can be seen in [Figures 19.16](#), [19.17](#) and [19.19](#) as a slight feathering of the edges of the layers in some locations. Smearing is the result of one material being deformed and pushed into another by shear forces associated with mechanical planarization processes. With nickel and copper, smearing typically causes very thin films of nickel to protrude 1 to  $2\ \mu\text{m}$  beyond the desired edge, yielding a ragged appearance. With process optimization, however, it is expected that smearing can be reduced to submicron levels, as is the case with read/write heads that are planarized using similar methods.

### 19.10.1.2 Z Accuracy

Dimensional accuracy along the  $z$  (layer stacking, or vertical) axis is determined largely by the ability to accurately control the planarization process. This further requires very accurate, high-resolution  $z$ -axis measurement and control. The methods developed for use with the manual EFAB system provide  $z$  accuracy in the range of  $\pm 1$  to  $2\ \mu\text{m}$  per layer; however, improved methods developed for the EMS-Alpha should allow for a  $\pm 2\ \mu\text{m}$  *overall* height accuracy. This nevertheless assumes that the  $z$  coordinates of all important features are specifically designed to be integer multiples of the layer thickness; if not, then because  $z$ -axis coordinates are quantized as with any multilayer process, additional inaccuracies will result.

Another potential source of inaccuracy along the  $z$ -axis is residual stress. It is not uncommon in SFF and conventional microfabrication processes to observe curling of cantilevers and other stress-sensitive geometries. This is often due to the significant residual stresses these processes may produce in deposited materials (e.g., due to phase change of materials, thermal effects etc.) With EFAB, residual stresses can be made quite low. Electrodeposited nickel, for example, can be fine-tuned so that its measured residual stress is 0 to 15 MPa (either compressive or tensile). Of course, this optimization is highly material and process-parameter dependent, and some electrodeposited materials may exhibit much higher stresses.

## 19.10.2 Materials Properties

As of this writing, materials properties of structures made with EFAB such as hardness and tensile strength have not been directly measured. However, it is expected that for a given deposition bath chemistry and set of process parameters, these would be similar to those measured for commercial electroformed metal parts, and perhaps even more similar to those measured for LIGA-produced structures. In general, electrodeposited materials, while different microstructurally from materials processed using mechanical and thermal methods, offer very useful engineering properties such as hardness, tensile strength and Young's modulus. In some cases, electrodeposited materials can even have superior properties (e.g., tensile and yield strength) to traditionally processed materials [Schlesinger and Paunovic, 2000].

Because EFAB, like all mainstream SFF, is a multilayer process, the issue of interlayer bonding is critical, especially as low tensile strength along the z-axis would compromise structural integrity and functionality in many applications. Ideally, the interlayer adhesion would be comparable to the bulk yield strength of the material. Preliminary experiments with nickel suggest that the bond strength is strongly dependent on the preparation of the substrate, and that bond strengths ranging from approximately 20% to a very large fraction of the bulk strength can be achieved.

A related matter is electrical contact resistance between layers. This is of particular importance in structures such as three-dimensional microinductors that might be made with EFAB, but which would require many interlayer junctions. Kelvin-type measurements performed with a four-point probe on stacked nickel layers having an  $85 \times 85\text{-}\mu\text{m}$  cross section indicated a per-layer contact resistance of less than  $5\ \mu\Omega$ . This low value is encouraging and is actually less than the bulk resistance of each nickel layer in the stack, therefore, it seems that complex microelectrical devices should indeed be feasible with EFAB.

## 19.11 EFAB Compared with Other SFF Processes

---

While EFAB is similar to, and inspired by, macroscale SFF processes, it is also different in some very significant ways. The fabrication of very small features and very thin layers is one obvious difference between EFAB and other SFF processes. Another is the emphasis on functional materials and the capability of depositing multiple materials (through successive masking operations on a given layer) to build sophisticated functional devices.

Still another difference is the batch fabrication capability needed for volume production, which leads to the use of fixed tooling (Instant Masks) in EFAB, rather than the "direct write" approach common to most SFF processes. The trade-off in general is between processes that are directly CAD driven but serial (e.g., stereolithography or e-beam lithography) and thus too slow and costly for volume production, and processes that use tooling (e.g., conventional semiconductor manufacturing using photomasks) but which can achieve high productivity and low cost when making devices in quantity. Because of the need for production volumes of microdevices rather than just prototypes, EFAB takes the latter approach, requiring the need for tooling. Nevertheless, to allow economical prototyping, EFAB is downward scalable, perhaps more easily so than conventional microfabrication and semiconductor fabrication. This is achieved by making use of smaller substrates than is practical with photoresist processing,<sup>9</sup> by combining multiple cross sections onto a single Instant Mask to reduce the cost of photomasks and by automation that minimizes substrate handling.

## 19.12 EFAB Compared with Other Microfabrication Processes

---

Table 19.2 compares the major microfabrication processes, as well as microstereolithography, with EFAB. While EFAB offers certain potential advantages over these other processes in some areas, there are clearly some applications for which it is not the best choice among alternative methods.

---

<sup>9</sup>Substrates as small as 1.7-mm diameter have been used.

**TABLE 19.2** EFAB Compared with Other Micromachining Processes

Characteristic	EFAB	Bulk Micromachining	Surface Micromachining	LIGA	Microstereolitho- graphy
True three-dimensional geometry (100s–1000s of levels)	Y	N	N	N	Y
No cleanroom needed for device fabrication	Y	N	N	N	Y

Dielectric structural materials available	N	(N/A for now) <sup>f</sup>	Y	Y	Y (limited)
Exotic structural materials available (e.g., piezoelectrics)	N <sup>g</sup>	N	Y	Y	N
Vertical build rate (after photolithography, where applicable)	~10 μm/hr	N/A	<<1 μm/hr	20–100 μm/hr <sup>h</sup>	Area dependent

<sup>a</sup> Exposure of thick resist to high-energy X-rays can, however, cause radiation damage to an underlying IC.

<sup>b</sup> The process is compatible in principle, but because the structure produced is an insulating polymer, IC integration is probably not very useful.

<sup>c</sup> At least one version uses a dynamic mask to expose the layer simultaneously.

<sup>d</sup> Vargo et al. (2000).

<sup>e</sup> <http://greenmfg.me.berkeley.edu/LIGA/right.htm>.

<sup>f</sup> Yes, if EFAB is supplemented by other processing, and with future extensions.

<sup>g</sup> Not directly, but this can be done by hybridizing EFAB with conventional deposition processes.

<sup>h</sup> Madou (1997).

## 19.13 EFAB Limitations and Shortcomings

Regarded as an SFF process, EFAB has certain limitations and shortcomings. The first is throughput. Electrodeposition is considerably faster (typically 25 to 100 μm/hr) than vacuum deposition processes used, for example, in surface micromachining, and the overall productivity (e.g., number of layers per day) of EFAB promises to be tens of times greater than that of surface micromachining. However, by macroscale SFF standards, the vertical build rate of EFAB is fairly low. For example, three-dimensional printing, a fast commercial SFF technology, can deposit centimeters of material per day, while EFAB can only deposit several hundred microns per day. On the other hand, there is no fundamental limit to the horizontal extents of the layer which EFAB produces. Thus, EFAB could simultaneously produce thousands or potentially millions of microdevices in a single process tool. When combined with the fact that microdevices tend to be only tens to hundreds of microns tall, the cost per device can still be very reasonable. Nevertheless, because of the build-rate limitations, EFAB is not expected to be economical

in most cases for production of small macroscale devices (e.g., taller than 5 to 10 mm)<sup>10</sup> unless there is no alternative fabrication technology that can provide the required geometrical complexity or materials properties. Another limitation already noted is that EFAB requires tooling. There is, therefore, a tooling cost and a delay of several days following completion of the design before fabrication can begin. Finally, because of the use of sacrificial material, geometries are not entirely unrestricted: the need to remove the sacrificial material imposes some constraints on the design, though constraints are far fewer than if sacrificial material were not employed.

In the context of micromachining, the major liability of EFAB as an electrodeposition-based process, especially compared with surface micromachining, is probably the incorporation of dielectric materials into fabricated structures in an arbitrary fashion. Certainly, EFAB structures can be deposited onto a substrate that comprises dielectric materials, air can be used as a dielectric when the design permits, and structures can be backfilled with dielectric. But, the ultimate goal of allowing the designer the flexibility to place dielectric material anywhere within a structure is more challenging. Several approaches to extending EFAB in this direction are under consideration, and it is believed this limitation will be overcome with further development.

When compared with surface micromachining again, EFAB is somewhat more restricted in the choice of materials, as it is possible to vacuum-deposit (using sputtering, chemical vapor deposition, evaporation etc.) an extremely wide variety of materials. However, it is believed that EFAB can be combined with conventional deposition processes in a hybrid fashion so as to expand the range of materials that can be integrated. Finally, compared with alternative microfabrication processes, EFAB's minimum  $x$ - $y$  features are—at  $20 \times 20 \mu\text{m}$ —some 4 to 10 times larger, at least at present. Because EFAB can deposit multiple thick layers, device footprints can be larger than usual without loss of stiffness, thus obviating the need for smaller features in many cases. Small gaps between structures can be achieved, however, when necessary by exploiting the multilayer nature of EFAB: Structures can be fabricated on different layers in a pre-aligned fashion and then deformed in a massively parallel manner to render them co-planar. Also, future improvements are expected to reduce as-fabricated minimum features to 5 to 10  $\mu\text{m}$ .

## 19.14 EFAB Applications

---

Broadly speaking, it is believed that with further development EFAB will be capable of fabricating a wide variety of microscale parts, micromachines, microelectromechanical systems (MEMS) and microoptoelectromechanical systems (MOEMS). The market for microscale devices in many industries (e.g., medical, automotive, electronics, aerospace) is rapidly growing. Some general areas of application include:

- Three-dimensional microscale mechanical devices (e.g., springs, screws, helical gears, drive chains)
- Monolithically fabricated multicomponent micromachines (e.g., gearboxes, motors, valves, pumps, solenoids)
- Microelectromagnetic devices requiring three-dimensional coils (e.g., on-chip high-Q and high-inductance inductors, motors, solenoids, sensors)
- Metal tooling for mass production of three-dimensional microcomponents in polymers and ceramics

Some specific application areas being investigated for EFAB include micro-power generators, switches for optical networking, microsurgical instruments and implantable medical devices (e.g., stents), micro-relays, electronics packaging and thermal management devices.

---

<sup>10</sup>Unless perhaps if the  $x$ - $y$  extents are very small, allowing many devices to be made simultaneously.

## 19.15 The Future of EFAB

---

As a fabrication technology for the microscale, major developments expected for EFAB in the next few years include:

- Commercial EFAB machines for prototyping and volume production
- Monolithic, on-chip integration of EFAB-produced structures with integrated circuits
- The ability to process additional materials, especially dielectrics

## Acknowledgments

---

The author wishes to express his gratitude to the Defense Advanced Research Projects Agency (DARPA), Defense Sciences Office and Microsystems Technology Office, for primary funding of EFAB development under the Mesoscale Machines and MEMS Programs, and to the University of Southern California/Information Sciences Institute for additional funding. The author also wishes to acknowledge all the people who have been involved to date in the development of EFAB, most particularly Gang Zhang, Uri Frodis, Fan-Gang Tseng and John Evans.

## Definitions

---

**EFAB:** A multilevel three-dimensional microfabrication process based on electrochemical deposition and the use of Instant Masking to define the geometry of the fabricated device on each layer.

**Instant Masking:** A micropatterning method involving a conformable patterned mask, an electrically active bath, and a source of current. When used for electrodeposition, the mask is mated with a substrate in the presence of an electrodeposition bath and current is applied to deposit material onto the substrate in regions not contacted by the mask.

**Instant Mask:** A mask used for Instant Masking consisting generally of a conformable, patterned insulating material laminated to a rigid support structure.

**Layerize:** Special-purpose software developed for use with EFAB that imports a three-dimensional geometry file produced by standard three-dimensional CAD systems and exports a two-dimensional geometry file in a format acceptable to standard photomask pattern generators. The photomask produced is then used to fabricate an Instant Mask.

**Solid freeform fabrication (SFF):** A group of fabrication processes that produce structures having complex, nearly freeform, three-dimensional shapes through additive means. Typically, SFF methods deposit and stack together multiple layers of material one by one and are driven by a three-dimensional CAD model of the desired structure.

**Submask:** A portion of an Instant Mask used to pattern a single cross section of a device.

### 20.1 Introduction

---

For the purpose of precision instrumentation to better enable accurate measurements in high-temperature environments ( $>500^{\circ}\text{C}$ ), there is a growing need for sensing and electronic devices capable of operating reliably for a reasonable length of time in such a harsh environment. Typical applications for sensors that function at high temperature include automotive, aeropropulsion (both commercial and military), process control in materials engineering, and a host of others. Temperatures in these can go as high as  $500^{\circ}\text{C}$  or greater. However, most existing electronic components are limited to temperatures lower than  $200^{\circ}\text{C}$ , primarily due to the thermal limitations imposed by the conventional materials used in their manufacture (most notably silicon). Robust device architecture based on silicon-on-insulator (SOI) technology can extend device operation to near  $400^{\circ}\text{C}$ , either for brief period of time or with water-cooling-assisted packaging. However, at  $500^{\circ}\text{C}$  the thermomechanical deformation of silicon becomes the ultimate factor limiting high-temperature silicon microelectromechanical (MEMS) devices [Huff et al., 1991]. Therefore, to meet the increasing need for higher temperature instrumentation, new and innovative devices from materials more robust than silicon are being developed by various groups.

Technological advancement in the growth of wide band-gap semiconductor crystals such as silicon carbide (SiC) has made it possible to extend the operation of solid-state devices and MEMS beyond  $500^{\circ}\text{C}$ . Silicon carbide has long been viewed as a potentially useful semiconductor material for high-temperature

**TABLE 20.1** Comparison of Properties of  $\alpha$ -6H-SiC and Silicon

Properties	Silicon	6H-SiC

Maximum operating temperature (°C)	300	1240

applications. Its excellent electrical characteristics—wide band-gap, high-breakdown electric field and low intrinsic carrier concentration—make it a superior candidate for high-temperature electronic applications [Pearson et al., 1957]. Table 20.1 shows a comparison of relevant electrical and mechanical properties between 6H-SiC and silicon. The fact that SiC exhibits excellent thermal and mechanical properties at high temperature combined with its fairly large piezoresistive coefficients makes it well suited for use in the fabrication of high-temperature electromechanical sensors. On the basis of the above discussion, there are growing efforts by different research groups to develop sensors based on SiC [Okojie et al., 1996; Berg et al., 1998; Mehregany et al., 1998]. SiC crystals appear in various crystal structures called *polytypes*. The polytypes most frequently available for use are the cubic-SiC (also referred to as 3C-SiC or beta-SiC) and two of the hexagonal polytypes, 4H-SiC and 6H-SiC. The main physical differences between the 4H- and the 6H-SiC are the stacking sequence of the silicon-carbon atomic bi-layers, the number of atoms per unit crystal cell, and the lattice constants. The hexagonal crystals are grown in large boules and sliced into wafers, with the current largest commercially available size of 76 mm in diameter. Homo-epitaxial growth by chemical vapor deposition (CVD) can be performed on the single-crystal substrate to obtain epilayers of thickness and doping level (nitrogen doping for n-type and aluminum or boron for p-type) as desired for various devices. In the case of 3C-SiC, there is no viable technology in existence for growing it as a single-crystal boule of acceptable quality. Therefore, hetero-epitaxial CVD was adopted to grow it on silicon substrate. However, the large lattice mismatch that exists at the 3C-SiC/Si heterojunction causes numerous crystal defects in the 3C-SiC hetero-epilayer that greatly degrades the performance of electronic devices fabricated in it. The existence of such defects in 3C-SiC and the fact that it has the lowest band gap (2.3 eV vs. 2.9 eV for 6H- and 3.2 eV for 4H-SiC) diminish its attractiveness for broader sensor applications, especially those that require significant high temperature electronics integration.

The discussions in this chapter will focus on the fundamental technological challenges that exist in the implementation of MEMS-based SiC pressure sensors. The SiC pressure sensor is chosen as representative of other SiC-based MEMS sensors due to its identification as a crucially needed technology and the fact that it is one of the most mature with the potential for commercialization. Furthermore, an application environment (turbine engines) already exists where it can be readily inserted. Appreciable advancements in its development have been made recently that bring it significantly closer to viable commercialization. This chapter is delineated into five sections to enable readers to better understand the fundamental challenges of this emerging technology. The basic fabrication principles of single-crystal silicon carbide are presented in Section 20.2, in which SiC device fabrication by photoelectrochemical etching (PECE) and conventional electrochemical etching (ECE) are discussed. Important etching parameters leading to the fabrication of resistor and diaphragm structures for sensors will be discussed in this section. Relevant SiC fabrication processes using more recently developed deep reactive ion etching are discussed in Chapter 21. In strain-sensor technology, the output of the device is a function of the gauge factor (GF) and temperature coefficient of resistance (TCR). Because the GF is a critical parameter used to determine the sensitivity to mechanical stimulus, Section 20.3 will discuss characterization of the SiC gauge factor and its temperature dependency, including the TCR. Metallization that is stable at the desired high operating temperature is recognized as critical for a successful implementation of high

temperature sensor. Two specific approaches to realize thermally stable ohmic contacts on SiC sensor material are presented in Section 20.4, along with the deleterious effects of oxygen on the contacts. Section 20.5 discusses the process integration of various components leading to the realization of a 6H-SiC pressure sensor. Finally, Section 20.5 will discuss sensor testing and performance characteristics.

## 20.2 Photoelectrochemical Fabrication Principles of 6H-SiC

The difference between PECE and ECE is basically the photo-induced electron-hole pair (EHP) generation that is required for the former. The ECE process is a conventional anodization process in which high voltage or current is used. In both cases, the sample substrate acts as the anode electrode. The PECE process is adopted where anisotropic etching is critical. For example, in the PECE of resistors, it is important to minimize isotropic etching in order to maintain uniform resistor geometry with minimum undercut. Nonuniform geometry of the resistors typically leads to imbalance in the Wheatstone bridge circuit in which they are configured. The effect will be to induce high null output values, away from the ideal zero output voltage if the bridge is balanced.

Unlike silicon technology, processes associated with fabrication of structures in single-crystal SiC are limited generally to ECE and reactive ion etching. This arises from the nearly inert surface chemistry of SiC, which makes conventional wet chemical etching impossible at room temperature. Carrabba et al. (1989) used PECE process on SiC, but the visible light source used in his study resulted in very slow etch rates. Shor et al. (1992) utilized ultraviolet (uv) laser radiation and achieved very high rates of SiC etching, though the morphology of the etched surface was very rough. In this section, emphasis will be on electrochemical etching methods of SiC with the awareness that rapid progress has been made in deep reactive ion etching of SiC [Beheim and Salupo, 2000]. The process of using deep reactive ion etching for fabricating MEMS structures in SiC is described in detail in Chapter 21 of this book. The fabrication of piezoresistor-based sensors in single-crystal SiC requires at least one intentionally doped epilayer, usually n-type, grown on a p-type substrate. However, in PECE or ECE processes, it is often necessary to have two epilayers grown on an n-type substrate as shown on Figure 20.1. The bottom epilayer is p-type, followed by a top epilayer of n-type. The resistor sensing elements are fabricated in the n-type layer. The p-type epilayer primarily functions as an etch-stop during PECE of the n-type resistors. On the backside n-type substrate, the ECE process is applied with high voltage or current that enables high etch rates to form a cavity as deep as 200  $\mu\text{m}$ .

While the fabrication principles of both photo and dark electrochemical etching are to be discussed in further detail, this discussion briefly describes the method used to fabricate both the pressure sensor and the beams that are utilized for characterizing the piezoresistor properties of single crystal SiC. The fabrication of the piezoresistor for use as a strain sensor requires a thorough investigation of the etching characteristics of the n<sup>+</sup>-type SiC epilayer. The preference for the highly doped epilayer is due to the associated low resistivity and lesser sensitivity to temperature variations relative to lower doped epilayers. However, this preference leads to a trade-off in lower strain sensitivity due to reduction in gauge factor. In order to fabricate a SiC diaphragm transducer, a fully controllable etching process for thinning and forming of deep cavities in the backside must be developed. For diaphragm fabrication, the desirable etch

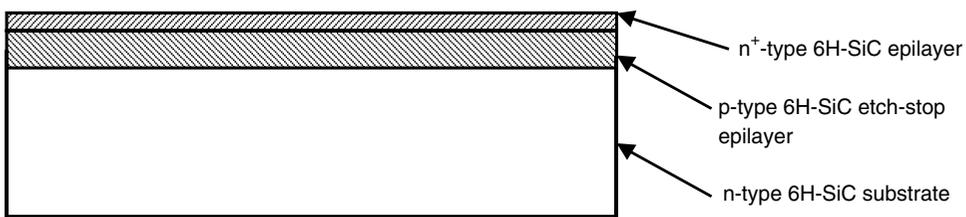

FIGURE 20.1 Typical SiC substrate with two epilayers for use in photoelectrochemical etching (PECE).

rates should be in the range of 1  $\mu\text{m}/\text{min}$ . It has been shown [Okojie, 1996] that by utilizing electrochemical etching in dilute HF, cavities with depth greater than 100  $\mu\text{m}$  in both p- and n-type 6H-SiC can be fabricated. In many cases of using dilute HF during ECE, a porous layer is formed in the process of the anodization. The texture of this layer depends on the concentration of HF in water and the voltage or current density applied. At low HF concentration, the anodization process leaves a soft, highly porous layer, while anodization at higher HF concentrations produces a hard layer of low porosity. Because these porous layers have large crystal surface areas, enhanced thermal oxidation occurs within it relative to the bulk. Subsequent stripping in conventional oxide etchant (such as buffered hydrofluoric acid, BHF) can easily remove all the porous material to reveal the etched cavity. In n-type SiC, ECE is possible only when the positive anode voltage (with the SiC as the anode electrode) is sufficiently high to cause the semiconductor space charge layer at the SiC/electrolyte interface to break down. Under this condition, electrons are injected from the SiC/HF interface into the bulk of the semiconductor, resulting in dissolution reactions at the surface. The voltage required for the breakdown depends on the doping level of the semiconductor and the concentration of the electrolyte. Two ECE experiments were conducted with n-type SiC: (1) anodization in a 0.625% HF in a two-electrode cell (SiC-anode with platinum counter-electrode) and subsequent thermal oxidation to remove the porous layer, and (2) anodization in a 0.625% HF in a three-electrode configuration (SiC-anode, platinum counter-electrode and reference standard calomel electrode) and oxidation to remove the porous layer. Both experiments demonstrated rapid etching of n-type SiC. In the first, the average etch rate was 0.3  $\mu\text{m}/\text{min}$ , while in the second an etch rate of 0.8  $\mu\text{m}/\text{min}$  was obtained. At average current densities ( $J_{\text{av}} \sim 100 \text{ mA}/\text{cm}^2$ ) used in both experiments higher etch rates should have been obtained if etching was the only process occurring. The actual etch rates obtained from the experiments suggested that other parallel processes were occurring (e.g., water decomposition) which used up part of the anodization current.

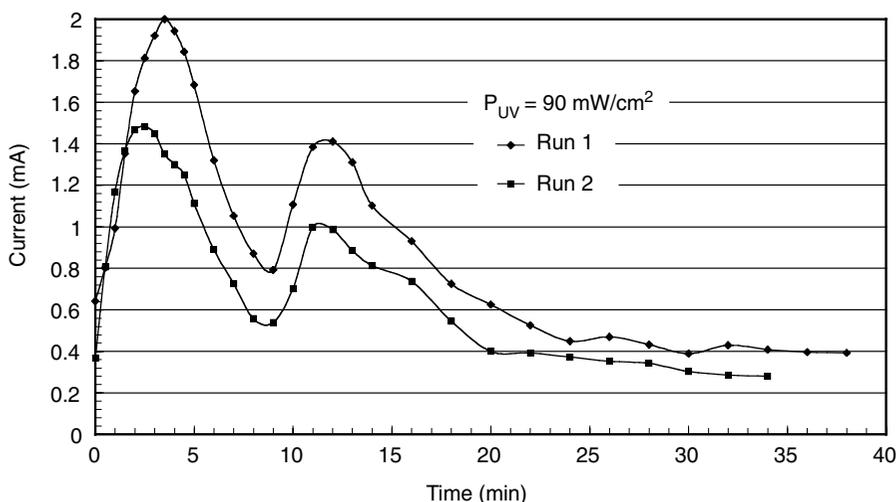

Materials must possess certain properties to be used as a mask in electrochemical etching. In dilute HF the mask should be inert in the concentrations used, and no electrolytic reaction should occur during anodization that might interfere with the etching process. Two masking materials were investigated. Platinum, which is very resistant to HF, generated gas bubbles at the high anodic potentials used, resulting in nonuniform etching. Silicon nitride did not form bubbles because it is an insulator, however, it is not completely resistant to HF. Because the process of deep etching to form a diaphragm takes a long time (200 min to etch a 200- $\mu\text{m}$ -deep cavity at 1  $\mu\text{m}/\text{min}$ ), a certain minimum thickness of nitride is required to survive the dilute HF electrolyte during the anodization process in order to prevent the complete stripping of the nitride mask and consequent undesired etching of the entire SiC surface. The investigations briefly described above led to the following important experimental conclusions [Okojie, 1996]: At a fixed voltage of 12 V:

1. Etching in 2.5% HF occurs at higher rates than in 0.625% HF.
2. Etching in 2.5% HF produced deep etch pits and/or hillocks on the surface of SiC, while no etch pits or hillocks were observed on surfaces etched in 0.625% HF. The pits are attributed to the enhanced electrochemical etching around the micropipes in the SiC substrate.
3. The surface of the etched region was smoother and the depth more uniform when etched in 0.625% HF.

In an attempt to further optimize the etching process for forming n-type SiC diaphragms, an additional series of experiments was conducted with different etching parameters and concentrations of HF. Hillocks ranging in size from 10 to 50  $\mu\text{m}$  formed randomly on the diaphragm surface. The presence of uncontrollable discontinuities of this size results in nonuniform stress distributions that adversely affect the operation of a sensor. Although the cause of the hillock formation was not conclusively determined, there was evidence that the formations were associated with bubbles generated during the high-rate etching. The existence of micropipes in the SiC wafers, which could lead to high current-density concentrations in localized areas, could result in selectively high etch rates around the defect sites, increasing the possibility of etch pit formation.

Although the etching potential of highly doped n-type SiC using the ECE process is much higher than that of p-type SiC, it is possible to stop the etching process at the n–p junction if the ohmic contact used for anodization potential control is made only to the n<sup>+</sup>-SiC epilayer (refer to Figure 20.1). The positive anodic potential on the n<sup>+</sup>-SiC layer will cause the junction to be reverse biased, thereby preventing the flow of current through the underlying p-SiC epilayer. In order for an etch-stop to be effective, the breakdown voltage of the n–p junction must be higher than the etching potential of the n<sup>+</sup>-SiC epilayer. Also, the p-type layer should have a doping level significantly lower than that of the n<sup>+</sup>-SiC epilayer to minimize the possibility of tunneling current. Details of this conductivity selective process can be found in Shor et al. (1993).

The process of utilizing PECE of SiC for the purpose of fabricating well-defined resistor structures is described below. As shown in Figure 20.1, the starting wafer is an n-type 6H-SiC substrate upon which a 5- $\mu\text{m}$ -thick, lightly doped ( $3 \times 10^{18} \text{ cm}^{-3}$ ), p-type epilayer is grown by CVD, followed by a 2- $\mu\text{m}$ -thick, n<sup>+</sup>-type 6H-SiC epilayer. An ohmic contact metallization, preferably nickel, is deposited and patterned into a circular shape on the top n<sup>+</sup>-SiC epilayer to enable anodization potential control during the PECE process. Platinum is sputtered on to the top of the wafer covering the patterned ohmic contact metal and the entire n<sup>+</sup>-SiC epilayer. The platinum in direct contact with the epilayer is then patterned into the shape of serpentine resistor elements. This platinum acts as etch mask so that the serpentine resistor patterns can be transferred onto the n<sup>+</sup>-SiC during the PECE process. Contact electrode wire is bonded on the section of the platinum mask that is in direct contact with the nickel ohmic contact. A thin layer of black wax is then applied over areas of the sample that will not be etched, including the contact electrode wires. The wafer is then immersed in the dilute HF electrolyte with the side to be etched facing up. This face is then exposed to a UV light source with the anodization potential set at 1.7 V<sub>SCE</sub> (SCE stands for standard calomel electrode, which is the reference electrode against which the anode voltage is measured). Under this condition, the exposed sections of the n<sup>+</sup>-SiC epilayer are photoelectrochemically etched while the sections under the serpentine-shaped platinum etch mask are unetched. After the anodization process, the wax is stripped in acetone while the platinum mask and nickel ohmic contacts are stripped in *aqua regia* and a 50:50 nitric/hydrochloric acid mixture, respectively. After stripping, the resistor patterns transferred to the n<sup>+</sup>-epilayer are revealed. The current vs. time curves of a typical PECE are shown in Figure 20.2. For the epilayer thickness used, the photocurrent rises to a first maximum in the first 5 min, then drops rapidly due to the blocking action of the bubbles during the release of gaseous products. A second maximum

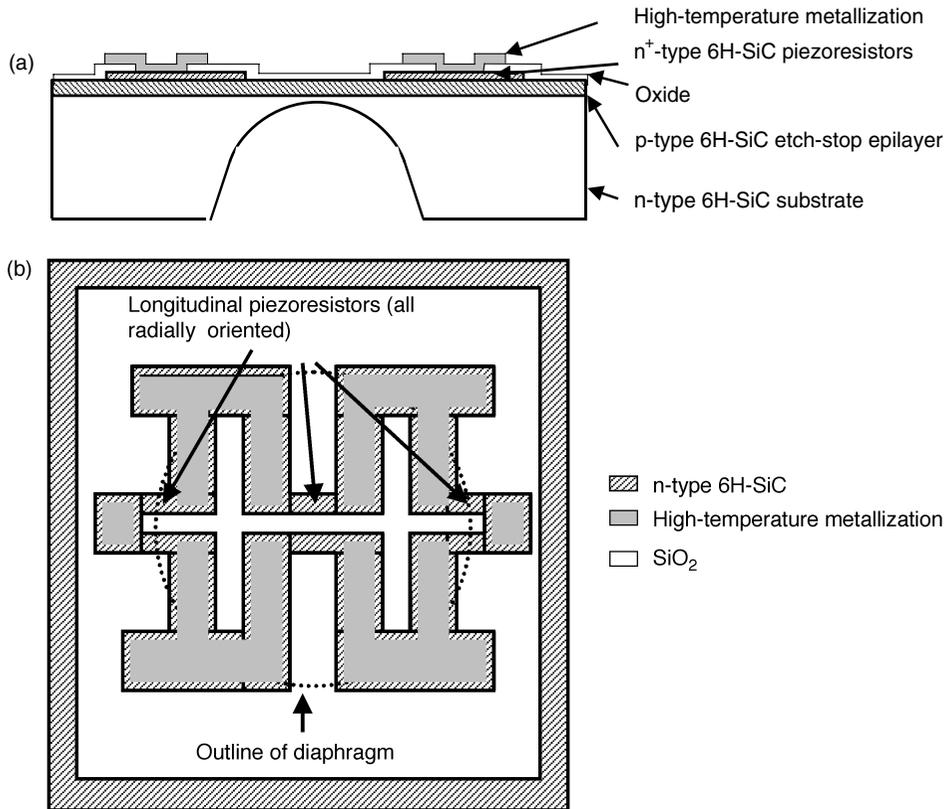

**FIGURE 20.2** Current density vs. time during photoelectrochemical etching of n-type 6H-SiC in dilute HF electrolyte. Two anodization I-t characteristics indicate the reproducibility of the process as long as ohmic contact is present.

appears in the curve after 12 min when the bubbles deflate, after which time the current density gradually decreased. The initial rise of the current is due to the rapid generation of electron-hole pairs (EHPs) during the initial stages of the etching process. These carriers are available near the surface of the SiC to participate in the chemical reaction process. A combination of various mechanisms leads to the gradual decay of the current as observed in [Figure 20.2](#). As the etching progresses, the reacting species will need to diffuse through the porous SiC layer being formed to get to the bulk SiC surface just as the products of the reaction need to diffuse out. Therefore, as the porous SiC thickness increases, the mass transport process is slowed down, resulting in a reduced rate of reaction. The porous SiC will also shade the bulk SiC from the UV intensity, resulting in a drop in the EHPs needed to keep the reaction going. Once the etching reaches the underlying p-type epilayer, the abrupt change in epilayer conductivity from n<sup>+</sup>-SiC to that of the underlying p-type SiC causes the etching to stop. Because most of the electric field is confined within the n<sup>+</sup>-SiC and that the applied 1.7-V<sub>SCE</sub> anode potential causes the n-p junction to be reverse biased, only an insignificant leakage current will flow through the p-epilayer and be transported to participate in the etching process at the electrolyte interface. The current-time curves are repeatable between two etching runs, as can also be seen in [Figure 20.2](#). It should be noted that the etch rates of the n<sup>+</sup>-SiC epilayer are dependent on the UV intensity and the doping level of the epilayer. By increasing the UV intensity, which causes more EHPs to be generated, the n<sup>+</sup>-SiC epilayer can be etched more rapidly and more selectively between n- and p-type because fewer carriers are present at the p-epilayer to participate in the etching. SiC etch rates greater than 20 nm/min have been achieved. The wafer is thermally oxidized and then dipped in 49% HF to remove the porous layer that formed during anodization. After the process of selective etching, the n-p junction is sometimes not well isolated electrically, which leads to unsteady outputs during device operation. To prevent this from occurring, the etching time of the n<sup>+</sup> piezoresistor epilayer is increased so that the PECE process partially occurs in the p-epilayer. Poor electrical isolation can also be avoided if the junction isolation is verified immediately after PECE before the mask is stripped. Usually, a second thermal oxidation is carried out to ensure that the n-p junctions of all the devices are well isolated. A metal contact via is opened in the oxide by a conventional photolithographic process and BHF wet etching to expose sections of the resistors. Subsequently, ohmic contact metallization is deposited and patterned over the via to form the electrical contacts. This is followed by the deposition and patterning of the diffusion barrier to form the final device shown in the cross section of [Figure 20.3a](#). The top view drawing of the sensor is shown in [Figure 20.3b](#).

Another process that can be utilized to pattern n<sup>+</sup>-SiC epilayers is the ECE. As stated earlier, when the small positive anodic potential is applied through the ohmic contact on the n<sup>+</sup>-SiC, current cannot flow between the n<sup>+</sup>-SiC epilayer and the underlying p-SiC substrate. Therefore, the p-type SiC epilayer acts as an etch-stop. However, experiments with ECE on the n<sup>+</sup>-SiC epilayer demonstrated that by applying a reverse bias on the n-p junction, it is possible to achieve an etch-stop at the p-type SiC buried epilayer when the n<sup>+</sup>-SiC top epilayer is being etched in the dark. It is critical that the junction leakage current be significantly low for this approach to work. However, etching selectivity may not be as high as in the PECE, as leakage current will increase for the voltage needed to perform a high etching rate with dark current.

After the platinum mask is removed, the surface of the underlying resistor is sometimes pitted. The pitting is the result of the pinholes in the platinum, which allow electrolyte to seep through the mask and etch the otherwise protected n<sup>+</sup>-SiC surface. Therefore, it is important to ensure that the etch mask used for the pattern transfer is free of pinholes. Undercutting of the piezoresistors during etching may also occur as a result of the small dark current between the edge of the etching n<sup>+</sup>-SiC and the electrolyte under bias of the anodic potential. Although this potential is made small enough to avoid reverse bias current flow between the n-type epilayer and the underlying p-type epilayer, lateral current conduction between the expanding side of the n-type SiC epilayer and the electrolyte allows undercutting etching to proceed during the PECE process. The above problems typically lead to undesirable nonuniformity in the resistor patterns. Using n-type epilayers with lower doping reduces dark etching at anodization potentials of about 1.7 V<sub>SCE</sub> can minimize these effects. This is due to the fact that at that anodic potential fewer carriers from the dark current are injected into the electrolyte relative to the EHPs generated by the UV light source. However, this approach means the gauge factor and the temperature effects of the piezoresistor will change, as gauge factor is dependent on doping level. By substituting platinum with

**FIGURE 20.3** (a) Cross-section view of 6H-SiC after PECS of the top  $n^+$ -epilayer and ECE of the backside cavity. Notice the curvature in the cavity, which is characteristic of the ECE process. (b) Top view of patterned piezoresistors in n-type 6H-SiC.

another appropriate mask, such as polyimide or polyimide on silicon nitride, anodization reaction will only occur at the appropriate areas. The polyimide can prevent the pinhole formation while the silicon nitride can minimize the effect of undercutting. Polyimide is highly conformal and therefore will plug the pinholes. Silicon nitride is not conductive and is therefore electrically and chemical inactive during PECE. One effective method used to neutralize pinholes in platinum is by double-layer deposition. After the deposition of the first platinum layer, the film is sputter-etched, and subsequently a second platinum layer is deposited. This significantly reduces pinhole formation and pitting associated with the platinum etch mask. In many cases, the p-type SiC layer is not a fully effective etch-stop. This effect was observed in p-type SiC with low doping levels ( $N_a \sim 10^{18} \text{ cm}^{-3}$ ). Apparently, in lightly doped material, the electric field in the space-charge region is not high enough to prevent all the photogenerated carriers from reaching the surface to cause etching. In addition, the UV light incident on the n-p junction causes higher leakage currents across the junction than higher doped p-type SiC. Although the anodic voltage is applied only through the ohmic contact on the top n-type SiC epilayer, the light-induced current through the junction leads to etching of the p-type SiC. To avoid etching of the p-type SiC epilayer, the reference voltage ( $V_{SCE}$ ) must be reduced to a level that curtails the drifting of photocarriers assisted by electric field when the p-epilayer is eventually exposed to the electrolyte. This fabrication procedure described above can be adopted to produce resistors in n-type epilayers with any doping level.

The characteristics of a diaphragm-based pressure sensor device are determined by the piezoresistors and by the dimensions of the diaphragm. Two key dimensions that characterize any circular diaphragm are thickness and radius. Because the radius is generally a fixed value determined by the pressure range and

package specification, thickness is left as the main controlling variable. Therefore, the process of etching of the diaphragm to achieve a desired thickness and shape is of primary importance in diaphragm-based pressure-sensor technology. Until recently, the application of SiC diaphragms as pressure-sensing devices was almost nonexistent. Fortunately, SiC microfabrication technology has advanced significantly over the last decade, largely due to the ability to perform high-energy plasma etching of various types of structures. Some structures have been selectively etched in SiC using reactive ion etching (RIE), but the etch rates reported were too low for practical use in the wafer thinning and shaping [Palmour et al., 1987] needed for pressure-sensor fabrication. Rapid progress has been made in the area of deep reactive ion etching (DRIE) with etch rates up to 1  $\mu\text{m}/\text{min}$  already reported.

### 20.3 Characterization of 6H-SiC Gauge Factor

Generally, the design of devices that sense physical phenomena and provide electrical readouts calls for the interpolation of two or more kinds of mathematical relationships. In the design of high-temperature pressure sensors, the equations that explain the physical phenomena (i.e., pressure and diaphragm deflection) are interpolated with the electrical equations that express the resulting output voltage. The equations that model deflecting diaphragms are classified in two main categories. One category models maximum diaphragm deflections less than the diaphragm thickness (linear case), while the other supports diaphragms with maximum deflections greater than the diaphragm thickness (nonlinear case). A fundamental reason for having separate expressions has to do with the problem of linearity of the membrane deflection. If the maximum deflection of the membrane is less than its thickness, as occurs in applications of short-range pressure measurement, there is generally a reasonable degree of linearity of diaphragm deflection in response to applied pressure. For wide-band pressure measurements, however, the deflection of the diaphragm in response to applied pressure is no longer linear. For the device to be used continuously over a long period of time, the membrane must be capable of repeatedly deflecting under applied pressure with precision and little hysteresis. To achieve this, the membrane must retain its elastic property after it is subjected to maximum applied pressures. To that effect, there is need to choose materials with an appreciable linear region on the stress-strain curve. For the diaphragm to retain its elastic integrity, the stress induced by pressure must not exceed the yield or fracture point. In essence, the maximum operating stress should be at a point below the yield/fracture stress limit. If the operating stress reaches the elastic or fracture limit, there is very strong likelihood the diaphragm would lose its elasticity, becoming permanently deformed, and/or fracture.

The choice of the resistance of the piezoresistors represents a compromise between several conflicting requirements. The pressure sensitivity of a bridge containing four active piezoresistors is directly proportional to the sheet resistance and the supply voltage. The temperature stability, on the other hand, is inversely proportional to the sheet resistance and the supply voltage. The requirement for good temperature stability conflicts with the requirements for pressure sensitivity.

The piezoresistive effect is associated with changes in resistance as a result of an applied mechanical stimulus. Based on this effect, strain gauges were developed. When an object is mechanically strained, the strain sensor changes its resistance. The resistance can be measured by incorporating the gauge within a Wheatstone bridge configuration and the resultant output voltage is related to the applied force. The piezoresistive effect is rather small in metals, but in semiconductors it is much more pronounced. The explanation can be found in Eq. (20.1) for the gauge factor:

$$GF = \frac{dR}{R\epsilon} = 1 + 2\nu + \frac{d\rho}{\rho\epsilon} \quad (20.1)$$

where  $GF$  = gauge factor;  $R$  = electrical resistance ( $\Omega$ );  $\rho$  = electrical resistivity ( $\Omega\text{-cm}$ ) of the gauge material,  $\nu$  = Poisson ratio (a geometrical effect), and  $\epsilon$  = applied strain. The change in the resistance with strain is dependent on two terms: One is associated with the geometrical piezoresistive effect and the second originates from the strain dependency of the resistivity, as shown in Eq. (20.1). In metals, this

latter term is zero, while it is significantly nonzero in semiconductors. In semiconductors, the contribution of the geometrical term to the gauge factor is of the same order as in metals. Therefore, the gauge factor in semiconductors is related to the large strain sensitivity of the resistivity. This can be explained on the basis of the energy-band structure of semiconductors. In n-type semiconductors that have multiple valleys in the conduction band, such as 6H-SiC, the piezoresistive effect is associated with a change in the relative energy positions of the multivalley minima under applied stress. This effect causes the electrons to transfer between the valleys, causing a net change in the mobility, which in turn has a dominant effect on the strain (stress) dependency of the resistivity [Herring and Vogt, 1956].

### 20.3.1 Resistor–Diaphragm Modeling

A resistor on a circular diaphragm arranged tangentially, with current flowing parallel to the resistor, will experience a longitudinal stress induced by the tangential strain component. It will also experience a transverse (radial) strain component (strain perpendicular to resistor length), which usually inserts a negative piezoresistance coefficient. On the other hand, as depicted in [Figure 20.3b](#), the radially oriented resistor, with current flowing parallel along its length, will be dominated by the stress induced by the longitudinal strain component. The transverse effect is introduced via the tangential stress, with its corresponding negative piezoresistance coefficient. The above has been extensively verified and utilized in silicon. The output of the sensor is strongly affected by how the resistors are oriented. Therefore, the resistor geometry and orientation should be such that only one strain component exists while the other is suppressed.

When the maximum deflection,  $w$ , of a clamped circular plate is less than its thickness, the equation that describes it is expressed as [Timoshenko and Woinowsky-Krieger, 1959]:

$$w = 0.89 \frac{Pa^4}{64D} \quad (20.2)$$

where  $P$  is the applied pressure (Pa),  $a$  is the radius of the diaphragm ( $\mu\text{m}$ ), and  $D$  is the flexural rigidity (N-m) of the membrane material.  $D$  is expressed as:

$$D = \frac{Et^3}{12(1-\nu^2)} \quad (20.3)$$

where  $E$  is the Young's modulus (Pa) and  $t$  = membrane thickness (m). The total stress on the membrane associated with such small deflection at the clamped edge is expressed as:

$$(\sigma_r)_r = \frac{3Pa^2}{4t^2} \quad (20.4)$$

The choice of a large or small deflection equation, as stated before, is basically dictated by device application. A circular diaphragm can be easily mounted, and, in the case of materials with high elastic moduli, high pressures can be applied on diaphragms with reasonable diameter to thickness ratios. According to the theory of plates and shells by Timoshenko and Woinowsky-Krieger (1959), the radial and tangential stresses ( $\sigma_r$  and  $\sigma_t$ , respectively) at any point on the front side of a circular diaphragm with edges fixed can be related to the applied pressure,  $P$ , on the front of the diaphragm; its thickness,  $t$ ; radius,  $a$ ; and the distance,  $r$ , from the center of the point of interest as:

$$\sigma_r = -\frac{3Pa^2}{4t^2} \left[ (\nu + 3) \frac{r^2}{a^2} - (\nu + 1) \right] \quad (20.5)$$

and

$$\sigma_t = -\frac{3Pa^2}{4t^2} \left[ (1 + 3\nu) \frac{r^2}{a^2} - (\nu + 1) \right] \quad (20.6)$$

The same set of equations can be used to define stresses on the back of the diaphragm, when pressure is applied there, but with negative sign. A simple analysis of the radial and tangential stress distribution on the front side of the diaphragm shows that both stresses change (as a result of applied pressure from the front side), at a certain distance from the center of the diaphragm, from compressive to tensile. When pressure is applied to the front side of the diaphragm, any piezoresistor on the back or on the front side of the diaphragm will be subjected to parallel and perpendicular stresses, depending on its location. Therefore, the functional relationship between the fractional change in electrical resistance ( $\Delta R/R$ ) of the piezoresistor and the perpendicular and parallel stress components is given by:

$$\frac{\Delta R}{R} = \pi_t \sigma_{\parallel} + \pi_r \sigma_{\perp} \quad (20.7)$$

where  $\pi_t$  and  $\pi_r$  are parallel and perpendicular piezoresistive coefficients, respectively, and  $\sigma_{\parallel}$  and  $\sigma_{\perp}$  are parallel and perpendicular stress components, respectively. For tangentially and radially oriented piezoresistors on a circular diaphragm whose radius is large as compared with the resistor dimensions, this fractional change in resistance can be expressed as follows:

For tangential resistors:

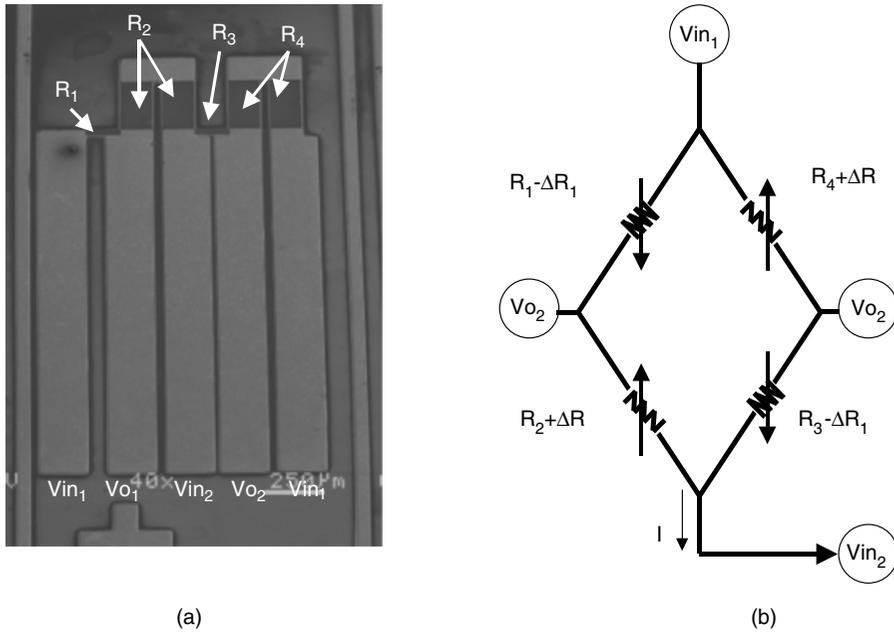

$$\left(\frac{\Delta R}{R}\right)_t = \pi_t \sigma_t + \pi_r \sigma_r \quad (20.8)$$

For radial resistors:

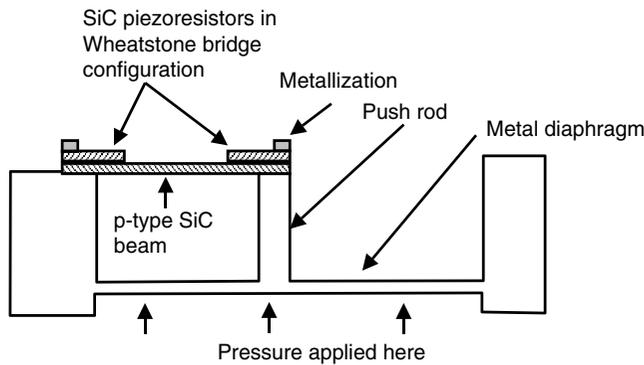

$$\left(\frac{\Delta R}{R}\right)_r = \pi_r \sigma_r + \pi_t \sigma_t \quad (20.9)$$

In the case of semiconductors with hexagonal crystal structure (such as 6H-SiC) the problem is much more complicated in terms of resolving the piezoresistive constants in different directions. Earlier attempts by Russian scientists [Rapatskaya et al., 1968; Azimov et al., 1974; Guk et al., 1974a; 1974b] to characterize the piezoresistance of 6H-SiC as a function of crystallographic orientation yielded significant differences in the obtained values. Possible reasons for this discrepancy include the differences and imperfections of the Lely (1955) platelets, the only crystal available at that time, and also the variable quality of the metal ohmic contacts. Recent advances in SiC technology have led to the mass production of more reproducible, better quality SiC wafers and ohmic contacts, making it possible to obtain more reliable results.

In order to measure the gauge factor of 6H-SiC, resistors were etched in 6H-SiC epilayers (p- and n-type) by PECE means described in Section 20.2. The configuration of the resistors was such that two legs were transversely oriented while the other two were longitudinally oriented. The substrate was then diced into rectangular chips, each containing a pair of Wheatstone bridge circuits, one of which is shown in Figure 20.4a. The equivalent circuit of the Wheatstone bridge is shown in Figure 20.4b. It depicts one of each transverse and longitudinal piezoresistors arranged alternately. While all the resistors have current running parallel to their length, the transverse resistors,  $R_1$  and  $R_4$  will experience a perpendicular strain (strain perpendicular to current flow) while the longitudinal resistors,  $R_2$  and  $R_3$  will experience a parallel strain (strain parallel to current flow). The purpose of using two Wheatstone bridges on a single chip is to simultaneously compare the measured responses from both tensile and compressive states of the bridges. The rectangular chip is then attached to a machined metal diaphragm made of Incoloy<sup>TM</sup>, as shown in the cross-section schematic of Figure 20.5. One Wheatstone bridge is at the edge of the metal diaphragm while the other one is at the push rod. Pressure was applied to the diaphragm through a back port (not shown), which caused the boss of the metal diaphragm to deflect the beam. One set of piezoresistors, closer to the center of the metal diaphragm, was placed in tension, while the other, closer to the periphery of the diaphragm, was in compression. The  $\Delta R$  of each arm of the bridge was measured in order to obtain

**FIGURE 20.4** (a) Top view SEM picture of 6H-SiC beam with resistors, and (b) equivalent Wheatstone bridge configuration.  $R_1$  and  $R_4$  are the transverse piezoresistors, while  $R_2$  and  $R_3$  are the longitudinal piezoresistors.

**FIGURE 20.5** Integrated beam transducer used for gauge factor characterization.

the longitudinal and transverse gauge factors. All the beams were uniaxially deformed perpendicular to within  $4^\circ$  of the 6H-SiC crystal's basal plane, which is in the (0001) direction. Because the beam is integrated with the metal diaphragm, it is necessary to calculate the strain and stresses on the surface of the beam and to analyze their distribution across the beam. The problem is solved as a superposition of two systems, namely: (1) one with an edge-fixed diaphragm and (2) one with a beam, one edge of which is fixed (clamped) and the second guided. Deflection,  $w_p$ , at the center resulting from uniform loading (pressure) on the front of the metal diaphragm is expressed as:

$$w_p = \frac{Pa^4}{64D_m} \quad (20.10)$$

where  $D_m$  is the flexural rigidity (N-m) of the metal membrane material and is expressed as:

$$D = \frac{E_m t_m^3}{12(1 - \nu_m^2)} \quad (20.11)$$

where  $E_m$  represents the Young's modulus (Pa) of the diaphragm,  $t_m$  (m) is the metal diaphragm thickness and  $\nu_m$  is the metal Poisson constant. Deflection of the metal diaphragm,  $w_f$ , at the center resulting from a concentrated load at the center is

$$w_f = \frac{F a^2}{16\pi D_m} \quad (20.12)$$

where  $F$  (N) is the concentrated load or the contact force on the boss section of the metal diaphragm. The net deflection resulting from combined loading, when the concentrated load acts in the opposite direction of the applied pressure, is determined by:

$$w_{\text{net}} = w_p - w_f = \frac{a^2}{16D_m} \left( \frac{P a^2}{4} - \frac{F}{\pi} \right) \quad (20.13)$$

Applying the Castigliano (1966) method solves the problem of deflection of a beam fixed (clamped) on one end and "guided" on the other (guided means that the slope at the guided point is always zero, but slight deflection is allowed and may change):

$$w_b = \frac{F l^3}{12 E_b I_b} \quad (20.14)$$

where  $w_b$  = beam deflection (m);  $l$  = length of the beam (m);  $E_b$  = modulus of elasticity of the beam (Pa);  $I_b$  = moment of inertia of the beam, expressed as:

$$I_b = \frac{b h^3}{12} \quad (20.15)$$

where  $b$  = beam width (m) and  $h$  = beam thickness (m). During loading, the deflection of the beam will be equal to that of the diaphragm; therefore, Eqs. (20.13) and (20.14) can be set equal to solve for the contact force,  $F$  (which is contact force between the diaphragm boss and the beam). Because the radius of the diaphragm and the length of the beam are for all intents and purposes equal, the equation for  $F$  simplifies to:

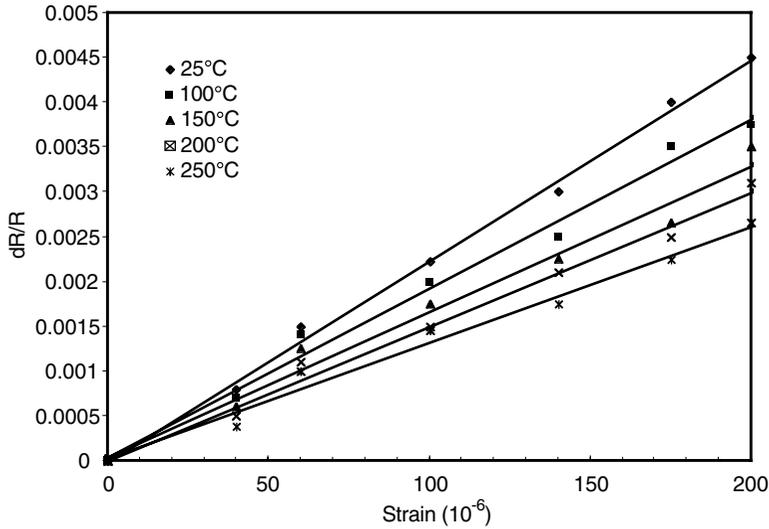

$$F = \frac{3}{4} \left( \frac{P a^2 \pi E_b b h^3}{4 a E_m t_m^3 \pi + 3 E_b b h^3} \right) \quad (20.16)$$

However, the maximum strains ( $\epsilon_{\text{max}}$ ) occur at either end of the beam and have opposite signs:

$$\epsilon_{\text{max}} = \frac{F a t}{4 E_b I_b} \quad (20.17)$$

The maximum stress,  $\sigma_{\text{max}}$ , at the edge of the beam can be calculated from Hook's Law:

$$\sigma_{\text{max}} = \epsilon_{\text{max}} E_b \quad (20.18)$$

**FIGURE 20.6** Normalized changes in resistivity vs. applied strain in longitudinal n-type 6H-SiC gauges with two doping levels.

Based on the dimensions of the bossed metal diaphragm and beam (diaphragm thickness,  $t_m = 0.2$  mm; Young's modulus,  $E_d = 207$  GPa; diaphragm radius,  $a = 4$  mm; beam thickness,  $h = 305$   $\mu\text{m}$ ; beam length,  $l = 4$  mm; beam width,  $b = 1.52$  mm; beam Young's modulus,  $E_b = 488$  GPa), the strain in the SiC beam calculated from the dimensions of the metal diaphragm was approximately 1 nanostrain/Pa ( $\sim 7$  microstrains/psi). With the above modeling, it becomes possible to calculate the gauge factor of the 6H-SiC material, as there is a direct relationship between the applied strain and gauge factor, as indicated in Eq. (20.1).

The gauge factor and TCR of n-type 6H-SiC were analyzed in the basal (0001) plane. The characteristics of 6H-SiC piezoresistors were established individually in a four-arm Wheatstone bridge. The load on the beam was applied through pressure exerted on the metallic diaphragm, previously described, and transmitted by the boss acting as a push rod to the beam. Patterned strain gauges were fabricated in homoepitaxially grown 2- $\mu\text{m}$  n-type epilayers on p-type 6H-SiC substrates with two n-type doping levels, namely  $2 \times 10^{17} \text{ cm}^{-3}$  and  $3 \times 10^{18} \text{ cm}^{-3}$ . In hexagonal crystals, because the piezoresistance tensor is isotropic in the basal (0001) plane, the gauge may be rotated about the  $c$ -axis without affecting the piezoresistivity [Davis et al., 1988]. Longitudinal and transverse gauges were measured, yielding results corresponding to the piezoresistive coefficients  $\pi_{11}$  and  $\pi_{12}$ , respectively. Figure 20.6 shows normalized change in the resistance vs. applied strain in longitudinal n-type 6H-SiC gauges for the two n-type doping levels. The measured gauge factors were approximately  $-25$  for the lower doping level and  $-20$  for the higher doping level. Measurements conducted on the transverse piezoresistors ( $N_d = 3 \times 10^{18} \text{ cm}^{-3}$ ) yielded a gauge factor of approximately 11. The longitudinal and the transverse piezoresistance coefficients,  $\pi_{11}$  and  $\pi_{12}$ , can be calculated from the relationship [Rapatskaya et al., 1968]:

$$\frac{dR}{R} = \frac{dV}{V} = \pi_{11} \sigma \quad (20.19)$$

where  $dV$  represents the bridge output of the Wheatstone bridge circuit, while  $V$  is the input voltage. By using the stress obtained from Eq. (20.18), the longitudinal gauge factor was found to be about  $-5.12 \times 10^{-12} \text{ cm}^2/\text{dyne}$  for the SiC gauge with the lower doping level and  $-4.3 \times 10^{-12} \text{ cm}^2/\text{dyne}$  for the SiC gauge with the higher doping level. One initial conclusion is that an increase in doping level results in a decrease of the gauge factor. Because the piezoresistive effect is an energy band transport phenomenon, factors

such as impurities, donor ionization energy, mobility, defect density and overall quality of the crystal may influence it substantially. This behavior is similar to the one observed in silicon.

### 20.3.2 Temperature Effect on Gauge Factor

The piezoresistive properties of a 6H-SiC beam transducer were measured between 25 and 250°C. Measurements were carried out on a beam consisting of longitudinal and transverse n-type 6H-SiC (doping level  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ) beams fabricated as described previously. Figure 20.7a shows the relative change in resistance of the longitudinal piezoresistors as a function of strain at different temperatures. At all temperatures a linear relationship is observed between  $\Delta R/R$  and strain, but the strain sensitivity decreases with increasing temperature. Figure 20.7b shows the longitudinal gauge factor as a function of temperature. At 250°C the gauge factor is approximately 60% of its room-temperature resistance for this doping level. The bridge output as a function of pressure and temperature is shown in Figure 20.7c. The decrease in output due to increasing temperature is explained in terms of intravalley carrier transport, in which the external applied heat energy leads carriers to acquire more energy that enables more of them to be transported and occupy other energy minima. Therefore, when strain is applied under heat, only a few electrons can be transported to the energies yet occupied. As a result of the fewer electrons available for intravalley exchange, the piezoresistance decreases. The bridge gauge factor decreases linearly with temperature as seen in Figure 20.7b. The relative change in resistance vs. strain of the transverse piezoresistors is shown in Figure 20.8, from which the transverse gauge factor can also be calculated. In order to check the reproducibility of the measurements, another beam transducer structure was built and the bridge output as a function of pressure was measured. For comparison, Figure 20.9 shows the results obtained on both beams. In both cases, the dependence between the bridge output and the applied pressure is linear; however, one of the beams exhibited a slightly lower sensitivity. This was probably a result of either a geometrical factor (i.e., the metal diaphragm in both cases did not have exactly the same dimensions) and/or the mounting procedure. Random temperature variations made it difficult to measure the gauge factor of an individual bridge element, especially the transverse resistors, which exhibited very small changes in resistance with pressure.

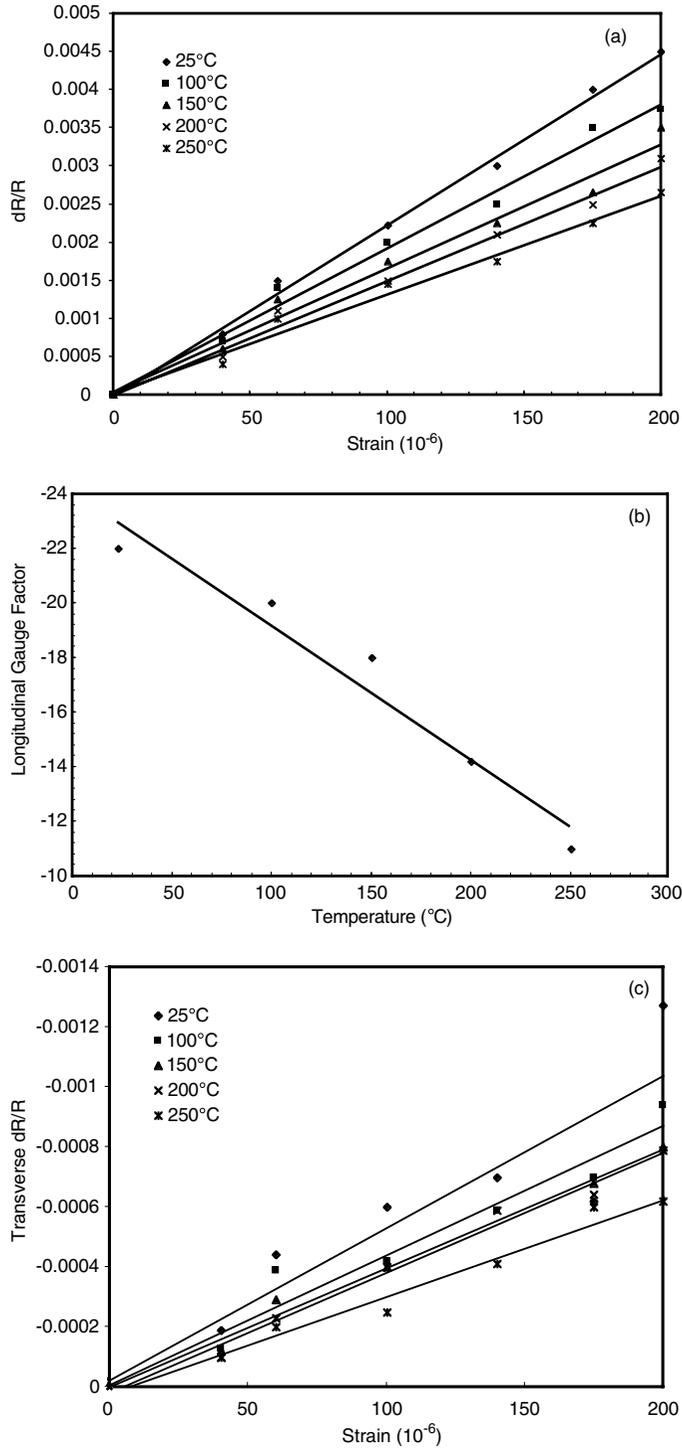

### 20.3.3 Temperature Effect on Resistance

In addition to the gauge factor, another important consideration in the selection of a resistor for high- or low-temperature applications is the way its electrical resistance changes with the temperature. Resistance variation with temperature is usually expressed as a temperature coefficient of resistance (TCR), defined as:

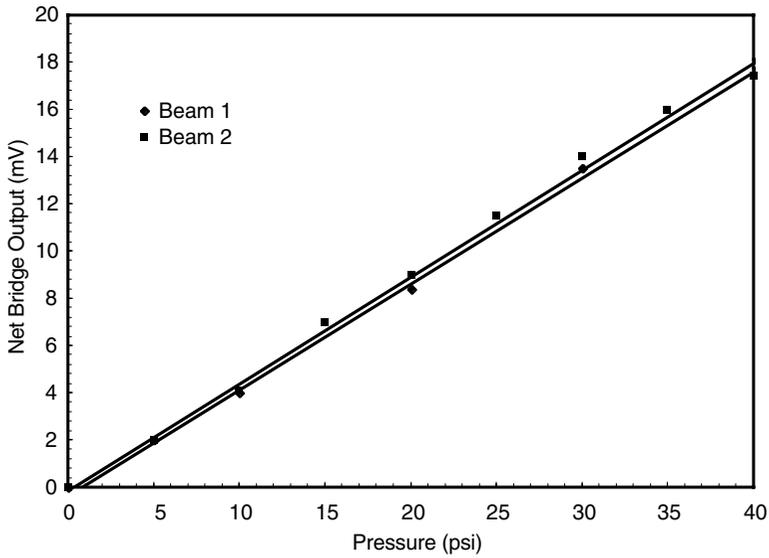

$$\text{TCR} = \frac{1}{R_o} \frac{R_f - R_o}{T_f - T_o} \quad (20.20)$$

where  $R_o$  = resistance at room or reference temperature ( $\Omega$ ),  $R_f$  = resistance at operating temperature,  $T_o$  = room or reference temperature (usually 25°C) and  $T_f$  = operating temperature. The TCR may be positive or negative and is usually given either in ppm/°C or in %/°C. Practically, the TCR can be influenced by resistor structure as well as by processing conditions such as uniformity of the resistivity across the wafer.

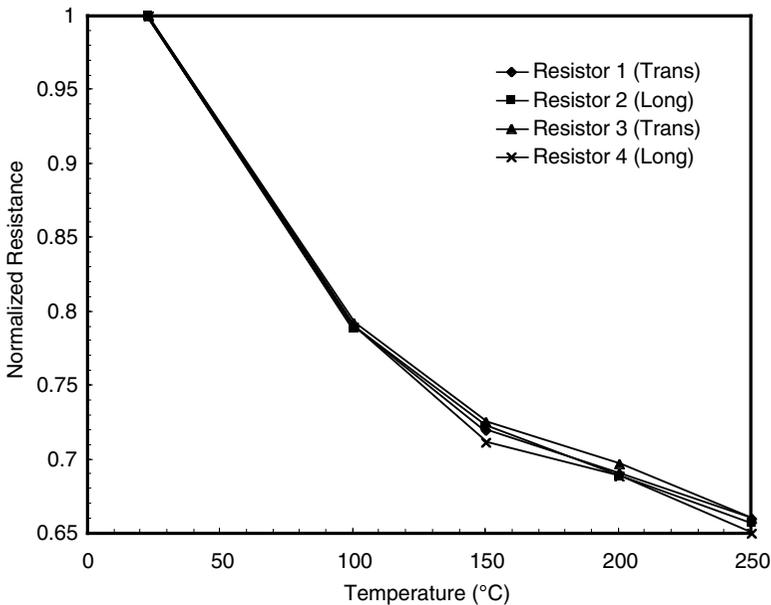

To evaluate the TCR behavior of SiC, the resistances of four individual gauges ( $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ) in a transducer were measured and plotted as a function of temperature (Figure 20.10). All measured resistances in this sample decreased with temperature up to 250°C, due to increasing ionization of the donors in the heavily doped SiC. In contrast, the initial resistance measurements carried out with the lower doped n-type 6H-SiC ( $1.8 \times 10^{17} \text{ cm}^{-3}$ ) decreased with temperature in the range from -60 to 25°C. Above 25°C, the resistance increased. Using Eq. (20.20), the average TCR value for the range 25 to 625°C was found to be 0.56%/°C. In the  $3 \times 10^{18} \text{ cm}^{-3}$  doped samples the resistance was observed to decrease

**FIGURE 20.7** (a) Relative change in resistance of the longitudinal piezoresistors as a function of strain at different temperatures ( $n^+$ -6H-SiC,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ). (b) Longitudinal gauge factor as a function of temperature. At 250°C the gauge factor is approximately 60% of its room-temperature value ( $n^+$ -6H-SiC, 2- $\mu\text{m}$ -thick epilayer,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ). (c) Net bridge output as a function of pressure at five different temperatures ( $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ). Bridge input voltage is 5 V.

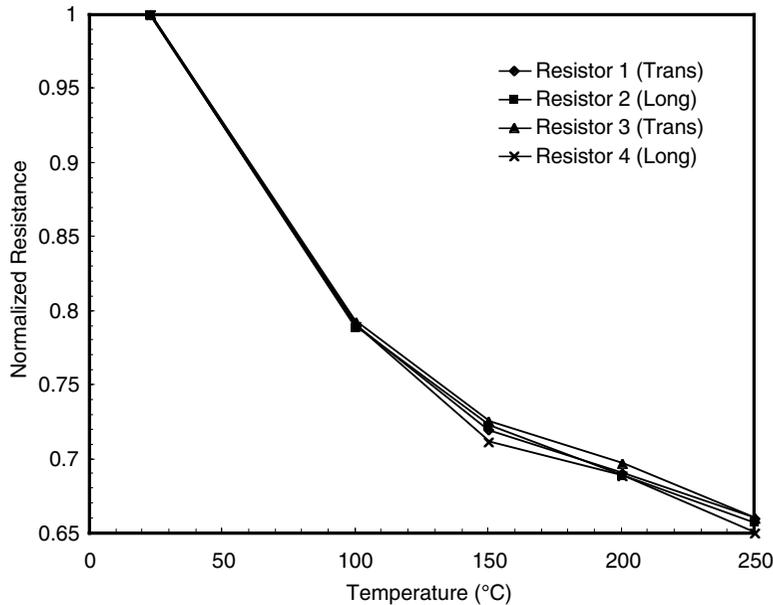

**FIGURE 20.8** Relative change in resistance of the transverse piezoresistors as a function of strain at different temperatures ( $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ )

**FIGURE 20.9** Net bridge output as function of pressure of two different beam sensors. In both cases the dependence is linear ( $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ).

up to 100°C and then increase. The average TCR value for this sample in the range 100 to 625°C was found to be 0.28%/°C. The decrease in resistance with increase of temperature below a certain temperature limit, which typically lies between 0 and 25°C, is associated with the increasing ionization of dopant impurities. In this temperature range the semiconductor resistance is primarily controlled by carrier ionization. Once most dopant impurities have become ionized, carrier phonon-related lattice scattering

**FIGURE 20.10** Change in normalized resistance of four individual gauges in a transducer as a function of temperature. All measured resistances decrease as the temperature increases ( $n^+ \text{-6H-SiC}$ ,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ).

increases with the temperature to increase the resistance. This observed behavior is consistent with well-known semiconductor carrier statistics and carrier transport physics. In highly doped n-type SiC, the impurity ionization is completed at higher temperature due to the large number of impurities and its wide bandgap.

## 20.4 High-Temperature Metallization

There is growing demand for devices to operate in high-temperature environments beyond the capability of silicon and gallium arsenide technology. Most existing semiconductor electronic devices are limited to ambient temperatures below 200°C, primarily due to the degradation of the intrinsic properties of the associated materials (silicon and gallium arsenide). Silicon-on-insulator (SOI) technology was developed to extend device operation to about 300°C. However, long-term SOI reliability beyond this temperature remains unproven. SiC-based technology appears to be the most mature, wide-band-gap semiconductor material with the proven capability to function at temperatures above 500°C [Jurgens, 1982; Palmour et al., 1991]. However, the contact metallization of SiC typically undergoes severe degradation beyond this temperature due to enhanced thermochemical reactions and microstructural changes. The causative factors of contact failures include interdiffusion between layers, oxidation and compositional and microstructural changes. These mechanisms are potential device killers by way of contact failure. Liu et al. (1996) and Papanicolaou et al. (1998) have demonstrated stable ohmic contacts at 650°C for up to 3000 hours and 850°C for a short duration in vacuum. Vacuum aging is, however, not representative of the environmental condition in which SiC pressure-sensor devices are expected to operate.

In order to build any high-temperature electronic device, it is essential to fabricate ohmic contacts and diffusion barriers capable of withstanding the device operational temperatures. It is necessary to identify metals and alloys that form acceptable ohmic contact to 6H-SiC. For the ohmic contacts on n-type SiC, the metals include titanium and its alloys of nickel–titanium and titanium–tungsten. It has been shown [Zeller et al., 1987] that titanium contacts deposited on 3C-SiC withstand 20 hours at 650°C. Nickel is also known to be a good ohmic contact to n-type SiC but exhibits severe adhesion problems.

Nickel–titanium alloys may combine the favorable electrical properties of nickel with high reactivity and adhesion of titanium. Titanium–tungsten alloys exhibit good diffusion barrier properties and may also be ohmic.

Several research groups have also demonstrated the effectiveness of TiN as a diffusion barrier. This section will start with the examination of the use of TiN as a diffusion barrier in a multilayer metallization scheme. The disadvantages associated with this scheme will be discussed. A recently investigated alternative scheme that uses a TaSi<sub>2</sub> diffusion barrier will then be presented; this technique shows promising performance characteristics able to support stable device operation at 600°C in air.

### 20.4.1 General Experimental and Characterization Procedure

Several (0001)-oriented, Si-face, 6H-SiC substrates (tilt angle 3.5°) having n-type 1-μm-thick epilayers of different doping levels were used. The wafers were initially cleaned by modified RCA method and dipped in 49% HF for 5 sec, after which they were rinsed with deionized water and blow-dried with nitrogen. They were then thermally oxidized in dry oxygen ambient at 1150°C for 4 hr to yield an oxide thickness of about 60 nm. This oxide was then stripped in 49% HF, and the samples were rinsed and dried again. A second thermal oxidation for 5 hr at 1150°C was performed, yielding a cleaner thermal oxide layer. Photoresist was applied and patterned into circular patterns. Circular contact holes were then etched through the oxide with BHF to expose circular sections of the epilayer surface. The contact holes consisted of 12 rows, each row being made up of four circular contact holes of the same diameter, *d*, with 225-μm equidistant separations between their centers, as shown in Figure 20.11. The diameter of the contacts ranged from 6 to 28 μm. After stripping the photoresist, the samples were RCA cleaned again, but with no HF dip to ensure that a very clean epilayer surface with a monolayer of oxide is formed. The samples were immediately transferred into the sputtering chamber for metal depositions. A 300°C dehydration process in vacuum for 20 min followed to remove any water trapped within micropipes in the wafers.

The I–V characteristic measurement of epilayer contacts was conducted by probing two adjacent contacts from the same row. The contact resistivity was measured using the modified four-point method of Kuphal (1981) expressed as:

$$r_{cs} = \frac{A}{I_{AD}} \left[ V_{AB} - V_{BC} \frac{\ln\left(\left(3\frac{s}{d}\right) - \left(\frac{1}{2}\right)\right)}{2\ln 2} \right] [\Omega\text{-cm}^2] \quad (20.21)$$

where  $V_{AB}$  is the voltage measured across contacts *A* and *B* in Figure 20.11 while  $V_{BC}$  measures the voltage between contacts *B* and *C* (epilayer resistance); *A* = contact area (μm); *s* = distance between adjacent contacts (μm); and *d* = diameter of the contact (μm). Current,  $I_{AD}$ , was passed through the circular contact pad, *A*, as shown in Figure 20.11, and out through pad *D*. Unless otherwise specified, the applied current was set at 1 mA. Measurements were made with four probes coming in contact with the Shockley

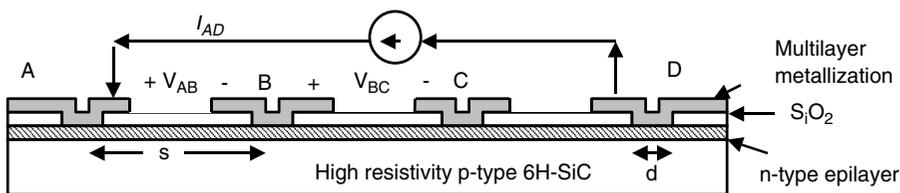

FIGURE 20.11 Cross-sectional view of multilayer metallization contact on n-type 6H-SiC epilayer for contact resistivity measurements.

pads that extend over the oxide. Therefore, the spreading and contact resistance,  $R_s$  and  $R_c$ , respectively, can be calculated by:

$$R_s + R_c = \frac{V_{AB} - V_{BC}}{I_{AD}} \quad (20.22)$$

The resistance of the probes in these measurements was negligible. Because the main parameter of interest in these measurements was the overall change in resistance under the contact,  $R_c$  and  $R_s$  were lumped together in determining the contact resistivity. As a result of lumping the spreading and contact resistances, the result obtained could be considered to be the high end of possible values of the specific contact resistivity.

## 20.4.2 Characterization of Ti/TiN/Pt Metallization

Several (0001)-oriented, highly resistive, Si-face, p-type 6H-SiC substrates each having n-type epilayers (1  $\mu\text{m}$  thick) of different doping levels ranging between  $3.3 \times 10^{17} \text{cm}^{-3}$  and  $1.9 \times 10^{19} \text{cm}^{-3}$  were purchased from Cree Research, Inc. The wafers were initially cleaned by modified RCA method and dipped in 49% HF for 5 sec, followed by rinsing and blow-drying. An *ex situ* dehydration process followed this at 200°C in nitrogen ambient for 20 min to desorb water trapped within the micropipes. Depositions of Ti (50 nm)/TiN (50 nm)/Pt (100 nm) were made on the samples by sputtering without breaking vacuum. Titanium nitride was obtained by reactive sputtering of titanium in 20% nitrogen/argon ambient. The top platinum layer was etched in light *aqua regia* to form rectangular and circular probe pads that overlap the field oxide. The exposed TiN/Ti on the field oxide was selectively etched in 1:1 EDTA:H<sub>2</sub>O<sub>2</sub> to electrically isolate it. The pads offered total coverage of the contact regions and facilitated broad area probe contact during testing.

In the as-deposited state the titanium contact on the n-type epilayer was ohmic for the sample with the highest doping level ( $1.9 \times 10^{19} \text{cm}^{-3}$ ). The contact resistance using Eq. (20.21) was found to be approximately  $1 \times 10^{-5} \text{cm}^2$ . In order to obtain ohmic contact to n-type 6H-SiC with lower doping levels ( $3.3 \times 10^{17}$ – $10^{18} \text{cm}^{-3}$ ), high-temperature annealing was required.

The experimental results of the Ti/TiN/Pt ohmic contact are summarized in Table 20.2. The I–V characteristics of the as-deposited metallization on all samples were rectifying, except for the highest doped sample ( $1.9 \times 10^{19} \text{cm}^{-3}$ ). After 30 to 60 sec of rapid thermal anneal at 1000°C in argon ambient, ohmic contact was achieved on all samples except for the lightest doped, which remained rectifying after 3.5 min of annealing.

The average barrier height before annealing was obtained from the forward I–V characteristic curve using the thermionic emission model:

$$J = J_s [e^{(qv/nkT)} - 1] \quad (20.23a)$$

**TABLE 20.2** Summary Results of Electrical Characteristics of Ti/TiN/Pt Metallization on n-Type 6H-SiC Epilayers

Sample No.	Conc. ( $\text{cm}^{-3}$ )	As-Deposited	Annealed	Total time (min)	SBH <sub>as-dep</sub> (eV)	$r_{cs}$ ( $10^{-4} \Omega \text{cm}^2$ )
A	$3.3 \times 10^{17}$	Rectifying	Rectifying	3.5	0.84	—
B	$1.4 \times 10^{18}$	Rectifying	Ohmic	.5	0.82	3.42
C	$1.5 \times 10^{18}$	Rectifying	Ohmic	1	0.74	2.5
D	$1.7 \times 10^{18}$	Rectifying	Ohmic	0.5	0.82	2.1
E	$2.7 \times 10^{18}$	Rectifying	Ohmic	0.5	0.80	1.5
F	$1.9 \times 10^{19}$	Ohmic	Ohmic	0.5	—	.15

where  $J$  is the forward current density ( $\text{A}/\text{cm}^2$ ),  $V$  is the applied voltage,  $q$  is the electronic charge,  $k$  is the Boltzmann constant,  $T$  is the temperature (K) and  $n$  is the ideality factor that models the deviation from the theoretical ideal I–V characteristic depending on the integrity of the metal/epilayer interface. The saturation current density,  $J_s$ , is expressed as:

$$J_s = A^* T^2 e^{(-q\phi_B/kT)} \quad (20.23b)$$

where  $A^*$  is the effective Richardson constant ( $\text{Acm}^{-2}\text{K}^{-2}$ ) and  $\phi_B$  (V) is the Schottky barrier height (SBH) between the metals in intimate contact with the 6H-SiC epilayer. The ideality factors before and after annealing ranged from 1 to 1.05 and  $J_s$  in the range of  $9.44 \times 10^{-8}$  to  $4.4 \times 10^{-3}$  ( $\text{Acm}^{-2}$ ). In this work, the effective Richardson constant was estimated by:

$$A^* = 120(m_e^*/m_o)[\text{Acm}^{-2}\text{K}^{-2}] \quad (20.23c)$$

where  $m_e^*/m_o$  is the ratio of the effective electron mass to the electronic rest mass. For a value of 0.45  $m_o$ ,  $A^*$  was calculated to be  $54 \text{ Acm}^{-2}\text{K}^{-2}$ . The obtained average SBH values ranged from 0.54 to 0.84 eV.

The ohmic contact obtained after annealing is believed to be due to the barrier-lowering effect caused by the change at the metal–SiC interface during annealing. The annealing is believed to cause the formation of low-work-function titanium carbide at the epilayer surface and changes in the density of surface states. The Auger electron spectroscopy (AES) depth profile of [Figure 20.12a](#) indicated distinct boundaries of the as-deposited metals on the SiC epilayer. However, in [Figure 20.12b](#), intermixing and zone reactions after annealing are evident and a new layer consisting mainly of Pt, Ti, Si and C atoms is observed in direct contact with the epilayer. The synchronous tracking of Ti and C atoms at a constant ratio of almost 1:2 (discounting the primary Ti–N signal that was difficult to distinguish) strongly suggested the formation of a TiC species. Several groups had previously confirmed the formation of  $\text{TiC}_{1-x}$  and  $\text{Ti}_5\text{Si}_3$  species for wafers annealed in the range of 500 to 1200°C. The decrease in the SBH could be associated with the low work function of TiC (3.35 eV) compared to that of titanium (4.1 eV) [Smithells].

The contact resistivity plotted against the impurity concentration is shown in [Figure 20.13](#), which exhibited the characteristic exponential dependence of contact resistivity on impurity concentration. In order to estimate the specific contact resistivity,  $r_c$ , the spreading resistance,  $R_s$ , and the contact resistance,  $R_c$ , were decoupled. TiC was assigned  $R_s$  on the assumption that it was the new layer in contact with the 6H-SiC epilayer. Therefore,  $R_s$  was evaluated with respect to its thickness by using the method of Cox and Strack (1967):

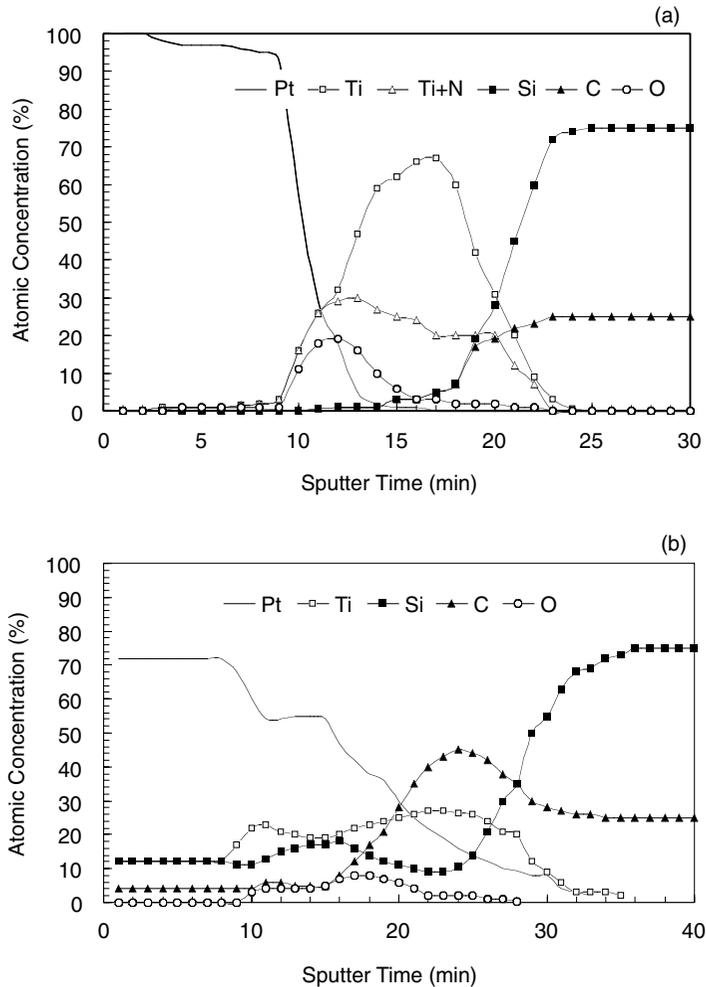

$$R_s = \rho_{\text{TiC}} \frac{t}{\pi(d/2)^2} \quad (20.24)$$

where  $d$  is the contact diameter ( $\mu\text{m}$ ),  $\rho_{\text{TiC}}$  is the resistivity ( $\mu\Omega\text{-cm}$ ) of the assumed TiC layer and  $t$  is the thickness ( $\sim 100$  nm). Substituting for  $R_s$  with Eq. (20.24) in Eq. (20.22), we have:

$$\rho_{\text{TiC}} \frac{t}{\pi(d/2)^2} + R_c = \frac{1}{I_{AD}} [V_{AB} - V_{BC}] \quad (20.25)$$

For a TiC resistivity of 200  $\mu\Omega\text{-cm}$  [Toth, 1971], the contact resistance,  $R_c$ , and the specific contact resistivity,  $\rho_c$ , was then evaluated. The values of obtained were such that  $R_s \ll R_c$ .

A comparison of the [Figure 20.12](#) Auger depth profile of the annealed samples to the as-deposited samples reveals the reactions at the TiN/Pt and 6H-SiC/Ti interfaces. The oxygen content (at. 17%) between the former interface was an artifact of the deposition system. The degree of its effect on the

**FIGURE 20.12** (a) Auger electron spectroscopy (AES) depth profile of as-deposited Ti/TiN/Pt metallization on n-type 6H-SiC. (b) AES of Ti/TiN/Pt after rapid thermal anneal at 1000°C for 30 sec in argon atmosphere. Synchronous 2:1 ratio tracking between titanium and carbon suggested the formation of  $\text{TiC}_{1-x}$  on the epilayer surface.

electrical characteristics was not known, but the 6H-SiC-Ti interface was relatively free of oxygen contamination. The surface of the top platinum layer exhibited a faint brown coloration after annealing, indicating the appearance of titanium species, which was confirmed by Auger surface spectral analysis.

The average contact resistivity ranging from  $1.5 \times 10^{-5}$  to  $3.42 \times 10^{-4} \Omega\text{-cm}^2$  and a Schottky barrier height between 0.8 and 0.84 eV were in reasonable agreement with previously published results [Waldrop and Grant, 1993]. Interlayer delamination, sometimes attendant in the preprocessed titanium layer, was not observed. Auger electron spectroscopy revealed the out-diffusion of titanium-silicon species. The continued presence of the TiN layer after annealing at 1000°C suggested its partial survivability, but it did not offer a full barrier against platinum diffusion. In order for this multilayer high-temperature metallization to be applicable, the oxygen contamination in the metal must be kept to less than 3 at. % oxygen. High levels of oxygen contamination at the interfaces of Pt-TiN and/or TiN-Ti could be the result of full or partial decomposition of the titanium nitride layer at high temperature and replacement by a layer of titanium oxide due to the high affinity of titanium toward oxygen. Formation of titanium oxide results in two deleterious effects: (1) it greatly reduces the effectiveness of the diffusion barrier and (2) it forms a dielectric layer, leading to rectification and failure of the ohmic contact. Another destructive

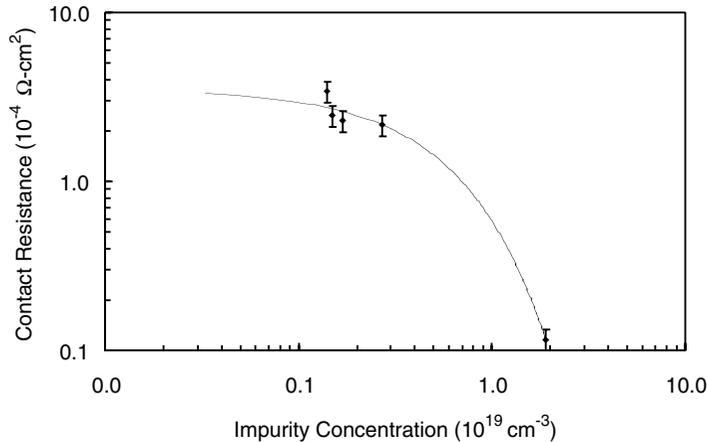

FIGURE 20.13 Bulk contact resistance as function of doping level.

effect is penetration of oxygen through the outer platinum layer. Inspection with scanning electron microscopy (SEM) indicated that the deposited platinum layer contained a high density of pinholes. At high temperature, oxygen would diffuse through the pinholes, thereby degrading the titanium nitride diffusion barrier. Oxygen also reacts with the titanium beneath the barrier, forming a solid titanium oxide layer with undesirable rectifying properties that extends to the 6H-SiC surface. For the metallization scheme to work effectively in air, the issue of oxygen contamination must be resolved. There is a need to investigate other schemes that would be more durable in air.

### 20.4.3 Ti/TaSi<sub>2</sub>/Pt Scheme

This section discusses an ongoing effort to develop high reliability contact metallization schemes capable of supporting SiC sensors and electronics operating within a temperature range of 500 to 600°C in air. Oxygen contamination generally poses a big problem for the Ti/TiN/Pt scheme, but the risk is reduced if the device with such metallization is hermetically sealed. However, the diffusion barrier integrity of the TiN layer against platinum diffusion to the semiconductor interface is also undesirable. A robust high-temperature metallization scheme must have at a minimum the following attributes: (1) Ohmic contact with reasonably low contact resistance relative to the bulk epilayer, (2) long-term contact stability in the harsh environment, (3) compatibility with SiC large-scale integrated electronics fabrication technology, (4) good wirebond strength and (5) compatibility with high-temperature interconnect and packaging technology.

In order to meet the criteria mentioned above, it was necessary to identify metallization schemes that would both form an ohmic contact on n-type SiC and at the same time offer an excellent diffusion barrier against oxygen penetration as well as preventing migration of any top-layer metallization such as platinum toward the contact SiC interface. In addition, such a scheme should have a top surface that is essentially wire-bondable. In developing this new scheme, thermodynamic and thermochemical issues were taken into consideration with the recognition that at 600°C the activation energies of several metals are enough to promote reactions or intermixing between metals. Metal layers with low mutual diffusivities were identified in order to keep intermixing at a minimum. In the case where they mix, however, the alloys formed must be thermodynamically, mechanically and electrically stable. The scheme must maintain excellent diffusion barrier characteristics. By combining the ability of titanium to form ohmic contact on n-type SiC, the diffusion barrier characteristics of TaSi<sub>2</sub> and the relative stability of the interface of the two layers, a new scheme was developed with a result that proved far superior to the Ti/TiN scheme.

A sequential deposition of Ti (100 nm)/TaSi<sub>2</sub> (200 nm)/Pt (300 nm) multilayer contacts was performed in a three-gun, UHV/load-lock, sputtering system. Details of the deposition parameters are shown in

**TABLE 20.3** Process Parameters for Deposition of Ti/TaSi<sub>2</sub>/Pt

Layer	Thickness(nm)	Deposition Conditions				
		Power (W)	Gas Flow (sccm)	Time (min)	Deposition Method	
Ti	100	6 mTorr	200 R.F.	50 Ar	16.5	Sputtering
TaSi <sub>2</sub>	200	6 mTorr	100 R.F.	50 Ar	33.3	Sputtering
Pt	300	9 mTorr	75 D.C.	50 Ar	6.3	Sputtering

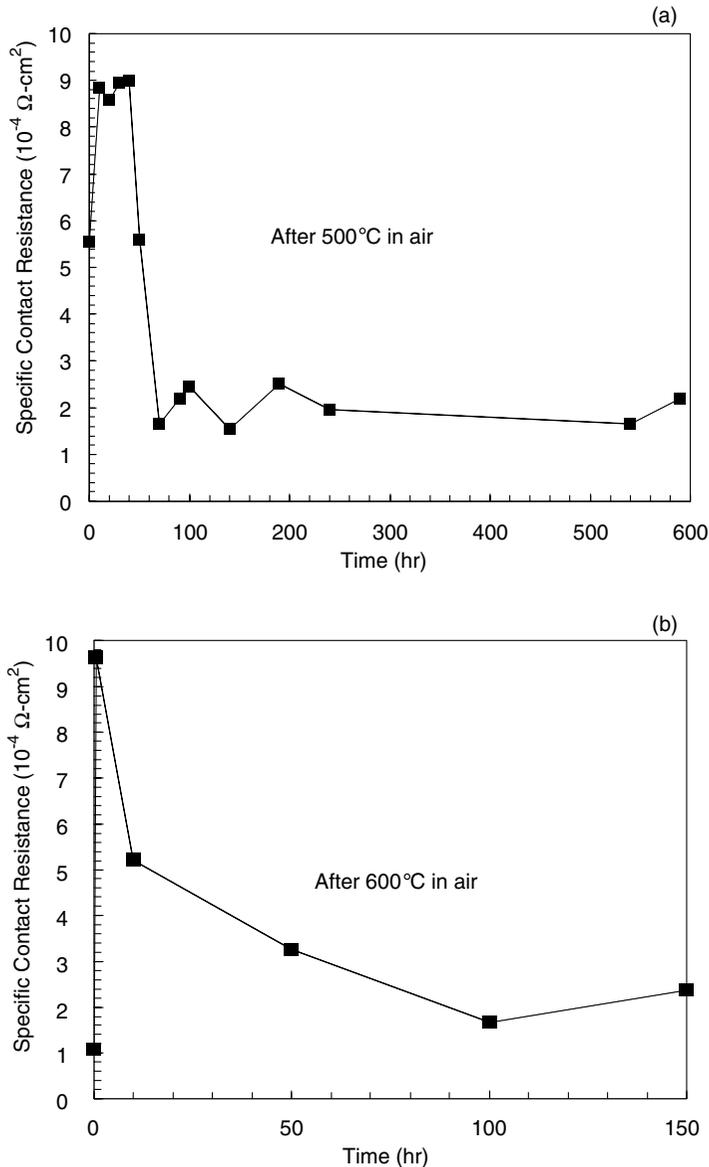

**Table 20.3.** A 2- $\mu\text{m}$  aluminum layer was deposited by e-beam evaporation and used as an etch mask during reactive ion etching to pattern the multilayer metallization into Shockley probe pads over the contacts. Following the RIE, the etch mask was selectively removed with an aluminum etchant to expose the underlying platinum layer. The specific contact resistance,  $\rho_{cs}$ , was calculated using the modified four-point probe measurement method described earlier.

The specific contact resistances of the sample sets as a function of time at 500 and 600°C in air atmosphere are shown in [Figures 20.14a](#) and [20.14b](#), respectively. The samples treated at 500°C, shown in [Figure 20.14a](#), exhibited higher contact resistance values initially which remained high for the first 40 hr. The contact resistance dropped after then and practically remained constant for the entire period between 70 and 600 hr. The results of the samples tested at 600°C in air for 150 hr are shown in [Figure 20.14b](#). The specific contact resistance also increased after an initial 30-min anneal at 600°C in forming gas, but subsequent heat treatments in air, however, saw a nearly exponential decrease in the contact resistance values that appeared to taper off after 100 hr.

There is an obvious difference in the contact resistance values between the two sample sets in the first 40 hr, as depicted in [Figure 20.14](#). This observed differences could perhaps be attributed to one or a combination of three things: (1) oxygen contamination of samples treated at 500°C in air, (2) the probable existence of surface states and (3) incomplete reaction product formation at the SiC interface after the initial 30-min anneal at 600°C in forming gas, which might be accelerated by the subsequent heat treating at 600°C. Because the heat treatments in air between the sample sets are different, variations in activation energies may cause differences in product formation, thereby leading to variations in electrical characteristics. After the contrast in results for times less than 100 hr between both sample sets, the average specific contact resistance for both sets leveled off to values around  $2\text{--}3 \times 10^{-4} \Omega\text{-cm}^2$ .

To begin understanding the active mechanisms, we examined the relationship between the electrical and thermochemical characteristics within the context of diffusion barrier formation and interfacial reactions. The Auger profiles after annealing at 600°C for 30 min in forming gas and after 50 hr at 500°C in air are shown in [Figures 20.15a](#) and [20.15b](#), respectively. Generally, the two figures are similar in terms of phenomenological changes taking place within the layers. [Figure 20.15a](#) shows the unidirectional migration of silicon preferentially into platinum and toward the surface. This is of significant importance as it forms the basis for the diffusion barrier characteristics of the metallization. This migration creates a silicon-depleted zone inside the metallization, as depicted in [Figure 20.15b](#). The AES profiles show a build-up of silicon, at a nearly consistent platinum-to-silicon ratio of 2:1 within the platinum layer. Because we anticipate stable titanium silicide and titanium carbide as the reaction products between titanium and SiC, no new source of silicon exists that will migrate to the surface. Although no strong indications of titanium carbide and titanium silicide signals were observed at the epilayer interface, the extension of the contact boundary a few nanometers into the epilayer strongly suggests an underlying physical and chemical reaction.

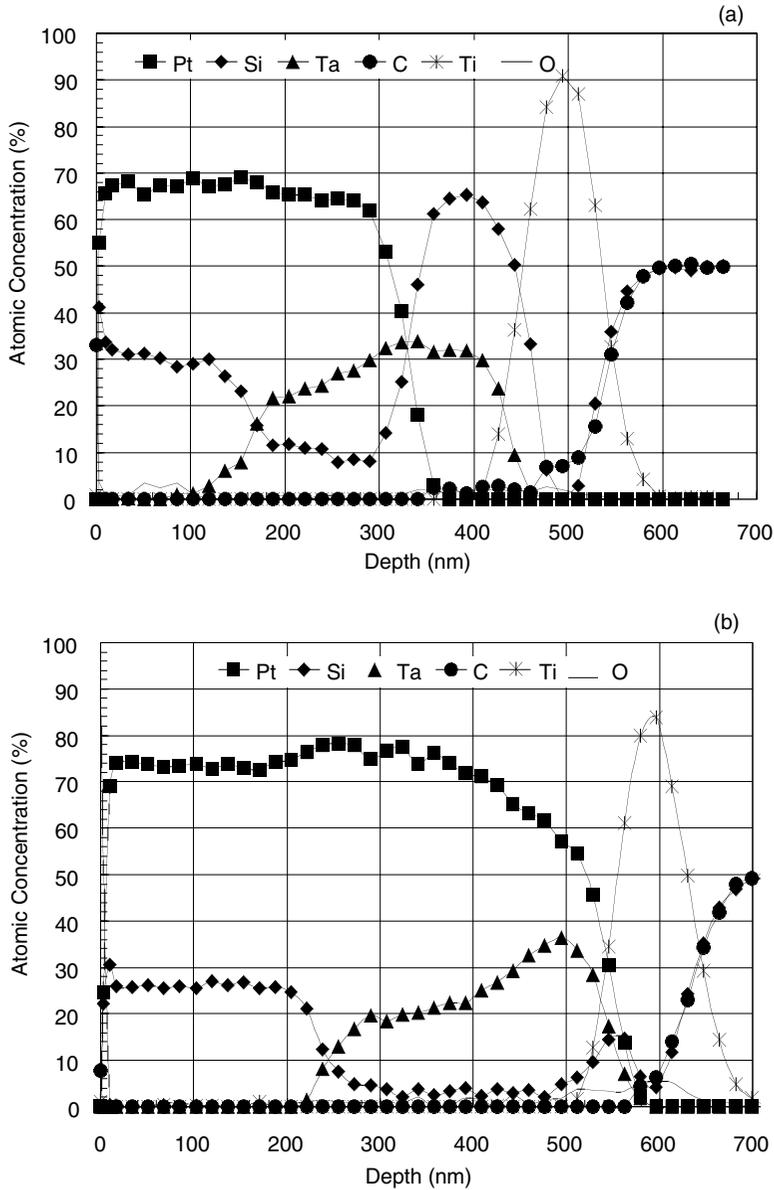

The representative I–V characteristics after various conditions for both sets of samples are shown in [Figure 20.16](#). The I–V curve shown in [Figure 20.16a](#) is that of the as-deposited condition, which was the same for both sample sets. The observed weak rectification could be related to low-level oxidation issues previously discussed in this chapter. The entire sample set exhibited linear I–V characteristics after annealing at 600°C in H<sub>2</sub> (5%)/N<sub>2</sub> forming gas for 30 min, as shown in [Figure 20.16b](#). The slight curvature observed was attributed to the ongoing reaction at the SiC interface. [Figure 20.16c](#) shows that

**FIGURE 20.14** (a) Average specific contact resistance as a function of time after 500°C in air. The high contact resistance in the first few hours may be attributed to conditions stated in the text. (b) Average specific contact resistance as a function of time after 600°C in air. The high contact resistance in the first few hours may be attributed to condition sated in the text.

the representative I-V characteristic of the sample set after 630 hr at 500°C in air remained practically unchanged relative to Figure 20.16b. The observed slight change in the I-V slope was an artifact of the oxidation process occurring on the Shockley pads and necessitated scratching the surface with the probe tips to get good electrical contact between the pad and the probe tip. For the sample set treated at 600°C in air, the slope of the I-V characteristic after 150 hr, shown in Figure 20.16d, compares very well with that of Figure 20.16b and c, given that they were all from the same wafer (net epilayer doping level,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ). This result is an indication of the improved thermal stability of the new SiC interface.

An understanding of these chemical reactions can be drawn from works by Bellina and Zeller (1987) and Chamberlain (1980). The temperatures in which we performed the heat treatments were in a range

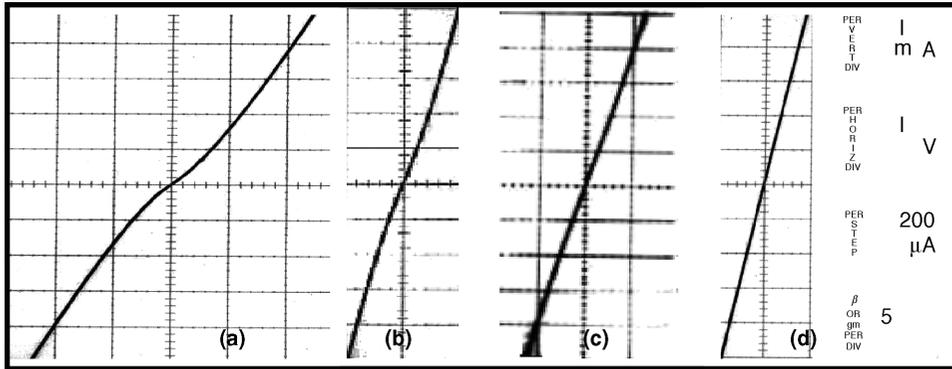

**FIGURE 20.15** (a) Auger depth profile of 6H-SiC/Ti/TaSi<sub>2</sub>/Pt after heat treatments at 600°C anneal in H<sub>2</sub> (5%) /N<sub>2</sub> for 30 min. (b) Auger depth profile of 6H-SiC/Ti/TaSi<sub>2</sub>/Pt after heat treatments at 500°C in air for 50 hr.

consistent with the work of Chamberlain, who identified the formation of titanium carbide and silicide at similar temperatures. Applying Chamberlain's parabolic reaction rate relation gives an approximation of the minimum thickness of reaction products:

$$x^2 = x_o + 2K(t - t_o) [\text{cm}^2] \quad (20.26a)$$

$$K = K_o \exp\left(\frac{-262.7 \text{ KJmol}^{-1}}{RT}\right) [\text{cm}^2 \text{ s}^{-1}] \quad (20.26b)$$

**FIGURE 20.16** I–V characteristics of samples measured at different stages: (a) as-deposited, (b) 600°C annealed in H<sub>2</sub> (5%)/N<sub>2</sub> forming gas for 30 min, (c) sample treated at 500°C in air for 630 hr and (d) sample treated at 600°C in air for 150 hr. The current and voltage scales are the same for all I–V plots.

where  $k_0$  is the reaction rate constant ( $\text{cm}^2 \text{s}^{-1}$ );  $K$  is the temperature dependence of the rate constant;  $x_0$  and  $t_0$  are initial distance and time constants, respectively, which in our case were set to zero; and  $R$  is the universal gas constant ( $8.314 \text{ J}\cdot\text{mol}^{-1}\text{K}^{-1}$ ). Without correction for pressure, a layer of no less than 2 nm of new products would have formed at the epilayer interface after 30 min of anneal at 600°C. While in-depth analysis is ongoing, thermodynamic and reaction-limited kinetics are tentatively proposed to be acting in sequence, such that the decomposition of TaSi<sub>2</sub> in the presence of platinum proceeds with a final reaction:

If this reaction proceeds to the right, the limiting reactant would be silicon, as it is fully consumed by platinum. This proposition is made more likely given that the heat of formation of Pt<sub>2</sub>Si ( $-\Delta H_f \sim 10 \text{ kcal mol}^{-1}$ ) is less than that of TaSi<sub>2</sub> ( $-\Delta H_f \sim 28 \text{ kcal mol}^{-1}$ ) [Andrews and Phillips, 1975].

It is important to examine the oxygen concentrations in Figures 20.15a and b. Both parts of the figure show very little migration of oxygen into the metallization. This implies a much more stable contact structure than the Ti/TiN/Pt approach [Okojie et al., 1999], which was affected by significant oxidation of the metals in the contact. Various groups have extensively studied the oxidation kinetics of the silicides. Murarka (1988) concluded that the oxidation mechanism for most silicides essentially have the same heats of formation as normal oxides. Lie et al. (1984) and Razouk et al. (1982) confirmed that the oxidation kinetics of tantalum disilicide has a parabolic rate. This implies that it would take an appreciable length of time for oxygen to diffuse through the entire contact.

## 20.5 Sensor Characteristics

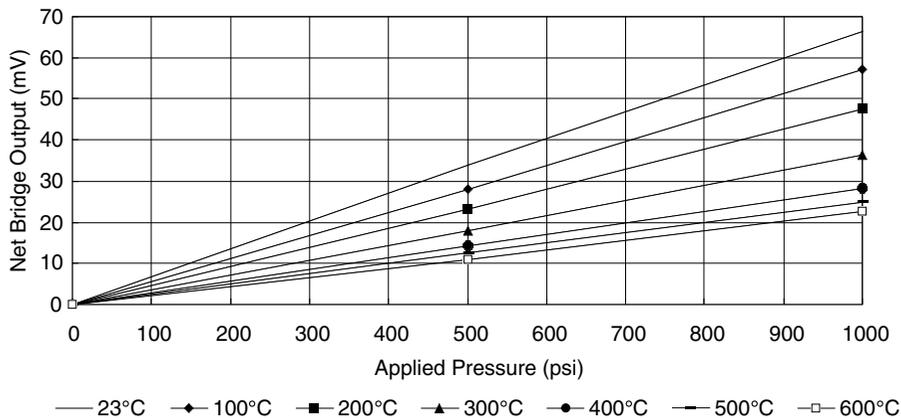

On the backside of the wafer, a circular cavity mask was aligned to each set of piezoresistors that form a Wheatstone bridge network. Electrochemical etching as previously described was used to fabricate the circular diaphragm cavities. The irregularity of the sidewalls and base of the cavity indicates that a consistent control of the electrochemical etching process is required. This batch of sensors had a diaphragm thickness of about 50 μm and chip area of 1.48 mm<sup>2</sup>. The above process was followed by a 20-hr wet oxidation at 1150°C to ensure complete p–n junction isolation and passivation of the active elements.

Contact holes were etched through the oxide using BHF to expose sections of the resistor elements. This was followed by *in vacuo* sputter deposition of the Ti/TaSi<sub>2</sub>/Pt high-temperature metallization and patterning of the metallization by the method described earlier. The wafer was then diced into chips and individually mounted on specially designed pressure-sensor headers. Gold wires were bonded from the sensor to the header pins to facilitate external electrical connection.

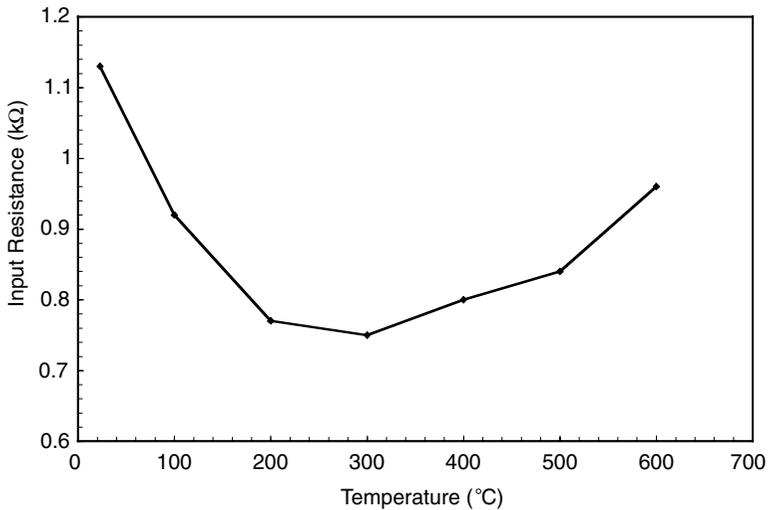

**FIGURE 20.17** Net bridge output voltage of 6H-SiC pressure sensor as function of pressure at various temperature regimes.

The performance characteristics of the three sensors shown in Table 20.4 are representative of multiple batch fabrication and diaphragm thickness. The room-temperature net output voltage as a function of applied pressure at various temperatures is shown in Figure 20.17 for sensor 10. With a bridge input of 5 V, the full-scale output (FSO) was 66.42 mV at room temperature for an applied pressure of 1000 psi, indicating a sensitivity of 0.013 mV/V/psi. Very low hysteresis of 0.7% FSO and nonlinearity of -0.9% FSO were obtained. The 600°C output of 25.04 mV indicated a 62% output drop from the room-temperature value.

**FIGURE 20.18** Temperature coefficient of gauge factor of 6H-SiC (calculated over 100°C increments) as function of temperature (epilayer doping level,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ).

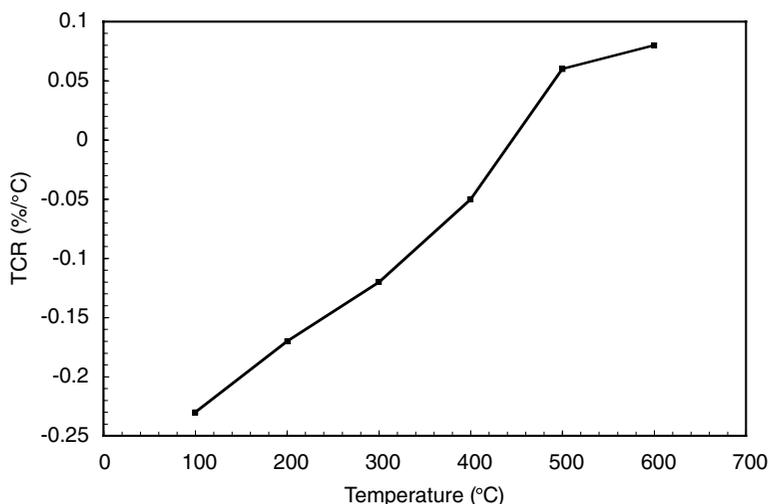

**FIGURE 20.19** Bridge resistance of 6H-SiC piezoresistive pressure sensor as function of temperature.

The characterization of the gauge factor, described in Section 20.3, showed a linear drop in gauge factor with increased temperature. The output was observed to decrease as temperature increased, but became gradually insensitive to temperature as temperature approached 600°C. Keyes (1960) had previously predicted this behavior in silicon. The temperature coefficient of gauge factor (TCGF), a measure of the output sensitivity to temperature, is defined here as:

$$\text{TCGF} = \frac{1}{V_{(T_0)}} \frac{V_{(T)} - V_{(T_0)}}{T - T_0} 100 \text{ [%/}^\circ\text{C]} \quad (20.28)$$

where  $V_{(T_0)}$  and  $V_{(T)}$  are the full scale outputs at room temperature and final temperature. The TCGF (calculated over 100°C increments) shown in Figure 20.18 indicated an initial pronounced sensitivity that approached smaller (less negative) values as the temperature increased. The TCGF response is expected to

**FIGURE 20.20** Temperature coefficient of resistance of 6H-SiC (calculated over 100°C increments) as function of temperature (epilayer doping level,  $N_d = 2 \times 10^{19} \text{ cm}^{-3}$ ).

be lower in magnitude for doping levels greater than  $2 \times 10^{19} \text{ cm}^{-3}$ . The effect of temperature on the resistance is shown in Figure 20.19. It indicates a gradual decrease from a room-temperature bridge resistance value of 1.13 k $\Omega$  to about 750  $\Omega$  at 300°C due to carrier ionization. The upward swing of the resistance is associated with the growing dominance of lattice scattering mechanism [Streetman, 1990]. From this result, the temperature coefficient of resistance from Eq. (20.20) was calculated over 100°C increments and is shown in Figure 20.20. The negative TCR characteristic, relative to the room-temperature resistance, was consistent with the n-type 6H-SiC epilayer of this doping level ( $2 \times 10^{19} \text{ cm}^{-3}$ ). For more heavily doped crystals, the negative TCR will extend to higher temperatures, thereby allowing for a less complex compensation scheme.

## 20.6 Summary

It is noteworthy that the development of SiC sensor technology is fundamentally motivated by the need to perform instrumentation in extreme environments of temperature, vibration and harsh chemical media. Accurate measurement in such environment therefore requires a new generation of sensors that can survive in such environments. In that respect, this chapter has presented critical technology issues that have been investigated in recent years as part of the effort toward realizing a new generation of microelectromechanical systems (MEMS) in single-crystal silicon carbide. Three important areas were addressed, namely, electrochemical etching methodologies for resistors and diaphragm structures, piezoresistance characterization in terms of strain and pressure, and high-temperature metallization to support sensor and electronic operation at high-temperatures. Photoconductive selectivity as a method to fabricate structures on either n-type or p-type SiC was demonstrated. This principle was then utilized to fabricate piezoresistors in n-type epilayers by applying photoelectrochemical etching. The p-type epilayer beneath the n-type epilayer served as an etch-stop. The newly developed process for resistor fabrication can be applied with minor adjustments to fabricate resistors with any n-type doping level. This work also demonstrated preferential oxidation of porous SiC to facilitate good pattern definition and fast removal of residues. The thinning and cavity etching to form the diaphragm were carried out by applying dark etching on the back side of the n-SiC wafer. The resulting cavities are relatively free of etch pits and hillocks. The average etch rates were found to be 0.6 to 0.8  $\mu\text{m}/\text{min}$ . Thermally stable Ti/TaSi<sub>2</sub>/Pt ohmic contact was demonstrated on n-type SiC, which is predominantly the conductivity of choice for piezoresistive SiC sensors. On the basis of these efforts, a first-generation, batch-microfabricated,

6H-SiC diaphragm-based piezoresistive pressure sensor was produced. Efforts are underway by various groups to overcome existing technological challenges that act as barriers against global commercialization. Issues such as temperature compensation, packaging and overall cost reduction are currently being pursued.

## Acknowledgments

---

The bulk of this work was funded by NASA Glenn Research Center (then NASA Lewis Research Center) under a Phase II SBIR contract NAS3-27011 awarded to Kulite Semiconductor Products, Leonia, NJ, and monitored by Dr. Lawrence G. Matus. My appreciation goes to Dr. Anthony D. Kurtz, the chairman of Kulite, for thrusting upon me the challenge to implement the objectives of this project, the bulk of which culminated in my doctoral thesis. My gratitude goes to Dr. William N. Carr for giving me the opportunity to be his graduate student. At Israel Institute of Technology, Technion, many thanks go to Drs. Ben Z. Weiss and Ilana Grimberg for their technical support. Also at Kulite, the full support of Alex N. Ned is greatly appreciated. I am grateful to the entire staff of department 200 with special reference to Gary Provost (formerly at Kulite) for metallization/dielectric depositions and other equipment support, to Mahesh Patel for support in testing the sensors and to Scott Goodman for material support in testing the sensors. Here at NASA Glenn Research Center, where some more recent advanced work in Ti/TaSi<sub>2</sub>/Pt metallization has been performed, I thank the various efforts of the technician cadre and Dr. Phillip G. Neudeck for his critical review of this chapter.

### 21.1 Introduction

---

It is often desired to insert microsensors and other microelectromechanical systems (MEMS) into harsh (e.g., hot or corrosive) environments. Silicon carbide (SiC) offers considerable promise for such applications, because SiC can be used to fabricate both high-temperature electronics and extremely durable microstructures. One of the attractive characteristics of SiC is the compatibility of its process technologies with those of silicon, which allows for the co-fabrication of SiC and silicon MEMS. However, a very important difference in the processing of these semiconductors arises from the chemical inertness of SiC, a characteristic that makes it attractive for use in corrosive environments but also makes it very difficult to micromachine.

Realization of the full potential of SiC MEMS will require the development of a set of micromachining tools for SiC comparable to the tool set available for silicon. Micromachining methods are generally classified as bulk, in which the wafer is etched, or surface, in which deposited surface layers are patterned. Surface micromachining methods for deposited SiC layers have been developed to a high level [Mehregany et al., 1998]. Silicon carbide can be readily etched to the required depths of just several microns using reactive ion etching (RIE) processes [Yih et al., 1997]. Further work remains to be done, however, in developing RIE processes with greater selectivity for SiC. Current RIE processes lack the selectivity needed to etch a SiC layer entirely through while minimally modifying an underlying silicon or silicon dioxide layer. This limitation has motivated the development of a micromolding method in which SiC is deposited into molds formed by RIE of silicon or silicon dioxide [Yasseen et al., 1999].

The emphasis here is bulk micromachining of SiC, for the fabrication of SiC microstructures with vertical dimensions from approximately 10  $\mu\text{m}$  to several hundred microns. Three methods for bulk

micromachining of SiC have been developed: electrochemical etching, micromolding and deep reactive ion etching (DRIE). Each of these has an important role to play in SiC MEMS fabrication.

Electrochemical etching of SiC can provide the high rates ( $>1 \mu\text{m}/\text{min}$ ) needed for economical deep etching [Shor and Kurtz, 1994]. In addition, electrochemical etching provides a high degree of selectivity to other materials, and it allows for the use of p–n junction etch-stops for precise depth control. Etch directionality, however, is poor, resulting in significant undercutting of the mask. Highly directional (or anisotropic) etch processes, which provide vertical etch sidewalls, are needed to accurately transfer the mask pattern deeply into the wafer.

Bulk micromolding methods have been developed to circumvent the limitations of available deep-etch processes for SiC [Lohner et al., 1999]. Here, silicon molds are fabricated using highly developed silicon DRIE processes. The molds are filled with polycrystalline SiC using chemical vapor deposition (CVD) and then removed by wet etching. Thick, finely featured SiC microcomponents have been fabricated using this approach. The molded polycrystalline SiC, however, does not have the excellent mechanical and electronic properties of single-crystal SiC. In particular, deep etching of single-crystal SiC wafers is required if high-quality SiC electronics are to be integrated with thick SiC microstructures.

Conventional parallel-plate RIE is not well suited for deep etching (i.e., etch depths greater than about  $10 \mu\text{m}$ ) of SiC because it provides low etch rates, high rates of mask erosion and relatively poor directionality (although superior to that which can be achieved using electrochemical etching). The use of advanced high-density-plasma (HDP) reactors can alleviate all these difficulties. High-density plasma has enabled the DRIE process for silicon, and its usefulness for deep etching of SiC is becoming well established.

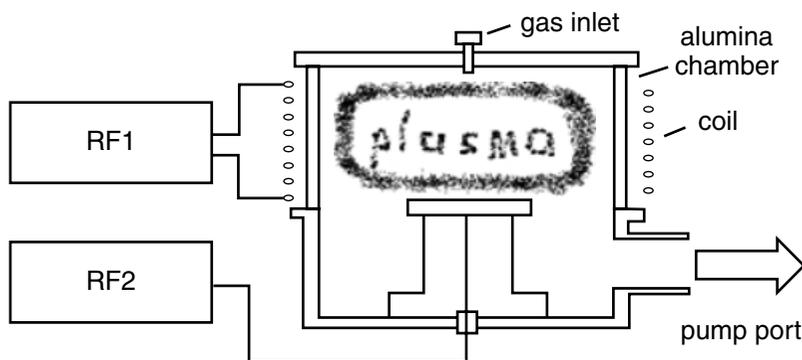

## 21.2 Fundamentals of High-Density Plasma Etching

---

The advantages of high-density plasma for DRIE are primarily the results of a more highly reactive plasma, which provides for increased etch rates, and a lower operating pressure, which improves directionality by minimizing the scattering of ions. There are several types of HDP systems, the most common being electron cyclotron resonance (ECR) and inductively coupled plasma (ICP). Inductively coupled plasma has come to dominate the HDP market [Bhardwaj and Ashraf, 1995], in large part due to lower complexity and cost (ICP uses RF frequencies, while ECR uses microwaves to generate the plasma). The focus here will be on etching with ICP, although ECR etching shares many of the same characteristics.

Inductively coupled plasma has several important advantages relative to conventional RIE. First, ICP can have a plasma density (ions per unit volume) which is two orders of magnitude higher than that of conventional RIE. This produces a much greater flux of ions and reactive species to the substrate surface. Also, ICP etching is performed at lower pressures, which helps minimize bowing of the etch sidewalls caused by scattering of ions. Lower pressures also facilitate the transport of etchants and etch products into and out of narrow trenches. In addition, the low operating pressure helps to provide smoother surfaces, as sputtered mask materials are less likely to be scattered back onto the etched surface, which can cause micromasking and the formation of “grass” or other etch residues. Another important advantage of ICP is the independent control it provides for the plasma density and the energy with which ions bombard the substrate. This allows for the adjustment of the chemical and mechanical components of the etch process to give a satisfactory trade-off between etch rate and the erosion rate of the mask. The ratio of the substrate and mask etch rates, the mask selectivity, is an important parameter for deep etching as it determines the maximum depth that can be etched with a given mask thickness.

A schematic of an inductively coupled plasma etching system is shown in [Figure 21.1](#). Typically, a fluorinated gas, such as  $\text{SF}_6$ , is supplied to the reactor at a controlled rate. A high throughput pumping system maintains the system at a low pressure and enables a high gas flow to rapidly replenish depleted etchants. A plasma is generated by supplying RF power to a coil wrapped around the ceramic walls of the chamber. Power supplied to the coil produces a time-varying axial magnetic field inside the chamber. This induces an azimuthal electric field, which accelerates the electrons to high energies. The circumferential electric field helps to confine the electrons to the plasma, which results in the much higher plasma

**FIGURE 21.1** Schematic of an inductively coupled plasma (ICP) etching system. The RF generators are labeled RF1 and RF2.

densities characteristic of ICP. Because confinement of the electrons increases the probability that an electron will undergo an ionizing collision with a gas molecule before it leaves the plasma, the ionization rate is increased. The plasma can therefore be sustained at lower pressures (as low as 1 mTorr), which increases the mean path length the electrons travel between collisions. This enables the acceleration of the electrons to higher energies, which increases the likelihood that a collision with a gas molecule will break the molecule apart. An ICP reactor, therefore, is very effective at dissociating a relatively inert fluorinated feed gas, such as  $\text{SF}_6$ , to produce high concentrations of atomic fluorine and other highly reactive radicals.

At the same time the substrate is subjected to a high flux of reactive radicals, it can be bombarded with energetic ions. A second generator supplies RF power to an electrode, onto which the wafer is clamped. Upon application of the AC voltage, electrons and ions are alternately attracted. The less massive electrons are considerably more mobile so the electrode acquires a negative charge, which gives it a time-averaged negative potential with respect to the plasma. This negative bias potential acts to repel electrons, preventing further net accumulation of charge. The potential gradient between the plasma and substrate electrode causes ions drifting out of the plasma to be accelerated across the dark space (or sheath) between the plasma and substrate. Typically, the ions are accelerated to energies from several tens of electronvolts to several hundred electronvolts. The damage which these ions cause to the substrate can dramatically increase the etch rate—for example, by creating highly reactive dangling bonds. The ions strike the substrate at normal incidence, provided they do not undergo scattering collisions with gas molecules in the sheath. Inductively coupled plasma enables highly anisotropic etching, as the low operating pressures of ICP ensure that ions strike only the horizontal wafer surfaces and are not scattered to the etch sidewalls.

### 21.3 Fundamentals of SiC Etching Using Fluorine Plasmas

The use of fluorine-based plasma etch chemistries is most easily implemented, as, unlike chemistries based on other halogens such as chlorine, it allows the use of nontoxic feed gases such as  $\text{SF}_6$ . The plasma dissociates the relatively inert fluorinated gas (e.g.,  $\text{SF}_6$ ) to produce highly reactive radicals such as atomic fluorine. For DRIE of silicon, a fluorine etch chemistry is almost always used, in part because of convenience, but primarily because fluorine provides the high rates needed for economical deep etching. Fluorine plasmas are widely used in SiC etching, also. Limited experimentation with chlorine plasma etching of SiC has yielded relatively low etch rates [Wang et al., 1998].

The reactivity of SiC in a fluorine plasma contrasts strongly with that of silicon. Exposure to atomic fluorine produces rapid isotropic etching of silicon, as shown in [Figure 21.2](#). Silicon reacts spontaneously with atomic fluorine, producing volatile etch products (e.g.,  $\text{SiF}_4$  and  $\text{SiF}_2$ ) which rapidly desorb from

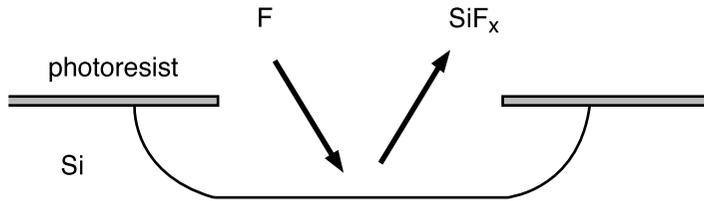

FIGURE 21.2 Etching of silicon in a fluorine plasma, using a photoresist etch mask.

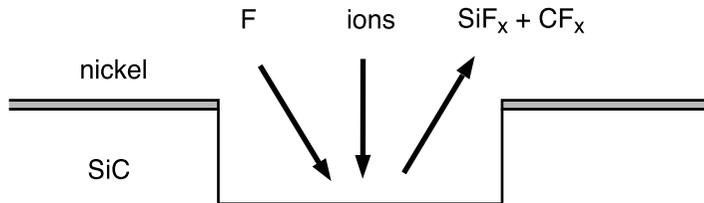

FIGURE 21.3 Etching of SiC in a fluorine plasma, using a nickel etch mask.

the surface. Etching proceeds laterally as well as vertically, which results in an isotropic profile. In contrast, the etch rate of SiC when exposed to atomic fluorine is extremely low, unless energy is supplied to the surface. In reactive ion etching, this energy is provided by ion bombardment, which results in an anisotropic etch profile, as shown in Figure 21.3. Energetic ions damage the SiC lattice (e.g., breaking Si–C bonds) which promotes reactions with atomic fluorine to produce volatile  $\text{SiF}_x$  and  $\text{CF}_x$  species. If the ions are well collimated, only the horizontal surfaces are etched, producing the desired anisotropy.

In fluorine-based DRIE of silicon, the required anisotropic profile is produced by modifying the process to cause the formation of a passivating layer on the etch sidewall. Most commonly, the reactor is programmed to switch back and forth between etching of silicon and deposition of an etch-resistant fluorocarbon polymer. Low energy ion bombardment is used during the etch step to remove the polymer from the horizontal surfaces, while leaving it intact on the etch sidewalls. Proper balancing of the etch and passivation steps produces a vertical sidewall, which at high magnification in a scanning electron microscope has a scalloped appearance.

In DRIE of SiC, the low reactivity of the substrate makes the etch profile inherently anisotropic. However, the low reactivity of SiC creates a number of other problems, including low etch rate, low selectivity to the mask and a tendency for the formation of residues on the etched surfaces. The net result is that DRIE of SiC is decidedly more difficult than DRIE of silicon. It is the high reactivity of silicon with fluorine that enables the high rate, photoresist etch masks and tunable sidewall slope of the DRIE process for silicon. Because the silicon DRIE process uses low ion energies, it provides a high selectivity with respect to photoresist, the most economical etch mask. Also, the silicon DRIE process provides excellent control of the etch profile, as the sidewall can be adjusted from outward to inward sloping by simply increasing the duration of the etch step relative to that of the passivation step. With inherently anisotropic etch processes, such as DRIE of SiC, it may prove more difficult to obtain the same high aspect ratios (etch depth divided by minimum feature size) that can be realized in silicon.

The high ion energies needed to etch SiC at acceptable rates make it impractical to use photoresist as an etch mask, as the etch rate of photoresist under these conditions is not much different from that of SiC. Nickel and indium–tin–oxide (ITO) are widely used because these materials do not form a volatile reaction product with fluorine and so are etched only by sputtering.

The formation of residues on the etched surface is a significant problem in SiC etching. The highly energetic ions cause significant erosion of the etch mask, and sputtered mask materials that deposit onto the SiC surface act as micromasks. Because the etch process is highly anisotropic, such micromasks are not undercut and pillar-like features and other residues can result. High pressures increase the likelihood

of residue formation, as sputtered mask materials are more likely to be scattered back onto the SiC surface. Also, the use of aluminum masks, rather than nickel or ITO, has been found to promote the formation of etch residues.

## 21.4 Applications of SiC DRIE: Review

---

Throughput is a key economic factor, and much work has focused on the development of high-rate etch processes for SiC. Various types of HDP reactors have been used to demonstrate SiC etch rates greater than 1  $\mu\text{m}/\text{min}$ , which compares fairly well with the 2- $\mu\text{m}/\text{min}$  rates typical of silicon DRIE. In SiC, however, the attainment of such a high etch rate necessitates highly energetic ion bombardment, which dramatically increases the sputter erosion of the etch mask. This can severely limit the etch depths that can be obtained using practically feasible mask thicknesses. In addition, high-rate etching often does not provide the smooth etched surfaces needed, due to the increased tendency for micromasking.

Several groups have demonstrated deep reactive ion etching of SiC. In one case, a parallel-plate RIE was used to etch a via through an 80- $\mu\text{m}$ -thick substrate at a rate of 0.23  $\mu\text{m}/\text{min}$  [Sheridan et al., 1999]. The feed gas was  $\text{NF}_3$ , and the chamber pressure was relatively high, 225 mTorr, which provided for a high concentration of reactive species. The high operating pressure also resulted in relatively low ion energies, which minimized sputtering of the mask. The selectivity to the mask was only 25, and thick electroplated nickel-alloy masks were used for deep etching of SiC. Anisotropy was quite good for the roughly 100- $\mu\text{m}$ -diameter via, but scattering of ions will limit the aspect ratios that can be achieved at such a high pressure.

Etching of 4H-SiC was reported using a helicon HDP reactor [Chabert et al., 2000]. The feed gas was  $\text{SF}_6$  and 25%  $\text{O}_2$ . It was stated that the addition of  $\text{O}_2$  did not affect the etch rate but prevented the deposition of sulfur compounds on the chamber walls. A 50- $\mu\text{m}$ -thick nickel sheet was used as a shadow mask to etch a via through a 330- $\mu\text{m}$ -thick 4H-SiC substrate. The wafer was etched through in approximately 6 hr, giving an etch rate of 0.9  $\mu\text{m}/\text{min}$ . The selectivity with respect to the nickel mask was 40:1. Etch rates as high as 1.35  $\mu\text{m}/\text{min}$  were obtained, but rough surfaces were produced at these high rates.

Using an ICP reactor with  $\text{SF}_6$  and 33%  $\text{O}_2$ , holes were etched to a depth of 97  $\mu\text{m}$  in 4H-SiC, at a rate of 0.32  $\mu\text{m}/\text{min}$  [Cho et al., 2000]. A cross-sectional scanning electron micrograph showed that the bottom of the etched hole was relatively clean. The low operating pressure of 2 mTorr may have been the key to providing clean etched surfaces despite the use of an aluminum mask, which often results in micromasking. Selectivity with respect to the mask was reported to be greater than 50.

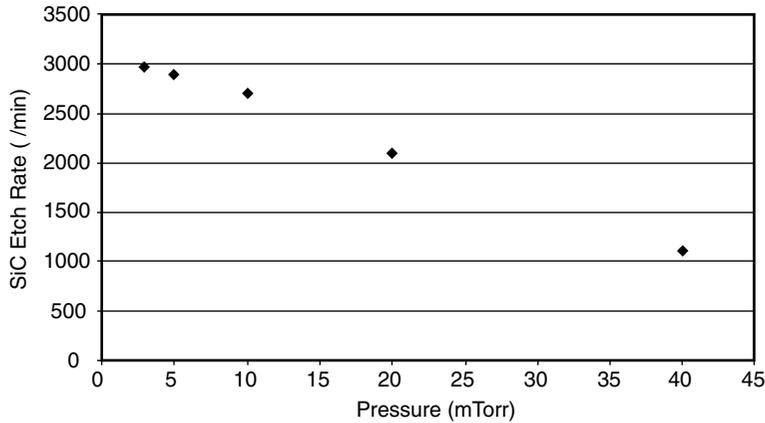

Using an ICP reactor with  $\text{SF}_6$ , very smooth etched surfaces were obtained for an etch depth of 45  $\mu\text{m}$ , and a via was etched through a 100- $\mu\text{m}$ -thick 6H-SiC wafer [Beheim and Salupo, 2000]. At a rate of 0.3  $\mu\text{m}/\text{min}$ , the selectivity with respect to a nickel mask was 80. Since the presentation of these results, this laboratory has made substantial progress in SiC DRIE, as will be described in the next section.

## 21.5 Applications of SiC DRIE: Experimental Results

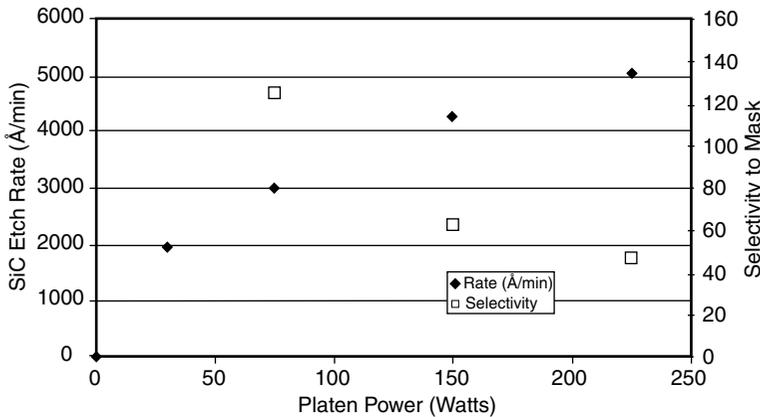

---

This section will present experimental results for DRIE of SiC using an inductively coupled plasma reactor (STS Multiplex ICP). The reactor has an automated load-lock and a 1000-L/sec turbopump with a dry backing pump. Helium is supplied to the backside of the electrostatically clamped wafer to provide effective heat transfer to a water-cooled chuck. The SiC substrates, which range in size from 10  $\text{mm}^2$  to 50-mm diameter, are attached to 100-mm silicon carrier wafers using a thin layer of photoresist. The use of a sacrificial carrier wafer (which etches at approximately 2  $\mu\text{m}/\text{min}$ ) helps to minimize roughness caused by the sputtering of etch-resistant materials onto the SiC surface.

Liftoff of electron-beam evaporated films is a convenient means of fabricating both nickel and ITO etch masks. Liftoff of ITO masks as thick as 3.5  $\mu\text{m}$  was readily accomplished, while film stresses limited the evaporated nickel masks to thicknesses no greater than 2500  $\text{\AA}$ . For extremely deep etching, nickel masks with thicknesses up to 15  $\mu\text{m}$  were fabricated by selective electroplating.

**FIGURE 21.4** Etch rate of n-type 4H-SiC as a function of pressure for 800-W coil power, 75-W platen power and 100% SF<sub>6</sub>.

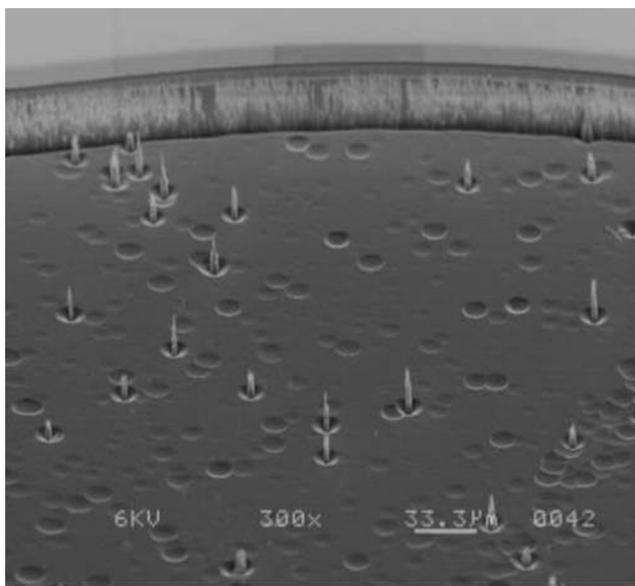

**FIGURE 21.5** Etch rate of n-type 4H-SiC and selectivity to a nickel mask as functions of platen power for 800-W coil power, 5-mTorr pressure, and 100% SF<sub>6</sub>.

A series of experiments was performed to determine the effects of various process parameters on the SiC etch rate and selectivity to the mask. During these experiments, the coil power was 800 W and the feed gas was 100% SF<sub>6</sub>. The gas flow was maintained as high as practical, given the constraints of the pumping system and the mass flow controller. The 10-mm<sup>2</sup> n-type 4H-SiC substrates were masked using evaporated nickel.

Figure 21.4 shows the etch rate of 4H-SiC as a function of pressure for a fixed platen power of 75 W. The highest etch rate of 0.30 μm/min was obtained at a pressure of 5 mTorr. The etch rates for 4H-SiC are not significantly different from those reported for the 6H polytype [Beheim and Salupo, 2000]. The dopant type also has been found to have little effect on the etch rate.

Figure 21.5 shows the SiC etch rate and the selectivity to the nickel mask (ratio of the SiC and Ni etch rates) as functions of the power supplied to the substrate electrode or platen. The platen power determines the kinetic energy of the ions which bombard the substrate. Selectivity was found to decrease with increasing ion energies, due to increased sputtering of the mask. For a platen power of 75 W, the etch rate was 0.30 μm/min and the selectivity to the nickel mask was 125.

An investigation was performed to determine the effects of the various parameters on the surface morphology of deeply etched features. It was found that 5-mTorr pressure and 75-W platen power, in conjunction with 800-W coil power and 55-sccm SF<sub>6</sub>, provide a deep etch that is satisfactory for many applications.

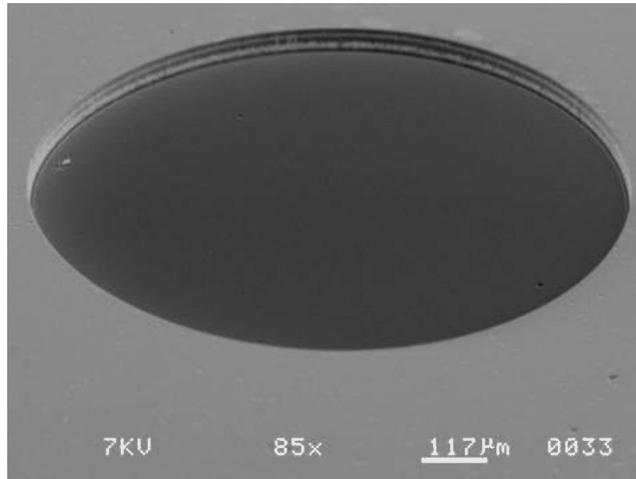

**FIGURE 21.6** 6H-SiC (n-type) etched to a depth of 45  $\mu\text{m}$  using the baseline 100%  $\text{SF}_6$  process. The SiC substrate was cleaned in hot sulfuric acid prior to etching. The electroplated nickel etch mask has not been stripped.

Relative to these baseline process parameters, higher platen powers give lower selectivity to the mask and higher pressures promote residue formation, while lower pressures cause increased trenching at the base of the sidewall.

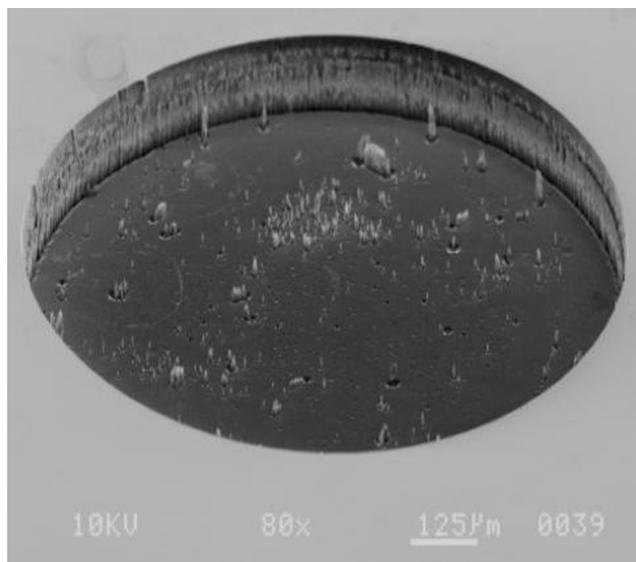

The morphology of the etched surface was found to be strongly influenced by the cleanliness of the surface at the start of the etch process. A number of cleaning procedures (solvents, hot sulfuric acid etch, oxidation followed by etch in hydrofluoric acid) were tried, but none was found satisfactory. [Figure 21.6](#) shows results typical of those obtained by cleaning a 6H-SiC substrate using standard methods prior to loading it in the reactor. After etching to a depth of 45  $\mu\text{m}$ , the etched surface is covered with dimples and spike-like residues.

An *in situ* plasma cleaning procedure was found to be effective at providing smooth surfaces for etch depths up to roughly 75  $\mu\text{m}$ . [Figure 21.7](#) shows the result when the SiC surface was sputter cleaned in argon immediately prior to a 45- $\mu\text{m}$ -deep etch using the baseline process. A disadvantage of the argon sputter clean is the significant mask erosion that it causes. The 10-min sputter etch in argon was found to remove 1  $\mu\text{m}$  of ITO, or 2500  $\text{\AA}$  of nickel, while removing only 800  $\text{\AA}$  of SiC. An oxygen plasma cleaning process, with moderately energetic ion bombardment (75W platen power), was found as effective as the argon sputter cleaning, while causing much less mask erosion. In the case of ITO masks, however, the oxygen plasma pretreatment was found to leave etch-resistant residues on the SiC surface, unless the openings in the mask were quite wide ( $>100 \mu\text{m}$ ).

When the SiC surface is plasma cleaned prior to deep etching, the etched surface is initially smooth, but with increasing etch depth, first dimples and then rough residues gradually appear. For etch depths less than roughly 75  $\mu\text{m}$  the surfaces are generally smooth, but for greater depths the etched surfaces become increasingly rough. [Figure 21.8](#) shows a 160- $\mu\text{m}$ -deep etch of a p-type 6H-SiC substrate, which was oxygen-plasma cleaned prior to the start of the baseline etch process. Auger analysis of the rough residues showed small quantities of aluminum. The residues are apparently the result of micromasking caused by aluminum sputtered from the vacuum chamber. The rough residues are found only if dimples are also present. The surface of a dimple may react more readily with aluminum than the untextured SiC surface, thereby trapping aluminum to produce a micromask. If no dimples are present, aluminum may remain mobile on the surface until it is sputtered off, thereby causing no roughening of the surface. Experimentally, residual hydrocarbons and water were found to greatly increase the density of dimples,

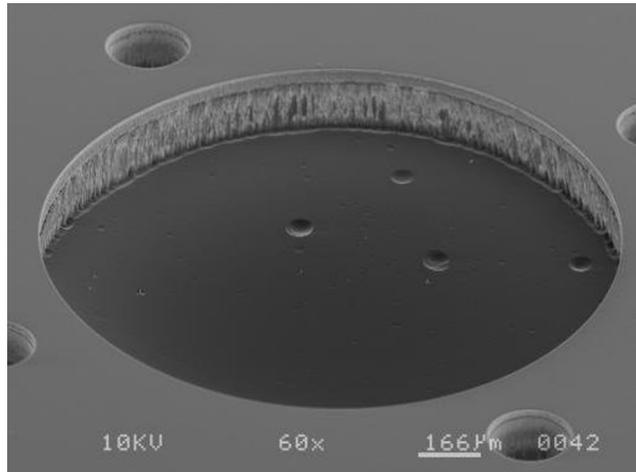

**FIGURE 21.7** A 1-mm-diameter well etched to a depth of 45 μm in n-type 6H-SiC using the baseline 100% SF<sub>6</sub> etch process, after an *in situ* sputter cleaning in argon. The ITO etch mask has been stripped.

**FIGURE 21.8** A 1-mm-diameter well etched to a depth of 160 μm in p-type 6H-SiC using the baseline 100% SF<sub>6</sub> etch process, after an *in situ* oxygen plasma clean using energetic ion bombardment. The ITO etch mask has been stripped.

in the absence of *in situ* plasma cleaning prior to etching. As determined by X-ray photon spectroscopy (XPS), the etched SiC surface was found to be covered with a thin (<10 Å) fluorocarbon layer, which mediates the etch reaction. Hydrogen is known to reduce the thickness and passivating properties of such a fluorocarbon layer on an etched silicon surface, so it is feasible that hydrogen-bearing contaminants may cause the local enhancement of etch rate which results in the dimples observed here. The texture-inducing contaminants are apparently found in the background vacuum of the chamber, as the dimples gradually appear with continued etching, despite an initial *in situ* cleaning of the surface.

Smooth surfaces, even for extremely deep etching, were obtained by diluting the SF<sub>6</sub> etchant gas with argon to cause continuous sputter cleaning of the surface throughout the etch process. In a series of

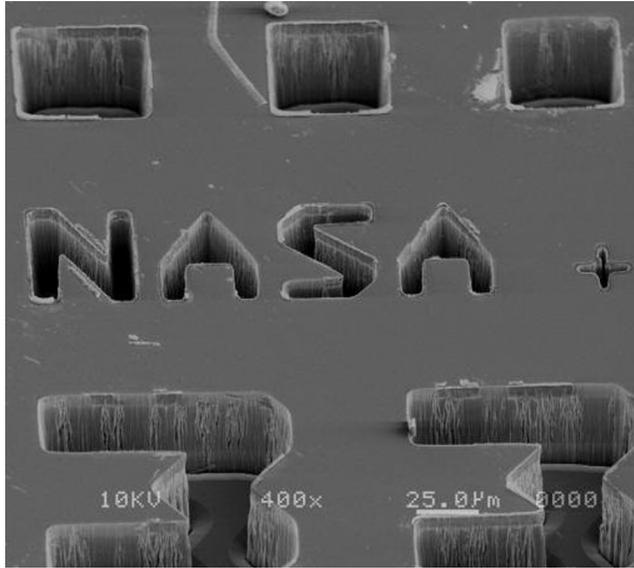

**FIGURE 21.9** A 1-mm-diameter well etched to a depth of 245  $\mu\text{m}$  in p-type 6H-SiC using the  $\text{SF}_6$  + 85% Ar etch process, after an *in situ* sputter cleaning using argon. The electroplated nickel mask has not been stripped.

experiments, the argon concentration was gradually increased until smooth etched surfaces were obtained at 85% argon and 15%  $\text{SF}_6$ . Other parameters were unchanged from the baseline process (5-mTorr pressure, 800-W coil and 75-W platen powers). Dilution with 85% argon reduces the SiC etch rate from 0.30 to 0.22  $\mu\text{m}/\text{min}$ . The selectivity to nickel is reduced from 125 to 55. The selectivity to ITO is only 20, insufficient for deep etching. For DRIE using the Ar-diluted  $\text{SF}_6$  process, thick nickel masks were fabricated by selective electroplating. Figure 21.9 shows the smooth surface that resulted after etching p-type 6H-SiC to a depth of 245  $\mu\text{m}$ , using  $\text{SF}_6$  and 85% argon. The mask in this case was 6- $\mu\text{m}$ -thick electroplated nickel.

A key attribute of the silicon DRIE process is its ability to accurately transfer finely detailed features deep into the wafer, as quantified by the aspect ratio, or etch depth divided by lateral feature size. Typically, DRIE of silicon can provide aspect ratios of 30 or greater. Deep RIE processes suitable for the fabrication of high-aspect-ratio SiC microstructures are still in the very early stages of development. Figure 21.10 shows trenches with moderately high aspect ratios which were fabricated by DRIE of n-type 6H-SiC. The etch depth was 60  $\mu\text{m}$ , and the trenches which form the letters shown were 10  $\mu\text{m}$  wide, for an aspect ratio of 6. The electroplated nickel mask (initially 6  $\mu\text{m}$  thick) was stripped prior to SEM. The wafer was etched using the standard 100%  $\text{SF}_6$  etch for 200 min, after a 10-min sputter clean in argon. In developing a high-aspect-ratio DRIE process for SiC, the primary objective will be to control the deposition of passivating polymer on the etch sidewall in order to minimize the sidewall roughness apparent in Figure 21.10. This can be accomplished by using a switched process, as for DRIE of silicon, or by modifying the SiC DRIE process to provide for simultaneous etching and polymer deposition.

## 21.6 Applications of SiC DRIE: Fabrication of a Bulk Micromachined SiC Pressure Sensor

This section will describe a practical application for SiC DRIE—specifically, a piezoresistive SiC pressure sensor, which can be used at temperatures as high as 500°C. Silicon piezoresistive pressure transducers were some of the first MEMS sensors and now represent a large fraction of the MEMS devices manufactured. Silicon pressure sensors with precisely controlled dimensions can be inexpensively fabricated using highly anisotropic wet etch processes. At moderate temperatures, silicon is a nearly ideal elastic material; however, at about 450°C, silicon begins to deform plastically. Silicon carbide is a superior material for high-temperature pressure sensors, because SiC maintains its excellent mechanical properties

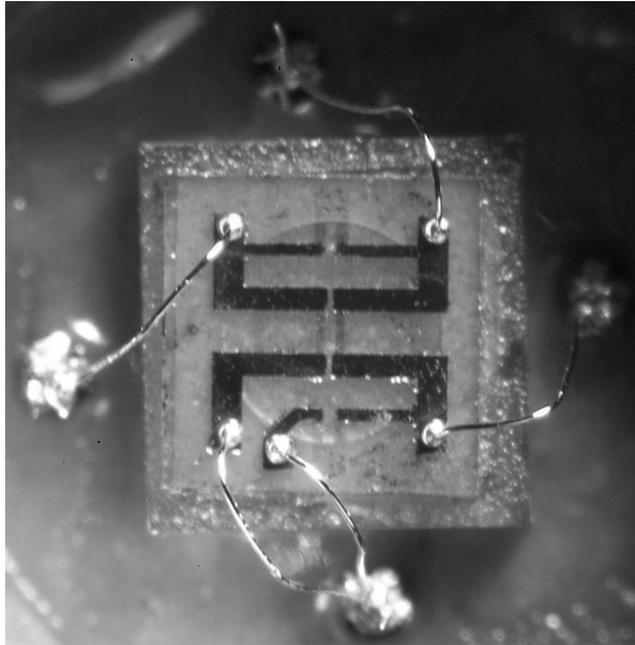

**FIGURE 21.10** 6H-SiC (n-type) etched to a depth of 60  $\mu\text{m}$  using the 100%  $\text{SF}_6$  baseline process, after an *in situ* sputter cleaning using argon. The electroplated nickel mask has been stripped. Visible on the tops of the sidewall are fragments of the polymer layer which had built up on the edge of the mask.

to very high temperatures ( $>1000^\circ\text{C}$ ). A production-worthy DRIE process for SiC is a key to the successful commercialization of high-temperature SiC pressure sensors, as DRIE is the only bulk-micromachining method for SiC that provides the required dimensional control.

The packaged SiC pressure sensor chip is shown in [Figure 21.11](#) [Ned et al., 2001]. A SiC diaphragm is micromachined by using DRIE to etch a 1-mm-diameter well to a depth of about 60  $\mu\text{m}$  in the backside of a 120- $\mu\text{m}$ -thick 6H-SiC wafer. On the front side of the diaphragm, four SiC strain gauges are fabricated in an n-type epitaxial layer. An underlying p-type epitaxial layer provides electrical isolation between the strain gauges. The strain gauges are defined using a photoelectrochemical etch process which automatically stops when the p-type layer is reached. The strain gauges are configured in a Wheatstone bridge, with two gauges positioned over the edge of the diaphragm while the other two gauges are positioned in the center of the diaphragm. The gauges on the edge of the diaphragm have the greatest sensitivity to pressure, while the sensitivity of the gauges in the center of the diaphragm is smaller and opposite in sign. The output of the Wheatstone bridge responds to the difference in the resistances of the edge-mounted and center-mounted gauges. The temperature-induced resistance changes, therefore, are compensated, as they are largely the same for all four gauges. A three-layer metallization system, consisting of layers of titanium, tantalum silicide and platinum, is used to electrically contact the SiC piezoresistors.

The highly anisotropic DRIE process for SiC produces diaphragms that are uniform in thickness and have precisely positioned edges. This maximizes the sensitivity and provides a high uniformity of response from one sensor to the next, as the sensitivity is strongly influenced by the positions of the strain gauges in relation to the edge of the diaphragm. For a 60- $\mu\text{m}$  etch depth, the 1-mm-diameter diaphragm was determined to have a thickness that was uniform to better than  $\pm 1 \mu\text{m}$ .

The SiC pressure sensor of [Figure 21.11](#) was tested in the compressor discharge of a gas turbine engine. The sensor performed as expected during this hour-long test, in which it was exposed to gas temperatures as high as  $520^\circ\text{C}$ . Current efforts are focused on reducing the cross-sensitivity to temperature: first by refining the design and fabrication processes to more accurately balance the bridge, and, second, by incorporating an on-chip temperature sensor to enable the compensation of temperature-induced changes in gauge factor.

**FIGURE 21.11** (Color figure follows p. 12-26.) Packaged SiC pressure-sensor chip. Through the semitransparent SiC can be seen the edge of the well that has been etched in the backside of the wafer to form the circular diaphragm. The metal-covered, n-type SiC that connects the strain gauges is highly visible, while the n-type SiC strain gauges are more faintly visible. There is a U-shaped strain gauge over the edge of the diaphragm at top and bottom, and there are two vertically oriented linear gauges in the center of the diaphragm.

## 21.7 Summary

---

Deep RIE of SiC is a key to enabling the development of a wide range of SiC MEMS for use in harsh environments. High-density plasma makes DRIE of SiC possible, as it provides the required high chemical reactivity, low operating pressure and independent control of ion energy. Deep RIE of silicon carbide is quite different from DRIE of silicon, due to the chemical inertness of SiC. The need for energetic ion bombardment to produce an appreciable etch rate causes RIE of SiC to be inherently anisotropic. Energetic ion bombardment necessitates the use of a nonreactive etch mask such as nickel or ITO. The attainable etch depth is typically limited by sputter erosion of the etch mask. Often, higher ion energies can be used to increase the SiC etch rate, but this can produce an unacceptable reduction in the selectivity with respect to the mask. The etch depths for which smooth residue-free surfaces are obtained can be limited by background contaminants in the reaction chamber. Argon can be introduced to the chamber to provide continuous sputter cleaning of the surface during the etch process, but this has detrimental effects on etch rate and mask selectivity. At present, SiC DRIE processes have been developed which are well suited for the fabrication of low-aspect-ratio microstructures such as pressure sensors. However, high-aspect-ratio DRIE processes are still in the early stages of development.

### Defining Terms

**Anisotropy:** Degree of directionality of an etch process. In reactive ion etching, an ideal anisotropic process provides negligible etching in the lateral direction.

**Aspect ratio:** Etch depth divided by lateral feature size. Highly anisotropic etch processes are needed to fabricate microstructures with high aspect ratios.

**Deep reactive ion etching (DRIE):** Highly anisotropic plasma etching to depths greater than about 10  $\mu\text{m}$ .

**High-density plasma (HDP):** A reactor that employs some means of electron confinement to produce a plasma density (ions per unit volume) which is typically two orders of magnitude greater than that of a conventional parallel plate RIE.

**Inductively coupled plasma (ICP):** A type of high-density plasma reactor in which power is coupled to the plasma using a coil. The time-varying magnetic field induced by the coil helps to confine electrons to the plasma, which increases the plasma density.

**Mask selectivity:** The substrate etch rate divided by the etch rate of the mask.

**Micromasking:** The formation of residues due to the masking effect of materials sputtered from the etch mask onto the etched surface. In some reactors, sputtering of the substrate electrode can also cause micromasking.

### 22.1 Introduction

---

The advent of microelectromechanical systems (MEMS) technology is important in the development and use of chemical sensor technology for a range of applications, especially those that include operation in harsh environments or effect safety. As will be discussed in this chapter, chemical microsensors can provide unique information that can significantly improve safety and reliability while decreasing costs of a system or process. Such information can also be used to improve a system's performance and reduce its effect on the environment. Chemical sensor data also can complement data derived from physical measurements such as temperature, pressure, heat flux etc., further improving overall knowledge of a system and expanding its capabilities.

However, the application of even traditional macrosized chemical sensor technology can be problematic. Chemical sensors often need to be specifically designed (or tailored) to operate in a given environment. It is often the case that a chemical sensor that meets the needs of one application will not function

adequately in another application. The more demanding the environment and specialized the requirement, the greater the need to modify existing chemical sensor technologies to meet these requirements or, as necessary, develop new chemical sensor technologies. Four common parameters are typically cited as relevant in determining whether a chemical sensor can meet the needs of an application: *sensitivity*, *selectivity*, *response time* and *stability*. Sensitivity refers to the ability of a sensor to detect the desired chemical species in the range of interest. Selectivity refers to the ability of the sensor to detect the species of interest in the presence of interfering gases, which also can produce a sensor response. Response time refers to the time it takes for the sensor to provide a meaningful signal (often defined as 90% of the steady-state signal) when the chemical environment is changed. Finally, stability refers to the degree to which the sensor baseline and response to a given environment change over time. Simply stated, for micro- and macrochemical sensing systems, one needs a sensor that will accurately determine the species of interest in a given environment with a response large and rapid enough to be of use in the application and whose response does not significantly drift over its designed operational lifetime. Depending on the application, it is often difficult to find a suitable sensor material that provides the required sensitivity, selectivity, response time and stability.

The microfabrication of chemical sensors involves much more than just making a macrosized sensor smaller. The processing used to produce a sensor material as a macroscopic bulk pellet can change considerably when it is desired to fabricate the material as part of a miniaturized system. For example, a chemical sensor in the form of a macroscopic bulk pellet can be fabricated from the powder of a starting material, pressed into a pellet containing lead wires and then sintered at high temperatures to form the resulting sensor. However, using the same starting material, pressing the material onto a substrate to form a smaller or even microscopic sensor is often not a viable option. Rather, a thin or thick film of the sensor material must be deposited onto a substrate, which itself, at a minimum, must support the sensor and allow for connections to the outside world. The underlying substrate with sensor film may not survive the sintering that typically is done with the pellet sensor material.

Further, given the surface-sensitive nature of many chemical sensors, the effects of miniaturization can be dramatic and include significant changes in sensor sensitivity and response time. This is in part due to the fact that the sensor film is often produced by techniques such as sputtering which may result in different material properties than those of bulk materials. The resulting surface-to-volume ratio of a thin film is larger than that of a bulk material: Surface effects that may affect only a small percentage of a sensor in the bulk form may occur within a significantly larger percentage volume of a thin-film sensor. This can strongly affect the response of the sensor. For example, oxidation may occur on the surface of a sensor exposed to high temperatures. In a bulk material, this oxidation may only be a small percentage of the sensor's volume, while in a thin-film material the same oxidation thickness may account for a sizable percentage of the sensor's volume. If the sensor's detection mechanism relies on bulk conduction, this oxidation could significantly affect the sensor response by changing the nature of the volume of the sensor. In addition, stresses in sensor thin films that degrade sensor response or catastrophically damage the sensor structure may be less of a factor in bulk materials [e.g., Hughes et al., 1987; Hunter et al., 1998]. Therefore, new technical challenges often must be overcome as sensor technology is miniaturized.

This chapter will discuss the development and application of microfabricated chemical sensor technology for aerospace (aeronautics and space) applications. These applications are particularly challenging, as often they include operation in harsh environments or have requirements that have not been previously emphasized by commercial suppliers. Section 22.2 discusses the chemical sensing needs of three important aerospace applications: leak detection, emission monitoring and fire detection. For each application, the use and advantages of MEMS-based approaches will be discussed. Each application has vastly different problems associated with the measurement of chemical species. Nonetheless, the development of a common base technology can address the measurement needs of a number of applications. Section 22.3 explores three base technologies being used to develop chemical sensors for these applications: microfabrication techniques as applied to chemical sensors, nanomaterials and high-temperature silicon carbide (SiC)-based electronics. Section 22.4 discusses the use of these base technologies to produce chemical sensors for a range of species: hydrogen ( $H_2$ ), nitrogen oxides ( $NO_x$ ), oxygen ( $O_2$ ), hydrocarbons ( $C_xH_y$ ),

carbon monoxide (CO) and carbon dioxide (CO<sub>2</sub>). The following two sections discuss the integration, application and future direction of chemical sensor technology in aerospace applications and provide a summary.

## 22.2 Aerospace Applications

---

Aerospace applications vary considerably in their requirements for chemical sensor technology. In general, there are three envisioned uses of chemical sensor technology in aerospace vehicle applications: (1) system development and ground testing and where the sensor provides information on the state of a system that does not fly; (2) vehicle health monitoring (VHM), which involves the long-term monitoring of a system in operation to determine the health of the vehicle system (e.g., whether or not the engine is losing performance, increasing emissions or developing a leak in the fuel system); (3) active control of the vehicle in a feedback mode where information from a sensor is used to change a system parameter in real time (e.g., fuel flow to the engine changing due to sensor measurements of emissions). A sensor could be used in all three applications: qualifying the system on the ground, monitoring its health in flight and using this information in real time to change the operation parameters. These applications have a strong impact on vehicle safety, performance and reliability. The design of each individual sensor depends on the requirements of each application. As will be discussed below, very different sensor technology is necessary depending on temperature range, ambient gas, interfering gases etc. For example, the sensor technology used for ground testing for leaks in an air ambient is very different from that used for leak testing in an inert (no oxygen) ambient. This section illustrates the needs of three specific aerospace applications and how MEMS-based technology can address these needs by examining a ground-based/VHM application (leak detection), an in-flight VHM application (fire detection) and an application (emission monitoring) that can be included in all three aerospace application areas: ground testing, VHM and active control.

### 22.2.1 Leak Detection

Launch vehicle safety requires the rapid and accurate detection of fuel leaks. One major application is the detection of low concentrations of H<sub>2</sub> associated with the launch and operation of the Space Shuttle. Hydrogen leaks can lead to hazardous situations and, unless their locations can be rapidly identified, explosive situations, delays in vehicle launches and significant costs. In the summer of 1990, hydrogen leaks on the Space Shuttle while it was on the launch pad temporarily grounded the fleet until the leak source was identified and repaired. The standard leak-detection system was a mass spectrometer connected to an array of sampling tubes placed throughout the region of interest. Although able to detect hydrogen in a variety of ambient environments, the mass spectrometer leak-detection approach suffered delay times, as gas had to be transported from the fuel pipe through the sampling tubes to the remotely located mass spectrometer. Pinpointing the exact location of the leak was also problematic, as often the fuel pipes were covered with insulation. A leak emitted from the pipe could travel in the insulation and exit the insulation in a location different from the leak source. Thus, the mass spectrometer leak-detection approach was unable to adequately isolate the location of the hydrogen leaks, leading to a delay in Shuttle launches. Problems with hydrogen leak detection on the Shuttle continue. As recently as 1999, the launch of STS-93 was delayed for 2 days due to an ambiguous signal in the mass spectrometer leak-detection system. The Shuttle hydrogen leak-detection system must be improved in order to allow improved safety and reduced operational costs.

No commercial hydrogen sensors existed at the time of the 1990 leaks that operated satisfactorily in this and other space-related applications, primarily due to the conditions in which the sensor must operate. The hydrogen sensor must be able to detect hydrogen from low concentrations (ppm range) through the lower explosive limit (LEL) which is 4% in air. The sensor must be able to survive and preferably function, even during exposure to 100% hydrogen, without damage or change in calibration. Further, the sensor may be exposed to gases emerging from cryogenic sources which could cool the sensor

and cause undesired changes in sensor output. Thus, sensor temperature measurement and control are necessary. Operation in inert environments is also necessary, as the sensor may have to operate in areas purged with helium. The ability to operate in a vacuum is preferred to allow leak detection even in space. Commercially available sensors, which often required oxygen (air) to operate or depended upon moisture [Hunter, 1992a], did not meet the needs of this application (especially operation in inert environments), thus development of new types of hydrogen sensors was initiated [Hunter, 1992a].

NASA has been active in efforts to improve fuel leak-detection capabilities for propulsion systems. The long-term objective has been an automated detection system using MEMS-based, point-contact hydrogen sensors. The application of MEMS-based sensor technology allows the fabrication of sensors with minimal size, weight and power consumption to beneficially decrease vehicle weight and power requirements. A number of these sensors placed in the region of interest could allow multiplexing of the signals and “visualization” of the magnitude and location of the hydrogen leak. Potential locations for sensors include fuel lines, inside insulation and throughout chambers inside the vehicle. The ability to launch a vehicle on schedule depends on a leak-detection system that can monitor key regions in the vehicle and automatically locate a leak in a limited time which can reduce costs and manpower associated with the detection and location of leaks as well as improve overall system reliability.

Hydrogen is not the only fuel that may be used in launch vehicle applications. Other potential fuels considered for launch vehicles include propane, methane, ethanol and hydrazine. Leak-detection sensors for these fuels will have to meet many of the same requirements as the hydrogen sensor: sensitive detection of the fuel in possibly inert or cryogenic environments, sensor survival in high concentrations of the fuel and minimal size, weight and power consumption. Methane, which is a naturally occurring by-product of animal wastes, already exists in small quantities in the environment. This increases the difficulty of its measurement in some applications. Further, the detection mechanism that may readily allow the detection of hydrogen may not work for the detection of methane or ethanol [Chen et al., 1996]. Hydrazine is toxic, which adds further importance to leak-detection systems: The gas must be detected not only for reasons of explosion prevention but also for personnel health safety reasons. Just as hydrogen sensor technology in 1990 did not meet the needs of launch vehicle safety applications, suitable fuel leak-detection systems still do not exist for launch vehicles that use alternate fuels to hydrogen.

## 22.2.2 Fire Safety Monitoring

The detection of fires onboard commercial aircraft is extremely important to avoid catastrophic situations. Although dependable fire-detection equipment currently exists within the cabin, detection of fire within the cargo hold has been less reliable [Grosshandler, 1997]. In aircraft where cargo-hold fire detection is required, the fire-detection equipment used in many commercial aircraft relies on the detection of smoke. These smoke detectors either are optically based or depend on ionization of particles. Although highly developed, these sensors are subject to false alarms, with estimated false alarm rates varying from 10:1 to 500:1. Because some cargo areas are inaccessible to the flight crew during flight, visual confirmation is not possible. The presence of false alarms decreases the confidence of pilots in these systems and may potentially cause accidents if pilots react to reported fires that may not exist. These false alarms may be caused by a number of sources, including changes in humidity, condensation on the fire detector surface and contamination from animals, plants or other contents of the cargo bay.

A second, independent method of fire detection to complement the conventional smoke-detection techniques, such as the measurement of chemical species indicative of a fire, will help reduce false alarms and improve aircraft safety. Although many chemical species are indicative of a fire, two species of particular interest are CO and CO<sub>2</sub> [Grosshandler, 1995]. Some requirements for these chemical sensors differ from those of leak detection and emission monitoring. The sensor must withstand temperatures ranging from -30 to 50°C, pressures from 18.6 to 104 kPa and relative humidities from 0 to 95%. Different types of fires produce different chemical signatures [Grosshandler, 1995]; the sensor must be able to detect the presence of a real fire and must not be affected by the presence of gases produced by contents of the cargo hold. The response must be quick and reliable and able to provide relevant information to the pilot.

The use of MEMS-based chemical sensing technology for fire detection would be similar to that for the leak-detection application above: a number of sensors placed throughout a region that give an indication of the chemical signature of a fire and its location. Similar to the leak-detection application, a smaller system is preferred. In larger sensor systems, fewer sensors can be placed in a cargo bay, and the likelihood of them being dislodged is greater because they stick out into the chamber. The ideal is to have a multifunctional sensor array that provides all the information necessary to determine the presence of the fire while being easily integrated with existing fire-detection systems and cargo bay.

### 22.2.3 Engine Emission Monitoring

One of the NASA agency goals is to significantly reduce emissions of future aircraft. Control of emissions from aircraft engines is an important component in the development of the next generation of these engines. A reduction of engine emissions can be achieved, in principle, if the emissions of the engine are monitored in real time and that information is fed back and used to modify the combustion process of the engine. This active combustion control also depends on the development of actuators that control the combustion process as well as a control system to interpret the sensor data and appropriately adjust the engine parameters. The ability to monitor the type and quantity of emissions being generated by an engine is also important in determining the operational status of the engine. For example, by monitoring the emission output of the engine and correlating changes in the emissions produced with previously documented changes in engine performance, long-term degradation of engine components might be monitored. If such an emission-monitoring system were developed, an initial use would be measurement of emissions during the developmental stage of the engine.

Very few sensors available commercially are able to measure the components of engine emissions *in situ*. The harsh conditions, such as high temperatures, inherent near reaction chambers of the engine render most sensors inoperable. A notable exception to this limitation in sensor technology is the commercially available oxygen sensor currently used in automobile engines [Logothetis, 1991]. This sensor, which is based on the properties of zirconium dioxide ( $ZrO_2$ ), has been instrumental in decreasing automotive engine emissions. However, comparable sensors for other components of the gas stream do not exist. Highly sensitive monitoring of emissions of nitrogen oxides, hydrogen and hydrocarbons is not currently possible *in situ* with point-contact sensors placed near the engine. Even the traditional  $ZrO_2$ -based sensor has sensitivity limits as well as size, weight and power consumption requirements that discourage its use in some applications.

The development of a new class of sensors for monitoring of emissions from aircraft engines is necessary. The difficulties inherent with larger sensors placed in the engine stream include: (1) added weight to the engine; (2) reduced ability to pinpoint the chemical signature of the stream at a given location if the sensors vary in position due to their size; (3) greater turbulence experienced by the array in the engine flow stream and more interference with the flow of gases in the engine; (4) size of the projectile if the sensor array is dislodged from the measuring site and emitted into the engine. Thus, an emission sensor array should be as small as possible. This implies the use of MEMS-based technology.

The environment in which a sensor must operate in emission-monitoring applications varies drastically from the environment of launch vehicle propellant leak applications. The sensor must operate at high temperatures and detect low concentrations of the gases to be measured. Although the measurement of  $NO_x$  is important in these applications, the measurement of other gases present in the emission stream such as  $C_xH_y$ , CO,  $CO_2$  and  $O_2$  is also of interest. Table 22.1 provides a partial listing of gases of interest in an emissions stream identified by the Glennan Microsystems Initiative (see For Further Information section). The measurement ranges depend on the chemical species and the engine, but generally the detection of  $NO_x$  and  $C_xH_y$  may be necessary at sensitivities down to 5 to 10 ppm, CO down to 50 ppm,  $O_2$  from 0 to near 25% and  $CO_2$  from 2 to 14%. Such a wide range of detection requirements demands multiple types of sensor technology, each of which should have stable or at least predictable performance for extended periods of time. Given the limited number of appropriate sensors for this application, development of new sensor technology is also necessary for this application.

**TABLE 22.1** Partial Listing of Gases of Interest in an Emissions Stream as Identified by the Glennan Microsystems Initiative

Chemical Species	Concentration Range
CO	50–2000 ppm
CO <sub>2</sub>	2–14%
NO <sub>x</sub>	10–2000 ppm
O <sub>2</sub>	0–25%
C <sub>x</sub> H <sub>y</sub>	5–5000 ppm

## 22.3 Sensor Fabrication Technologies

In order to meet the chemical sensor needs of aerospace applications described in Section 22.2, the development of a new generation of sensor technologies is necessary. Active development of chemical sensor technology to meet these needs is taking place at NASA Glenn Research Center (NASA GRC) and Case Western Reserve University (CWRU) based on recent progress in three technology areas: (1) micromachining and microfabrication technology to fabricate miniaturized sensors, (2) the use of nanocrystalline materials to develop sensors with improved stability combined with higher sensitivity and (3) the emergence of silicon carbide (SiC) semiconductor technology to provide electronic devices and sensors operable at high temperatures. This section will give a brief overview of these technologies, while Section 22.4 discusses chemical sensor technology development and application.

### 22.3.1 Microfabrication and Micromachining Technology

Microfabrication and micromachining technology is derived from advances in the semiconductor industry [Madou, 1997]. A significant number of silicon-based microfabrication processes were developed for the integrated circuit (IC) industry. Of the various processing techniques, lithographic reduction, thin-film metallization, photoresist patterning and chemical etching have found extensive use in chemical sensor applications. These processes allow the fabrication of microscopic sensor structures. The ability to mass-fabricate many of these sensors on a single wafer (batch processing) using currently available semiconductor processing techniques significantly decreases the fabrication costs per sensor. A large number of sensors are fabricated simultaneously with the same processing, resulting in high reproducibility of response between the sensors. The smaller sensor size also enables better sensor performance, especially in low concentration measurements, where the small surface area of the sensor allows a smaller number of molecules to have a larger relative effect on the sensor output.

However, these processes produce mainly two-dimensional planar structures, which have limited application. By combining these processes with micromachining technology, three-dimensional structures can be formed that have a wider range of application to chemical-sensing technology. Micromachining technology is generally defined as the means to produce three-dimensional micromechanical structures using both bulk and surface micromachining techniques. The techniques used in micromachining fabrication include chemical anisotropic and dry etching, the sacrificial layer method and LIGA (*lithographie, galvanofornung, abformung*). Chemical anisotropic etching is an etching procedure that depends on the crystalline orientation of the substrate. For silicon etching, potassium hydroxide (KOH) and tetramethyl ammonium hydroxide (TMAH) solutions are most commonly used as etching agents. Dry-etching processes include ion milling, plasma etching, reactive ion etching and reactive ion beam etching. These dry-etching processes are not dictated or limited by the crystalline structure. LIGA techniques have been used to produce high-aspect-ratio multistructures [Madou, 1997].

The sacrificial layer method employs a deposited underlayer that can be chemically removed. This technique can be used to make a chamber electrode structure to protect the integrity of the sensor element. For many applications, temperature control is necessary. Incorporation of a microfabricated heating element and a temperature detector allows feedback control of the operating temperature. In these

microstructures, a small thermal mass is desirable in order to minimize heat loss and heat energy consumption. This is accomplished by micromachining techniques that allow the selective removal of the underlying silicon substrate, producing a suspended diaphragm structure. This diaphragm structure underneath the sensing element, combined with a heater and temperature detector integrated as part of the sensor, is useful as a sensor platform that has small thermal mass that quickly reaches thermal equilibrium with less heat loss and energy consumption. The sacrificial layer method can also be used to make a chamber structure surrounding the sensor and protecting the integrity of the sensing element.

Microelectromechanical systems processes allow the mass production of sensors tailored for a given applications which have minimal size, weight and power consumption. This sensor processing can be done using silicon (Si) either as a substrate on which a structure is built or as a semiconductor that is part of an electrical circuit. Alternative materials to Si may be used as substrates as long as they are compatible with IC processing; however, micromachining of materials other than Si is less developed, and different processes are often necessary to produce the same structures in, for example, ceramics.

### 22.3.2 Nanomaterials

Nanocrystalline materials are materials whose grain size is less than 100 nm. Nanocrystalline materials have several inherent advantages over conventionally fabricated materials including increased stability and sensitivity at high temperature. The improved stability is due to the fact that the mechanisms involved in the material grain growth are different for nanocrystalline materials than for materials with micro- or macrosized grains. This means that these materials are more stable than conventional materials. Drift in the properties of gas-sensitive materials such as tin oxide ( $\text{SnO}_2$ ) with long-term heating due to grain boundary annealing have been previously noted [e.g., Jin et al., 1998; Hunter, 1992a and references therein]. This drift causes changes in the sensor output with time and reduces sensor sensitivity. The use of nanocrystalline materials such as nanocrystalline  $\text{SnO}_2$  is being investigated to stabilize the sensor materials for long-term operation. Further, as the detection mechanism of materials such as  $\text{SnO}_2$  depends on the number of grain boundaries [Hunter, 1992a], nanocrystalline materials have a higher density of grains and thus a higher sensitivity. However, while nanomaterials may provide advantages as sensor materials, their use in microsensor platforms depends on the capability to process them in a manner compatible with the processing used for the other components of the sensor structure.

### 22.3.3 SiC-Based High-Temperature Electronics

Silicon carbide-based semiconductor electronic devices are currently being developed for use in conditions under which conventional semiconductors cannot adequately perform. Due to its wide band gap and low intrinsic carrier concentration, SiC operates as a semiconductor at significantly higher temperatures than possible with silicon (Si) semiconductor technology. SiC is now available commercially, and processing difficulties associated with fabrication of SiC devices are being addressed [Neudeck, 1995].

Silicon carbide occurs in many different crystal structures (polytypes) with each crystal structure having its own unique properties. In many device applications, the exceptionally high breakdown field (>5 times that of Si), wide bandgap energy (>2 times that of Si) and high thermal conductivity (>3 times that of Si) of SiC could lead to substantial performance gains. Due to its other material properties, such as superior mechanical toughness, SiC is an excellent material for use in a wide range of harsh environments.

The capability of SiC to function in extreme conditions is expected to enable significant improvements to a wide range of applications and systems, including: (1) greatly improved high-voltage switching for energy savings in public electric power distribution; (2) more powerful microwave electronics for radar and communications; (3) electronics, sensors and controls for cleaner burning, more fuel-efficient jet aircraft and automobile engines. A potentially major application of SiC as a semiconductor is in a gas-sensing structure. One set of approaches used to produce SiC-based gas sensors is discussed in Section 22.4.4.

## 22.4 Chemical Sensor Development

As discussed in the previous sections, the needs of aerospace applications are driving the development of a new generation of chemical microsensor technology. While the sensor design and sensing approach depend strongly on the application, the application needs nevertheless have some common factors:

1. Optimally, the detection of gas should take place *in situ*, thus, it is strongly preferred that the sensor operate in the environment of the application.
2. The sensor must have minimal size, weight and power consumption to allow placement of multiple sensors in a number of locations without, for example, significantly increasing the weight or power consumption of the vehicle.
3. Ideally, the sensors should be readily multiplexed to allow a number of sensors to be placed in a given region and the results of the measurement fed back to monitoring hardware or software. This will allow the accurate monitoring of a region and, by coordinating the signals from an array of sensors determine, for example, the location of a leak or fire.

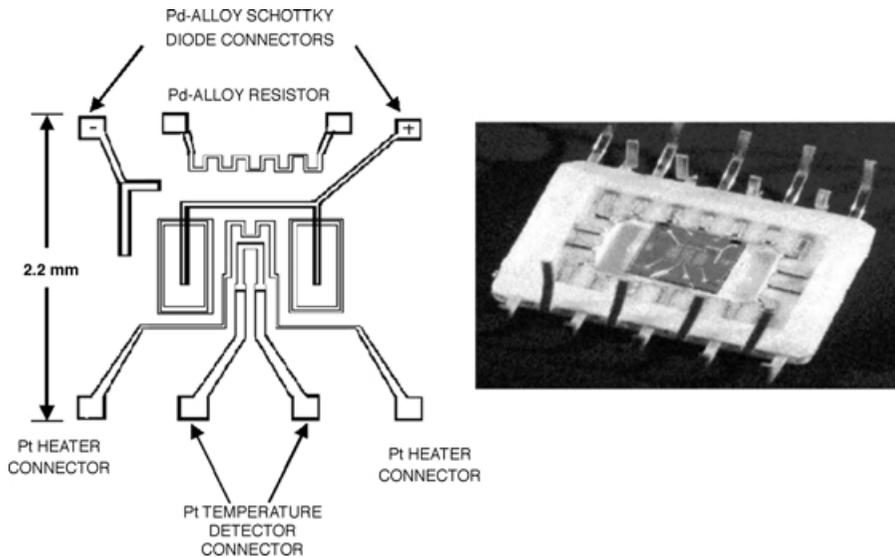

This section discusses the work at NASA GRC and CWRU using microfabrication technology, nano-materials and SiC semiconductor technology to develop H<sub>2</sub>, C<sub>x</sub>H<sub>y</sub>, NO<sub>x</sub>, CO, O<sub>2</sub> and CO<sub>2</sub> sensors. Three different sensor platforms are used: a Schottky diode, a resistor and an electrochemical cell. A brief description is given of each sensor configuration and its current stage of development. The Si-based hydrogen sensor is at a relatively mature stage of development while the state of development of the other sensors ranges from the proof of concept level to prototype stage. Integration of the sensor technology with hardware and software as well as system demonstrations are also taking place in specific applications with Makel Engineering, Inc. (MEI).

### 22.4.1 Si-Based Hydrogen Sensor Technology

The needs of hydrogen detection for the aerospace leak detection applications discussed above require that the sensor work in a wide concentration range: from the ppm range to 100% hydrogen in inert environments. The types of sensors that work in these environments are limited, and finding one sensor to completely meet the needs of this application is difficult. For example, metal films that change resistance upon exposure to hydrogen have a response proportional to the partial pressure of H<sub>2</sub>:  $(P_{H_2})^{1/2}$ . This dependence is due to the sensor detection mechanism: migration of hydrogen into the bulk of the metal changing the bulk conductance of the metal [Hunter 1992b]. This results in low sensitivity at low hydrogen concentrations but a continued response over a wide range of hydrogen concentrations. In contrast, Schottky diodes, composed of a metal in contact with a semiconductor (metal-semiconductor, MS) or a metal in contact with a very thin oxide on a semiconductor (metal-oxide semiconductor, MOS), have a very different detection mechanism. For hydrogen detection, the metal is hydrogen sensitive (e.g., palladium, Pd). For Pd-SiO<sub>2</sub>-Si Schottky diodes, hydrogen dissociates on the Pd surface and diffuses to the Pd-SiO<sub>2</sub> interface, affecting the electronic properties of the MOS system and resulting in an exponential response of the diode current to hydrogen [Lundstrom, 1989].

This exponential response has higher sensitivity at low concentrations and decreasing sensitivity at higher concentrations as the sensor saturates. Thus, by combining both a resistive sensor and a Schottky diode, sensitive detection of hydrogen throughout the range of interest can be accomplished. Further, temperature control is necessary for both sensor types for an accurate reading. MEMS-based technology enables fabrication in a limited area of both sensors (resistor and Schottky diode) with temperature control while having minimal size, weight and power consumption.

NASA GRC and CWRU have developed palladium alloy Schottky diodes and resistors for hydrogen sensors on Si substrates. Palladium alloys are more resilient than pure Pd to damage caused by exposure to high concentrations of hydrogen [Hughes et al., 1987]. Although the sensor signal is affected by the presence of oxygen, the sensor does not require oxygen to function. The NASA GRC/CWRU design uses a palladium-chrome (PdCr) alloy due to its ability to withstand exposure to 100% hydrogen

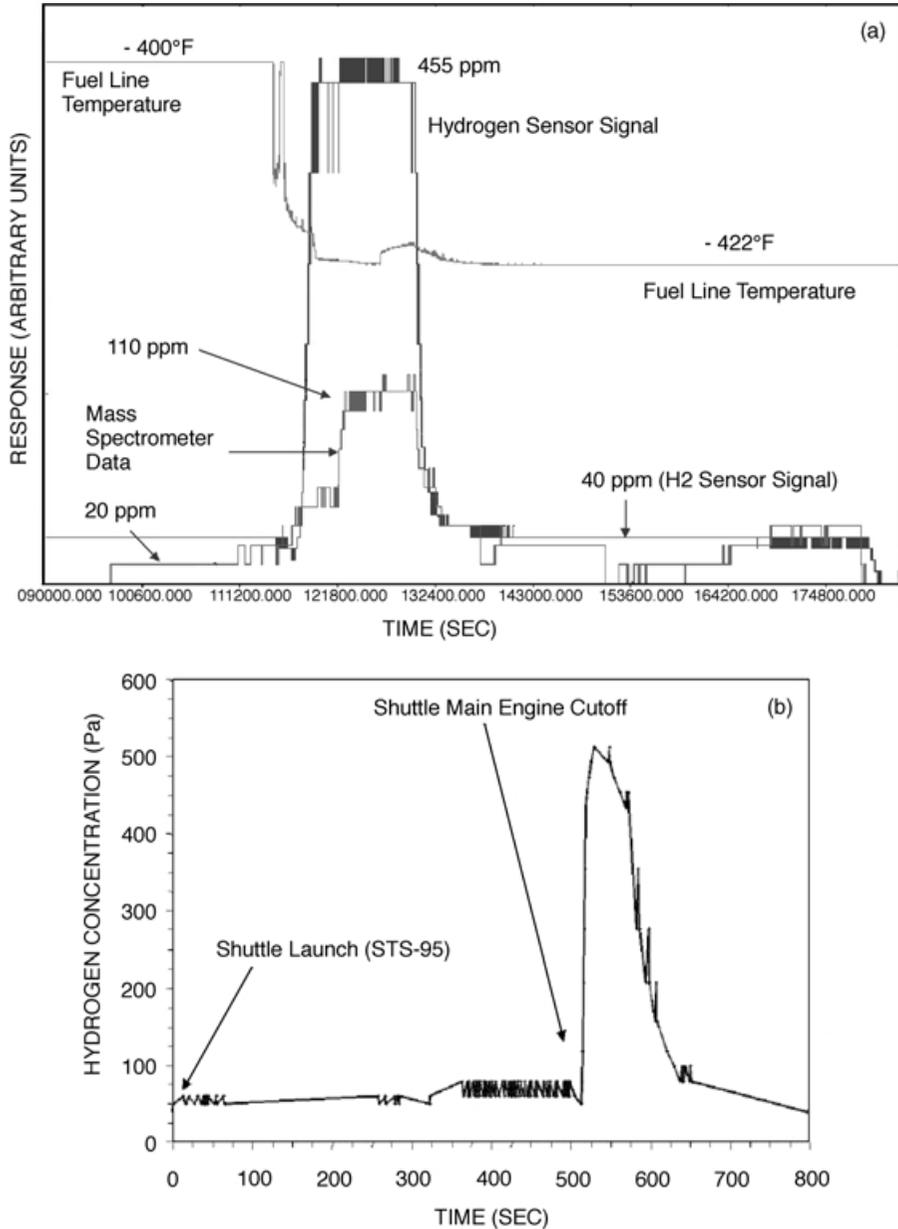

**FIGURE 22.1** Schematic diagram and picture of the silicon-based hydrogen sensor. The Pd alloy Schottky diode (rectangular regions) resides symmetrically on either side of a Pt heater and temperature detector. The Pd alloy Schottky diode is used for low-concentration measurements, while the resistor is included for high-concentration measurements.

[Hunter et al., 1998]. The sensor structure is shown in [Figure 22.1](#) and includes a PdCr Schottky diode, a PdCr resistor, a temperature detector and a heater all incorporated in the same chip. The sensor dimensions are approximately 2.2 mm on a side. The combination of the Schottky diode and resistor sensing elements results in a sensor with a broad detection range; the Schottky diode provides sensitive detection of low concentrations of hydrogen up to near 1%, while the resistor provides sensitivity from 1% up to 100% hydrogen. However, if the sensor is only exposed to low concentrations of hydrogen, then a different alloy, palladium silver (PdAg), can be used in the Schottky diode structure for higher sensitivity.

The MEMS-based hydrogen sensors using both PdCr and PdAg alloys have been selected for use and/or demonstrated in several applications. These sensors have been used on the assembly line of Ford Motor Company (see [Section 22.6](#)) and on the Space Shuttle. They have also been selected for use on the safety system of the experimental NASA X-33 vehicle and the water purification system for the International Space Station. Supporting hardware and software have also been included with the sensor to provide signal conditioning and control of the sensor temperature and to record sensor data [Hunter et al., 1998; 2000]. Each application has had different requirements; the entire system from sensors to supporting hardware and software has been tailored for each application. It should be noted that the successful operation of these MEMS-based sensors depends on this supporting technology and associated packaging.

This complete hydrogen-detection system (two sensors on a chip with supporting electronics) flew on the STS-95 mission of the Space Shuttle (launched in October 1998) and again on STS-96 (launched in May 1999) [Hunter et al., 1999a; 2000]. The hydrogen-detection system was installed in the aft main engine compartment of the Shuttle and used to monitor the hydrogen concentration in that region. Currently, a mass spectrometer monitors the hydrogen concentration in the aft compartment before launch, while after launch “grab” bottles are used. The inside of these “grab” bottles is initially at vacuum. During flight, the “grab” bottles are pyrotechnically opened for a brief period of time and the gas in the aft compartment is captured in the bottle. Several of these bottles are opened at different times during the takeoff and after the Shuttle returns to earth and their contents are analyzed to determine the time profile of the gases in the aft chamber. However, this information is only available after the flight and cannot be used to monitor the Shuttle condition in real time.

**FIGURE 22.2** The response of a MEMS-based PdCr hydrogen sensor in the aft compartment of the Space Shuttle: (a) Compared to the response of a mass spectrometer during loading of liquid hydrogen while on the launchpad; the time scale, in seconds, refers to a clock associated with the Shuttle monitoring system. (b) Recorded data in flight during the launch of the Shuttle; the time scale, in seconds, refers to time after launch.

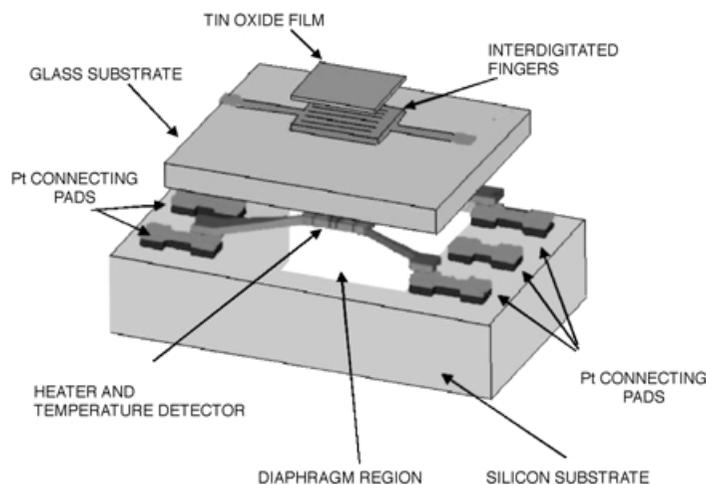

Data from the STS-95 mission are shown in Figure 22.2. The response of the hydrogen sensors was compared to that of the mass spectrometer and the information obtained by the “grab” bottles. During ground monitoring, the hydrogen sensor (Schottky diode) response was compared with that of the mass spectrometer. The sensor and the mass spectrometer intakes were located at different points in the aft compartment. The results are shown in Figure 22.2a, where the hydrogen sensor signal, the mass spectrometer hydrogen signal and the hydrogen fuel line temperature are shown as a function of time.

The decrease in the fuel-line temperature corresponds to the onset of fuel flow to the Shuttle hydrogen tanks. As this fueling begins, a small increase in hydrogen concentration is observed with both the hydrogen sensor and mass spectrometer. After the initial signal, the hydrogen concentration is seen to drop by both the sensor and the mass spectrometer. Overall, the hydrogen sensor response is seen to generally parallel that of the mass spectrometer but with a larger signal and quicker response time (perhaps due to the relative location of the each measuring device with respect to the hydrogen source). These results are for just one sensor monitoring the chamber; a number of these MEMS-based sensors placed around the chamber could be used to “visualize” the location of the leak.

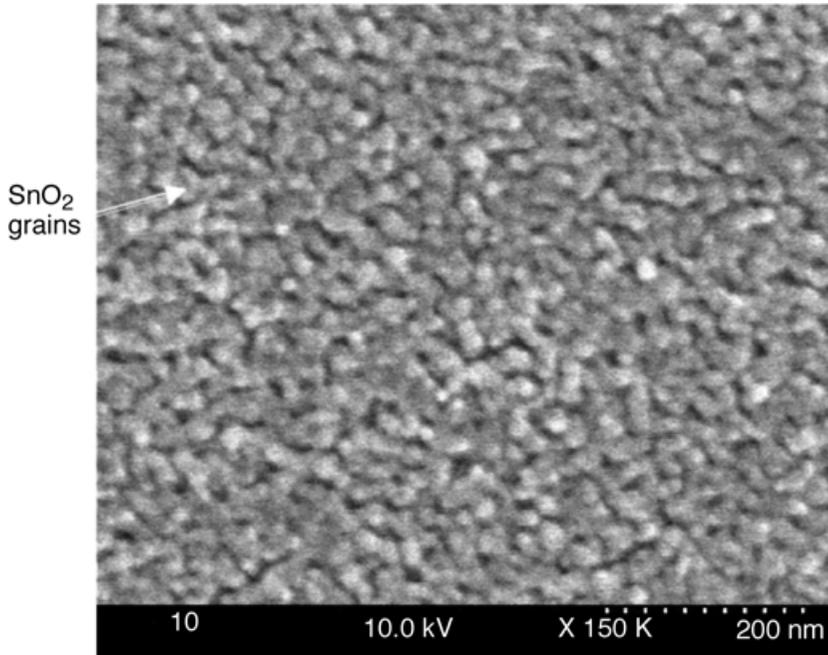

The hydrogen sensor response during the launch phase of flight is shown in [Figure 22.2b](#). No significant sensor response is seen until the cutoff of the Shuttle main engine. Near this time, a spike in the hydrogen concentration is observed that decreases with time back to baseline levels. These results are qualitatively consistent with the leakage of very small concentrations of unburned fuel from the engines into the aft compartment after engine cut-off. These observations also qualitatively agree with those derived by analyzing the contents of the grab bottles. Moreover, the advantage of this microsensor approach is that the hydrogen monitoring of the compartment is continuous and, in principle, could be used for real-time health monitoring of the vehicle in flight.

#### 22.4.2 Nanocrystalline Tin Oxide Thin Films for NO<sub>x</sub> and CO Detection

The detection of NO<sub>x</sub> and CO can be accomplished using nanocrystalline SnO<sub>2</sub> materials deposited on a microfabricated and/or micromachined substrate [Hunter et al., 2000]. The substrate can be either Si or ceramic. [Figure 22.3](#) shows the basic structure of the sensor design with a Si substrate. It consists of two components, Si and glass, which are fabricated separately and then bonded together. The microfabrication process allows the sensor to be small in size with low heat loss and minimal energy consumption. Energy consumption is further reduced by depositing the sensor components (temperature detector, heater and gas-sensing element) over a diaphragm region. This minimizes the thermal mass of the sensing area, thereby decreasing power consumption for heating and the time to reach thermal equilibrium. The substrate utilized for the Si-based design is a 0.15-mm-thick glass. On one side of the glass are the heater and temperature detector, while the sputtered platinum interdigitated fingers reside on the other side. The width of the fingers and the gap between them is 30 μm each. The overall sensor dimensions are approximately 300 μm on a side with a height of 250 μm.

**FIGURE 22.3** Structure of a SnO<sub>2</sub>-based sensor on a Si substrate. The sensor has Si and glass components and includes a temperature detector and heater.

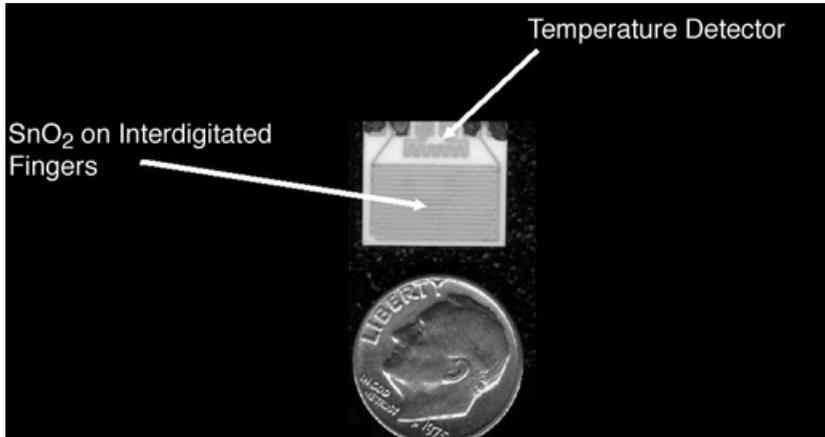

**FIGURE 22.4** Nanocrystalline SnO<sub>2</sub> after annealing at 700°C for 1 hr. Each SnO<sub>2</sub> grain is on the order of 10 nm.

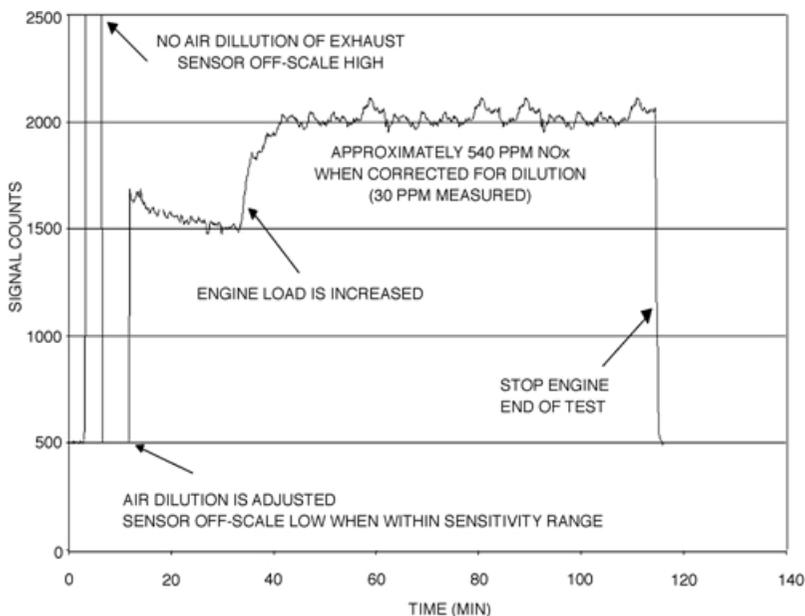

The SnO<sub>2</sub> is placed across the interdigitated fingers using a sol-gel technique [Jin et al., 1998]. The gel containing the nanocrystalline SnO<sub>2</sub> particles is spun on the substrate and patterned across the interdigitated finger region using conventional photolithography. This film is subsequently fired, yielding a nanocrystalline SnO<sub>2</sub> film whose conductivity is measured across the fingers. An example of a fired nanocrystalline SnO<sub>2</sub> film is shown in Figure 22.4. The size of each grain of SnO<sub>2</sub> is on the order of 10 nm, with the porosity between the grains being of roughly equal dimensions. Changes in the conductivity of SnO<sub>2</sub> across the interdigitated electrodes are measured and correlated to CO and NO<sub>x</sub> concentration. The detection of NO<sub>2</sub> has been demonstrated down to the 5-ppm level at 360°C, with the highest level of sensitivity in the lower ppm with a very stable response [Hunter et al., 1999a]. Similar results with the detection of CO have been obtained [Jin et al., 1998].

Two major components of this development work are to optimize the SnO<sub>2</sub> response to a given gas and to stabilize the SnO<sub>2</sub> for long-term, high-temperature operation. Doping the SnO<sub>2</sub> can improve both the selectivity of the sensor to a specific gas [Jin et al., 1998] as well as sensor stability. For example, the inclusion of Pt has been shown to improve sensitivity to CO, while the inclusion of SiO<sub>2</sub> has been shown to significantly decrease the grain growth of the SnO<sub>2</sub> [Hunter et al., 2000]. Another component of the work is to fabricate the nanocrystalline SnO<sub>2</sub> films on alternate substrates for different applications. For example, for fire detection applications a Si substrate is generally preferred. For emission-sensing applications, deposition on a ceramic substrate, as shown for the sensors in Figure 22.5, is often advantageous. While the configuration of interdigitated fingers, temperature detector and heater are easily transferable to ceramics, micro-machining and substrate bonding for high-temperature applications are more problematic.

A tin oxide-based NO<sub>x</sub> sensor has been tested in a ground-based power generation turbine engine. The sensor was fabricated on an alumina substrate as shown in Figure 22.5 and placed in a region where the exhaust flow stream from the engine is extracted and passed over the sensor. Supporting electronics were placed in a cooler region near the sensor. The temperature of the gas flowing over the sensor is near 350°C, and the sensor temperature is maintained at that temperature using the built-in temperature detector and heater. The response of the sensor was compared to an industry-standard, continuous emission monitoring (CEM) system which was simultaneously measuring the NO<sub>x</sub> production. As seen

**FIGURE 22.5** Tin oxide-based sensors fabricated on ceramic substrates for high-temperature operation. Shown are the interdigitated fingers on which SnO<sub>2</sub> is deposited and the temperature detector. The heater is on the backside of the ceramic.

**FIGURE 22.6** The response of a SnO<sub>2</sub>-based NO<sub>x</sub> sensor in a ground-based turbine engine emission test. The emission stream is diluted with air by 18:1 near the beginning of the test to avoid saturation of the sensor. The sensor output is display as signal counts processed by the supporting electronics.

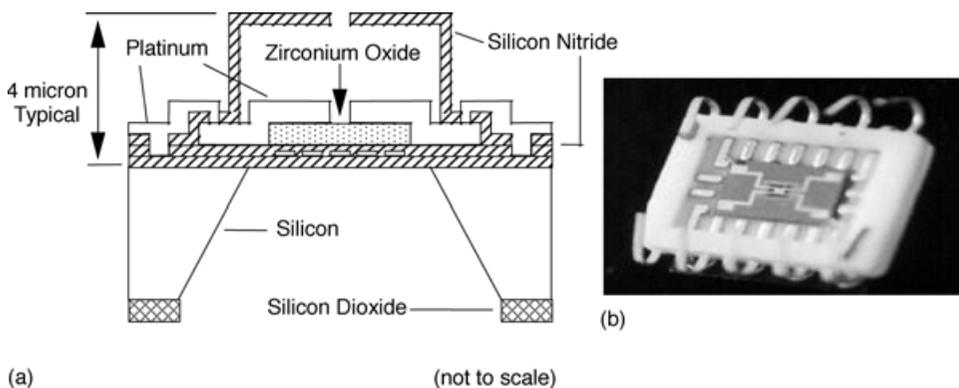

in [Figure 22.6](#), the sensor is initially saturated by the high level of NO<sub>x</sub>. By diluting the flow into the sensor region with air by a factor of 18 (i.e., 18 parts air to 1 part exhaust), the sensor response is brought back into detection range. The engine load is then increased, which correspondingly increases the NO<sub>x</sub> production. This is reflected by the both response of the microfabricated sensor ([Figure 22.6](#)) as well as the readings of the CEM. The two readings show good agreement: The sensor measured 540 ppm NO<sub>x</sub> (after correction for the dilution) compared to the CEM measurement of 593 ppm. These results support the viability of replacing instrument-rack-sized CEM systems with MEMS-based chemical sensor technology.

### 22.4.3 Electrochemical Cell Oxygen Detection

A microfabricated  $O_2$  sensor has applications both in fuel leak detection and, as demonstrated in the automotive emissions control example in Section 22.2.3, emissions control. Commercially available  $O_2$  sensors are typically electrochemical cells using  $ZrO_2$  as a solid electrolyte and platinum as the anode and cathode. The anode is exposed to a reference gas, usually air, while the cathode is exposed to the gas to be detected. Zirconium dioxide becomes an ionic conductor of  $O^-$  at temperatures of  $600^\circ C$  and above. This property of  $ZrO_2$  to ionically conduct  $O_2$  means that the electrochemical potential of the cell can be used to measure the ambient oxygen concentration at high temperatures [Logothetis, 1991]. However, the operation of these commercially available sensors in this potentiometric mode limits the range of oxygen detection. This sensor is very sensitive near 0%  $O_2$  but has limited sensitivity at higher  $O_2$  concentrations. Further, the current manufacturing procedure of this sensor, using sintered  $ZrO_2$ , is relatively costly and results in a complete sensor package with a power consumption on the order of several watts.

The objective of the research described below is to develop a  $ZrO_2$  solid electrolyte  $O_2$  sensor using microfabrication and micromachining techniques. As noted in previous sections, the presence of  $O_2$  often affects the response of  $H_2$ ,  $C_xH_y$ , and  $NO_x$  sensors. An accurate measurement of the  $O_2$  concentration would help to better quantify the response of other sensors in environments where the  $O_2$  concentration is varying. Thus, the combination of an  $O_2$  sensor with other microfabricated gas sensors is envisioned to optimize the ability to monitor emissions.

A schematic cross section of the microfabricated  $O_2$  sensor design is shown in Figure 22.7. As discussed in Section 22.4.2, CO and  $NO_x$  detection, microfabricating the sensor components onto a micromachined diaphragm region allows the sensor to be small in size and to have decreased energy consumption and reduced time to reach thermal equilibrium. When operated in the amperometric (current measuring) mode, the current of this cell is a linear function of the surrounding  $O_2$  concentration. This linear response to oxygen concentration significantly increases the  $O_2$  sensor detection range over  $O_2$  sensors operated in the potentiometric mode. A chamber structure with a well-defined orifice can be micromachined to cover the sensing area. This orifice provides a pathway to control oxygen diffusion which is important in amperometric measurements. A filter may also be placed over the sensor to minimize flow and provide protection. As discussed in the introduction to this chapter, fabrication of a MEMS-based version of a macrodevice is not just a matter of decreasing the dimensions of the macrodevice. As discussed in Ward (1999), the fabrication of a microfabricated version of the oxygen sensor is a significant technical challenge with obstacles not encountered in the fabrication of the macrosized sensor. These challenges include adhesion between the various layers to each other and the substrate, pinhole electrical leaks between the layers and diffusion effects caused by heating the sensor to high temperatures. Testing of a complete  $O_2$  sensor has been accomplished and further improvements on the design are planned.

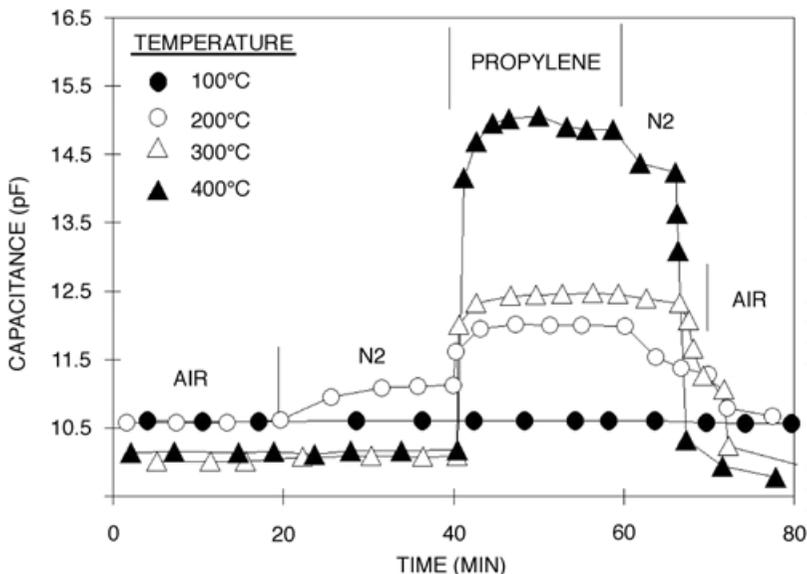

**FIGURE 22.7** The structure of a microfabricated amperometric oxygen sensor and a packaged sensor without a protective orifice.

## 22.4.4 SiC-Based Hydrogen and Hydrocarbon Detection

Hydrogen and hydrocarbon sensors are being developed using SiC semiconductors in order to meet the needs of leak detection and emission monitoring applications. Like the Si-based system discussed in Section 22.4.1, the SiC-based Schottky diode does not need oxygen to operate. In contrast to the Si-based Schottky diode sensors, which are limited by the properties of the Si semiconductor to lower temperature operation (significantly below 350°C), SiC can operate at high enough temperatures (at least 600°C) as a semiconductor to allow the detection of hydrocarbons or NO<sub>x</sub>. This opens the possibility of using SiC-based gas sensors in engine emission-sensing applications. The development of high-temperature SiC-based gas sensors for use in harsh environments at GRC/CWRU has focused on the development of a stable gas-sensitive Schottky diode. One main advantage of a Schottky diode sensing structure is its high sensitivity, which is useful in emission sensing applications where the concentrations to be measured are low (see Table 22.1).

The detection mechanism of SiC-based Schottky diodes is similar to that for Si-based diodes discussed in Section 22.4.1. For hydrogen, this involves the dissociation of the hydrogen on the surface of a catalytic metal. The atomic hydrogen migrates to the interface of the metal and the insulator, or the metal and the semiconductor, forming a dipole layer. Given a fixed forward-bias voltage, this dipole layer affects the barrier height of the diode, resulting in an exponential change of current flow with the change in barrier height. The magnitude of this effect can be correlated with the amount of hydrogen and other gas species (especially oxygen) present in the surrounding ambient. The detection of gases such as hydrocarbons is made possible if the sensor is operated at a temperature high enough to dissociate hydrocarbons and produce atomic hydrogen. The resulting atomic hydrogen affects the sensor output in the same way as molecular hydrogen [Baranzahi et al., 1995; Hunter et al., 1995].

The major advantage of SiC as a semiconductor for Schottky diode gas sensors is shown in Figure 22.8, which shows the zero-bias capacitive response of a Pd/SiC Schottky diode to one hydrocarbon, 360 ppm propylene, in nitrogen at a range of temperatures [Chen et al., 1996 and references therein]. The sensor temperature is increased from 100 to 400°C in steps of 100°C and the sensor response is observed. At a

**FIGURE 22.8** The temperature dependence of the zero-bias capacitance of a Pd/SiC Schottky diode to various gas mixtures. The sensor response to propylene is seen to require a temperature above a minimum temperature (~200°C) and to be strongly temperature dependent.

given temperature, the sensor is exposed to air for 20 minutes,  $N_2$  for 20 minutes, 360 ppm of propylene in  $N_2$  for 20 minutes,  $N_2$  for 10 minutes and then 10 minutes of air. There are two points to note in the sensor behavior as shown in Figure 22.8. First, the baseline capacitance in air does not change between 100 and 200°C, but decreases to a slightly lower value as the temperature is raised to 300°C and above, suggesting the possibility that temperature-dependent chemical reactions that affect the diode electronic properties may have an onset at temperatures above 200°C. Second, Figure 22.8 clearly shows that the magnitude of sensor response to 360 ppm propylene depends strongly on the operating temperature. A sensor operating temperature of 100°C is too low for propylene to dissociate on the Pd surface, so the device does not respond at all. The three other curves for 200, 300 and 400°C show that elevating the temperature increases the response of the sensor to propylene. The presence of propylene can be detected at any of these higher temperatures, with 200°C being the minimum operating temperature determined in this study. Because the standard long-term operating temperature of Si is usually below 200°C, these results demonstrate the significant advantages of using SiC rather than Si in gas-sensing applications.

Several SiC-based Schottky diode structures have been investigated. Two MS structures investigated are Pd on SiC (Pd/SiC) and PdCr on SiC (PdCr/SiC). Very sensitive detection, on the order of 100 ppm of hydrogen and hydrocarbons in both inert and oxygen containing environments, has been demonstrated. Although the Pd/SiC sensor response is affected by prolonged high-temperature heating at 400°C, the PdCr/SiC structure has been shown to be much more stable with comparable sensitivity [Hunter et al., 1997]. The difference in behavior appears to be linked to reduced migration of Si into the PdCr metal from the SiC substrate and less formation of  $SiO_2$  on the surface of the metal. Metal contacts to SiC for durable high-temperature operation, either as chemical sensors or as electrical device connections (see elsewhere in this book), are areas of continued investigation.

The third structure involves the incorporation of chemically reactive oxides into the SiC-based Schottky diode structure [Hunter et al., 1997; 1999a]. A wide variety of materials (e.g., metal oxides such as  $SnO_2$ ) are sensitive to  $C_xH_y$  and  $NO_x$  at high temperatures. These materials could be incorporated as a sensitive component in MOS structures. Unlike silicon, SiC-based devices can be operated at high enough temperatures for these materials to be reactive to gases such as  $C_xH_y$  and  $NO_x$ . This results in a different type of gas sensitive structure: a metal reactive-oxide semiconductor structure (MROS). The potential advantages of this type of SiC-based structure include: (1) increased sensor sensitivity, as the diode responds to gas reactions due to both the catalytic metal as well as the reactive oxide; (2) improved sensor stability, as the gas reactive oxide can act as a barrier layer between the metal and SiC, potentially stabilizing the structure of the sensor against degradation at high temperature; and (3) the ability to vary sensor selectivity by varying the reactive oxide element. This MROS approach has been demonstrated using a  $SnO_2$  film resulting in a Pd/ $SnO_2$ /SiC structure. This structure has been shown to have improved stability and significantly different responses than those of the Pd/SiC structure. Further, the geometry and processing conditions by which the  $SnO_2$  is deposited affects the sensor response. Multiple types of oxide layers are envisioned to produce different selectivities for the SiC-based Schottky diodes which would improve the ability to selectively determine the concentration of a specific gas (see Section 22.5.4).

Development of SiC-based sensor packaging to allow sensor operation at temperatures greater than 300°C is also an active research area. For example, temperatures above 300 to 400°C will likely be necessary to optimally measure gases such as propylene and methane. Unlike the  $SnO_2$  sensors in Section 22.4.2 which can be directly deposited onto a MEMS-based structure, the SiC-based sensors are semiconductor chips processed separately and then packaged. The type of packaging depends on the application. For leak-detection applications in a room-temperature ambient, one difficulty with operating sensing elements functioning at higher temperatures than ambient is that a considerable amount of power (order of several watts) may be necessary to properly heat the sensing element. Such power demands to achieve optimal sensing temperatures may limit sensor use in some applications. For these applications, one approach towards minimizing the heating element power demand is to mount the sensor in a MEMS-based package that thermally isolates the sensors and decreases the thermal mass. An early prototype SiC-based packaged sensor design is discussed in Hunter et al. (1999b). For emissions applications, the objective is to package

the sensor, with connections to the outside world, for operation in high-temperature engine environments. Thus, issues such as stable electrical contacts to SiC and the integrity of electrical insulation at high temperatures are of importance. Micromachining processes for SiC are being developed to enable formation of, for example, diaphragm structures that decrease the thermal mass and power consumption of the sensor in the same manner as is done with Si structures. These issues are discussed in more detail elsewhere in this book (see Chapter 21).

### 22.4.5 NASICON-Based CO<sub>2</sub> Detection

The detection of CO<sub>2</sub>, like the detection of oxygen, can be based on the use of a solid electrolyte; however, the solid electrolyte CO<sub>2</sub> sensor is NASICON (sodium super ionic conductor) rather than zirconia. NASICON is an ionic conductor composed of Na<sub>3</sub>Zr<sub>2</sub>Si<sub>2</sub>PO<sub>12</sub> that is useful for CO<sub>2</sub> detection. A sol-gel technique will be used to fabricate the NASICON. The sensor structure will be similar to that of [Figure 22.7](#): a microfabricated, miniaturized sensor structure that can be incorporated into a package with other sensors such as the CO sensor. The ability to detect CO<sub>2</sub> over a range of concentrations has been demonstrated [Hunter et al., 1999a]. However, the largest challenges to application of this technology involves incorporation of NASICON onto the MEMS-based structure: film adherence, material compatibility and regeneration of the electrolyte are technical challenges associated with this approach.

## 22.5 Future Directions, Sensor Arrays and Commercialization

---

The long-term goals of NASA include significantly improving safety and decreasing the cost of space travel, significantly decreasing the amount of emissions produced by aeronautic engines, and improving the safety of commercial airline travel. In order to reach these goals, the development of “smart” vehicle technology is envisioned: a vehicle that can monitor itself and adapt to changing conditions. This monitoring, maintenance and management must take place throughout the operational lifetime of the vehicle to ensure high safety, integrity and reliability with decreased maintenance and costs. In order for self-monitoring to be effective, both physical and chemical parameters must be measurable throughout the vehicle, including the propulsion system. Thus, implementation of sensor technology in a variety of locations including harsh environments, vacuum or turbulent conditions will be necessary. Large, single sensors measuring a single parameter using a single detection mechanism will no longer be a viable technology approach. Rather, MEMS-based microsensor arrays which can measure several parameters of interest simultaneously and are integrated on a single device will be necessary to meet the objective of a “smart” vehicle.

One of the factors behind the reluctance to apply sensor technology throughout a vehicle is the reliability of the sensor technologies. Widespread use of sensors has been hampered, for example, by the fact that sensors can be damaged, require calibration, or produce unreliable results as they drift from calibration. Thus, integrated hardware and software that can monitor and condition the sensor, detect problems, perform self-calibration as necessary and provide this information to the user are also required: The accompanying electronics are what make a MEMS-based sensor system “smart.” Further, these complete “smart” systems must meet the system requirements of the vehicle on which it is installed. As seen below for space-based systems, this may include military-grade components or being able to use the power available on the vehicle.

The sections that follow discuss work ongoing toward the development of MEMS-based chemical microsensor arrays. This discussion includes high-temperature membranes selective to individual gases as well as examples of arrays in development with supporting electronics. The particular examples given are a leak-detection array and a high-temperature electronic nose. The most advanced of these activities is the leak-detection array work: some of the same techniques being developed for that system can also be applied to other array systems. Finally, the non-aerospace, commercial applications of this technology are then discussed.

### 22.5.1 High-Selectivity Gas Sensors Based on Ceramic Membranes

Chemical sensors often lack selectivity and display similar responses to several different gaseous species [Hunter et al., 2000]. The selectivity of these sensors can be improved through the use of a gas selective membrane over the sensor to exclude other interfering gaseous species from reaching the sensing element. A selective membrane with a narrow distribution of pore sizes can filter gas molecules according to molecular size, thereby offering size selectivity to species of interest. Because the gas molecules of interest are on the order of several angstroms, the pore size would also have to be only several angstroms in diameter.

Zeolites appear particularly well suited to this filtering application. Zeolites are crystalline ceramic materials that contain open channels (or pores) as a natural part of their structure. Zeolites are composed primarily of aluminum, silicon and oxygen. The elements combine to form  $\text{SiO}_4$  and  $\text{AlO}_4$  tetrahedra which arrange in three-dimensional networks yielding uniform channels through the ceramic crystal. While these channels are identical in size or diameter within each crystallite of a zeolite, the diameters of these channels can vary significantly (from 3 to 12 Å), depending mainly on the ratio of aluminum to silicon. The effective diameters of the crystalline channels can be modified by the size of ions within the channels. Different ions may be incorporated into the crystalline channels by ion exchange. Further, as a ceramic material, zeolites are capable of withstanding the high temperatures and harsh environments that may be encountered in gas measuring applications.

Composite membranes containing zeolites have been prepared using various processing techniques to achieve desired selectivity, including sol-gel and electrochemical vapor deposition methods [Hunter et al., 2000]. Figure 22.9 shows the grain structure of one of the prototype films. The gas-selective membranes are being integrated with electrochemical sensors to further enhance the selectivity to gas molecules of interest.

### 22.5.2 Leak-Detection Array

The development of miniaturized chemical sensor microsystems using the hydrogen and oxygen sensor elements combined in one package is currently underway. A prototype MEMS-based leak-detection sensor system has integrated both hydrogen and oxygen sensors into a single substrate and realized

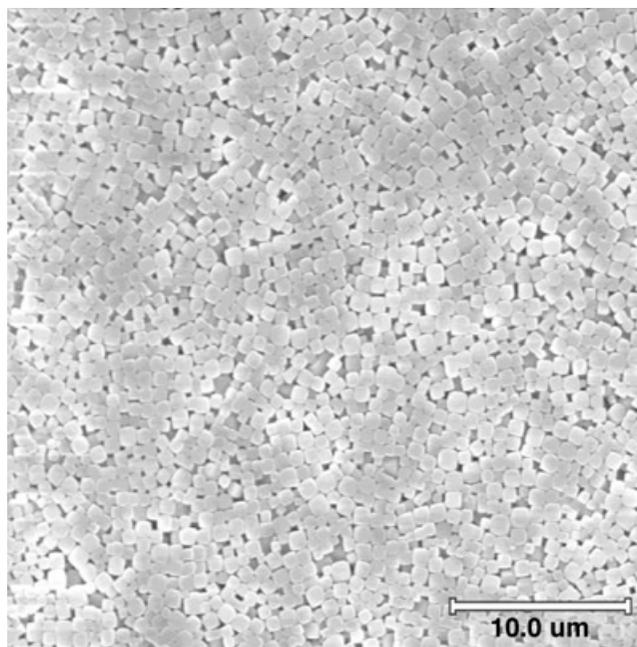

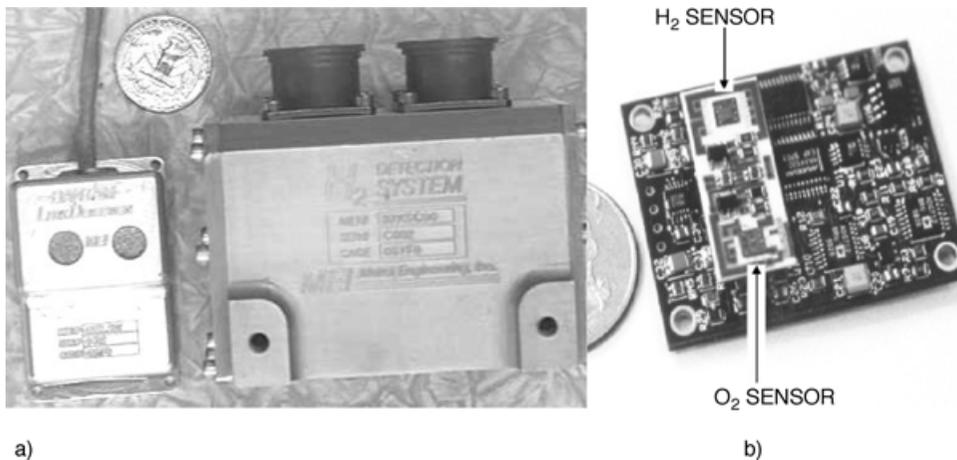

FIGURE 22.9 A scanning electron micrograph of a prototype of a selectively permeable zeolite thin-film membrane.

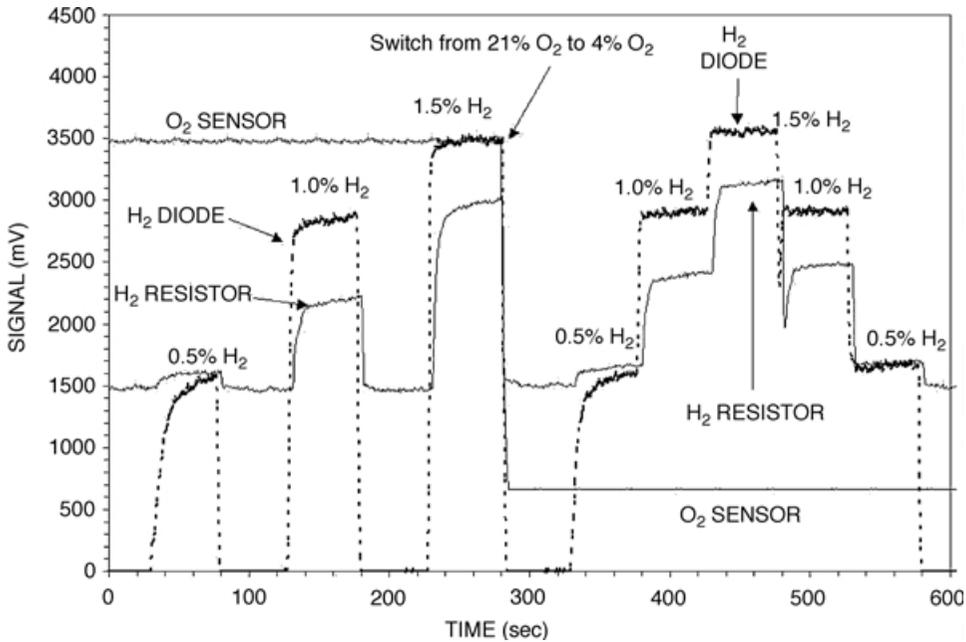

**FIGURE 22.10** (a) (right) Shuttle system hardware ( $H_2$  sensor with electronics); (left) prototype miniature smart sensor with hydrogen and oxygen sensors and control electronics with protective cover. (b) Electronics of miniaturized systems showing the  $H_2$  and  $O_2$  sensors.

improvements in the hardware supporting the sensor array. The size of the electronics is determined, in part, by the aerospace application. For space-based applications, electronics must often meet military specifications, be radiation hard, or function on vehicle voltage supplies not optimized for small-scale electronics (e.g., 28 V rather than 5 V). The smallest, most powerful electronics may not meet these specifications, or a bulky transformer may have to be added to the system to accommodate power restrictions.

Some results of these restrictions in one case are shown in the right-hand side of [Figure 22.10a](#) for the flight hardware that flew on the Shuttle. While the sensor size is 2 mm on each side and wafer thin, the associated packaging and hardware necessary for a system qualified for manned space flight are orders of magnitude larger. Nevertheless, significant improvements are possible. [Figure 22.10b](#) shows a prototype of an existing system: two sensors, hydrogen and oxygen, are integrated on the same board as the “smart” electronics. The smart sensor package contains all required analog and digital electronics, including CPU, memory and communications devices. The total volume of the package is less than  $5\text{ cm}^3$ . The supporting electronics have been chosen for flight readiness while other components are still in the process of being qualified.

The operation of the prototype sensor unit with combined hydrogen and oxygen sensors is shown in [Figure 22.11](#). The responses to changes in gas concentrations of the two hydrogen-sensing elements (a hydrogen-sensitive resistor and Schottky diode) as well as an oxygen sensor are shown. In a nitrogen ambient, all three sensors are first exposed to 21%  $O_2$  and the concentration of hydrogen is varied from 0% to a maximum of 1.5% and back to 0%. Then, the oxygen background is changed from 21 to 4%  $O_2$  and the hydrogen concentration stepwise increased and then decreased through the same hydrogen concentration range (0 to 1.5%). The hydrogen-sensitive resistor provides higher sensitivity at higher hydrogen concentrations, while the Schottky diode provides a larger response at lower hydrogen concentrations. The  $O_2$  concentration is measured independently. The hydrogen sensor responses are seen to be somewhat affected by changing the  $O_2$  concentration. However, unlike a number of other sensing techniques, the detection mechanisms of the sensors do not require  $O_2$  for operation [Hunter et al., 1998 and references therein].

The combined responses from both the  $H_2$  and  $O_2$  sensors yield a powerful tool for leak detection. Because the  $H_2$  sensor response weakly depends on the  $O_2$  concentration, the  $O_2$  signal can be used to more accurately determine the  $H_2$  concentration. More importantly, because the LEL of the combustible gas depends, in part, on the corresponding concentration of the oxidizer, knowing the relative ratio of the gases is necessary to determine if an explosive condition exists. Using the sensor system shown in [Figure 22.11](#), information is provided on both the concentration of the combustible gas ( $H_2$ ) and the

**FIGURE 22.11** The response of a hydrogen- (two sensors) and oxygen-detection system with associated electronics to multiple concentrations of hydrogen in a changing oxygen ambient. The responses of all three sensors to varying hydrogen concentrations at two different oxygen concentrations are shown.

oxidizer ( $O_2$ ) simultaneously, thus a more accurate determination of the hazardous conditions can be determined. This work demonstrates the beneficial use of multiple sensors with different detection mechanisms yielding improved information about the chemical constituents of an environment. It is envisioned that this multiple microsensor approach, combined with MEMS-based fabrication of the component parts, can allow the placement of sensors in a number of locations to better determine the safety of the region of interest.

### 22.5.3 High-Temperature Electronic Nose

Integration of a number of the individual high temperature gas sensors discussed above into a single platform will enable the formation of a sensor array. This array, composed of a range of sensors, will allow for the detection of a number of gases on a single chip operable in high-temperature environments such as an engine. The formation of an array of the high-temperature-capable sensors discussed in this chapter could detect  $H_2$ ,  $C_xH_y$ ,  $NO_x$ ,  $CO$ ,  $O_2$  and  $CO_2$ . Development of a such a microfabricated gas sensor array operable at high temperatures and high flow rates would be a dramatic step toward realizing the goal of monitoring and control of emissions produced by an aeronautic engine. Such a gas sensor array would, in effect, be a high-temperature electronic nose and be able to detect a variety of gases of interest. Several of these arrays could be placed around the exit of the engine exhaust to monitor the emissions produced by the engine. The signals produced by this nose could be analyzed to determine the constituents of the emission stream, and this information then could be used to control those emissions. Microfabrication of these sensors is necessary: a conventional bulky system would add weight to the aircraft and impede the flow of gases leaving the engine exhaust. The component parts and packaging of this sensor array for a high-temperature environment would be fundamentally different than those used in the leak-detection example discussed in the previous section. The concept of an electronic nose has been in existence for a number of years [Gardner and Bartlett, 1994].

Commercial electronic noses for near-room-temperature applications currently exist and there are a number of efforts to develop other electronic noses. However, these electronic noses often depend significantly on the use of polymers and other lower temperature materials to detect the gases of interest. These polymers are generally unstable above 400°C and thus would not be appropriate for use in harsh engine environments. Thus, a separate development is necessary for a high-temperature electronic nose.

The development of such a high-temperature electronic nose has begun by using the high-temperature sensors discussed in this chapter. In addition to the higher temperature limit of the sensors that constitute this nose, another major difference in approach compared to conventional noses is that there are three very different sensor types that constitute the high-temperature electronic nose: resistors, electrochemical cells and Schottky diodes. As discussed earlier in this chapter, each sensor type relies on different mechanisms to detect gases so that each sensor type gives fundamentally different responses to the gas environment. For example, in general, electrochemical cells have logarithmic responses to different gas concentrations while Schottky diodes have exponential responses; resistors may have a sensitivity to many gases, while electrochemical cells can be operated to detect only gases that have certain binding energies; the time response of a Schottky diode is largely determined by migration of a chemical species into a film, while the time response of resistors such as SnO<sub>2</sub> is related to surface effects. Thus, each sensor type provides very different types of information on the environment. This is in contrast to a conventional array of sensors that generally consist of elements of the same type (e.g., SnO<sub>2</sub> resistors doped differently for different selectivities). Each sensor in this conventional system provides information available through the SnO<sub>2</sub> resistors (reactions occurring on the surface of the sensor film) but do not provide information determined by electrochemical cells or Schottky diodes. It is envisioned that the high-temperature electronic nose will sense responses from this array of very different high-temperature MEMS-based sensors (resistors, diodes and electrochemical cells) and integrate this information with neural net processing to allow a more accurate determination of the chemical constituents of harsh, high-temperature environments.

## 22.6 Commercial Applications

---

The gas sensors being developed at NASA GRC and CWRU are meant for aerospace applications but they can also be used in a variety of commercial applications, as well. For example, an early design of the Pd alloy hydrogen sensors, using PdAg, was adapted from space applications for use in an automotive application. GenCorp Aerojet Corporation, in conjunction with NASA Marshall Space Flight Center, developed hardware and software to monitor and control the NASA GRC/CWRU sensors to enable the sensors to monitor and display the condition of the tank of a natural gas vehicle. Several of these systems have been purchased for use on the Ford Motor Company assembly line to test for leaks in the valves and fittings of natural gas vehicles. This complete system received a 1995 R&D 100 Award as one of the 100 most significant inventions of that year.

Likewise, the high-temperature C<sub>x</sub>H<sub>y</sub>, NO<sub>x</sub> and O<sub>2</sub> sensors are being developed for aeronautic applications but can also be applied to commercial applications. For example, the conditions in an aeronautic engine are similar to those of an automotive engine. Thus, sensors that work in aeronautic engine applications may be operable in automotive engine applications. The hydrogen sensors that can detect leaks in propulsion systems can be used to detect hydrogen evolution in fuel cells. Other possible applications include combustion process monitoring, catalytic reactor monitoring, alarms for high-temperature pressure vessels and piping, chemical plant processing, polymer production and volatile organics detection.

## 22.7 Summary

---

The needs of aerospace applications require the development of chemical gas sensors with capabilities beyond those of conventional commercial gas sensors. These requirements include operation in harsh environments, high sensitivity and minimal size, weight and power consumption. MEMS-based sensor technology is being developed to address these requirements using microfabrication and micromachining

technology as well as SiC semiconductor technology. The combination of these technologies allows for the fabrication of a wide variety of sensor designs with responses and properties that can be tailored to the given application. Integration of these sensors with supporting packaging technology, hardware and software is necessary for their application. Sensors designed for aerospace applications also have significant commercial applications. Although each application is different and the sensor must be tailored for that environment, the base technology being developed for aerospace applications can have a significant impact on a broad range of fields.

---

The authors would like to acknowledge the contributions of Dr. Jih-Fen Lei, Dr. Philip G. Neudeck, Mr. Gustave Fralick, Dr. Daniel L. P. Ng and Mr. Paul Raitano of NASA GRC; Dr. Liang-Yu Chen and Dr. Valarie Thomas of the Ohio Aerospace Institute; Mr. Q. H. Wu and Mr. Benjamin Ward of the CWRU Electronics Design Center; Mr. William Rauch and Dr. M. Liu of the Georgia Institute of Technology and Mr. Greg Hall and Mr. José Perotti of the NASA Kennedy Space Center; also, the technical assistance of Mr. Drago Androjna and Mr. Carl Salupo of Akima/NASA GRC.

## Defining Terms

**Ambient:** The gas composition dominant in the surrounding environment (air, pure nitrogen, pure helium, etc.).

**Detection mechanism:** The chemical and/or physical reaction by which a sensor responds to a given chemical species.

**Interfering gases:** Gases that can cause a competing response in a sensor and can thus mask or interfere in the response of the sensor to a given chemical species. For example, many sensors that respond to hydrogen can also respond to carbon monoxide; thus, carbon monoxide is an interfering gas in the measurement of hydrogen.

**LIGA:** *Lithographie, galvanofornung, abformung* (i.e., lithography, plating, molding), a German acronym signifying a combination of deep-etch X-ray lithography, electroplating and molding.

**Lithographic reduction:** The reduction in size of patterns, such as those used for microfabricated structures, onto a photolithographic mask. These patterns are eventually transferred from a mask to a thin film in the formation of a sensor structure.

**Lower explosive limit (LEL):** The lowest concentration at which a flammable gas becomes explosive. This limit depends on the flammable gas and the corresponding amount of oxidant. For hydrogen in air, this limit is a hydrogen concentration of 4%.

**Micromachining technology:** The fabrication of three-dimensional miniature structures using processing techniques such as etching and LIGA.

**Photoresist patterning:** The use of a polymer film, photoresist, to create miniature features after exposure to ultraviolet radiation and removal by a developer.

**Response time:** The time it takes for a sensor to respond to the environment. Because some sensors never completely stabilize and reach a stable maximum value, often a value equal to 90% of the steady-state value is cited.

**Sacrificial layer:** A thin layer of material added to a multilayer structure for the purpose of later being removed (or sacrificed) to open up that region of that structure.

**Selectivity:** The ability of a sensor to respond to only one chemical species.

**Sensitivity:** The amount of change in output of a sensor from baseline to a given chemical species.

**Sol-gel:** The formation of a compound through the use of organic compounds and water which, upon drying, form a gel that can be applied to a substrate. Higher temperature processing removes the organics and leaves the chemically sensitive material.

**Stability:** The reproducibility and repeatability of a sensor signal and baseline over time.

**Thin Film:** Typically, a film whose thickness is less than 1  $\mu\text{m}$ .

**Vehicle health monitoring (VHM):** The capability to efficiently perform checkout, testing and monitoring of vehicles, subsystems and components before, during and after operation. This includes the ability to perform timely status determination, diagnostics and prognostics. The use of both sensors to determine the vehicle health and software to interpret the data is necessary.

### 23.1 Introduction

---

Microelectromechanical system (MEMS) devices, as they are defined, are both electrical and mechanical devices. Via microlevel mechanical operation, MEMS devices, as sensors, transform mechanical, chemical, optical, magnetic and other nonelectrical parameters to electrical/electronic signals; as actuators, MEMS devices transform electrical/electronic signal to nonelectrical/electronic operations. Therefore, MEMS devices very often interact with the environment electrically, magnetically, optically, chemically and mechanically. In order to support these nonconventional device operations (i.e., the device mechanical operation and the nonelectrical interactions between the device and their environments), new packaging capabilities beyond those provided by conventional integrated circuit (IC) packaging technology are required [Madou, 1997]. A chemically inert, optically dark and electromagnetically “quiet” environment for packaging conventional ICs, provided by hermetic sealing and electromagnetic screening, is no longer suitable for packaging most MEMS devices. Because MEMS devices have very specific requirements for their immediate packaging environment, it is expected that the design of MEMS packaging will be very device dependent. This is in contradiction to the conventional IC packaging practice in which a universal package design can accommodate many different ICs. Compared to conventional IC packaging, the most distinct issue of MEMS packaging is to meet the requirements imposed by the mechanical operability and reliability of MEMS devices.

NASA is interested in using harsh-environment-operable MEMS and electronic devices [Neudeck et al., 2000; McCluskey and Pecht, 1999; Kirschman, 1999; Willander and Hartnagel, 1997] to characterize *in situ* combustion environments of aerospace engines and the atmosphere of inner solar planets such as Venus. The operation environment of a high-temperature pressure sensor, one of the most wanted sensors by NASA and the aerospace industry for diagnosis and control of a new generation of aerospace engines, specifies the general requirements for packaging these harsh-environment MEMS: This pressure sensor must operate in an engine combustion chamber and be completely exposed to the combustion environment in order to measure *in situ* combustion chamber pressure in real time. The specifications of the high-temperature pressure sensor and the standard of *in situ* operation environment have all been determined by the Propulsion Instrumentation Working Group [PIWG, 2001]. The sensor operates at temperatures up to 500°C in a gas ambience composed of chemically reactive species such as oxygen in air, hydrocarbon/hydrogen in fuel, and catalytically poisoning species such as NO<sub>x</sub> and SO<sub>x</sub> in combustion products. The sensor operation environment is summarized as high temperature, high dynamic pressure and chemically corrosive. This is indeed a typical harsh environment compared to the standard operation conditions for most advanced (commercial) sensors/electronics, so the packaging materials and basic components—including substrate, metallization material(s), electrical interconnections (such as wire-bond) and die-attach—must be able to withstand an environment that is 500°C, corrosive and especially oxidizing/reducing and with high dynamic pressure. As discussed in Chapter 20, one of the suggested high-temperature pressure sensors is a semiconductor piezoresistive device. The sensing mechanism of this device depends on the mechanical deformation of semiconductor resistors residing on a diaphragm fabricated by micromachining. Therefore, this device is very sensitive to external forces applied to the device. The major source of undesired external force is the thermal mechanical stress from the die-attach structure due to mismatches of coefficients of thermal expansion (CTE) of the die material (such as SiC), the substrate material and the die-attaching material. The thermal stress of the die-attach must be suppressed in order to achieve precise and reliable device operation because the thermally induced stress may generate unwanted device response to the changes in thermal environment, and in the extreme case thermal stress can cause permanent mechanical damage to the die-attach.

A high-temperature pressure sensor is needed for a planned space mission to determine the atmospheric pressure profile of Venus, where the temperature is up to 500°C and the gas ambient is chemically corrosive. Normal conditions of the operating environment of these pressure sensors include high temperatures (500°C), chemical corrosion and high dynamic pressure, under which most conventional electronic packaging materials can no longer operate. Therefore, development of revolutionary MEMS devices operable in harsh environments presents significant challenges to the device packaging field. In the next section, general material requirements for the major components of harsh-environment MEMS packaging are analyzed by adopting the basic structure of conventional IC packaging, in which the die is attached to a substrate using a die-attaching material layer and the die is electrically interconnected to the package by wirebond.

## 23.2 Material Requirements for Packaging Harsh-Environment MEMS

---

A summary of the basic requirements of the major materials needed for packaging harsh environment MEMS may help to establish the general guidelines for material selections.

### 23.2.1 Substrates

The basic function of the packaging substrate is to provide a framework for attaching the device die, metallization for electrical interconnection (such as wirebond), mounting the leads connecting the chip to the external environment, building nonelectrical signal paths and mechanical and possibly also electromagnetic shielding. Plastic/polymer-type materials are not suitable for 500°C operation because of melting and depolymerization at temperatures above 350°C [McCluskey et al., 1997; Pecht et al., 1999].

Most metal and alloy materials suffer severely from corrosion, especially, from oxidation at temperatures approaching 500°C in air. So the remaining material system suitable for substrate is ceramics, which meets the basic requirements for a substrate: excellent and stable chemical and electrical properties in a harsh environment, especially at high temperatures and corrosive gas ambience. After selecting the substrate material, a metallization scheme (both materials and processing) and associated sealing materials matching the substrate material must be identified or developed simultaneously. In order to reduce the thermal stress of the die-attach, the CTE of the substrate material must match that of the device material (such as SiC). The properties of substrate surface and the interfaces formed at high temperature with other packaging materials, such as the die-attach material, also become very important. At high temperatures, the surfaces of some ceramics (nitrides and carbides) gradually react with gas ambience, such as oxygen and water vapor, and therefore would lead to changes in properties such as surface resistivity and surface adhesiveness. Concerns such as these regarding the surface properties of “well-known” ceramic materials in high-temperature corrosive gas ambience may lead to valuable results from research into packaging materials for high-temperature MEMS.

### 23.2.2 Metallization/Electrical Interconnection System

Most metals and alloys, including some noble metals, oxidize at temperatures approaching 500°C in air. So the metals and alloys commonly used in conventional IC packaging such as Cu, Al and Au/Ni coated Kovar are excluded from packaging applications at 500°C and above, unless a perfectly hermetically sealed inert/vacuum condition is achievable. Intermetallic phases form at the interfaces of different metals such as Al and Cu at temperatures above 200°C. The intermetallic phase very often may reduce mechanical strength of an interconnection system, so achieving material consistency of an interconnection system becomes extremely important to avoid thermal mechanical failure at high temperatures.

Because of their chemical stability and good electrical conductivity, precious metals are naturally considered for applications in substrate metallization and electrical interconnection. Some precious metals (e.g., platinum and palladium) react with atomic hydrogen to form H-rich alloys at elevated temperatures [Lewis, 1967]. Though this is desirable for gas-sensing devices [Hunter et al., 1999] it is not for electrical interconnection applications, because the phase transition may cause significant changes in the physical and electrical properties. Gold (Au) is widely used for both substrate metallization and wirebond in packaging and hybridizing conventional high-frequency, high-reliability ICs. Besides the high conductivities and superior chemical stability at high temperatures, Au also has a low Young's modulus and a narrow elastic region. If Au is used as a die-attaching material, these properties of Au are helpful to reduce thermal stress generated at the Au–die and the Au–substrate interfaces due to CTE mismatches. These features of Au are especially desirable for applications in packaging 500°C-operable MEMS because a wide range of operating temperature is of concern. It has been reported that Au thin film/wire with small grain size suffers from electromigration of Au atoms at grain boundaries at high temperature under extreme current density ( $\sim 10^6$  A/cm<sup>2</sup>) operation [Goetz and Dawson, 1996]. Surface modification and coating have been suggested for the Au conductor to withstand high-temperature and high-current-density operation [Goetz and Dawson, 1996]. The electrical migration effect is proportional to  $J^2$  ( $J$  is the current density); therefore, the obtainable lifetime of a Au conductor operated at high temperature but low current density may still be substantial even without the surface modification as demonstrated in the next section. Developing a low-cost, highly conductive and thermally and chemically stable conductor with excellent thermal–mechanical properties for electrical interconnection is a valuable goal for packaging harsh-environment (high-temperature) devices [Grzybowski and Gericke, 1999; Harman, 1999].

### 23.2.3 Die-Attach

The basic function of die-attach is to provide mechanical, electrical and thermal support to the die. Most die-attaching (adhesive) materials used for packaging conventional ICs for operation at temperatures below 250°C are not suitable for 500°C operation. The basic failure mechanisms are depolymerization of epoxy-type materials, oxidizing and melting of eutectic-type materials and softening and melting of glass-type materials. Generally, we expect the die-attach materials to be electrically and thermally

conductive and physically and chemically stable at high temperatures and to permit a low-temperature attaching process. For applications in packaging MEMS devices, the thermal mechanical properties of the die-attach material such as CTE, Young's modulus, fatigue/creep properties and their temperature dependences are very much of concern, as the die-attaching material is the material in intimate contact, both thermally and mechanically, with the die and the substrate. The material properties, especially the CTE, are expected to match those of the die and the substrate materials. In case the CTE of the die is not completely consistent with that of the substrate, the die-attaching material is ideally expected to thermomechanically compensate for any possible CTE mismatch between the die and the substrate materials by absorbing the thermal strain. Another major concern regarding die-attaching materials for packaging high-temperature MEMS devices is the long-term chemical and mechanical stability of the interfaces formed with the die (or the metallization of the die) and substrate (or the metallization of the substrate) materials at high temperatures. If the die-attach is expected to be electrically conductive, then the electronic properties of its interface with the die (or the metallization materials on the die) would also become critically important. Combining all these thermal mechanical, chemical and electrical requirements for die-attaching material, it is apparent that a material system for die attach with a suitable process is critical to success in packaging high-temperature MEMS device.

The thermomechanical stress in the die-attach due to the differences in properties of the materials of the die-attach structure (particularly CTE mismatch) may cause degradation and failure of packaged devices. The extreme case of die-attach failure caused by thermal stress is cracking of the die or the attaching material. Besides this catastrophic failure due to fatigue and creep of the die or the attaching material(s), thermal stress in die-attach can also cause the high-temperature MEMS device an undesired thermal response, irreproducibility of device operation, and output signal drift. Therefore, thermal mechanical failure due to CTE mismatches of the materials involved in the die-attach is expected to be a common and important thermal mechanical issue that must be addressed, especially for high-temperature MEMS devices.

### 23.2.4 Hermetic Sealing

The basic purpose of hermetic sealing is to create and maintain a stable and sometimes inert ambience for the packaged device. This simple function at low (room) temperature is difficult to achieve at temperatures approaching 500°C because, first, at such high temperatures most soft or flexible sealing materials such as plastic/polymer-based materials can no longer operate; second, sealing very often applies between different materials. The CTE mismatches of these materials make hermetic sealing difficult over a wide temperature range, especially under thermal cycling condition. Third, high temperatures activate and significantly promote thermal processes such as diffusion and degassing at material surfaces [Palmer, 1999], thus it becomes difficult to maintain an ambience in a small enclosure by sealing. Therefore, it is expected that creative sealing concepts are necessary to meet the requirements for packaging many high-temperature MEMS devices.

Harsh-environment MEMS packaging offers new challenges to the device packaging field. Discussions on the basic requirements of properties of the materials necessary for packaging harsh-environment MEMS are followed by addressing an electrical interconnection system (both electrically and mechanically) that is based on a ceramic substrate and thick-film metallization, with a compatible conductive die-attach scheme for chip-level packaging of low-power, harsh-environment SiC MEMS devices. The thermal mechanical optimization of Au thick-film material-based die-attach is discussed using nonlinear finite element analysis (FEA) results.

## 23.3 High-Temperature Electrical Interconnection System

---

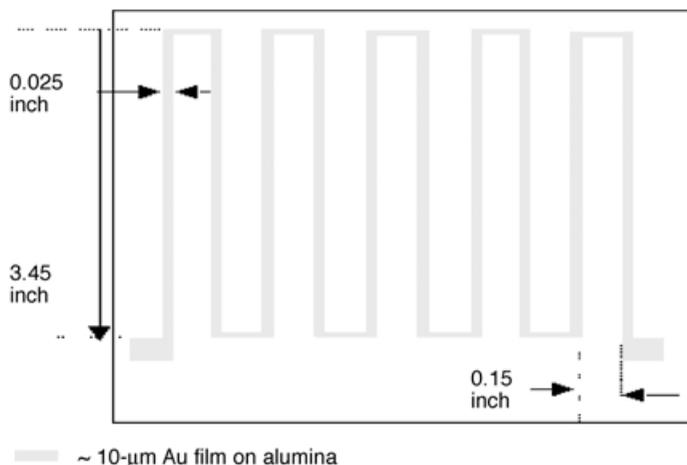

As discussed in the last section, ceramic materials are naturally selected as packaging substrate materials because of their superior high-temperature chemical and electrical stabilities. Aluminum oxide ( $\text{Al}_2\text{O}_3$ ) is a low-cost substrate widely used for conventional IC packaging. Another advantage of using  $\text{Al}_2\text{O}_3$  is that many thick-film materials have been developed for metallization of  $\text{Al}_2\text{O}_3$ . In comparison to  $\text{Al}_2\text{O}_3$ ,

aluminum nitride (AlN) has a higher thermal conductivity and a low CTE that is very close to that of SiC. These features of AlN make it be useful in packaging high-temperature and high-power devices [Martin and Bloom, 1999]. If the basic framework of conventional IC packaging is adopted, the next step after selecting the substrate is to identify metallization material(s). In this section we review a Au thick-film-based 500°C operable electrical interconnection system for chip-level, low-power, harsh-environment MEMS packaging [Chen et al., 2000a; 2000c].

Thick-film metallization materials are usually composed of fine metal (such as gold) powder, inorganic binder (such as metal oxides) and organic vehicle. The screenprinting technique is usually used for thick-film coating for thickness control and patterning. During the initial drying process (at 100 to 150°C), the organic vehicle evaporates and the paste becomes a semisolid phase mixture of metal powder and binder. In the final curing process (~850°C recommended for most thick-film products), the inorganic binder molecules migrate to the metal/substrate (e.g., Au–ceramic) interface and form reactive binding chains. Au thin wires can be bonded directly to Au thick-film metallization pads using commercialized wirebond equipment to provide electrical interconnection in the packaging. Some new thick-film materials may be applicable to various ceramic substrates such as alumina (Al<sub>2</sub>O<sub>3</sub>) [Keusseyan et al., 1996] and aluminum nitride [Chitale et al., 1994; Shaikh, 1994; Keusseyan et al., 1996]. Compared with direct thin-film metallization on ceramic substrate, thick-film metallization offers low cost, simple process, low resistance, and better adhesion provided by the reactive binders at metal–substrate interface. Both the electrical and mechanical properties of Au thick-film materials for applications in hybrid-packaging conventional ICs have been extensively validated at  $T < 150^{\circ}\text{C}$ . In order to evaluate Au thick-film materials for 500°C application, both electrical and mechanical tests at 500°C are necessary. Test results of Au thick-film-material-based electrical interconnections (Au thick-film printed wires and thick-film-metallization-based Au wirebond) and a conductive die-attach scheme using Au thick-film as die-attaching material for operation up to 500°C [Chen et al., 2000c] are reviewed as follows.

### 23.3.1 Thick-Film Metallization

A Au thick-film-printed wire circuit, as shown in Figure 23.1, was screenprinted on a ceramic substrate (AlN or 96% Al<sub>2</sub>O<sub>3</sub>) and cured at 850°C in air using the recommended curing process, forming printed wire and metallization pads for wirebond on ceramic substrate. The circuit was electrically and thermally tested at 500°C in air for a total of ~1500 hr by four-probe resistance measurement. The electrical resistance of the thick-film wire/circuit was first measured at room temperature; afterward, the temperature

**FIGURE 23.1** Schematic diagram of Au thick-film printed wire for high-temperature tests.

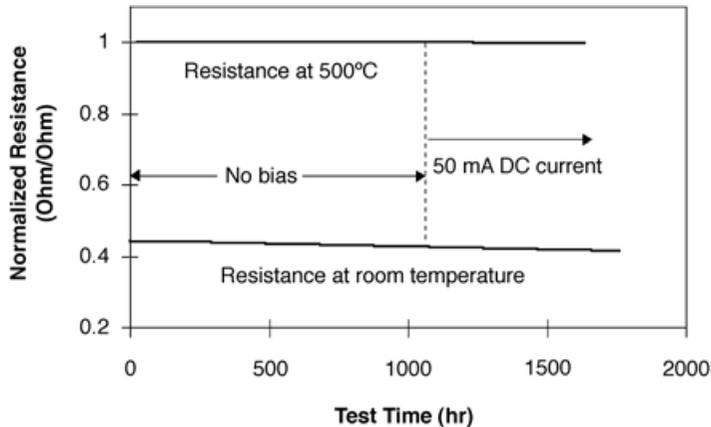

FIGURE 23.2 Normalized resistance of thick-film wire at various temperatures with and without dc bias.

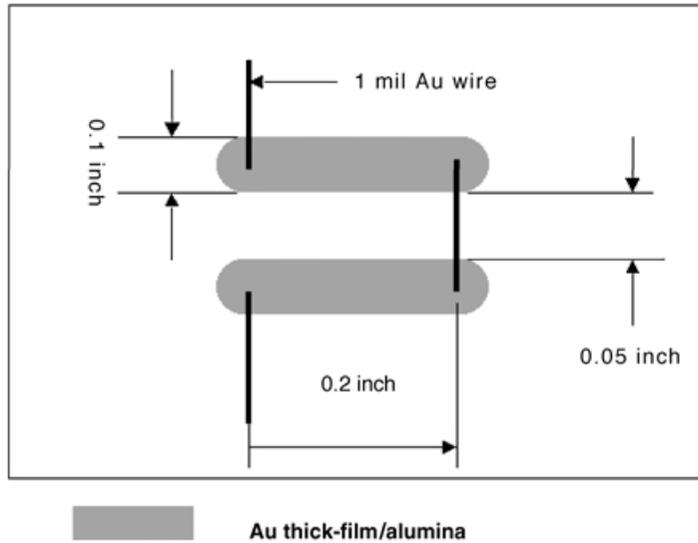

was ramped up to 500°C for ~1000 hr without electrical current flow, and the resistance of the wire was measured periodically during this period of time. The resistance slightly fluctuated within  $\pm 0.1\%$  during the 1000 hours test, as shown in Figure 23.2. After testing for 1000 hr without electrical bias, the circuit was biased with 50 mA dc current and the resistance was continuously monitored by four-probe resistance measurement. The resistance fluctuated slightly within  $\pm 0.1\%$  for 500 hr with electrical bias. This very small change in resistance is acceptable for almost all envisioned high-temperature device packaging application.

As discussed earlier, Au thick-film materials for various substrates have been systematically validated both electrically and mechanically for conventional IC packaging; however, in order to be reliably applicable at high temperatures, these Au thick-film material systems must be mechanically evaluated at elevated temperatures in addition to the electrical validation discussed above. The tensile strength of Au thick-film metallization on a 96%  $\text{Al}_2\text{O}_3$  substrate has been tested at room temperature after extended storage at 500°C [Salmon et al., 1998]. In order to examine the mechanical strength and the thermal dynamic stability of the binding system of Au thick films at high temperatures, the shear strength of selected Au thick-film metallization on 96%  $\text{Al}_2\text{O}_3$  substrate was tested at temperatures up to 500°C [Chen et al., 2001]. The shear strength (breaking point) at 500°C reduced by a factor of ~0.80 with respect to that at 350°C, while the shear strength (breaking point) at 350°C was close to that at room temperature. The shear strengths of selected Au thick films designed for AlN were not as high as those for  $\text{Al}_2\text{O}_3$ , but were sufficient for application in microsystem packaging operable at 500°C.

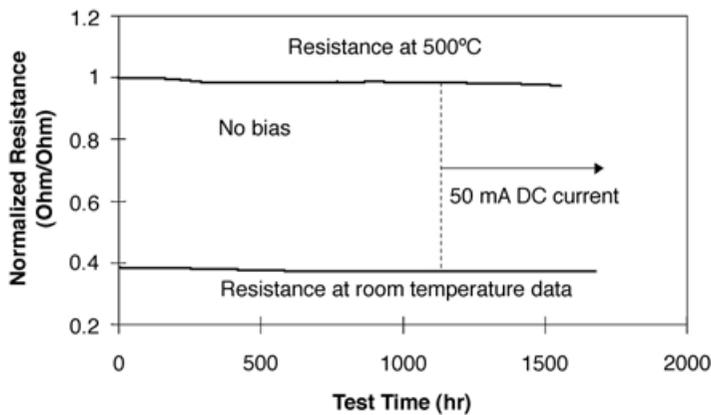

### 23.3.2 Thick-Film-Based Wirebond

After the qualifications of Au thick-film metallization, the thick-film-based wirebond needs to be evaluated for high-temperature operation. The electrical test circuit including Au thick-film printed wires/pads and multiple thin gold wires bonded to the thick-film pads is illustrated in Figure 23.3. The geometry of the printed thick-film conductor was designed so that the electrical resistance of the test circuit was dominated by the resistance of thin (0.0254-mm diameter) bonded gold wires. The thick-film conductive wires/pads were processed according to the standard drying and curing processes [DuPont, 1999] suggested by the material manufacturer. The thin gold wires were bonded to the thick-film pads on the substrate by a thermal-compression wirebonding technique.

The electrical resistance of a thick-film-metallization-based wirebond test circuit (Figure 23.3) includes those of thick-film conductive wire/pads, bonded thin Au wires, and the interfaces of the wirebonds. The resistances of 22 units (44 bonds) in series were measured at room temperature and 500°C vs. accumulated

**FIGURE 23.3** Schematic diagram of one unit of thick-film-metallization-based wirebond test circuit; 0.0254-mm (0.001 in.) Au wires were bonded to thick-film pads using the thermal-compression technique.

**FIGURE 23.4** Normalized resistance of thick-film-metallization-based wirebond at various temperatures with and without dc bias.

testing time at 500°C. The resistance was first measured at room temperature, after which the temperature was ramped to 500°C and the resistance was monitored in air without electrical bias for 670 hr. As shown in Figure 23.4, the temperature was then lowered back to room temperature and the resistance was recorded again. After this thermal cycle, the circuit resistance was continuously monitored for a total of 1200 hr at 500°C in air without electrical bias (current flow), followed by another 500 hr at 500°C with 50-mA (dc) current. The resistances under all these conditions were desirably low (less than 0.5 Ω per unit) and decreased slowly and slightly at an average rate of 2.7% over the 1500-hr testing period. The rate of resistance decrease under the dc bias is close to that without electrical bias.

An identical wirebond sample was electrically tested in a dynamic thermal environment. The same wirebond circuit was tested in thermal cycles between room temperature and 500°C with an initial temperature rate of 32°C/min for 123 cycles and a dwell time of 5 min at 500°C, then at the temperature rate of 53°C/min (higher than thermal shock rate) for an additional 100 cycles with 50-mA dc current.

The maximum change in electrical resistance, during the thermal cycle test, was 1.5% at room temperature and 2.6% at 500°C [Chen et al., 2001]. The electrical stability of this Au thick-film-based wirebond system should meet most interconnection needs for high-temperature, low-power applications.

### 23.3.3 Conductive Die-Attach

#### 23.3.3.1 SiC Test Die

The fabrication of a high-temperature SiC Schottky diode used to test the conductive die-attach scheme was previously reported in detail [Chen et al., 2000b]. An N-type (nitrogen, resistivity less than 0.03  $\Omega$ -cm), Si-terminated 4H-SiC wafer was used to fabricate test Schottky diode. The backside wafer (unpolished side) was first coated with a nickel (Ni) thin film by electron beam evaporation. The SiC wafer was then annealed at 950°C in argon in a tube furnace for 5 min, forming an ohmic contact on the backside of the SiC wafer. The device structure on the front side of the SiC wafer was fabricated by electron-beam evaporation of thin titanium (Ti) and thin Au films on cleaned SiC wafer and patterned with the liftoff technique.

#### 23.3.3.2 Conductive Die-Attach

After dicing, the 1-mm  $\times$  1-mm SiC diode chips were attached to a ceramic substrate (either AlN or 96% alumina) using selected Au thick-film materials, as shown in Figure 23.5. An optimized thick-film die-attaching process for SiC device results in a low-resistance, conductive die-attach that is very often required for packaging devices requiring backside electrical contact.

The SiC test die with a Ni contact on the back was attached to a ceramic substrate using an optimized two-step Au thick-film processing [Chen et al., 2000b]. A thick-film layer was first screenprinted on the substrate and cured at 850°C using the standard process. The SiC die was then attached to the cured thick-film pattern with a minimal amount of subsequent thick film. A slower drying process (120 to 150°C) was critical to keeping the thick-film bonding layer uniform and the die parallel to the substrate after the curing process. Following the drying, the attached die was processed at a lower final curing temperature (600°C).

This optimized Au thick-film die-attach process allows sufficient diffusion of inorganic binders toward the thick film–substrate interface, resulting in a good strength of binding to the ceramic substrate. Meanwhile, it prevents the attached semiconductor chip from being exposed to temperatures above the ultimate operation temperature of SiC devices (600°C) during the die-attach process. The second advantage of this die-attach process is that the distribution of the thick film (after the final curing) between the chip and the substrate can be better controlled because only a minimal amount of thick-film material is necessary to attach the chip to a cured thick-film pad. Therefore, many potential problems caused by nonuniform thick-film distribution at the chip–substrate interface might be avoided.

A 0.001-in.-diameter Au wire was bonded onto the top of the Au thin-film metallization area covered with a Au thick-film overlayer by the thermal-compression bonding technique. Thick-film material was also used to reinforce the top Au thin film for better wire bonding. The Au thin-film metallization area

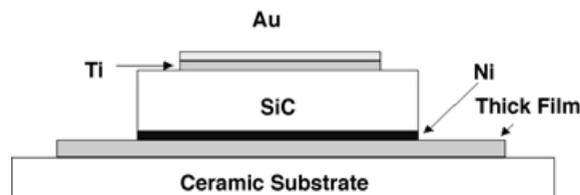

FIGURE 23.5 Schematic diagram of as-fabricated SiC device and die-attach structure.

was coated with thick film on the top then dried at 150°C for 10 min. The thick film on the device top was cured during the final die-attach process (at 600°C).

### 23.3.3.3 Electrical Test

The attached SiC test diode (Figure 23.5) was characterized by current–voltage (I–V) measurements at both room temperature and 500°C for various heating times at 500°C. A minimum dynamic resistance ( $dV/dI$ ) under forward bias which is reduced from the I–V curve was used to estimate the upper limit of resistance of the die-attach structure (both interfaces and materials) and to monitor the resistance stability of the die-attach, as shown in Figure 23.6. This dynamic resistance includes the forward dynamic resistance of the Au–Ti–SiC interface, SiC wafer bulk resistance, the die-attach materials/interfaces resistance, bonded wire resistance and the test leads resistance in series. The resistance contributed from test leads and bonded wire were measured independently and subtracted. The attached device was first characterized by I–V measurements at room temperature. The device exhibited rectifying behavior, and the minimum dynamic resistance after subtracting the test-leads/bond-wire resistance (which also applies to all of the following discussion) measured under forward bias was  $\sim 2.6 \Omega$ , as shown in Figure 23.7.

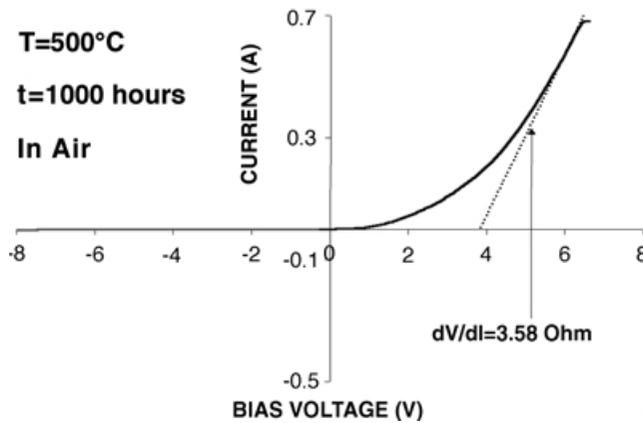

FIGURE 23.6 I–V curve of an attached SiC test diode characterized at 500°C after being tested for 1000 hr in 500°C oxidizing air.

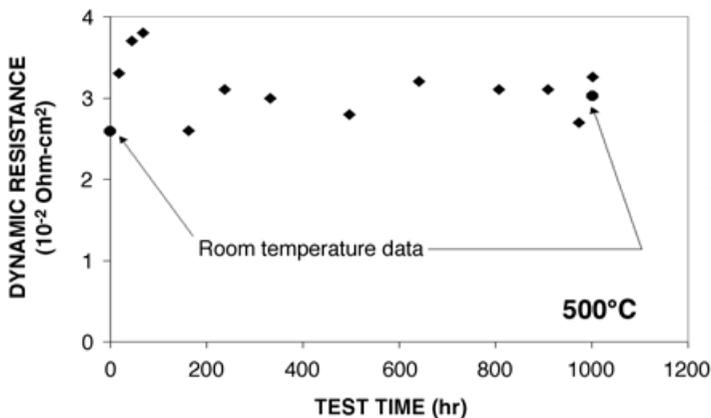

FIGURE 23.7 Minimum specific dynamic resistance (normalized to device area) calculated from I–V data vs. heating time at 500°C. This resistance includes resistances contributed from the Au(Ti)–SiC rectifying interface, SiC wafer and die-attach materials/interfaces. Resistances of the bonded wire and the test leads have been subtracted.

The temperature was then ramped up to 500°C (in air) and the diode was *in situ* characterized periodically by I–V measurement for ~1000 hr. During the first 70 hr at 500°C, the minimum dynamic resistance under forward bias increased slightly from 3.3 to 3.8 Ω. After that, the minimum dynamic resistance decreased slightly and remained at an average of 3.1 Ω. The diode was then cooled down to room temperature and characterized again. The minimum forward dynamic resistance measured at room temperature was 3.3 Ω. It is worth noting that the I–V curve of the device changed somewhat with time during heat treatment at 500°C. However, the minimum dynamic resistance of the attached diode remained comparatively low over the entire duration of the test and the entire temperature range, indicating a low and relatively stable die-attach resistance.

## 23.4 Thermomechanical Properties of Die-Attach

By adopting a conventional die-attach structure, in which the die backside is attached to a substrate using a thin attaching material layer, the die-attach using Au thick-film material discussed in the last section (illustrated in Figure 23.5) is a typical example of this structure. As discussed previously, the most important issue that concerns the thermal mechanical reliability of a packaged MEMS is the die-attach thermal stress and the guidelines for material selection, structure design and optimization of the attaching process to minimize the overall die-attach thermal stress effects on the mechanical operation of the device.

We start with a list of static equations governing the thermomechanical behavior of the die-attach structure to analyze the material properties and other factors determining the thermal mechanical properties of the structure. Following that, optimization of the die-attach thermal mechanical reliability is discussed using the simulation results of nonlinear finite element analysis [Lin, 2001].

### 23.4.1 Governing Equations and Material Properties

Assuming that the temperature distribution in the die-attach is static ( $\frac{\partial T}{\partial t} = 0$ ) and uniform ( $\frac{\partial T}{\partial x} = \frac{\partial T}{\partial y} = \frac{\partial T}{\partial z} = 0$ ), and the external force on the die-attach structure is zero, the general thermal mechanical governing equations for the die-attach system are

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 v}{\partial x \partial y} + \frac{\partial^2 w}{\partial x \partial z} + (1 - 2\nu)\nabla^2 u = 0 \quad (23.1)$$

$$\frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 u}{\partial x \partial y} + \frac{\partial^2 w}{\partial y \partial z} + (1 - 2\nu)\nabla^2 v = 0 \quad (23.2)$$

$$\frac{\partial^2 w}{\partial z^2} + \frac{\partial^2 u}{\partial x \partial z} + \frac{\partial^2 v}{\partial y \partial z} + (1 - 2\nu)\nabla^2 w = 0 \quad (23.3)$$

where  $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$ ;  $u$ ,  $v$  and  $w$  are the displacements in the  $x$ ,  $y$  and  $z$  directions, respectively;  $\nu$  is Poisson's ratio of the material. The normal stress distribution are determined by material properties, the temperature and the displacements [Lau et al., 1998]:

$$\sigma_x = \frac{\lambda}{\nu} \left[ (1 - \nu) \frac{\partial u}{\partial x} + \left( \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right) \right] - \beta(T - T_o) \quad (23.4)$$

$$\sigma_y = \frac{\lambda}{\nu} \left[ (1 - \nu) \frac{\partial v}{\partial y} + \left( \frac{\partial w}{\partial z} + \frac{\partial u}{\partial x} \right) \right] - \beta(T - T_o) \quad (23.5)$$

$$\sigma_z = \frac{\lambda}{\nu} \left[ (1 - \nu) \frac{\partial w}{\partial z} + \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \right] - \beta(T - T_o) \quad (23.6)$$

Shear stress are reduced from  $u$ ,  $v$  and  $w$  as:

$$\tau_{xy} = \frac{E}{2 + 2\nu} \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \quad (23.7)$$

$$\tau_{yz} = \frac{E}{2 + 2\nu} \left( \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right) \quad (23.8)$$

$$\tau_{zx} = \frac{E}{2 + 2\nu} \left( \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right) \quad (23.9)$$

where  $\lambda = \frac{\nu E}{(1 + \nu)(1 - 2\nu)}$ , and  $\beta = \frac{\alpha E}{1 - 2\nu}$ .  $E$  is Young's modulus and  $\alpha$  is the coefficient of linear thermal expansion (CTE). Material properties  $\alpha$ ,  $E$  and  $\nu$  generally vary from the die to the attaching layer and the substrate. If there is no residual stress at a certain temperature, such as the die-attaching temperature, then the mismatch of CTEs of the die-attach is the major source of thermal mechanical stress. This would become more apparent if the governing equations, Eqs. (23.1) to (23.3), are listed for the die, the attaching layer and the substrate separately. There would be an external force term in these equations because of the mechanical interactions at the boundaries—the interface between the die and the attaching layer and the interface between the attaching layer and the substrate. These external force terms are generated by the mismatch of material CTEs or the residual stresses. In case there is no residual stress and the CTEs match with each other, these external force terms vanish and solutions for the equations would be trivial.

In the temperature range for conventional IC packaging, all these material properties can be approximated as constants. However, in the operation temperature range from room temperature to 500°C, the temperature dependences of these material properties must be quantitatively considered for a precise solution for these equations.

The boundary conditions at the interface between the die and the attaching layer and the interface between the attaching layer and the substrate are largely determined by the bonding quality and the thermal mechanical stability of the die/attaching layer interface and the attaching layer/substrate interface. The simplest model of boundary conditions is ideal bonding: The continuity of all displacement components at interfaces in the entire temperature range  $u|_{S_s+} = u|_{S_s-}$ ,  $v|_{S_s+} = v|_{S_s-}$ ,  $w|_{S_s+} = w|_{S_s-}$ ,  $u|_{S_a+} = u|_{S_a-}$ ,  $v|_{S_a+} = v|_{S_a-}$  and  $w|_{S_a+} = w|_{S_a-}$ .  $S_s$  is the interface between the die and the attaching material, and  $S_a$  is the interface between the attaching material and the substrate, respectively.

The effects of thermal mechanical stress on the performance of a material/component are usually evaluated by either Von-Mises stress,  $\sigma_{VM} = 1/2 S_{ij} S_{ij}$  (the deviation stress tensor,  $S_{ij} = \sigma_{ij} - 1/3 \sigma_{\alpha\alpha} \delta_{ij}$ , where  $\delta_{ij} = 1$  for  $i = j$ , and  $\delta_{ij} = 0$  for  $i \neq j$ ), or the maximum principle stress  $\sigma_{MP}$  [Giacomo, 1996].

Assume:

1. The substrate size is much larger than that of die and the material is amorphous/polycrystalline (isotropic).
2. One of the basal planes of the chip crystal is parallel to the die-attach interface.
3. Boundary conditions at the interfaces are determined by ideal bonding; all displacement components are continuous at both the interface between the die and the attaching layer and the interface between the attaching layer and the substrate.
4. The die-attach structure is in a uniform temperature field.

Then, the maximum thermal stress distribution, either Von-Mises stress or maximum principle stress (MPS), is basically a function of the thickness of the die ( $\theta_d$ ); the thickness of the attaching material layer ( $\theta_a$ ); the properties  $E$ ,  $\alpha$  and  $\nu$  of the die material ( $E_d$ ,  $\alpha_d$  and  $\nu_d$ ); the properties of the attaching material ( $E_a$ ,  $\alpha_a$  and  $\nu_a$ ); the properties of the substrate material ( $E_s$ ,  $\alpha_s$  and  $\nu_s$ ); and the temperature deviation from the thermal stress relaxing temperature,  $T - T_R$ , where the  $T_R$  is thermal stress relaxing temperature:

$$\sigma = \sigma(x, y, z, \theta_d, \theta_a, \theta_s, \vec{M}_d, \vec{M}_a, \vec{M}_s, (T - T_R)) \quad (23.10)$$

where  $\vec{M}_{d,a,s}$  are material property parameters of the die, the attaching material and the substrate, respectively. For 500°C operable packaging, because the operation temperature range is, relatively, much wider compared to that for conventional ICs, the temperature dependencies of these material properties and their nonlinearity have to be considered for a precise assessment of the stress/strain distribution. Usually  $\sigma$  is symmetric about the vertical die central axis if the package dimensions are much larger than those of the die. For example, if the die is in a square shape,  $\sigma$  has approximately lateral fourfold (90°) symmetry about the vertical die central axis. In case the die surface is off the crystal basal plane, then  $\sigma$  depends on the angle off the basal plane, and the horizontal symmetry of  $\sigma$  reduces from 90° to 180°. Ideally, if the CTEs of the die, attaching materials and substrate are consistent with each other in the entire operation temperature range and stress is relaxed as an initial condition, then at any temperature:

$$\sigma = \sigma(x, y, z, \theta_d, \theta_a, \vec{M}_d = \vec{M}_a = \vec{M}_s, (T - T_R)) = 0 \quad (23.11)$$

At the relaxing temperature,  $T_R$ , the global thermal stress is largely relaxed:  $\sigma = \sigma(x, y, z, \theta_d, \theta_a, \vec{M}_d, \vec{M}_a, \vec{M}_s, (T = T_R)) = 0$ . Sometime the stress distribution at relaxing temperature may not be completely relaxed but reaches a minimum; this minimum stress depends on the die-attaching material, the physical and chemical processes of die-attaching and the thermal experience of the die-attach.

Consider thick-film material-based die-attach as an example.  $T_R$  is basically the final curing temperature if the cooling process after the final curing is so rapid that thermal stress does not have a chance to relax through sufficient diffusion at lower temperatures. However,  $T_R$  can be lower than the final curing temperature if the cooling process is so slow that a relaxing configuration is reached at lower temperatures. Therefore,  $T_R$  is initially determined by a die-attach processing temperature but it may change with the thermal history (temperature vs. time) after the attachment. The dependence of  $T_R$  on the thermal history is not desired because this may cause a reproducibility problem for device response. The basic physical/chemical attaching process certainly has significant impact on  $T_R$ . For some die-attach materials and attaching process, such as phase-transition material,  $T_R$  may not be the die-attach processing temperature.

In addition to the direct impact from material properties of the attaching layer, the thermomechanical properties of the interfaces between the die, the attaching layer and the substrate are also important to the thermal stress-strain configuration of the die-attach structure. The interfacial shear elastic/plastic properties, the interfacial fatigue/creep behavior, and their temperature dependencies are determined by the chemical/physical interactions between the materials composing the interface. If the materials chemically react at the interface, an interphase may form and dominate the interfacial thermomechanical properties. The thermal mechanical properties of these interphases can certainly be critical to the overall thermomechanical properties of the die-attach structure.

In order to improve the thermal mechanical reliability of the packaged device the thermomechanical properties of the die-attach need to be optimized either locally or globally through material selection, structure design and process control. The guideline for local optimization is to minimize the maximum local thermal stress where the device mechanically operates to optimize mechanical operation with the least thermal stress effects. The guideline for global optimization is to minimize the weighted global stress. The parameters that can be adjusted to thermomechanically optimize the die-attach structure are  $\vec{M}_a, \vec{M}_s, \theta_a$  and  $T_R$  after determination of die material and die size.

The thermal mechanical governing Eqs. (23.1) to (23.3) are so complicated that closed nontrivial (analytical) solutions of these equations are very difficult to obtain even for simple boundary geometry. The nonlinear temperature dependences of the material properties make it almost impossible to solve the equations with closed analytical solutions; however, numerical computing methods such as finite element analysis provide a powerful tool for simulation and optimization of the thermomechanical properties of a die-attach structure through material selection, structure design and processing control. Numerical methods make it possible to calculate the thermomechanical configuration of the packaging components/materials in a wide temperature range; however, it is still not trivial to optimize a die-attach

structure for operation in a wide temperature range using FEA simulation because of the following reasons:

1. The numerical calculations involved in FEA sometimes can be difficult, especially when the boundary geometry of the MEMS devices is complicated and the dimensions of the mechanical structures are much smaller than the die-attach size [Rudd, 2000].
2. Currently, thermomechanical and fatigue/creep properties of many electronic and packaging materials in such a wide and high temperature range are often not completely available.
3. If the die-attaching process is based on phase-transition phenomena, then detailed changes in the thermomechanical properties of the attaching material, before and after the phase transition, may not be completely known.
4. Quantitative modeling of interfaces between the die, attaching layer, and substrate can be difficult.

Lin and Zou used a Si stress-monitoring chip to measure surface stress–strain of a die-attach [Lin et al., 1997a; Zou et al., 1999]. This unique *in situ* stress–strain monitoring method can be modified by using a high-temperature-operable SiC stress-monitoring chip to optimize the die-attach for high-temperature MEMS packaging.

### 23.4.2 Thermomechanical Simulation of Die-Attach

For high-temperature MEMS packaging, the thermomechanical reliability of a die-attach structure needs to be addressed at two levels: (1) mechanical damages of a die-attach structure resulted from thermal mechanical stress, and (2) thermal stress–strain effects on the mechanical operation of the device. Failures at both levels are rooted in thermomechanical stress in the die-attach. In the remaining part of this section FEA simulation results [Lin, 2001] of the Au thick-film-based SiC die-attach reviewed in the last section are analyzed as an example of die-attach optimization for high-temperature MEMS packaging.

#### 23.4.2.1 High-Temperature Material Properties

The basic thermal and mechanical properties of SiC, Au, AlN and 96% Al<sub>2</sub>O<sub>3</sub> and their temperature dependences used for FEA simulation are listed in Table 23.1 [Lin, 2001]. The temperature dependence of Young's modulus of AlN in a wide temperature range has not been reported, so it is extrapolated as a constant from the data at room temperature. The Poisson's ratios of 4H single-crystal SiC and AlN are not available; they were estimated according to those of other carbides and nitrides. The thermal and mechanical properties of 4H-SiC were assumed to be isotropic. Because the yield strength of gold thick-film material has not been published either, the simulation was conducted in a range of values from 650 to 3000 psi. However, computations using the yield strength at the low end very often diverged so the calculation was difficult.

#### 23.4.2.2 Stress Distribution and Die Size Effects

Figure 23.8 shows Von-Mises stress and maximum principle stress contours of a quarter of a SiC–Au–AlN die-attach structure at room temperature assuming the relaxing temperature is 600°C. Horizontally, at the interface with the Au thick-film layer, the stress in the die basically increases with the distance from the center of the die-attach interface; the stress reaches a maximum at the area close to the die edges, especially at the corner area. This is understandable. The source of thermal stress of the die-attach structure is CTE mismatch at bonding interfaces. At the area far from the neutral point (larger distance from neutral point, DNP) the trends of relative displacement with respect to Au thick-film, driven by the CTE mismatch, would be larger. It can be predicted with these results that the maximum thermal stress would increase tremendously with the increase of die size or the attaching area. Vertically, the stress attenuates rapidly with the distance from the interface. At the die center region the stress near the die surface attenuates by a factor of 1/80 with respect to the stress at the interface. This picture of the thermal stress distribution indicates that flip-chip bonding would not be recommended for high-temperature MEMS

devices if the CTE mismatch is not well controlled, and a significantly thicker die (or a stress buffer layer of the same material as that of the chip) can reduce the thermal stress at the die surface region.

Figure 23.8c shows equivalent plastic strain (EPS) in the Au thick-film layer. Because of the same physical mechanism as that for the SiC die, the highest EPS in the Au layer is located in an area close to the corner where the DNP is larger. This indicates again that a smaller die size or attaching area may better satisfy die-attach thermomechanical reliability requirements.

### 23.4.2.3 Effects of Substrate Material

In comparison with the AlN substrate, a 96%  $Al_2O_3$  substrate has relatively higher CTE ( $\sim 6.2 \times 10^{-6}/^{\circ}C$  compared with  $\sim 3.9 \times 10^{-6}/^{\circ}C$  of AlN). In order to evaluate the substrate material effects on the thermomechanical stress of the die-attach structure, FEA simulation was used to compare the maximum stress in both the SiC die and the gold thick-film attaching layer using both substrates [Lin, 2001]. The results indicate that using AlN substrate would result in an improvement of maximum Von-Mises stress in the SiC die by a factor of 0.29, an improvement of Von-Mises stress in the substrate by a factor of

**FIGURE 23.8** (Color figure follows p. 12-26.) Thermal stress and strain distribution in SiC die and Au thick-film layer. (a) Von-Mises stress distribution in SiC die; (b) principle stress distribution in SiC die; (c) equivalent plastic strain in Au thick-film layer.

0.33, and an improvement of MPS in the Au thick-film layer by a factor of 0.42 assuming the yield strength of Au thick-film is 3000 psi. This improvement of thermal stress-strain corresponds to an improvement of fatigue lifetime by a factor of 4.3 to 9.0 (assuming that the power law exponent in the Coffin-Manson model,  $C$ , is  $-0.4$  and  $-0.6$ , respectively). So, in terms of the thermomechanical reliability of the die-attach, AlN is suggested for packaging SiC high-temperature MEMS devices when compared to 96%  $\text{Al}_2\text{O}_3$  owing to the fact that the CTE of AlN is closer to that of SiC.

SiC is another candidate substrate material for packaging SiC devices, but currently the cost of single-crystal SiC material is much higher compared with other ceramics suitable for packaging. The CTEs of  $\alpha$ - and  $\beta$ -polycrystalline SiC are very close to that of single-crystal SiC so thermomechanically they are ideal substrates for packaging large SiC die for high-temperature operation. However, both the dielectric constants and the dissipation factors of these materials are relatively high [Johnson, 1999]. In order to be used as packaging substrates, the surface properties of polycrystalline SiC must be modified, but these materials might still be suitable only for low-frequency application because of the high dissipation factors.

#### 23.4.2.4 Effects of Thickness of the Attaching Layer

The Au attaching layer contributes to the thermomechanical properties of the die-attach structure in two ways:

1. *Direct interface effect.* The Au layer forms interfaces with both the SiC die and the substrate, so the material properties and the configurations of the Au layer directly influence the thermal stress distributions in both the die and the substrate.
2. *Coupling effects.* As an interlayer between the die and the substrate, the Au layer couples the die with the substrate mechanically.

When the interlayer is very thick, the substrate and die are decoupled from each other, thus the second effect vanishes and the first effect dominates; if the thickness of the interlayer  $\rightarrow 0$ , then the die and the substrate are directly coupled with each other, the influence of Au material properties vanishes, and the second effect dominates.

Figure 23.9 shows maximum Von-Mises stress in the SiC die and the substrates vs. the thickness of the Au attaching layer,  $\theta_a$ . The maximum stress in the SiC die decreases by a factor of 0.75 with respect to the change in  $\theta_a$  from 20 to 50  $\mu\text{m}$  for an AlN substrate, while the maximum Von-Mises stress in the SiC die decreases by a factor of 0.5 with respect to the change in  $\theta_a$  from 20 to 50  $\mu\text{m}$  for the alumina substrate. The increase of Au layer thickness also significantly reduces the stress in the alumina substrate, as shown in Figure 23.9b. Figure 23.9c shows the maximum equivalent plastic strain in the Au layer vs.  $\theta_a$ . The increase of  $\theta_a$  from 20 to 50  $\mu\text{m}$  significantly reduces the EPS in the Au layer in both AlN and  $\text{Al}_2\text{O}_3$  cases. The maximum stress in SiC die and the substrate and EPS in Au attaching layer were calculated against the yield strength of Au thick-film.

#### 23.4.2.5 Effects of Relaxing Temperature

In addition to the dependence of thermal stress in the die-attach on material properties of the die, the attaching layer and the substrate, the thermomechanical stress in the die-attach structure also depends on the temperature deviation from the relaxing temperature,  $T_R$ , at which the structure is largely relaxed. Therefore, the relaxing temperature of the die-attach structure is another important factor determining thermomechanical configuration (stress and strain) of a die-attach structure at a certain temperature. Generally, the more the temperature deviates from the relaxing temperature, the higher the thermomechanical stress that exists in the die-attach structure. For the type of die-attaching using diffusion-based bonding (e.g., thick-film-material-based die-attaching), the relaxing temperature is likely to be close to the processing (curing) temperature. For phase-transition-phenomena-based die-attach processes, the residual thermal stress could exist at the processing/attaching temperature because of the changes in material properties during the phase transition. In this case, the die-attach structure reaches a minimum stress configuration at certain temperature but the residual stress may not be completely relaxed.

In order to assess the relaxing temperature effects on the thermal stress of die-attach structure, the stress distribution of the die-attach at room temperature is simulated by FEA assuming that the structure is relaxed at various temperatures (from 300 to 600°C). Figure 23.10 shows the maximum Von-Mises stress in the die and EPS in the Au thick-film layer vs. the relaxing temperature. If the relaxing temperature could be lowered from 600 to 300°C, the maximum Von-Mises stress in the die could be reduced by a factor of 0.8, and the maximum EPS in the Au thick-film layer could be reduced by a factor of 0.5. The fatigue lifetime corresponding to the stress reduction is improved by a factor of 3 (assuming the exponent

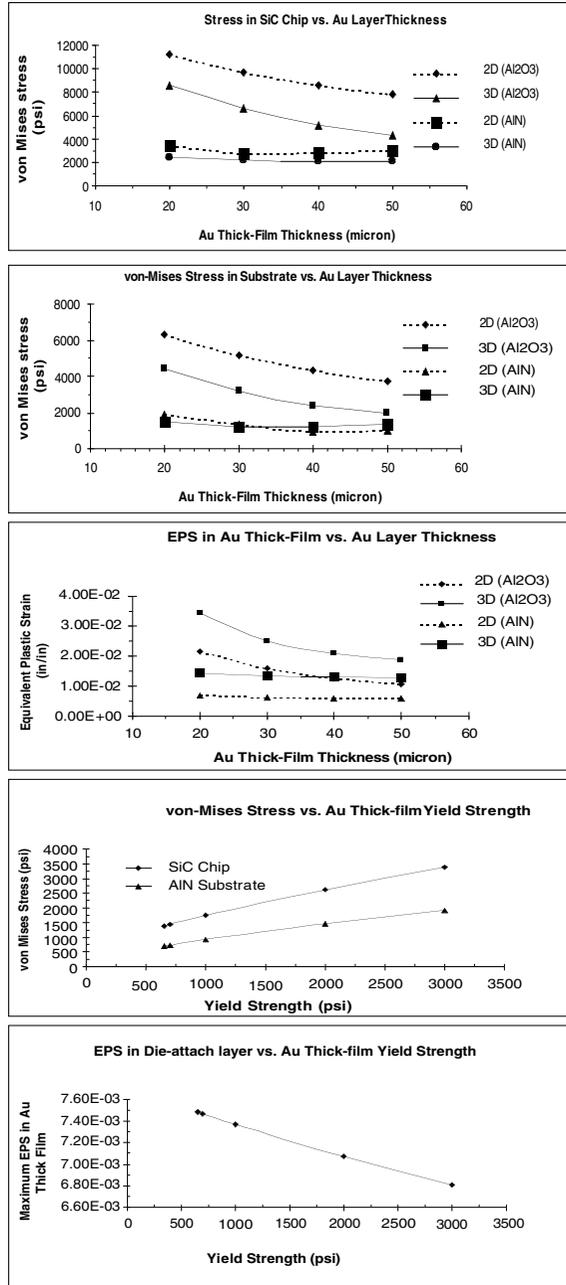

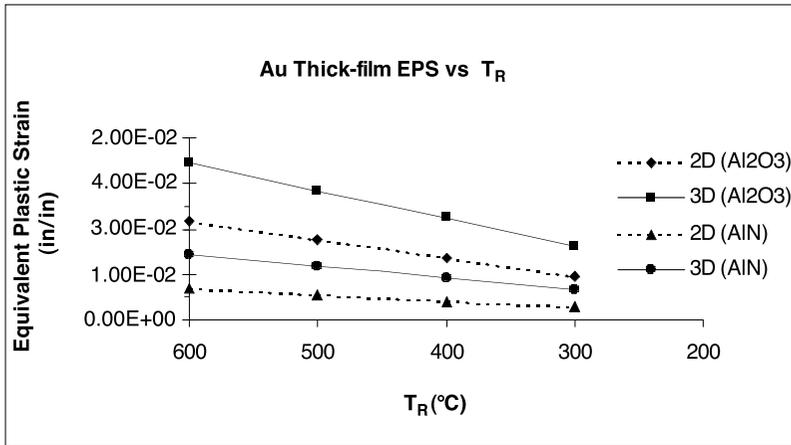

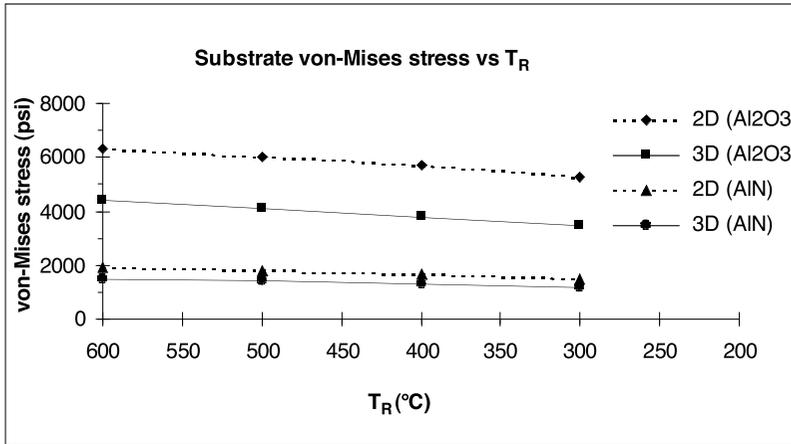

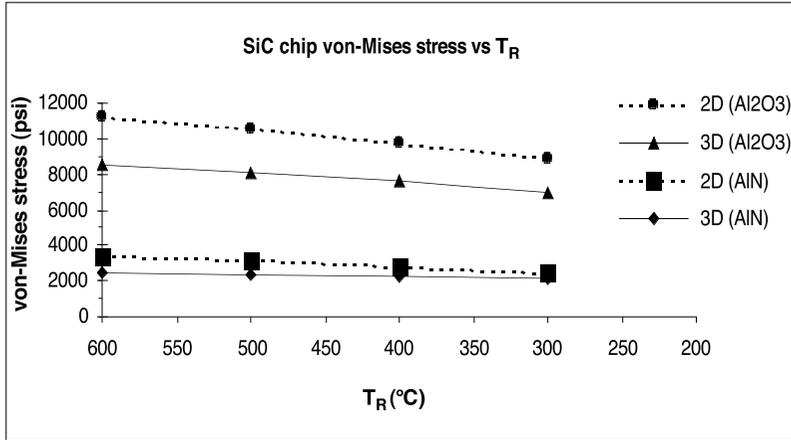

FIGURE 23.9 Dependence of stress–strain in SiC die, substrate and Au attaching layer on the thickness and the yield strength of Au thick-film layer. (From Lin, 2001. With permission.)

in the Coffin-Manson model of fatigue,  $C$ , is  $-0.6$ ). Ideally, the thermal mechanical property of the die-attach structure is optimized if the relaxing temperature could be set at the middle of the operation temperature range, but physically this is not always realistic.

Mathematically, optimization of the thermomechanical property of a die-attach is a complicated multi-parameter problem. So, even if the numerical computing is possible, both the skill and the amount of calculations required for the optimization can be considerable.

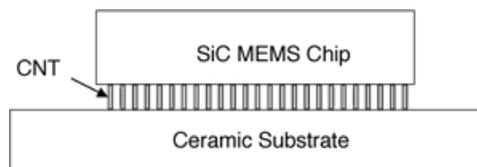

**FIGURE 23.10** Relaxing temperature dependence of maximum stress and strain in SiC chip, substrate and Au attaching layer. (From Lin, 2001. With permission.)

## 23.5 Discussion

The combination of versatile functions of MEMS devices and survivability/operability in harsh environments leads to a new generation of microdevices, harsh-environment MEMS, with revolutionary capabilities for aerospace and civil applications. Packaging these revolutionary devices, however, has generated new and challenging research in the device-packaging field. In order to meet these challenges, innovative packaging materials with superior physical/chemical properties suitable for harsh-environment operation, innovative packaging structures and designs to meet the requirements of microstructures and micromechanical operations and innovative packaging processes to utilize these innovative packaging materials to fabricate innovative packaging structures are expected.

### 23.5.1 Innovative Materials

An ideal die-attaching material suitable for use in a wide temperature range is an illustration of the need for innovative materials to package harsh-environment MEMS devices. In addition to the superior chemical and electrical stabilities at high temperatures and in a corrosive environment, the die-attaching materials must possess good thermal and electrical conductivity, unique features of metallic material; meanwhile, the CTE of such a material should match those of the die and the ceramic substrate. Ideally, if the CTE of the substrate slightly mismatches that of the die, the die-attach material should be able to compensate the CTE mismatch between the die and the substrate. A material with low Young's modulus and narrow elastic region certainly would help to absorb thermal strain, thus reducing the stresses in the die and the substrate. However, this would reduce the lifetime of the die-attach material layer in a dynamic thermal environment because of the accumulated permanent strain. Comparing the extraordinary material requirements listed above with the features of carbon nano tubes (CNT) we discover that CNT is an ideal die-attach interlayer that matches all these requirements: CNTs have been reported to have superior electrical and thermal conductivities [Saito et al., 1998; Hone et al., 2000]. The longitudinal mechanical strength (both elastic modulus and breaking point) of CNTs is very high in comparison with steel [Wong et al., 1997; Hernandez et al., 1998; Poncharal et al., 1999; Salvetat et al., 1999; Yu et al., 2000], but the shear modulus of single-walled CNTs is low [Salvetat, 1999]. The graphitic bond between neighboring in-wall carbon atoms of each CNT makes the interaction between the neighboring tube walls weak [Girifalco et al., 2000]. Combining all these features of CNTs we can visualize an innovative die-attaching interlayer material. If CNT can be vertically grown on the C face of a SiC (the C face of a SiC is usually used for die-attach because the Si face is favored for fabrication of most electronic devices) wafer, it may provide an ideal interlayer with excellent thermal and electrical conductivities, superior mechanical strength and very low lateral Young's modulus and thus possess the unique capability to manage the CTE mismatch between the die and the substrate. A schematic diagram using CNT as die-attach interlayer that is expected to decouple the die mechanically from the substrate is illustrated in Figure 23.11.

**FIGURE 23.11** Schematic diagram of die-attach structure using carbon nano tube as an interlayer with capability to match the CTEs of both SiC chip and the substrate.

## 23.5.2 Innovative Structures

As discussed in previous sections, suppressing thermal stress in the die-attach in a wide temperature range is a common thermomechanical concern for high-temperature MEMS packaging. A bellow structure was invented (for conventional MEMS packaging) to absorb thermal strain and thus release thermal stress in the area where the device operates mechanically [Garcia and Sniegowski, 1995]. The bellow structure can be fabricated between the mechanical operation part and the chip base so the mechanical operation part is mechanically decoupled laterally from the rest of the device chip. Or, the bellow structure can be fabricated between the device chip and the packaging substrate so the entire chip is mechanically decoupled from the packaging environment. A similar structure can also be used for harsh-environment MEMS packaging. Various thermal stress suppression methods for packaging conventional MEMS were summarized by Madou (1997). Some of these methods may be modified for applications in packaging high-temperature MEMS.

As discussed in Section 23.4.2.2, the thermomechanical stress in the SiC die of the die-attach structure discussed in the last section attenuates rapidly with the vertical distance to the interface composed of SiC and Au with different CTEs. Horizontally, the maximum thermal stress increases rapidly with the die size or die-attaching area. These results suggest a simple but effective thermal stress suppression method, side die-attach, which attaches the die through one of the die sides to the packaging base rather than the bottom of the die. This die-attach scheme allows a much larger distance from the mechanical operation area to the die-attach interface and reduces the die-attach area. The side die-attach structure is expected to be especially effective to release thermomechanical stress-strain in the direction vertical to the die-attach interface because the chip has no direct restraint in this direction.

## 23.5.3 Innovative Processes

In order to accommodate the microsize mechanical features of MEMS devices and support their microlevel mechanical operation, the immediate device packaging environment may have to meet micro-mechanical requirements in both alignment and assembly. An innovative, organic-solution-based, self-assembly method was used to integrate micro-sized GaAs light emission diodes (LED) onto a micromachined Si substrate [Yeh and Smith, 1994]. GaAs LEDs are suspended in ethanol above a micromachined Si wafer. Macro-vibration enables the LEDs to randomly walk in the solution. When a LED hits a vacancy on the Si wafer it fits in and gains the lowest potential there because of surface-ethanol-surface interactions. These interactions are so strong that perturbation from vibration would not free trapped LEDs. This is a good example of how innovative packaging processes at various levels beyond conventional IC packaging technology are introduced to package MEMS devices.

Madou (1997) summarized oxidation bonding, fusion bonding, field-assisted thermal bonding and modified field-assisted thermal bonding techniques developed for Si MEMS packaging. Low-pressure and low-temperature hermetic wafer bonding using microwave heating was introduced for Si wafer packaging [Budraa et al., 1999]. Some of these wafer-bonding methods may be modified for applications in high-temperature MEMS wafer materials such as SiC.

A microcavity is a common microstructure necessary to support the operation of many MEMS devices such as an absolute pressure sensor or a microresonator [Ikeda et al., 1990; Hanneborg and Øhlckers, 1990]. These microcavities are often included in the device fabrication instead of being assigned later to conventional packaging that typically is macrolevel processing. This reflects the trend that micromachining/fabrication processes initially used only for device fabrication now are also used to package MEMS devices. An extreme example of using microfabrication to package MEMS devices would be wireless “bug sensors” for operations *in vivo* and other harsh environments. The packaged device must be miniaturized; therefore, both the device and the package have to be microfabricated and micro-assembled. These MEMS devices become “self-packaged” because their fabrication and device packaging processes are completely merged [Santos, 1999]. These “self-packaged” MEMS devices may have the unique advantage of material consistency for operation at high temperatures.

## Acknowledgments

---

One of the authors (L.C.) is very grateful to Dr. Gary W. Hunter for introducing the author to the challenging and vivid research field of high-temperature device packaging. Dr. Lawrence G. Matus is thanked for proofreading the manuscript. Discussions with Drs. Philip G. Neudeck and Robert S. Okojie drawing upon their device perspectives were very helpful to writing this material. The FEA modeling of the die-attach was conducted by Dr. Shun-Tien (Ted) Lin at United Technologies Research Center with support of NASA Electronic Parts and Packaging Program through NASA Glenn Research Center. The authors would like to thank Dr. Lin for his very helpful input on the FEA modeling results. The harsh-environment microsystem packaging work at NASA Glenn Research Center is currently supported by the NASA Glenn Microsystems Initiative (GMI) and NASA Electronic Parts and Packaging (NEPP) program.

### 24.1 Introduction

---

Inertial sensors are designed to convert, or transduce, a physical phenomenon into a measurable signal. The physical phenomenon is an inertial force. Often this force is transduced into a linearly scaled voltage output with a given sensitivity. The methodologies used for macroscopic inertial sensors can and have been utilized for micromachined sensors in many applications. It is worth considering further what motivations have led to the introduction of micromachined inertial sensors. As will be demonstrated in this chapter, differences in accelerometer and gyroscopic application requirements do impact the choice of micromachining technology, transducer design and the system architecture. The definition of the system requirements often delineates micromachining technology options very clearly, although most sensing mechanisms and micromachining technologies have been applied to inertial sensors. First, design parameters will be reviewed for accelerometers. Accelerometers are the most straightforward inertial sensor system and will demonstrate the major physical mechanisms and micromachining technologies implemented to sense inertial displacement. Next, gyroscopic sensors, or sensors for rotational inertia, will be reviewed and will demonstrate how the technology can impact system and sensor, or transducer, design. Inertial device

parameters are tightly coupled with lessons from Part I of this handbook, applying material from Chapters 2 to 5 by Trimmer and Stroud, Sharpe, Gad-el-Hak, and Kirby et al., in particular. A thorough background in micromachining technologies that have been implemented in micromachined inertial devices can be found in Part II of this handbook. Systems issues of inertial sensing tie in with the control theory discussions found in Chapters 12 and 13 by Goodwine and Bewley, respectively.

## 24.2 Applications of Inertial Sensors

Three primary areas often motivate micromachined device applications: packaged volume or size, system cost and sometimes performance. Often these three drivers cannot be met in a single technology choice. Packaged volume or overall system size is often an easy goal for micromachined inertial sensors compared to the macroscopic counterparts. Micromachining technologies are capable of reducing the sensor element and electronics board components to the scale of one integrated or two co-packaged chips, potentially as small as an 8-pin dual inline package (DIP) or surface mount (SMT) plastic package. Figure 24.1 shows two such examples: (left) an integrated accelerometer technology produced by Analog Devices, Inc., and (right) a co-packaged accelerometer produced by Motorola, Inc.

Reducing the system cost is also a goal easily achieved by micromachined inertial sensors as compared to macroscopic systems. Due to their relation to the microelectronics industry, micromachined sensors can be batch fabricated, sharing process costs over large volumes of sensors, reducing the overall process constraints significantly. While many individual processes may be significantly more expensive than the macroscopic counterparts, the impact is greatly reduced because the benefits of scale can be applied.

Meeting a targeted device performance with sufficient profitability requires improvements in production costs per unit. One factor in this cost improvement is die area utilization. Maximizing device sensitivity per unit area minimizes die area. Current sensor device requirements for occupant safety systems have allowed the initial incorporation of surface micromachined technologies. Surface micromachining technologies use the successive deposition of sacrificial and structural layers to produce an anchored yet freestanding device typically made of polycrystalline silicon with a structural thickness of less than  $3\ \mu\text{m}$  [Ristic et al., 1992]. These technologies have been successful for current design requirements but are being replaced by technologies that demonstrate application flexibility and improved die area utilization.

**TABLE 24.1** Inertial Sensor Applications in the Automobile

	Range	Application Comments
Applications	$\pm 1\text{ g}$	Antilock braking systems (ABS), traction control systems (TCS), virtual reality (VR)
	$\pm 2\text{ g}$	Vertical body motion
	$\pm 50\text{ g}$	Front-airbag deployment, wheel motion
	$\pm 100\text{--}250\text{ g}$	Side (B-pillar) airbag deployment
	$\pm 100\text{--}250^\circ/\text{s}$	Roll and yaw rate for safety and stability control
Resolution	$<0.1\%$	Full-scale, all applications
Linearity	$<1\%$	Full-scale, all applications
Output noise	$<0.005\text{--}0.05$	Full-scale signal, all applications
	$\%FS/\sqrt{\text{Hz}}$	
Offset drift	$<1\text{ g/s}$	Accelerometer
	$<0.1^\circ/\text{s/s}$	Gyroscope
Temperature range	$-40\text{ to }85^\circ\text{C}$	Operational conditions
	$-55\text{ to }125^\circ\text{C}$	Storage conditions
Cross-axis sensitivity	$<1\text{ to }3\%$	Application dependent
Frequency response	dc to 1–5 kHz	Airbag deployment
	dc to 10–100 Hz	Gyroscope and 1- to 2-g accelerometers
Shock survivability	$>500\text{ g}$	Powered all axes
	$>1500\text{ g}$	Unpowered all axes

Source: Adapted from MacDonald, N.C. (1990) *Sensors and Actuators A*, 21, 303–307.

The system area least often demonstrating improvement due to micromachined sensors as compared to the macroscopic counterparts is system performance. The trade-off between system size and cost and performance is often directly coupled, although notable exceptions exist to that rule. Performance improvements have been the primary technology drivers for micromachined inertial sensors. Micromachined technologies have succeeded in applications driven by size and cost with modest performance requirements. One such application is the automobile.

The automobile is significantly driven by system cost and currently motivates most micromachined inertial sensor technology development. Automotive inertial sensor applications are listed in Table 24.1. Accelerometers are among the largest volume micromachined products used in airbag control systems in automobile occupant-restraining systems. Accelerometers designed for airbag systems typically require inertial sensitivities of 20 to 100 g full-scale for front-impact airbags and 100 to 250 g full-scale for side-impact airbags. (One g represents the acceleration due to Earth's gravity.) Single-axis inertial sensors are also used in vehicle dynamics for active suspension systems with typical required inertial sensitivities ranging from 0.5 to 10 g. Future occupant safety systems will likely require more sensors to tailor a system response to the conditions of the crash event. Crash variables can include impact location, occupant position and weight, use of seat belts and crash severity. A future occupant safety system may use many multi-axis transducers distributed around the automobile to determine whether an airbag should be deployed and at what rate.

Vehicle dynamics and occupant safety systems are increasing in complexity and capability. Used in active suspensions, traction control and rollover safety systems, low-g accelerometers, yaw rate sensors and tilt gyros are employed and tied into engine, steering and antilock braking systems to return control of the vehicle to the driver in an out-of-control situation. Combined with front- and/or side-impact airbag systems, the system will determine the severity of the event and deploy seat belt pretensioners, side bags, head bags, window bags and interaction airbags between occupants as necessary. Versions of these systems are being introduced on more and more vehicles today. The merger of many of these systems in the future will provide greater system capability and complexity.

Gyro technologies, encompassing pitch, roll and yaw sensing, require significantly higher sensitivities than the analogous accelerometer. Such devices typically exhibit milli-g resolution in order to produce stable measurements of rotational inertia with less than one degree per minute drift. Design considerations

for such devices encompass the same micromachining technologies but add significant device and system complexity to achieve stable and reliable results.

Outside the automotive marketplace there are many applications for sub-g inertial sensor products including virtual reality systems, intelligent toys, industrial motion control, hard drive head protection systems, video camera image stabilization systems, shipping damage detectors, robotic warehouse operations, GPS receivers and inertial navigation systems.

### 24.3 Basic Acceleration Concepts

Inertial sensing is dependent on the reference frame and what is being measured. Practically speaking, two primary applications define the required reference frames and measurements for most devices: the linear accelerometer and the rotational gyroscope. The accelerometer is generally defined in a Cartesian reference frame and measures the kinematic force due to a linear acceleration, as shown in Figure 24.2. The rotational gyroscope can be defined in a cylindrical or Cartesian reference frame and measures the angular velocity of a rotation about its primary axis due to the coupled Coriolis force on a rotating or vibrating body.

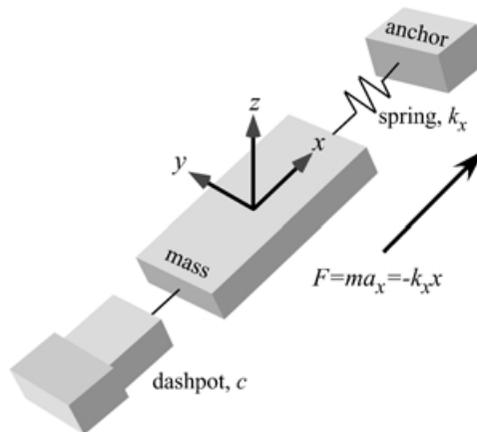

Linear acceleration,  $\mathbf{a}$ , can be defined as:

$$\mathbf{a} = \frac{d^2\mathbf{r}}{dt^2} = \frac{d\mathbf{v}}{dt} \tag{24.1}$$

where  $\mathbf{r}$  denotes linear displacement in meters (m) and  $\mathbf{v}$  is the linear velocity in meters per second (m/s). The equation is written in vector notation to indicate that, while in most systems only one axis of motion (where the scalar,  $x$ , would replace  $\mathbf{r}$ ) is allowed, off-axis interactions need to be considered in complex system design.

Rotational gyroscopes measure angular velocity,  $\omega$ , which is defined as:

$$\omega = \frac{d\theta}{dt} \tag{24.2}$$

**FIGURE 24.2** Cartesian reference frame for linear accelerometers. The figure shows an  $x$ -axis device for reference, including anchor, spring, seismic mass and dashpot.

where  $\theta$  is the angular displacement in radians, and the angular velocity,  $\omega$ , is measured in radians per second (rad/s). Angular acceleration,  $\alpha$ , may also be measured and is defined as:

$$\alpha = \frac{d^2\theta}{dt^2} = \frac{d\omega}{dt} \quad (24.3)$$

To measure the angular velocity of a moving body, the Coriolis effect is most often utilized in micromachined *vibratory* gyroscopic devices, although rotating micromachined gyroscopes have been demonstrated [Shearwood et al., 1999]. If a proof mass is driven into oscillation in one axis, rotation of the gyroscope reference frame will displace the oscillating mass into a second orthogonal axis. This coupling is the Coriolis effect and is given by:

$$\mathbf{F}_c = 2m\mathbf{v} \times \boldsymbol{\Omega} \quad (24.4)$$

which is a force produced when a vibratory mass,  $m$ , moving at a velocity,  $\mathbf{v}$ , is placed in a rotation,  $\boldsymbol{\Omega}$ . This Coriolis-induced force is orthogonal to the vibratory motion as defined by the vector cross product.

## 24.4 Accelerometer Design Parameters

The successful implementation of micromachining technology to produce an inertial sensor requires more than the micromachining technology. The trade-offs between transducer and circuitry define the system approach and often demonstrate the complexity of the machined systems these micromechanical systems intend to replace. All micromachining technologies exhibit limitations that must be accounted for in the design of the overall system. The design of the transducer and the design of the overall system are interwoven. The transducer design and technology capability must first be addressed. The integration of the transducer function at the system level also defines the partitioning and complexity of the technology.

The manufacturability of a transducer structure is of paramount importance and should be vigorously considered during the design stage. In theory, one may design a sensor structure as sensitive as desired, but if the structure cannot be manufactured in a robust manner the effort is wasted. For example, a too-large proof mass or a too-soft spring may dramatically increase the probability of stiction, resulting in yield loss. In this regard, the design must follow a certain guideline of design rules (design rules will differ from technology to technology) in order to improve the yield of manufacturing.

Two primary axes of inertial sensitivity are produced for accelerometers: in-plane, often called  $x$ -axis or  $x$ -lateral accelerometers, and normal to the wafer surface, or  $z$ -axis accelerometers. The choice of axis is primarily driven by the application. Front-airbag systems require in-plane sensing, or  $x$ -axis sensing, while side- and satellite-airbag sensors are often mounted vertically, calling for  $z$ -axis sensing. Gyroscopic sensors to measure angular rate require a minimum of two orthonormal axes of motion in order to suitably measure the small Coriolis force exerted on a resonating proof mass during rotation. Rollover gyros typically resonate in plane and sense normal to the surface. Axes of sensitivity for gyroscopic sensors are shown in [Figure 24.3](#).

Any inertial sensor design requires a seismic mass (also called a proof mass), an elastic spring, a dashpot and a method to measure the displacement of the seismic mass. The mass is used to generate an inertial force due to an acceleration or deceleration event, and the elastic spring to mechanically support the proof mass and to restore the mass to its neutral position after the acceleration is removed. The dashpot is usually the volume of air, or controlled ambient, captured inside the cavity and is designed to control the motion of the seismic mass and to obtain favorable frequency-response characteristics. The sense methodology converts the mechanical displacement to an electrical output.

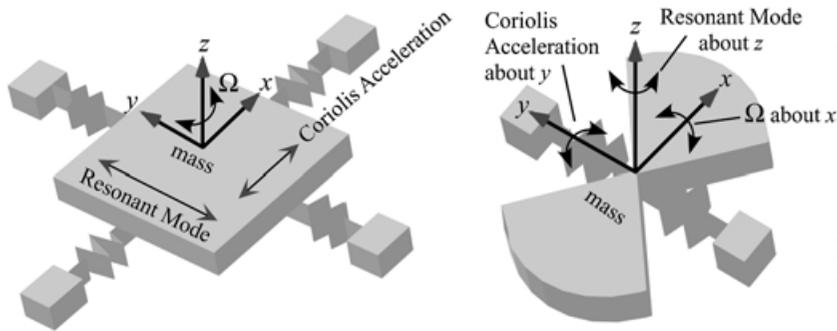

FIGURE 24.3 Reference frames for rotational gyroscopes based on the Coriolis effect showing axes of sensing for yaw and roll applications.

### 24.4.1 Converting Force to Displacement: The Seismic Mass and Elastic Spring

The application of an inertial load exerts a force on the proof mass, which is translated into a displacement by the elastic spring. The simple force equation for a static load is shown in Eq. (24.5), where  $m$  is the proof mass (kg),  $a$  is the static or steady-state inertial acceleration ( $m/s^2$ ),  $k$  is the elastic spring constant (N/m), and  $x$  is the displacement of the mass with respect to the reference frame generated by the inertial load. In the ideal case, the proof-mass displacement is well controlled and in one axis only. The ratio of the proof mass to spring constant defines the sensitivity of the system to inertial loads:

$$\text{sensitivity} = \frac{\text{output (displacement)}}{\text{input (acceleration)}} = \frac{x}{a} = \frac{m}{k} \quad (24.5)$$

The accelerometer design needs to precisely control the displacement of the seismic mass. The proof mass should be sufficiently massive and rigid to act in a well-behaved manner. In general, the design of a proof mass should provide at least an order of magnitude greater stiffness than the elastic spring stiffness in the axis of sensitivity. For a lateral sensor, the design of a sufficiently massive proof mass benefits by thicker structures. For a given transducer area, the mass increases linearly with thickness, and the stiffness out of plane increases by the third power.

In most applications, sufficient proof-mass stiffness is not difficult to achieve; however, design considerations may be impacted by other system requirements. For example, in lateral capacitive structures the incorporation of interdigitated sense fingers attached to the periphery of the proof-mass can complicate the proof-mass behavior. These sense fingers are often only a few times stiffer than the elastic springs and introduce a nonideal behavior to the sensitivity for large inertial loads. Minimizing this impact is often a significant design trade-off between device area and nominal capacitance for a device. Again, the thickness of the sense fingers improves the stiffness of a beam design and increases nominal capacitance per finger.

The elastic spring is required to provide kinematic displacement of the proof mass in the axis of sensitivity to produce a suitable sense signal while being sufficiently rigid in other axes to eliminate cross-axis sensitivity. The spring constant of a beam is governed by its geometry and material properties. In general, the spring constant of a beam of uniform material is defined by the proportion of its length to its cross-sectional area. Micromachined springs are often folded, or bent around a radius, to improve the performance of the overall device. Bent beams are often used to relieve residual intrinsic stress in the micromachined material and stabilize device parameters across wafers and production lots. Folded beams perform this function and reduce the device topology for the overall structure. Folded-beam elastic spring designs may also improve the sensitivity of the inertial sensor to package stress by reducing the spacing between anchored points of the springs around the periphery of the sensor structure.

For a lateral accelerometer, increasing the out-of-plane stiffness proves to be one of the major challenges for many micromachining technologies. Drop-shock immunity and cross-axis sensitivity are strongly impacted by the stiffness out of plane. Increasing the thickness of the beam increases the out-of-plane stiffness by the third power while the spring constant in the lateral axis of sensitivity only increases linearly. The aspect ratio, or ratio of the height to width of the spring, impacts the relative difference in spring constants in and out of plane. Because the spring constant in the lateral axis of sensitivity is defined to be the chosen geometry of the device, simply increasing its geometrical length or reducing the beam width can compensate the increase in spring constant of a beam. While this reduces the out-of-plane stiffness somewhat, it has a considerably smaller linear impact compared to the cubic increase in beam stiffness due to the increase in thickness.

For a rotational gyroscopic sensor, two axes of motion must be adequately controlled for the device to function properly. Drop-shock immunity and cross-axis sensitivity impact gyros, as well. Producing devices with sufficient stiffness off-axis to minimize the introduction of error and noise signals in a gyro is a major undertaking. Simply increasing the thickness of the micromachined layer impacts both axes of motion in a gyro, greatly increasing the complexity of the design effort.

#### 24.4.2 Device Damping: The Dashpot

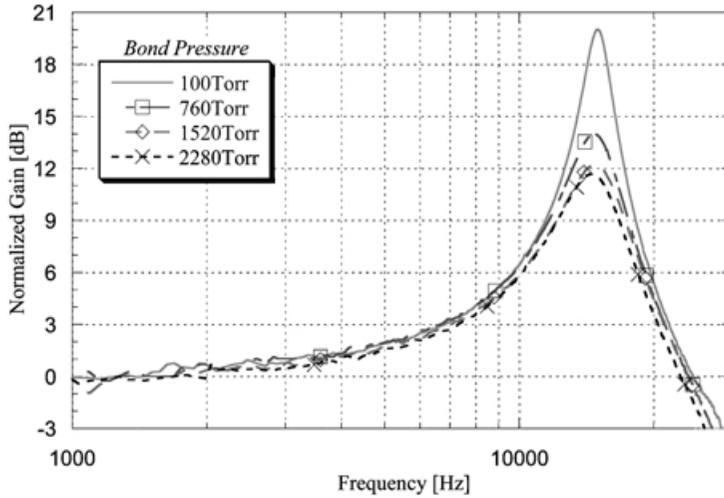

While the proof mass and elastic spring can be designed for a static condition, the design of the dashpot should provide an optimal dynamic damping coefficient through squeeze-film damping by the proper choice of the sensor geometry and packaging pressures. The extent of this effect is defined by the aspect ratio of the space between the plates and the ambient pressure. A large area-to-gap ratio results in significantly higher squeeze numbers, resulting in greater damping as described by Starr (1990).

Micromachined inertial sensor devices are often operated in an isolated environment filled with nitrogen or other types of gas such that the gas functions as a working fluid and dissipates energy. A gas film between two closely spaced parallel plates oscillating in normal relative motion generates a force, due to compression and internal friction, which opposes the motion of the plates. The damping due to such a force, related to energy loss in the system, is referred to as squeeze-film damping. In other cases, two closely spaced parallel plates oscillate in a direction parallel to each other, and the damping generated by a gas film in this situation is referred to as shear damping. Under the small-motion assumption, the flow-induced force is linearly proportional to the displacement and velocity of the moving plates. The coefficient of the velocity is the damping coefficient,  $c$ :

$$m \frac{d^2 \Delta x}{dt^2} + c \frac{d\Delta x}{dt} + k_x \Delta x = -m a_x \quad (24.6)$$

A single-axis dynamic model of an accelerometer is shown in Eq. (24.6). The solution to the differential equation demonstrates the fundamental resonant mode for the primary axis of motion shown in Eq. (24.6). More generally, inertial sensors have multiple on- and off-axis resonant modes to be controlled, but the resonance in the axis of sensitivity is the primary effect with the greatest impact on device operation. The magnitude of the resonance peak is determined by the magnitude of the damping coefficient,  $c$ . This is the major contributing factor in the stability of the system and demonstrates the trade-off between spring constant and seismic mass. Typically, the design intent is to push the resonant modes far beyond the typical frequencies of interest for operation. Too large a seismic mass or too low a device spring constant drops the magnitude of the fundamental resonant frequency and reduces the system margin for operation.

For a given inertial sensor design, the magnitude of the damping is impacted by the aspect ratio of the spaces surrounding the seismic mass, the packaged pressure and other internal material losses in the system. [Figure 24.4](#) shows how packaged pressure impacts the magnitude of the resonant peak for a surface micromachined lateral polysilicon accelerometer. By reducing the magnitude of the resonance

**FIGURE 24.4** Normalized mechanical response over frequency for a 3- $\mu\text{m}$ -thick lateral accelerometer capped at various pressures.

peak using squeeze-film damping at higher pressures, the motion of the seismic mass is brought under better control. In this case, for a given aspect ratio, increasing the pressure increases the damping coefficient,  $c$ , by approximately a factor of two. Alternatively, increasing the aspect ratio has a significant impact on the damping coefficient,  $c$ , for a given ambient pressure. In the case of high-pressure packaging, improving the aspect ratio of a design can minimize technology complexity by reducing the required packaging pressure to manageable and controllable values.

While the unit “N/m” (Newton per meter) for spring constant is well understood, the unit “kg/s” (kilogram per second) for damping coefficient is somewhat abstract, and it is often difficult to grasp its magnitude. Consequently, for a given mass-spring-dashpot oscillator, a nondimensional damping ratio,  $\xi$ , is often used in practice. An under-damped system corresponds to  $\xi < 1$ , a critically damped system corresponds to  $\xi = 1$ , and an over-damped system corresponds to  $\xi > 1$ . To correlate the dimensional damping,  $c$ , with the nondimensional damping,  $\xi$ , consider the following governing equation of motion for a forced simple harmonic oscillator:

$$m\ddot{x} + c\dot{x} + kx = f_0 \sin \omega t \quad (24.7)$$

where  $m$  is mass,  $c$  is damping coefficient, and  $k$  is spring constant. We then introduce a nondimensional damping,  $\xi$ , such that:

$$\xi = \frac{c}{2\sqrt{km}} \equiv \frac{c}{2m\omega_n} \quad (24.8)$$

where  $\omega_n = \sqrt{k/m}$  is the system’s natural frequency. With  $\xi$  and  $\omega_n$  defined, Eq. (24.7) can be written into a standard form of:

$$\ddot{x} + 2\xi\omega_n\dot{x} + \omega_n^2x = \frac{f_0}{m} \sin \omega t \quad (24.9)$$

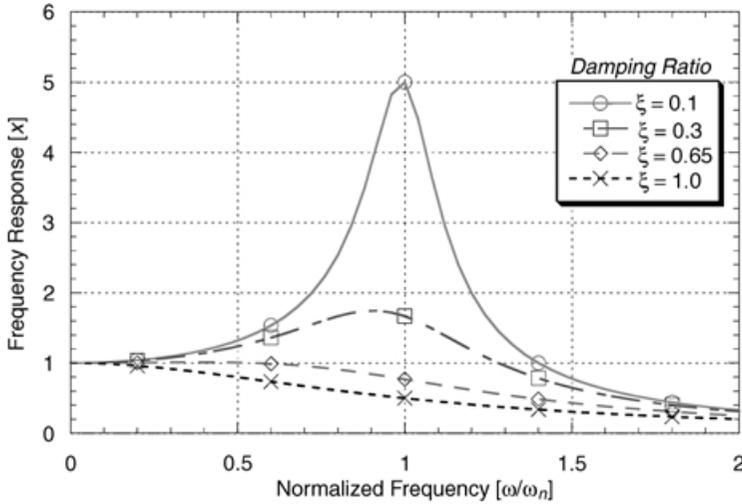

FIGURE 24.5 The frequency response  $\bar{x}$  vs. normalized frequency ratio  $\omega/\omega_n$ .

The steady-state solution to Eq. (24.9) is therefore:

$$x(t) = \frac{1}{\sqrt{\left[1 - \left(\frac{\omega}{\omega_n}\right)^2\right]^2 + \left[2\xi\frac{\omega}{\omega_n}\right]^2}} \times \frac{f_0}{k} \sin(\omega t - \phi) \equiv \bar{x} \sin(\omega t - \phi) \quad (24.10)$$

where  $\bar{x}$  is the amplitude of the response, and  $\phi$  is the phase difference. The damping ratio,  $\xi$ , has a large influence on the amplitude in the frequency region near resonance. For  $\frac{\omega}{\omega_n} \ll 1$ , the amplitude of response is simply the static displacement  $f_0/k$ . Near resonance, the amplitude of the response may be amplified greatly for small values of  $\xi$ . Although the critical damping condition of  $\xi = 1$  would eliminate the vibration altogether, the maximum flatness of the system response can be achieved at a damping of  $\xi = 0.65$ . This can be clearly seen in Figure 24.5.

Another terminology related to damping is the quality factor,  $Q$ . In forced vibration,  $Q$  is a measure of the sharpness of resonance. It is defined as a ratio of the system's natural frequency  $\omega_n$  over a bandwidth  $\omega_2 - \omega_1$ , where  $\omega_1$  and  $\omega_2$  are two frequencies at which the response,  $\bar{x}$ , is 0.707 of its peak value. Manipulating Eq. (24.10), it can be shown that, for small damping,

$$Q = \frac{\omega_n}{\omega_2 - \omega_1} = \frac{1}{\sqrt{1 + 2\xi} - \sqrt{1 - 2\xi}} \cong \frac{1}{2\xi} \quad (24.11)$$

Therefore, at low damping, the quality factor  $Q$  is approximately inversely proportional to damping  $\xi$ . A quality factor of 5 means a damping ratio of 0.1.

To eliminate resonance in a transducer, a damping of  $\xi > 0.65$  is required [Blech, 1983]. Both ambient pressure and the transducer structure influence the damping. To illustrate this, consider a sensing structure modeled for a 3- $\mu\text{m}$  polysilicon technology. The simulated damping at 1 atm is about 0.11. If a thicker sensing structure were used, the damping would increase approximately in a quadratic manner with thickness,  $t$ . At  $t = 10 \mu\text{m}$ , the damping ratio is 1.1, a factor of 10 increase. If the spring stiffness were kept at constant while increasing the thickness,  $t$ , the pace of damping increase would go up faster. At  $t = 10 \mu\text{m}$ , the damping is more than 2 and becomes over-damped.

If damping is too low in a micromachined lateral accelerometer, the severe degree of resonance of the accelerometer, upon an impact of external force, may produce a large signal that overloads the control

circuitry, resulting in system failure. High damping (near critical) is generally desired for accelerometers. As for yaw-rate gyroscopic sensors, on the other hand, low damping is required in order to achieve sufficient sensitivity of the system under a given driving force and for certain types of applications. Therefore, in designing a MEMS device, the consideration of damping must be taken into account at the earliest stage.

In general, the capping pressure for a micromachined system is below or much below the atmospheric pressure. As pressure decreases, the mean free path of the gas molecules (nitrogen for example) increases. When the mean free path is comparable to the air gap between two plates, one may no longer be able to treat the gas as a continuum. Therefore, an effective viscosity coefficient is introduced such that governing equations of motion for fluid at relatively high pressures can still be used to treat fluid motion at low pressures where the mean free path is comparable or even larger than the air gap of the plates.

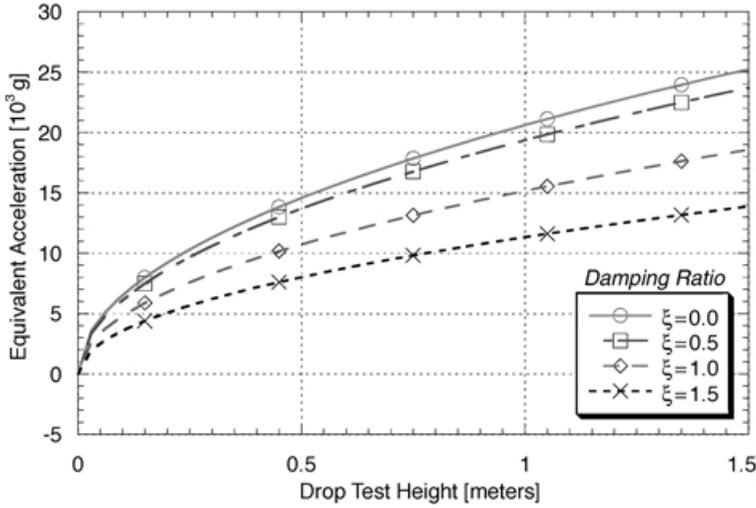

Based on earlier lubrication theory [Burgdorfer, 1959; Blech, 1983], Veijola et al. (1995, 1997, 1998) and Andrews et al. (1993, 1995) conducted extensive studies on squeeze-film damping. They showed that the viscous damping effect of the air film dominates at low frequencies or squeeze numbers, but the flow-induced spring becomes more prominent at high frequencies or squeeze numbers. For systems where only squeeze-film damping is present and for small plate oscillations, experimental studies [Andrews et al., 1993; Veijola and Ryhanen, 1995] for large, square, parallel plates are in general agreement with theory. In particular, the study carried out by Corman et al. (1997) is especially important for systems exposed to very low ambient pressures. For bulk micromachined resonator structures in silicon, they presented a squeeze-film damping comparison between theory and experiments for pressures as low as 0.1 mbar. The agreement between theory and experiment is considered to be reasonable. By employing the technique of Green's function solution, Darling et al. (1998) also conducted a theoretical study on squeeze-film damping for different boundary conditions. The resulting models are computationally compact and thus applicable for dynamic system simulation purposes. Additional studies by van Kampen and Wolffenbuttel (1998), Reuther et al. (1996) and Pan et al. (1998) also dealt with squeeze-film damping with an emphasis on numerical aspects of simulations. From these studies, one may get a comprehensive understanding of the micromachined systems and their dynamic behavior and gain insight on how to fine-tune the design parameters to achieve higher sensitivity and better overall performance.

It is also worth mentioning the experimental work by Kim et al. (1999) and Gudeman et al. (1998) on microelectromechanical systems (MEMS) damping. Kim and coworkers investigated the squeeze-film damping for a variety of perforated structures by varying the size and number of perforations. They found from finite element analysis that the model underestimated the squeeze-film damping by as much as 66% of the experimental values. Using a doubly supported MEMS ribbon of a grating light valve device, Gudeman and coworkers were able to characterize the damping by introducing a concept of "damping time." A simple linear relationship is found between the damping time of the ribbons and the gas viscosity when corrected for rarefaction effects.

All the above-mentioned literature is on squeeze-film damping for parallel plates oscillating in the normal direction. There are relatively few studies on shear damping in lateral accelerometers. A study by Cho et al. (1994) investigated viscous damping for laterally oscillating microstructures. It was found that Stokes-type fluid motion models viscous damping more accurately than Couette-type flow field. The theoretical damping was also compared with experimental data, and a discrepancy of about 20% still remains between theoretically estimated (from Stokes-type model) and measured damping.

### **24.4.3 Device Damping: Impact Dynamics**

Micromachined devices may demonstrate weaknesses not typically found in macroscopic sensor systems that occur during the system assembly of the micromachined inertial sensor with other electronic components. A common test to determine how robust a micromachined sensor is to system assembly is the drop test. When a packaged micromachined system is dropped from a tabletop to a hard-surface floor, both the package and the microstructure undergo sudden changes in their respective velocities. Assuming that there is no energy loss during the flight of the drop, both the package and the

**FIGURE 24.6** Calculation of the equivalent  $g$  load on an accelerometer due to an inelastic drop shock for several damping ratios. The device conditions are  $m = 0.6 \mu\text{g}$ ,  $k = 5 \text{ N/m}$ ,  $r = 0$ .

microstructure would have a downward velocity of  $v = \sqrt{2gh}$  immediately prior to impact. After impact, the package may be stuck to the ground or may bounce back with a smaller velocity. The motion of the package can be calculated by ignoring the influence of the microstructure, which is at least five orders of magnitude smaller than the mass of the package itself [Li and Shemansky, 2000]. The motion of the microstructure as a result of the impact is governed by a second order ordinary differential equation of a standard form, as in Eq. (24.9) [Meirovitch, 1975]. Equation (24.12) gives the maximum displacement:

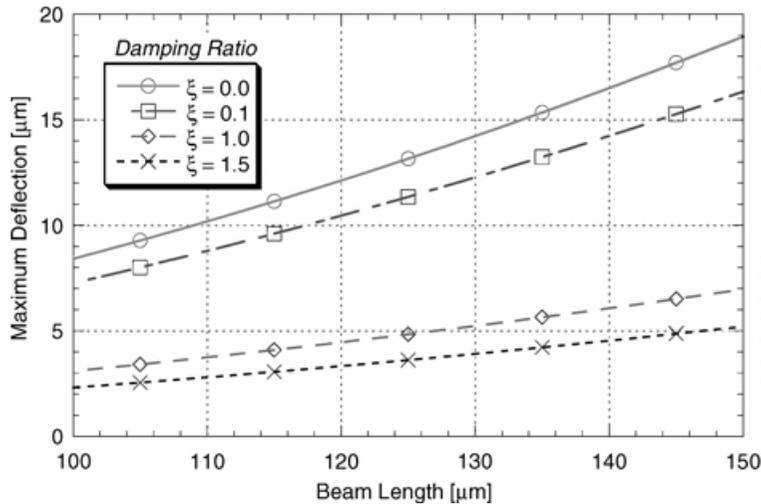

$$z_{\max} = \sqrt{\frac{2mgh}{k}} d_0(\xi, r), \quad (24.12)$$

where  $d_0(\xi, r)$  is a unit-less scaling function only of the damping ratio,  $\xi$ , and the elasticity of the collision as defined by a restitution coefficient,  $r$ , with  $0 \leq r \leq 1$  [Li and Shemansky, 2000]. Knowing the seismic-mass travel as a result of a mechanical drop, the equivalent  $g$  load on the structure can be determined in a similar fashion and is graphically shown in Figure 24.6 for a specific device application.

At a 1 m inelastic ( $r = 0$ ) drop, the impact experienced by the accelerometer is similar to a situation where it is subjected to an acceleration greater than 20,000  $g$ . At a damping ratio of 1.5 (over-damped), the equivalent acceleration is 14,000  $g$ . These values of acceleration would be doubled if the package impact with the floor is elastic ( $r = 1$ ). Nevertheless, it is clear that the drop-induced acceleration is large, much larger than one normally expects.

Analysis on a lumped mass and spring model helps to provide a picture regarding the magnitude of proof-mass travel and the large  $g$ -force induced by a drop. A MEMS structure, however, has distributed properties such as mass and stiffness. Therefore, it is sometimes necessary to carry the analysis one step further to take the flexibility of the micromachined structure into account. This is especially important for those lateral sensors and actuators of comb-type designs where the conductive movable component is large in lateral dimensions and is susceptible to bending. The maximum possible displacement in a spring-supported structure is the sum of the travel as a lumped mass and the bending caused by dropping.

A typical lateral accelerometer is basically comprised of an array of sensing and actuating electrodes, a central spine plate and multiple supporting springs. In such a design, both the movable and stationary sensing electrodes can be modeled as cantilevers such that when subjected to an acceleration, the fixed end follows the motion of the attachment and the free end deflects. As for the central spine plate, it can be modeled either as a hinged–hinged beam or a clamped–clamped beam, depending on the position of supporting springs.

**FIGURE 24.7** Calculation of the maximum beam displacement,  $z_{\max}$ , for a 2- $\mu\text{m}$ -thick cantilever beam with different damping ratios and lengths. (Adapted from Li, G.X., and Shemansky, F.A. (2000) *Sensors and Actuators A*, **85**, 280–286.)

The maximum displacement,  $z_{\max}$ , for a 2- $\mu\text{m}$ -thick polysilicon cantilever is graphically shown in Figure 24.7, where  $h = 1.2 \text{ m}$ ,  $E = 161,000 \text{ MPa}$ ,  $I = 4/3 \mu\text{m}^4$ , and  $r = 0.5$ . Assuming there is no damping, a 100- $\mu\text{m}$  cantilever would bend approximately 8.5  $\mu\text{m}$  near its free end, and the bending would be 19  $\mu\text{m}$  for a beam 150  $\mu\text{m}$  long. When damping is included, the beam deflection becomes smaller as indicated by the dashed and dotted curves in Figure 24.7. The damping ratio for a nominal lateral accelerometer of 2- $\mu\text{m}$ -thick polysilicon and 1.5- $\mu\text{m}$  finger gap is approximately 0.1. Therefore, depending on finger dimension, the drop-induced bending could be very excessive and cause structural damage.

#### 24.4.4 Mechanical to Electrical Transduction: The Sensing Method

Many viable approaches have been implemented to produce inertial sensors. The capability of any technology needs to be tempered by the cost and market focus required by the application. Many sensing methodologies have been successfully demonstrated for inertial sensors. Piezoresistive, resonant frequency modulation, capacitive, floating-gate field-effect transistor (FET) sensing, strain FET sensing and tunneling-based sensing will be discussed briefly below. Other variations continue to be demonstrated. A study of the materials used in micromachining can be found in Part II of this handbook. Detailed explanations of the electronic properties of materials utilized for sensing methodologies can be found in references such as *Semiconductor Physics: An Introduction* [Seeger, 1985] and others.

Piezoresistive sensing has been successfully demonstrated in bulk micromachined and single-crystal inertial sensors [Roylance and Angell, 1979; Partridge et al., 1998]. This sense method has been utilized for many years in pressure-sensor structures quite successfully, demonstrating very sensitive devices with marketable costs [Yoshii et al., 1997; Andersson et al., 1999]. This technique is sensitive to temperature variations but can be compensated electronically. Yoshii et al. (1997) and Ding et al. (1999) have demonstrated monolithic integration of circuitry with piezoresistive elements. Thermal sensitivity, junction noise and junction leakage are piezoresistive sensing issues that require compensation for highly sensitive systems.

Resonant frequency shifts in a structure caused by inertial forces has been applied to some of the most sensitive and highest performing inertial sensor products on the market today. Resonant-beam, tuning-fork-style inertial sensors are in production for many high-end applications. Zook et al. (1999) and others have demonstrated resonant systems providing a greater than 100-g full-scale range with milli-g resolution.

These techniques are sensitive to temperature and generally require sensitive and complex control circuitry to keep the transducers resonating at a controlled magnitude.

Of all the alternatives, capacitive sensing has the broadest application to current inertial sensor products. There are several reasons why capacitive sensing is enjoying broad interest. The methodology is inherently temperature insensitive, and appropriate precautions in transducer and circuit design result in nearly zero temperature coefficients of offset and sensitivity [Lee and Wise, 1981]. Scaling the method to suit different sensing ranges can be implemented by scaling the device capacitances to provide larger output signals for small inertial loads. The technique can be implemented in a wide variety of micro-mechanical process techniques ranging from bulk micromachining to surface micromachining [Hermann et al., 1995; Delapierre, 1999]. All axes of motion can be sensed capacitively. Complementary metal oxide semiconductor (CMOS) control circuitry is especially well suited to measure capacitances, leading to broader application of this technique being implemented with switched capacitor sense circuitry.

Kniffin et al. (1998) and others have demonstrated floating-gate FET structures to measure inertial forces. The technique allows a direct voltage transduction from the inertial force via a floating-gate FET structure. The technique is complicated, however, by the sensitivity of the air gap in such a structure to variations in work function and the difficulty in providing a stable bias condition for the FET device. Variations in packaged environment can result in quite large offsets in the response, which has made this methodology difficult to implement industrially.

The use of FET-based strain sensors has not been broadly studied for micromachined inertial sensors. Strain measurement in packaging development for large-scale CMOS circuits has been studied extensively [Jaeger et al., 1997] and has been extended to inertial sensing, providing direct voltage sensitivity to inertial forces as demonstrated by Haronian (1999). Concerns remain regarding the manufacturability and stability of a FET device at the base of a micromachined strain-gauge beam. However, this technique holds promise for direct integration of inertial sensing devices with CMOS.

Devices based on electron tunneling can provide extreme sensitivity to displacement. Because tunneling current is so strongly dependent on the space between the cathode and anode in the system, closed-loop operation is the most common configuration considered. Recent efforts to produce tunneling-based inertial sensors can be found in Rockstad et al. (1995), Wang et al. (1996) and Yeh and Najafi (1997). Significant challenges remain for this methodology. Drift and issues related to the long-term stability of the tunneling tip, as well as low-frequency noise sources remain [Grade et al., 1996]. As tunneling-based technologies expand in application, solutions will be found to mitigate the current limitations of the methodology.

## 24.5 Micromachining Technologies for Inertial Sensing

---

Coupled to the physical principle used to sense the inertial displacement is the micromachining technology implemented to produce the transducer device. Far more comprehensive details regarding these technological developments are described in Section II of this handbook. Bulk silicon micromachined technologies were first implemented for inertial sensors; however, polysilicon-based surface micromachined technologies dominate the current marketplace for micromachined inertial sensors. The trend for inertial sensors is to higher aspect ratio “surface” micromachined technologies.

Surface micromachined capacitive inertial sensors were broadly demonstrated commercially as a result of the collaboration between Analog Devices, Inc., and the University of California, Berkeley, in the introduction of the Analog Devices, Inc. iMEMS™ bipolar complementary metal oxide semiconductor (BiCMOS) integrated surface-micromachined accelerometer process technology, as shown in [Figure 24.1a](#), which embeds a 2- $\mu\text{m}$  micromechanical polysilicon layer into a BiCMOS process flow [Chau et al., 1996]. Sandia National Laboratories [Smith et al., 1995], Motorola Sensor Products Division [Ristic et al., 1992] and Siemens [Hierold et al., 1996] have all demonstrated industrial surface-micromachined inertial sensor technologies. Limitations to surface-micromachining are primarily related to its limitations in producing high-aspect-ratio structures that have demonstrated benefits for sensitivity, mechanical damping properties and insensitivity to off-axis motion.

Epitaxially deposited polysilicon eliminates the aspect-ratio limitations of standard low-pressure chemical vapor deposition (LPCVD) polysilicon deposition typically used in surface micromachining. This technology, sometimes referred to as “epipoly” technology, also allows the monolithic integration of CMOS or BiCMOS circuitry with higher aspect ratio capacitive transducers, typically on 10- to 12- $\mu\text{m}$ -thick epitaxial layers [Kirsten et al., 1995; Offenberget al., 1995; Geiger et al., 1999]. This technology has very few limitations. Epitaxial deposition of silicon is cost competitive for micromachining to thicknesses of 50  $\mu\text{m}$ . These high-aspect-ratio transducer structures are relatively insensitive to out-of-plane motion and provide suitable mechanical damping at reasonable packaging pressures. This material has been demonstrated to have desirable film properties with nearly immeasurable intrinsic stress and a high deposition rate [Gennissen and French, 1996].

With a reasonably flexible interconnect scheme, “epipoly” technologies have demonstrated monolithic integration with CMOS and BiCMOS circuitry as well as device thicknesses ranging from 8  $\mu\text{m}$  to over 50  $\mu\text{m}$ . The technology is not without challenges, however. Co-deposited epitaxial silicon and polycrystalline silicon have differing deposition rates complicating production. High-temperature polycrystalline films typical of epitaxial deposition also suffer from severe surface roughness and very large semiconical crystalline grains. Solutions to many of these issues have been documented by various sources [Kirsten et al., 1995; Gennissen and French, 1996].

Direct wafer bond (DWB) technology has long demonstrated the successful incorporation of thick capacitively or piezoresistively sensed inertial sensor structures. Recent advances in this technique have demonstrated improved device interconnect through the use of a silicon-on-insulator (SOI) handle wafer with defined interconnect [Ishihara et al., 1999]. Piezoresistive elements have also been incorporated on the sidewalls of very-high-aspect-ratio DWB structures to provide transducers with both piezoresistive and capacitive sensing mechanisms [Partridge et al., 1998]. DWB transducer technologies provide great process and device flexibility. Very-high-aspect-ratio structures are possible, approaching bulk-wafer thicknesses if necessary, providing excellent out-of-plane insensitivity and mechanical damping properties. Monolithic integration with CMOS is also possible. The technology requires significant process capability to successfully produce DWB structures at high yield.

As silicon-on-insulator microelectronic device technologies gain popularity for high-performance mainstream CMOS process technologies, the substrate material required for micromachining becomes cost competitive with alternative transducer technology approaches, making SOI more appealing for inertial sensing applications. SOI technology, as a descendant of DWB technology, provides technological flexibility with desirable device properties, including the out-of-plane insensitivity and high damping associated with high-aspect-ratio structures. SOI technology provides the advantage of single-crystal silicon sensor structures with very well-behaved mechanical properties and extraordinary flexibility for device thickness, as with DWB technologies. Thicknesses can range from submicron to hundreds of microns for structural layers. Unlike DWB, SOI technologies often lack the flexibility of pre-bond processing of the handle and active wafers to form microcavities or buried contact layers that are often implemented in DWB technologies. Another technology hurdle has been the choice of methodology to minimize parasitics to the handle wafer. Even so, SOI has demonstrated a significant increase in its popularity as a micromachining substrate [Delapierre, 1999; Lemkin et al., 1999; Park et al., 1999; McNie et al., 1999; Noworolski and Judy, 1999; Lehto, 1999; Usenko and Carr, 1999]. While technological hurdles still need to be overcome for broad industrialization of SOI MEMS devices, the technology holds great promise for a broad technological platform with few limitations. Lemkin et al. (1999) demonstrated the monolithic integration of SOI inertial sensors with CMOS.

MacDonald and Zhang (1993) at Cornell University developed a process known as SCREAM (single-crystal reactive etching and metallization) which produces SOI-like high-aspect-ratio single-crystal silicon transducers using a two-stage dry-etching technique on a bulk silicon substrate. This technology had been limited by the difficulty in electrically isolating the transducer structure from the surrounding substrate. Sridhar et al. (1999) demonstrated that this technology can now produce fully isolated high-aspect-ratio transducers in bulk silicon substrates. With fully isolated structures, this technology can produce 20:1-aspect-ratio devices for thicknesses to 50  $\mu\text{m}$  and can be monolithically integrated with

circuitry. Xie et al. (2000) have also demonstrated a related two-stage release methodology on capacitive inertial devices formed in a CMOS integrated technology. This technology shows promise for full integration of high-aspect-ratio lateral inertial structures with CMOS. Also, Haronian (1999) demonstrated an integrated FET readout for an inertial mass released using the SCREAM process.

The development of metal micromachined structures by electroforming has demonstrated 300- $\mu\text{m}$ -thick nickel structures with submicron gaps formed using LIGA (*Lithographie, Galvanoformung, Abformung*) techniques [Ehrfeld et al., 1987]. LIGA-like process techniques using reasonably high-resolution thick ultraviolet photoresist processes have resulted in inertial sensor development in nickel, permalloy and gold post-CMOS micromachining [Putty and Najafi, 1994; Wycisk et al., 1999]. Very thick structures are possible using these techniques with effective “buried” contacts to the underlying circuitry in the substrate. As a single-layer process addition, the technology adds minimal cost to the overall sensing system. High-aspect-ratio structures are possible. However, the material properties of electroformed materials are difficult to stabilize and can be prone to creep.

Traditionally a bulk micromachined technology, the application of deep anisotropic etching of (110)-oriented silicon wafers has produced novel inertial sensors with very high aspect ratios. Aspect ratios up to 200:1 have been demonstrated using this technique, although the practical application of the technology may limit the maximum aspect ratio to below 100:1 [Hölke and Henderson, 1999]. This technology allows an elegant solution that provides extremely high aspect ratios compared to anisotropic dry-etching techniques. The technology is somewhat limited in its application flexibility, as the deep trenches are crystallographically defined by the intersection of the (111) planes with the surface of the wafer and must be arranged in parallelograms in the etch mask. Circular and truly orthogonal structures are not easily configured for this technology.

## 24.6 Micromachining Technology Manufacturing Issues

---

The manufacturability of a transducer structure should be considered as important as the performance of the device. In theory, a sensor structure may be designed to be as sensitive as desired, but if the structure cannot be manufactured in a robust manner the effort is futile. Issues such as release or in-use stiction, stability of material properties and control of critical processes in the manufacture of inertial sensors should be investigated and understood. The impact of high-aspect-ratio technologies creates new challenges in controlling and maintaining processes.

### 24.6.1 Stiction

Stiction is a term used in micromachining to describe two conditions: release and in-use stiction. Release stiction is the irreversible latching of some part of the moveable structure in the device caused during the release etch and drying processes. In-use stiction is the irreversible latching of the moveable structure during device operation. All high-aspect-ratio technologies require a step to release the moveable structure from the supporting substrate or sidewalls at some point in the process flow. This process is not always, but most often is, a wet etch of a dielectric layer, often using a solution containing hydrofluoric acid and water. Release stiction typically occurs during the drying step following a wet solution process as the surface tension forces in the liquid draw the micromachined structure into intimate contact with adjacent surfaces. The close contact and typically hydrated surfaces result in van der Waals attraction along the smooth parallel surfaces, bonding the layers to each other [Mastrangelo and Hsu, 1993]. Too large a proof mass or too soft a spring may dramatically increase the probability of stiction, resulting in yield loss.

Many techniques are employed to reduce or eliminate release stiction. Supercritical  $\text{CO}_2$  drying processes avoid surface tension forces completely and often result in very good stiction yields. This technique has been difficult to implement in industrial process conditions. Surface modifications, often based on fluorinated polymer coatings, have been used to reduce surface tension forces on the micromachined

structure during release and drying with some success. As hydrophobic materials, these monolayer coatings require significant surface treatment and have not found broad industrial utilization yet. Other techniques have been employed with some success, all at the cost of additional process complexity and structural compromises. However, the problem with stiction yield loss is increased with aspect ratio because the surface tension forces act over a larger area. High-aspect-ratio structures must be designed with care to minimize the complications from release stiction.

In-use stiction issues are also increased with the aspect ratio of a device. For capacitive accelerometers, the proof mass closing in on an actuated electrode can cause electrostatic latching if the electrostatic force becomes larger than the elastic spring's restoring force. This condition is called pull-in or electrostatic latching and is design dependent. High-aspect-ratio designs result in more capacitive coupling force for a given device topography and can be more prone to latching. Many devices are designed with over-travel stops to reduce the risk from this compromising situation.

### **24.6.2 Material Stability**

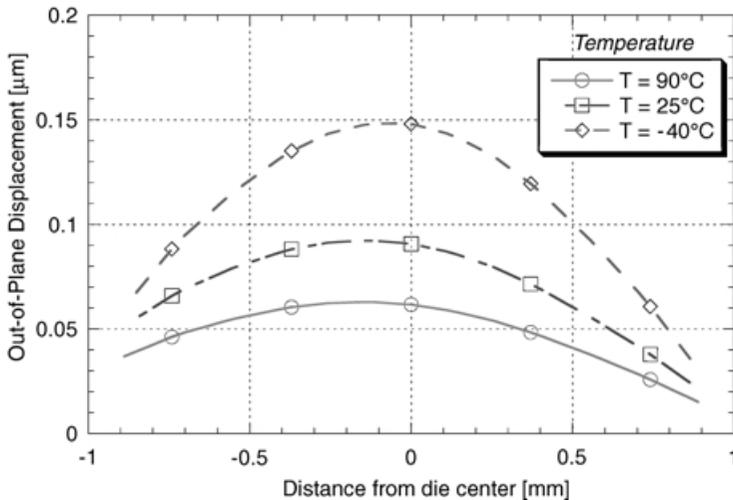

While providing design performance and off-axis stiffness, high-aspect-ratio devices remain sensitive to the stability of material properties. This is particularly important for polycrystalline silicon devices, as the deposition process can result in variations in the average intrinsic stress of a film as well as generate stress gradients throughout the sensor layer. However, all associated materials result in significant impacts on the device performance and repeatability. Stability and uniformity of backside film stacks, plasma-assisted deposited dielectric films and even the proximity of metallizations in the front-end process can impact the uniform and controlled behavior of a device.

### **24.6.3 High-Aspect-Ratio Etching**

High-aspect-ratio silicon based structures require high aspect ratio etching. In the case of (110) silicon technologies, this etch is a wet anisotropic etchant and uses crystallographic planes in the device material to control the profile of the trenches formed. Control of such processing requires accurate alignment of the etch mask to the crystallographic planes in order to successfully control the aspect ratio to a designed parameter [Hölke and Henderson, 1999]. The technique is also sensitive to impurities in the crystal. In most high-aspect-ratio technologies, however, a deep dry reactive ion etch (DRIE) of the trenches forms the structure. Deep trench etching has been implemented using various techniques, but an etch pioneered by Bosch [Laerme et al., 1999] has demonstrated a clear predominance in the field of alternatives. Control of the etch properties and profile is the challenge for high-aspect-ratio technologies. Many potential process conditions can degrade the etch profile or complicate the uniformity of the process for across-wafer and wafer-to-wafer variations in the process. These variations in profile and width strongly impact the design parameters such as spring constant and damping, etc.

### **24.6.4 Inertial Sensor Packaging**

Package interactions are just as critical as device technology choices and often contribute significant performance shifts from package to package [Li et al., 1998]. Micromachined inertial sensors, while robust on a microscale, are fragile at the assembly scale, are easily damaged, and often require two levels of packaging: (1) wafer level packaging, which is usually hermetic to provide damping control and to protect the MEMS devices from the subsequent assembly operations; and (2) conventional electronic packaging of die-bonding, wire-bonding and molding to provide a housing for handling, mounting and board-level interconnection. The package must fulfill several basic functions: (1) provide electrical connections and isolation, (2) dissipate heat through thermal conduction, and (3) provide mechanical support and isolate stress. An industrially relevant packaging process must be stable, robust and easily automated and must take testability into account.

**FIGURE 24.8** Die deformation due to a chip-packaging scheme, demonstrating the impact of packaging technologies on the industrialization of microelectromechanical systems. (Adapted from Li, G.X. et al. (1998) in *Proc. 3rd Int. Symp. on Electronic Package Technology (ISEPT '98)*, pp. 553–562.)

Wafer-level packaging techniques include silicon-to-glass anodic bonding [Dokmeci et al., 1997], thermocompression bonding using glass frit [Audet et al., 1997] or eutectic [Wolffenbuttel and Wise, 1994; Cheng et al., 2000], direct wafer bonding [Huff et al., 1991] and monolithic capping technologies [Burns et al., 1995] utilizing one or more wafers. These techniques allow the transducer device to be sealed at the wafer level to protect the movable components from damage during assembly. The wafer level package also provides the sensor with a controlled ambient to preserve the damping characteristics of the proof mass. Figure 24.1b shows a Motorola accelerometer die with a wafer-level cap in silicon to the right of the co-packaged CMOS control integrated circuit.

The unique challenge of sensor packaging is that in addition to providing a mounting foundation to a PC board, stresses induced by mismatch in the thermal expansion coefficients of the materials used to fabricate the package and the external thermal loading of the package must be controlled and kept at a level low enough to avoid impact to the sensor or to control circuitry performance. An example of this challenge is illustrated in Figure 24.8, where external package-induced stresses on an accelerometer die produced a 0.15- $\mu\text{m}$  curvature out of plane for the die from center to edge, resulting in a device offset that would not be present for the die in wafer form. For capacitive devices capable of resolving displacements at the nanometer or subnanometer scale, excessive curvature due to stress on the die at a late point in the assembly can be catastrophic. In general, different MEMS devices have different stress-tolerance levels. Therefore, each MEMS package must be uniquely designed and evaluated to meet special requirements [Dickerson and Ward, 1997; Tang et al., 1997].

## 24.7 System Issues for Inertial Sensors

The partitioning of the transduction and controlled output of an inertial sensing system has led to many variations on what an inertial sensor technology should look like. The coupling between the micromachined structure and the microsystem, including the method of control and the choice of interface electronics, is very close. A change in an aspect of one strongly impacts the requirements for the other. The motivations and potential for integration of the integrated circuit with the transducer and the impact of the control circuit architecture on the overall system reveal the many system design trade-offs required to produce a complete inertial sensing system.

### 24.7.1 System Partitioning: One-Chip or Multi-Chip

The sense methodologies and transducer technologies discussed above have all been demonstrated as both multicomponent and monolithically integrated systems. One-chip vs. package-level multichip integration of transducer and circuitry has generated many passionate discussions regarding the viability of each approach and motivations to choose one over the other. System cost and system capability are the two primary motivations for the choice to monolithically integrate or to co-package components and have been used as justification to pursue both types of integration.

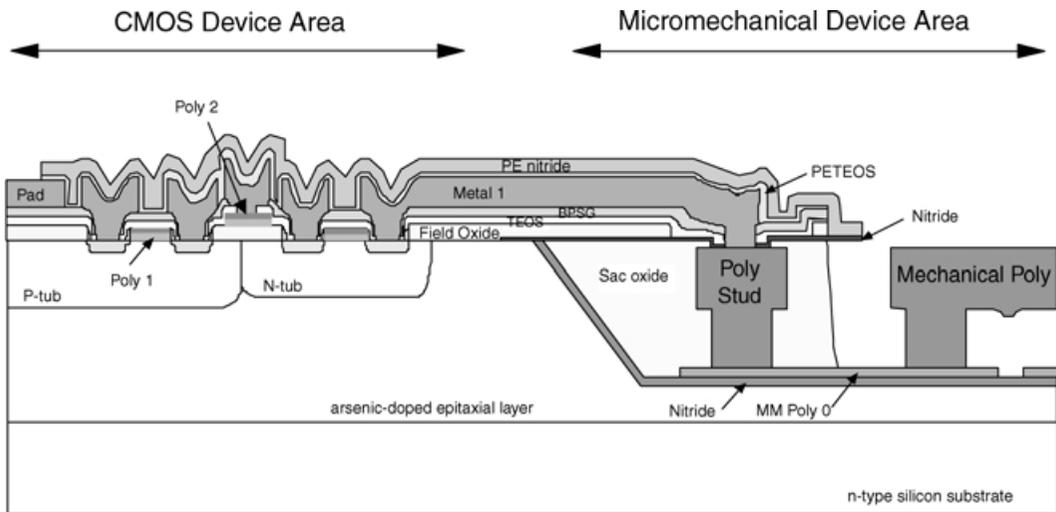

Silicon die area utilization, process complexity, wafer-scale testing requirements and packaging costs all significantly contribute to the overall production costs for any sensor system. Some multicomponent systems have mitigated process complexity by isolating transducer and integrated circuit processes and co-packaging the unique system pieces. System requirements have been met by this multichip methodology. Front-end silicon process complexity and cost have been traded for back-end testing and packaging costs, which make up a large fraction of the overall product costs. There is no clear application boundary for multichip system partitioning compared to single-chip integration. Industrialized sensor products have demonstrated two-chip solutions implemented successfully for even the most complex and demanding system requirements in military and aerospace applications [Delapierre, 1999].

Monolithically integrated transducer technologies have advantages in approaching the fundamental sensing performance limitations for many applications by mitigating inter-chip parasitics associated with multichip integration. Trade-offs in system costs are moving toward the incorporation of additional front-end complexity to design for testability and mitigate back-end testing and packaging costs. An additional benefit to monolithic integration of transducer and circuitry is the minimization of silicon die area. Die area may become *the* driving motivation to develop monolithic integration for future sensor applications. The drive to smaller outline package surface mount technologies also requires a smaller silicon footprint in the package, again driving toward integration.

There are significant reasons to consider monolithic integration of transducer technologies with circuitry for system performance and system cost. Each application should be reviewed carefully to provide system requirements with the least expensive high-performance technology. With future applications demanding greater performance in an increasingly small package, considering integratable transducer technologies for future technology applications is prudent. In monolithically integrated technology, the method of integration defines the manufacturability, process cost, testability and ability to integrate the technology. This decision includes both the integration method and the choice of integrated circuit technology and should fully address the system requirements.

### 24.7.2 Sensor Integration Approaches

Three methodologies classify the integration of a micromachined element into an integrated circuit process: transducer first, transducer middle or interleaved and transducer last integrations. All have demonstrated monolithically integrated inertial sensor technologies. All have noted strengths and weaknesses. The *transducer first* integration incorporates the transducer element processing prior to the integrated circuit fabrication. A notable example of a transducer first integration is the buried transducer process, now known as Sandia's integrated microelectromechanical systems technology, or IMEMS, demonstrated by Smith et al. (1995) at Sandia National Laboratories. The transducer is formed in a recessed region in the field of the wafer and sealed in a stack of dielectric films prior to the beginning of a CMOS process flow. This dielectrically sealed moat is planarized using chemical mechanical polishing (CMP) prior to the start of the CMOS flow with electrical interconnections formed as part of the CMOS process, with the transducer released as a final step in the process flow. A cross-sectional diagram is shown in [Figure 24.9](#). The benefit of this approach is that the transducer is largely decoupled from the remainder of the integrated circuit process and can be transported between integrated circuit processes. This allows the use of standard integrated circuit process steps, with minimal impact to the integrated circuit processing steps and only limited impact on thermal budget, allowing optimization of the transducer without impact on the standard integrated circuit process. The challenge of this versatile approach

**FIGURE 24.9** Cross-sectional diagram of the IMEMS process developed at Sandia National Laboratories demonstrating the transducer formed in a recessed moat and sealed prior to the high-density CMOS process commencing. (Photograph courtesy of Sandia National Laboratories.)

lies in the fact that all of the integrated circuit processing steps are still ahead, increasing the risk of contamination.

The *transducer middle* integration merges the process that created the transducer element into the standard integrated circuit process by reusing and minimally adjusting and inserting processing steps for the formation of the transducer. A well-known example of this technique is the Analog Devices iMEMS™ process [Chau et al., 1996]. This technology merges a 2- $\mu\text{m}$ -thick micromechanical polysilicon layer for the transducer with a high-density mixed-signal BiCMOS process technology, interleaving the transducer process with the integrated circuit flow. An example of this technology is shown in Figure 24.1a. The benefit of this approach lies in the reuse of existing integrated circuit process steps used in the creation of the transducer, which has the potential to minimize the number of additional process steps required to implement this approach. The risk for this approach lies in its specialization. Because the transducer is merged into an integrated circuit process, a unique process flow is generated for the specific system. A merged process will impact the integrated circuit device parameters as well as the transducer parameters. The reuse of existing process steps complicates the optimization of the transducer as well as the integrated circuit.

The *transducer last* integration merges the process of the transducer with the standard integrated circuit process by inserting the transducer formation at the end of the integrated circuit processing steps. This integration can take on many forms, including the approach taken by Xie et al. (2000) which uses layers and structures formed during the CMOS process to define post-processed regions for subsequent deep reactive ion etching of high-aspect-ratio structures, or that of Franke et al. (2000) or of Honer and Kovacs (2000) using low-temperature post-processing of structural layers to integrate micromechanical structures with circuitry. The benefit of this approach lies in the reuse of a minimal set of existing integrated circuit back-end processing steps used in the creation of the transducer, thereby having the potential to minimize the number of additional process steps required to implement this approach. Because the transducer is formed after the completion of all the standard integrated circuit device formation steps, the impact on integrated circuit device parameters is defined primarily by exposure of the circuitry to the maximum temperature of film deposition or the plasma processing required to form the transducer. In addition, there is some measure of transportability of the transducer process between existing integrated circuit platforms. The difficulty with this approach lies in the potential complexity of the integration approach and its impact on the isolation and interconnect aspects of the transducer. Because the

integrated circuit processing has been completed before formation of the transducer, the patterning of the transducer around the existing interconnect scheme becomes difficult, and the release etch in the absence of an adequate etch stop can be a real challenge. Solutions to that challenge have been proposed through dry release [Xie et al., 2000] or CMOS-benign release in hydrogen peroxide [Franke et al., 2000]. While transportability between different integrated circuit platforms is possible, a degree of optimization is required, which will be specific to the platform used.

The introduction of monolithically integrated inertial sensor technologies requires clever system design to understand the impact of the device behavior in the system. Improvements in test methodology and the potential to isolate transducer and integrated circuit behavior is required. In particular, suitable calibration of self-test forces and the decoupling of drive and sense responses are even more important for the active transducers required for rotational inertia sensing.

### 24.7.3 System Methodologies: Open- or Closed-Loop Control

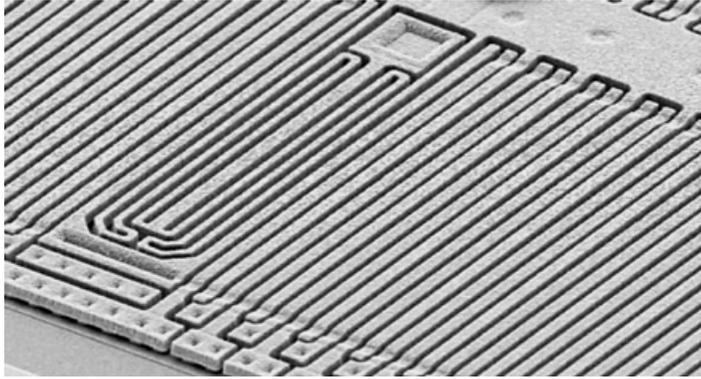

Sensing methodologies utilized in inertial sensing generally fall under two categories: open-loop or closed-loop control architectures. The chapters by Goodwine and Bewley consider these concepts in greater detail. Suffice it to say that there are motivations to pursue both open-loop and closed-loop force-feedback control for inertial sensing systems. Open-loop control systems measure changes in the sense signal, whether it be a change in piezoresistance or capacitance or other change, as a result of the inertial load displacing the seismic mass from its zero state position. These signals are typically amplified, compensated, filtered, buffered and output as control variables either as analog voltages or digital control signals to the larger system. Open-loop control schemes tend to be relatively immune to small production variations in the transducer element, are inherently stable systems relying on no feedback signals, provide ratiometric output signals and, possibly most importantly, are often smaller in die area than their closed-loop counterparts.

Closed-loop control schemes rely on feedback to control the position of the seismic mass via a force feedback, or force rebalancing, at its rest position. The force feedback required is proportional to the magnitude of the inertial load. The potential for this methodology is great. This force feedback defines the sensitivity of the system and acts as an electrostatic spring force, which is added in Eq. (24.5). It also contributes to Eq. (24.6), impacting the dynamic behavior of the system and modifying the damping conditions. The most prevalent system configuration utilizing force rebalancing is in capacitive inertial devices. A notable example of an inertial sensing system utilizing force rebalancing is the Analog Devices ADXL50, which is a lateral 50-g accelerometer product as described in Goodenough (1991) and Sherman et al. (1992). Closed-loop force feedback systems have the potential for very high sensitivity and have been implemented in gyroscopic systems due to the minute forces and displacements generated by the Coriolis effect [Putty and Najafi, 1994; Greiff and Boxenhorn, 1995].

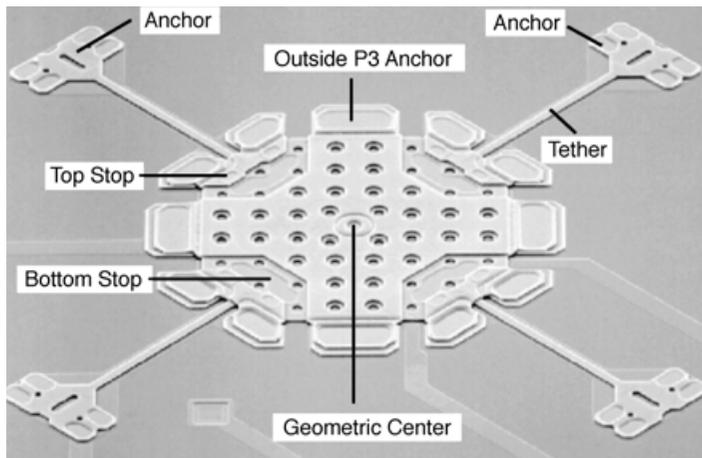

### 24.7.4 System Example: Motorola Two-Chip *x*-Axis Accelerometer System

Motorola's 40-g *x*-lateral accelerometer can be used as an example of a high-volume product that will demonstrate the design trade-offs and broad classes of issues required to produce inertial sensors. The packaged system, as shown in perspective in [Figure 24.1b](#) on a lead frame prior to final assembly, is comprised of a two-chip copackaged system in a dual in-line plastic package. The sensor die, capped with a hermetically sealed silicon cap, is wire-bonded to the adjacent integrated circuit control die. Low-stress adhesive and coating materials are used to minimize mechanical coupling of the sensor die to the metal lead frame and the plastic injection molding materials and to minimize system offsets.

The transducer, a portion of which is shown in a perspective-view scanning electron microscopy (SEM) image in [Figure 24.10](#), is produced using surface micromachining in polysilicon to form a suspended polysilicon, lateral, double-sided capacitive structure. The central proof-mass plate is configured to produce an over-damped *z*-axis response at a given capping pressure. The *x*-axis damping is defined by the aspect ratio between the suspended sense electrodes and the fixed capacitor plates forming the lateral

**FIGURE 24.10** SEM perspective view of a portion of an x-axis capacitive accelerometer in polysilicon. (Photograph courtesy of Motorola, Inc.)

**FIGURE 24.11** SEM perspective view of a z-axis capacitive accelerometer in a three-level polysilicon process. (Photograph courtesy of Motorola, Inc.)

capacitive structure. The folded-beam spring design, the anchor of which is at the top center of [Figure 24.10](#), minimizes coupling to external mechanical strains on the chip, controls the  $x$ -axis spring constant to the designed parameter, maximizes the  $y$ -axis spring constants to minimize off-axis coupling and provides the electrical connection to the center electrode for the lateral capacitive measurement. The  $z$ -axis motion in this device is constrained by a series of motion limiters, limiting the out-of-plane motion to a designed tolerance. The double-sided capacitor structure is formed by the definition of a plurality of adjacent left and right electrodes to the electrodes formed on the proof mass in a configuration often described as a capacitive “comb” structure. This comb structure, through the multiplication of the small capacitive coupling in each left, center and right set of electrodes provides sufficient capacitive coupling to suitably sense the inertial deflection of the proof mass center electrode with respect to the left and right differential electrodes.

This device demonstrates a clear system partitioning. Minimizing process complexity, the two-chip approach allows the potential maximization of process capability for both sensor and control circuitry for the given application. Alternatively, fabrication process and assembly costs can be minimized for the performance required by the application by isolating the micromechanical and circuit elements. This technique has been implemented in many other accelerometer and gyroscopic systems over the past decade. [Figure 24.11](#) shows a Motorola 40-g  $z$ -axis accelerometer implemented in a two-chip system

configuration similar to the  $x$ -lateral accelerometer as described in Ristic et al. (1992). Other inertial sensor systems have been demonstrated as two-chip approaches with vastly different system requirements [Greiff et al., 1991; Yazde and Najafi, 1997; Ayazi and Najafi, 1998; Hiller et al., 1998; Delapierre, 1999].

Two-chip methodologies do have some limitations. Inter-chip parasitic capacitances pre-load the control circuitry with a nonsensitive capacitance, requiring the control system to discriminate small capacitance changes in a total capacitance several times as large as the capacitance of the accelerometer device alone. This inter-chip parasitic capacitance can be on the order of two to five times the transducer nominal capacitance, requiring clever circuit techniques to minimize the impact of the parasitic coupling. Other capacitive sensor systems have implemented single-chip integration to eliminate the inter-chip parasitic coupling at the expense of increased process complexity.

## 24.8 Rotational Gyroscopes: Specific Design Considerations

Unlike an accelerometer, the transducer of a yaw-rate sensor needs to be driven into oscillation in order to function as a sensor. This requirement comes from the coupling of vibratory motion by the Coriolis effect to produce a positional shift sufficient for sensing. This requirement adds both transducer and circuit complexity to the system. Upon a rotation of the transducer about its sense axis, a Coriolis force is generated in the presence of a rotational velocity of the reference frame, which in turn drives the transducer structure orthogonally, as given in Eq. (24.4). The scalar governing equation of motion for a gyroscopic device with a resonating mass in the  $y$ -axis, rotated about the  $z$ -axis is given by:

$$\frac{d^2x}{dt^2} + 2\xi\omega_n \frac{dx}{dt} + \omega_n^2 x = 2\Omega_z \frac{dy}{dt} \quad (24.13)$$

where  $\Omega_z$  is the rate of rotation and  $y$  is linear velocity of the structure due to the drive. One may make the analogy that a yaw-rate sensor is acting just like an accelerometer if the Coriolis term ( $2\Omega_z dy/dt$ ) is considered as an acceleration. According to a typical automotive spec where the full range of angular velocity is 100 deg/s, then an equivalent acceleration,  $a$ , is given by:

$$a = 3.5 \frac{dy}{dt} \quad (24.14)$$

In general, the driving frequency is near resonance and the vibration amplitude of the transducer structure is about 1  $\mu\text{m}$ . Assuming a natural frequency of 10 kHz, the resulting Coriolis acceleration of Eq. (24.14) is

$$a = 0.022 \text{ mg} \quad (24.15)$$

demonstrating that this Coriolis-force-induced acceleration is very small.

For most applications, a single-axis angular rotation measurement is required. Such a single axis rate sensor can be built by sensing induced displacement from an oscillating rotor or from a linearly oscillating structure. Although these two types of rate sensor designs appear to be very different, the operation principles are the same. In both cases, when the reference frame, or device substrate, experiences a rotation along the input axis, the oscillating mass, either translational or rotary, in a direction perpendicular to the input axis (referred to as the drive axis) would induce a Coriolis force or torque in a direction perpendicular to both the input axis and the drive axis. With the amplitude of the drive oscillation fixed and controlled, the amplitude of the sensing oscillation is proportional to the rate of rotation of the mounting foundation.

Because the coupling of the Coriolis effect is orthogonal to the vibratory motion in a micromachined gyroscopic device, two degrees of mechanical freedom are required. One degree of freedom is utilized for the excitation of the vibratory motion, and the second degree of freedom orthogonal to the first is required for sensing. This requirement couples tightly into the technology choice for gyroscopic inertial sensors, as the axis of sensitivity defines which mechanical degrees of freedom are required to sense it. For example, a very thick high-aspect-ratio technology such as is possible with direct-wafer-bonded structures might not be the most suitable technology for a device required to move out of the plane of the wafer. However, as with accelerometers, most technologies and sensing methodologies have been applied to vibratory gyroscopes with new combinations of methodologies always under consideration.

Putty and Najafi (1994) provide a discussion of the varieties of vibrating gyroscopes, including vibrating prismatic beams [Greiff et al., 1991], tuning fork designs [Voss et al., 1997; Hiller et al., 1998], coupled accelerometers [Lutz et al., 1997; Kobayashi et al., 1999; Park et al., 1999] and vibrating shells [Putty and Najafi, 1994; McNie et al., 1999]. Multiple-axis systems have also been demonstrated [Juneau et al., 1997; Fujita et al., 1997]. In all cases, the vibrating structure is displaced orthogonal to the direction of the vibrating motion. This configuration can lead to system errors related to the transducer structure and the electronics. The primary error related to the transducer is called quadrature error.

### **24.8.1 System Considerations: Quadrature Error and Coupled Sensitivity**

Most of the earlier gyro sensor designs involve a single proof mass for both driving and sensing. The proof mass is supported by a set of multiple slender beam linkages, usually made of the same semiconductor materials as the proof mass, to allow for movement in two mutually perpendicular axes. A major drawback in a single proof-mass design is the cross-axis coupling between the drive axis and the sense axis, a phenomenon commonly referred to as quadrature error. This coupling can be attributed to defects or small nonorthogonalities in the mechanical structure. Because the sense displacement is a minute fraction of the typical drive displacement, small structural defects can generate large quadrature errors in the system. Quadrature is compensated by enhanced structural design, as will be demonstrated in the examples below, as well as through the generation of quadrature-canceling force feedback of position in the control electronics [Geen, 1998]. Fortunately, the quadrature error coupled from the drive vibration is 90 degrees out of phase with respect to Coriolis-induced vibration and can be phase-discriminated to a large degree in the control circuitry at the expense of additional control circuit complexity. However, the continued increasing complexity in the structural design in modern micromachined gyroscopes indicates that quadrature error cancellation cannot be completely resolved by the control circuit.

The sensitivity requirements for gyroscopes far exceed those for most accelerometer systems, both in terms of the transducer design and the circuit complexity. In vibrational gyroscopic systems, structural sensitivity and absolute stability in the control electronics are required to accurately measure rotational rate. Because the magnitude of the driven vibration is directly proportional to the magnitude of the Coriolis-induced output displacement, the structure and electronics are designed to maximize the coupling and stability of the magnitude. Structurally, the driven oscillations can have large displacements, on the order of microns or tens of microns in some cases. The devices are also commonly operated in a near-vacuum environment to minimize the impact of mechanical damping on the structure to maximize the resonant response of the system. Electronically, precise control of the driven vibration amplitude is paramount. Phase discriminating circuitry such as phase-locked loop (PLL) control is used to drive the device displacement at or near resonance to maximize the displacement while precise amplitude control is maintained. Phase discrimination and synchronous phase demodulators are also required to sense the Coriolis force displacement and cancel quadrature effects [Geen, 1998; Kobayashi et al., 1999]. As with accelerometer systems, the sense circuitry can be operated in open-loop or closed-loop force-feedback configurations to sense displacement with the system trade-offs discussed in the preceding section.

## 24.8.2 System Examples: Vibratory Ring Gyroscopes and Coupled Mass Gyroscopes

As an example, a study by Ayazi and Najafi (1998) presented a detailed analysis of the design and scaling limits of vibrating ring gyroscopes and their implementation using a combined bulk and surface micro-machining technology. A high-aspect-ratio p++/polysilicon trench and refill fabrication technology was used to realize the 30- to 40- $\mu\text{m}$ -thick polysilicon ring structure with 0.9- $\mu\text{m}$  ring-to-electrode gap spacing. The theoretical analysis of the ring gyroscope shows that several orders of magnitude improvement in performance can be achieved through materials development and design. By taking advantage of the high-quality factor of polysilicon, submicron ring-to-electrode gap spacing, the high-aspect-ratio polysilicon ring structure produced using deep dry etching, and the all-silicon feature of this technology, tactical-grade vibrating ring gyroscopes with a random walk as small as 0.05  $\text{deg}/\sqrt{\text{Hz}}$  were realized. Ayazi et al. (2000) enhanced this technology with an even higher aspect ratio 60- $\mu\text{m}$ -thick ring. This device demonstrated a random walk of 0.04  $\text{deg}/\sqrt{\text{Hz}}$  with a theoretical Brownian noise floor of 0.01  $\text{deg}/\sqrt{\text{Hz}}$ .

As an alternative to single proof-mass gyroscope designs, a design concept involving two coupled oscillating masses has emerged, one mass for driving and one mass for sensing. One of the first such designs was documented by Hsu et al. (1999), who have used an outer ring as the drive mass and an inner disk as the sense mass. The driving mass is actuated by a set of rotary comb structures and is oscillating about the  $z$ -axis (or the vertical axis). The sensing disk is anchored to the substrate in such a way that the stiffness about the  $z$ -axis is significantly greater than the stiffness about the other axes. The outer ring and the inner disk are connected by a set of flexible beams or linkages. When there is no input of angular rotation, the oscillation of the drive mass about the  $z$ -axis has virtually no impact on the motion of the sense disk. When the device experiences a rotation about either the  $x$ - or  $y$ -axis, the Coriolis-force-induced torque drives the inner disk into a rock motion about the  $y$ - or  $x$ -axis. Electrode pads underneath the disk measure the variation of capacitance, which is proportional to the input angular rate. Another advantage of this two-mass design is that the dual proof-mass structure permits the ring and the disk to be excited independently so that each can be dynamically compensated for manufacturing nonuniformity.

Several other vibrational gyroscopes have been demonstrated that also involving two mutually perpendicular oscillating masses [Kobayashi et al., 1999; Park et al., 1999]. In these designs, the drive mass is forced to oscillate along the  $y$ -axis by comb actuators and the sense mass is forced to oscillate along the  $x$ -axis by a Coriolis force. The magnitude of this Coriolis force is proportional to the input angular rate along the  $z$ -axis. The angular rate of rotation is measured by detecting changes in capacitance with interdigitated comb structures attached to the sense mass. The linkage between the drive and sense masses is designed in such a way that the Coriolis force is transferred from the drive mass to the sense mass in an efficient way and yet the feedback from the motion of the sense mass to the drive mass is kept to a minimum by frequency matching.

## 24.9 Concluding Remarks

---

Inertial sensors, both accelerometers and rotational gyroscopes, have seen broad commercial and industrial application of micromachining technologies driving system cost, size and performance. Many of the early automotive applications, driven initially by cost and package size with modest performance requirements, resulted in a niche-product field in which micromachined accelerometers could successfully compete with macroscopic competitors. As the technology field has matured and broadened, increasing performance expectations of what could now be considered *traditional* micromachined product areas (such as front-airbag crash sensing and future utilization of distributed sensor systems in automobiles for such systems as stability control, ride control, future-generation occupant safety systems, rollover and a cadre of potential new applications) will push the technology frontiers much further. Not only will micromachined inertial sensors continue to produce the low-cost, small-size parts as they have done so

successfully, but they will also have to demonstrate significant system performance gains while maintaining modest costs and packages in order to continue to flourish.

Pressure sensors represent one of the greatest successes of micromachining technology. They have benefited from developments in this field for about four decades, in which time both commercially available and research-oriented devices have been developed for a variety of automotive, biomedical and industrial applications. Automotive applications include pressure sensors for engine manifolds, fuel lines, exhaust gases, tires, seats and other uses. Biomedical applications that have been proposed or developed include implantable devices for measuring ocular, cranial or bowel pressure and devices built into catheters that can assist in procedures such as angioplasty. Many industrial applications related to monitoring manufacturing processes exist. In the semiconductor sector, for example, process steps such as plasma etching or deposition and chemical vapor deposition are very sensitive to operating pressures.

In the long history of the use of micromachining technology for pressure sensors, device designs have evolved as the technology has progressed, allowing pressure sensors to serve as a technology demonstration vehicle in some sense [Wise, 1994]. A number of sensing approaches that offer different relative merits have evolved, and there has been a steady march toward improving performance parameters such as sensitivity, resolution and dynamic range. Although multiple options exist, silicon has been a popular choice for the structural material of micromachined pressure sensors partly because its material properties are adequate and partly because significant manufacturing capacity and know-how can be borrowed from the integrated circuit industry. The primary focus in this chapter is on schemes that use silicon as the structural material. The chapter is divided into four sections. The first section introduces structural and performance concepts that are common to a number of micromachined pressure sensors. The second and third sections focus in some detail on piezoresistive and capacitive pick-off schemes for detecting pressure. These two schemes form the basis of the vast majority of micromachined pressure sensors available commercially and studied by the microelectromechanical systems (MEMS) research community. Fabrication, packaging and calibration issues related to these devices are also addressed in these sections. The fourth section concludes with a survey of alternative approaches that may be suitable for selected applications. It includes a few schemes that have been explored with nonmicromachined apparatus but may be suitable for miniaturization in the future.

## 25.1 Device Structure and Performance Measures

The essential feature of most micromachined pressure sensors is an edge-supported diaphragm that deflects in response to a transverse pressure differential across it. This deformation is typically detected by measuring the stresses that it produces in the diaphragm or by measuring the displacement of the diaphragm. An example of the former approach is the piezoresistive pick-off, in which resistors are formed at specific locations of the diaphragm to measure the stress; an example of the latter approach is the capacitive pick-off, in which an electrode is located on a substrate some distance below the diaphragm to capacitively measure its displacement. The choice of silicon as a structural material is amenable to both approaches because it has a relatively large piezoresistive coefficient and because it can serve as an electrode for a capacitor as well.

The deflection of a diaphragm and the stresses associated with it can be calculated analytically in many cases. It is generally worthwhile to make some simplifying assumptions regarding the dimensions and boundary conditions. A commonly made assumption is that, although the edges of the diaphragm are rigidly affixed (built-in) to the support around its perimeter, they are approximated as being simply supported. It is a reasonable approximation if the thickness of the diaphragm,  $h$ , is much smaller than its radius,  $a$ . This condition prevents transverse displacement of the neutral surface at the perimeter, while allowing rotational and longitudinal displacement. Mathematically, it permits the second derivative of the deflection to be zero at the edge of the diaphragm. Under this assumption, the stress on the lower surface of a circular diaphragm can be expressed in polar coordinates by [Timoshenko and Woinowsky-Krieger, 1959; Samaun et al., 1973; Middleoek and Audet, 1994]:

$$\sigma_r = \frac{3 \cdot \Delta P}{8h^2} [a^2(1 + \nu) - r^2(3 + \nu)] \quad (25.1)$$

$$\sigma_t = \frac{3 \cdot \Delta P}{8h^2} [a^2(1 + \nu) - r^2(1 + 3\nu)] \quad (25.2)$$

where Eq. (25.1) denotes the radial component and Eq. (25.2) the tangential component,  $a$  and  $h$  are the radius and thickness of the diaphragm,  $r$  is the radial coordinate,  $\Delta P$  is the pressure applied to the upper surface of the diaphragm, and  $\nu$  is Poisson's ratio (Figure 25.1). In the (100) plane of silicon, Poisson's ratio shows fourfold symmetry and varies from 0.066 in the (011) direction to 0.28 in the (001) direction [Evans and Evans, 1965; Madou, 1997]. These equations indicate that both components of stress vary from the same tensile maximum at the center of the diaphragm to different compressive maxima at its periphery. Both components are zero at separate values of  $r$  between zero and  $a$ . In general, piezoresistors located at the points of highest compressive and tensile stress will provide the largest responses. The deflection of a circular diaphragm under the stated assumptions is given by:

$$d = \frac{3 \cdot \Delta P (1 - \nu^2) (a^2 - r^2)^2}{16 E h^3} \quad (25.3)$$

where  $E$  is the Young's modulus of the structural material. Like Poisson's ratio, the Young's modulus for silicon shows fourfold symmetry in the (100) plane, varying from 168 GPa in the (011) direction to 129.5 GPa

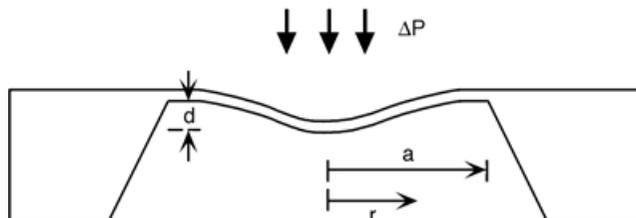

FIGURE 25.1 Deflection of a diaphragm under applied pressure.

in the (100) direction [Greenwood, 1988; Madou, 1997]. When polycrystalline silicon (polysilicon) is used as the structural material, the composite effect of grains of varying size and crystalline orientation can cause substantial variations. It is important to note that additional variations in mechanical properties may arise from crystal defects caused by doping and other disruptions of the lattice. Equation (25.3) indicates that the maximum deflection of a diaphragm is at its center, which comes as no surprise. More importantly, it is dependent on the radius to the third power and on the thickness to the fourth power, making it extremely sensitive to inadvertent variations in these dimensions. This can be of some consequence in controlling the sensitivity of capacitive pressure sensors.

It should be noted that the analysis presented here assumes that the residual stress in the diaphragm is negligibly small. Although mathematically convenient, this is often not the case. In reality, a tensile stress of 5 to 50 MPa is not uncommon. This may significantly reduce the sensitivity of certain designs, particularly if the diaphragm is very thin.

Pressure sensors are typically divided into three categories: absolute, gauge and differential (relative) pressure sensors. Absolute pressure sensors provide an output referenced to vacuum and often accomplish this by vacuum sealing a cavity underneath the diaphragm. The output of a gauge pressure sensor is referenced to atmospheric pressure. A differential pressure sensor compares the pressure at two input ports, which typically transfer the pressure to different sides of the diaphragm.

A number of different units are used to denote pressure, which can lead to some confusion when comparing performance ratings. One atmosphere of pressure is equivalent to 14.696 pounds per square inch (psi), 101.33 kPa, 1.0133 bar (or centimeters of H<sub>2</sub>O at 4°C), or 760 Torr (or millimeters of Hg at 0°C).

The performance criteria of primary interest in pressure sensors are sensitivity, dynamic range, full-scale output (FSO), linearity and the temperature coefficients of sensitivity and offset. These characteristics depend on the device geometry, the mechanical and thermal properties of the structural and packaging materials, and the selected sensing scheme. Sensitivity is defined as a normalized signal change per unit pressure change to reference signal:

$$S = \frac{1}{\theta} \frac{\partial \theta}{\partial P} \quad (25.4)$$

where  $\theta$  is output signal and  $\Delta\theta$  is the change in it due to the applied pressure  $\Delta P$ . Dynamic range is the pressure range over which the sensor can provide a meaningful output. It may be limited by the saturation of the transduced output signal such as the piezoresistance or capacitance. It also may be limited by yield and failure of the pressure diaphragm. The full-scale output of a pressure sensor is simply the algebraic difference of the end points of the output. Linearity refers to the proximity of the device response to a specified straight line. It is the maximum separation between the output and the line, expressed as a percentage of full-scale output. Generally, capacitive pressure sensors provide highly nonlinear outputs, and piezoresistive pressure sensors provide fairly linear output.

The temperature sensitivity of a pressure sensor is an important performance metric. The definition of temperature coefficient of sensitivity (TCS) is

$$\text{TCS} = \frac{1}{S} \frac{\partial S}{\partial T} \quad (25.5)$$

where  $S$  is sensitivity. Another important parameter is the temperature coefficient of offset (TCO). The offset of a pressure sensor is the value of the output signal at a reference pressure, such as when  $\Delta P = 0$ . Consequently, the TCO is

$$\text{TCO} = \frac{1}{\theta_0} \frac{\partial \theta_0}{\partial T} \quad (25.6)$$

where  $\theta_0$  is offset, and  $T$  is temperature. Thermal stresses caused by differences in expansion coefficients between the diaphragm and the substrate or packaging materials are some of the many possible contributors to these temperature coefficients.

## 25.2 Piezoresistive Pressure Sensors

The majority of commercially available micromachined pressure sensors are bulk micromachined piezoresistive devices. These devices are etched from single-crystal silicon wafers, which have relatively well-controlled mechanical properties. The diaphragm can be formed by etching the back of a (100)-oriented Si wafer with an anisotropic wet etchant such as potassium hydroxide (KOH). An electrochemical etch-stop, dopant-selective etch-stop, or a layer of buried oxide can be used to terminate the etch and control the thickness of the unetched diaphragm, which is supported at its perimeter by a portion of the wafer that was not exposed to the etchant and remains at full thickness (Figure 25.1). The piezoresistors are fashioned by selectively doping portions of the diaphragm to form junction-isolated resistors. Although this form of isolation can permit significant leakage current at elevated temperatures and the resistors present sheet resistance per unit length that depends on the local bias across the isolation diode, it permits the designer to exploit the substantial piezoresistive coefficient of silicon and locate the resistors at the points of maximum stress on the diaphragm.

Surface micromachined piezoresistive pressure sensors have also been reported. In Sugiyama et al. (1991), the structural material for the diaphragm was silicon nitride. Polycrystalline silicon (polysilicon) was used both as a sacrificial material and to form the piezoresistors. This fabrication approach permits small devices with high packing density to be fabricated. However, the maximum deflection of the diaphragm is limited to the thickness of the sacrificial layer and can constrain the dynamic range much like the capacitive device to be discussed in the following section. In Guckel et al. (1986), polysilicon was used to form both the diaphragm and the piezoresistors.

In an anisotropic material such as single-crystal silicon, resistivity is defined by a tensor which relates the three-directional components of the electric field to the three-directional components of current flow. In general, the tensor has nine elements expressed in a  $3 \times 3$  matrix, but they reduce to six independent values from symmetry considerations:

$$\begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \end{bmatrix} = \begin{bmatrix} \rho_1 & \rho_6 & \rho_5 \\ \rho_6 & \rho_2 & \rho_4 \\ \rho_5 & \rho_4 & \rho_3 \end{bmatrix} = \begin{bmatrix} j_1 \\ j_2 \\ j_3 \end{bmatrix} \quad (25.7)$$

where  $\epsilon_i$  and  $j_i$  represent electric field and current density components, and  $\rho_i$  represents resistivity components. Following the treatment in Kloeck and Rooij (1994) and Middleoek and Audet (1994), if the Cartesian axes are aligned to the (100) axes in a cubic crystal structure such as silicon,  $\rho_1$ ,  $\rho_2$  and  $\rho_3$  will be equal, as they all represent resistance along the (100) axes and are denoted by  $\rho$ . The remaining components of the resistivity matrix, which represent cross-axis resistivities, will be zero because unstressed silicon is electrically isotropic. When stress is applied to silicon, the components in the resistivity matrix change. The change in each of the six independent components,  $\Delta\rho_i$ , will be related to all the stress components. The stress can always be decomposed into three normal components ( $\sigma_i$ ) and three shear components ( $\tau_i$ ), as shown in Figure 25.2. The change in the six components of the resistivity matrix (expressed as a fraction of the unstressed resistivity  $\rho$ ) can then be related to the six stress components by a 36-element tensor. However, due to symmetry conditions, this tensor is populated by only three non-zero components, as shown:

$$\begin{bmatrix} \rho_1 \\ \rho_2 \\ \rho_3 \\ \rho_4 \\ \rho_5 \\ \rho_6 \end{bmatrix} = \begin{bmatrix} \rho \\ \rho \\ \rho \\ 0 \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} \Delta\rho_1 \\ \Delta\rho_2 \\ \Delta\rho_3 \\ \Delta\rho_4 \\ \Delta\rho_5 \\ \Delta\rho_6 \end{bmatrix}; \quad \frac{1}{\rho} \begin{bmatrix} \Delta\rho_1 \\ \Delta\rho_2 \\ \Delta\rho_3 \\ \Delta\rho_4 \\ \Delta\rho_5 \\ \Delta\rho_6 \end{bmatrix} = \begin{bmatrix} \pi_{11} & \pi_{12} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{11} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{12} & \pi_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \pi_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & \pi_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \pi_{44} \end{bmatrix} \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_1 \\ \tau_2 \\ \tau_3 \end{bmatrix} \quad (25.8)$$

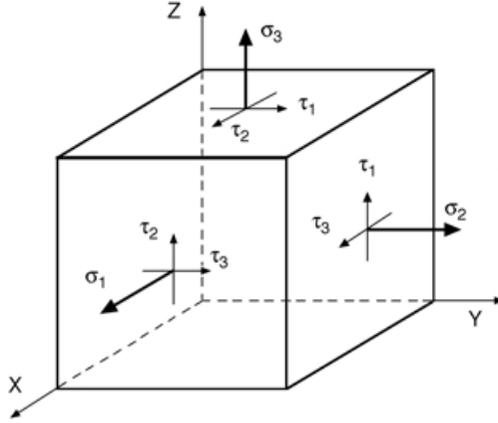

FIGURE 25.2 Definition of normal and shear stresses.

where the  $\pi_{ij}$  coefficients, which have units of  $\text{Pa}^{-1}$ , may be either positive or negative and are sensitive to doping type, doping level and operating temperature. It is evident that  $\pi_{11}$  relates the resistivity in any direction to stress in the same direction, whereas  $\pi_{12}$  and  $\pi_{44}$  are cross-terms.

Equation (25.8) was derived in the context of a coordinate system aligned to the (100) axes and is not always convenient to apply. A preferred representation is to express the fractional change in an arbitrarily oriented diffused resistor by:

$$\frac{\Delta R}{R} = \pi_l \sigma_l + \pi_t \sigma_t \quad (25.9)$$

where  $\pi_l$  and  $\sigma_l$  are the piezoresistive coefficient and stress parallel to the direction of current flow in the resistor (i.e., parallel to its length), and  $\pi_t$  and  $\sigma_t$  are the values in the transverse direction. The piezoresistive coefficients referenced to the direction of the resistor may be obtained from those referenced to the (100) axes in Eq. (25.8) by using a transformation of the coordinate system. It can then be stated that:

$$\pi_l = \pi_{11} + 2(\pi_{44} + \pi_{12} - \pi_{11})(l_1^2 m_1^2 + l_1^2 n_1^2 + n_1^2 m_1^2) \quad (25.10)$$

$$\pi_t = \pi_{12} - (\pi_{44} + \pi_{12} - \pi_{11})(l_1^2 l_2^2 + m_1^2 m_2^2 + n_1^2 n_2^2) \quad (25.11)$$

where  $l_i$ ,  $m_i$  and  $n_i$  are the direction cosines (with respect to the crystallographic axes) of a unit-length vector which is parallel to the current flow in the resistor, whereas  $l_2$ ,  $m_2$  and  $n_2$  are those for a unit-length vector perpendicular to the resistor. Thus,  $l_i^2 + m_i^2 + n_i^2 = 1$ . As an example, for the (111) direction, in which projections to all three crystallographic axes are equal,  $l_i^2 = m_i^2 = n_i^2 = 1/3$ .

A sample set of piezoresistive coefficients for Si are listed in Table 25.1. It is evident that  $\pi_{44}$  dominates for p-type Si, with a value that is more than 20 times larger than the other coefficients. By using the dominant coefficient and neglecting the smaller ones, Eqs. (25.10) and (25.11) can be further simplified. It should be noted, however, that the piezoresistive coefficient can vary significantly with doping level and operating temperature of the resistor. A convenient way in which to represent the changes is to normalize the piezoresistive coefficient to a value obtained at room temperature for weakly doped silicon [Kanda, 1982]:

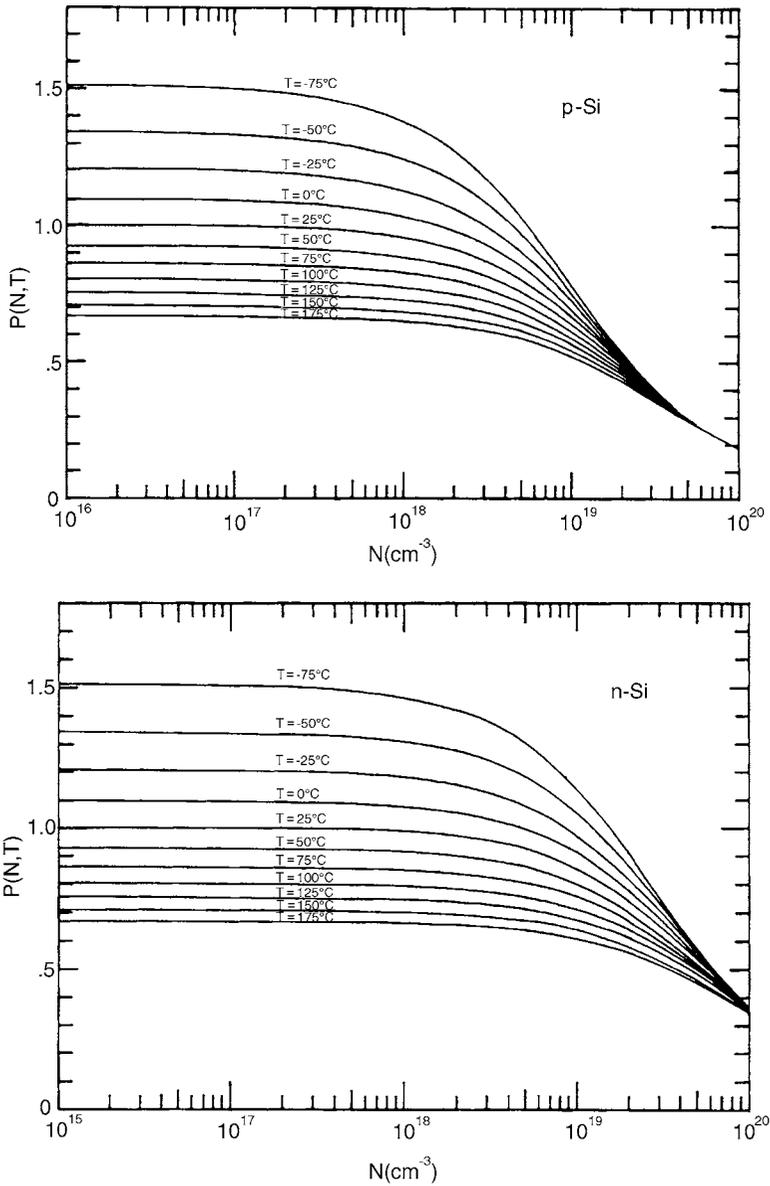

$$\pi(N,T) = P(N,T) \pi_{\text{ref}} \quad (25.12)$$

Figure 25.3 shows the variation of parameter  $P$  for p-type and n-type Si.

**TABLE 25.1** Sample of Room-Temperature Piezoresistive Coefficients in Si in  $10^{-11} \text{ Pa}^{-1}$

Resistivity	$\pi_{11}$	$\pi_{12}$	$\pi_{44}$

**FIGURE 25.3** Variation of piezoresistive coefficient for n-type and p-type Si. (From Kanda, Y. (1982) *IEEE Trans. Electron. Devices*, **29**, 64-70. With permission.)

Figure 25.4 plots the longitudinal and transverse piezoresistive coefficients for resistor orientations on the surface of a (100) silicon wafer. Note that each figure is split into two halves, showing  $\pi_l$  and  $\pi_t$  simultaneously for p-type Si in one case and n-type Si in the other case. Each curve would be reflected in the horizontal axis if drawn individually. Also note that for p-type Si, both  $\pi_l$  and  $\pi_t$  peak along (110), whereas for n-type Si they peak along (100). Since anisotropic wet etchants make trenches aligned to (110) on these wafer surfaces, p-type piezoresistors, which can be conveniently aligned parallel or perpendicular to the etched pits, are favored.

Consider two p-type resistors aligned to the (110) axes and near the perimeter of a circular diaphragm on a silicon wafer. Assume that one resistor is parallel to the radius of the diaphragm, whereas the other is perpendicular to it. Using the equations presented above, it can be shown that as pressure is applied, the fractional change in these resistors is equal and opposite:

$$\left(\frac{\Delta R}{R}\right)_{ra} = -\left(\frac{\Delta R}{R}\right)_{ta} = -\Delta P \cdot \frac{3\pi_{44}a^2(1-\nu)}{8h^2} \quad (25.13)$$

where the subscripts denote radial and tangentially oriented resistors. The complementary change in these resistors is well suited to a bridge-type arrangement for readout, as shown in Figure 25.5. (The bridge-type readout arrangement is suitable for square diaphragms as well.) The output voltage in this case is given by:

$$\Delta V_0 = V_s \frac{\Delta R}{R} \quad (25.14)$$

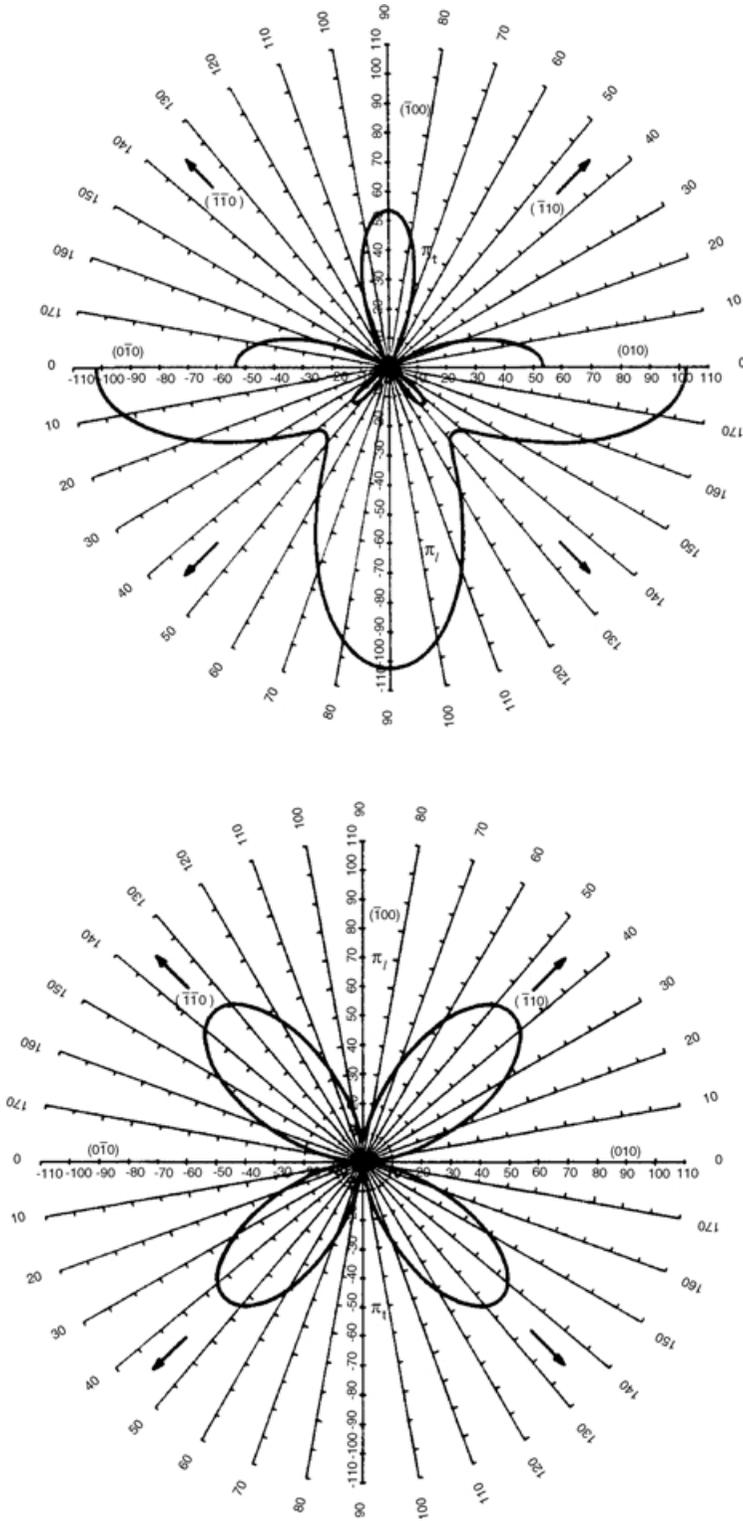

Since the output is proportional to the supply voltage  $V_s$ , the output voltage of piezoresistive pressure sensors is generally presented as a fraction of the supply voltage per unit change in pressure. Thus, a typical sensitivity is on the order of 100 ppm/Torr. The maximum fractional change in a piezoresistor is on the order of 1 to 2%. It is evident from Eqs. (25.13) and (25.14) that the temperature coefficient of sensitivity, which is the fractional change in the sensitivity per unit change in temperature, is primarily governed by the temperature coefficient of  $\pi_{44}$ .

A valuable feature of the resistor bridge is the relatively low impedance that it presents. This permits the remainder of the sensing circuit to be located at some distance from the diaphragm, without deleterious effects from parasitic capacitance that may be incorporated. As will be discussed in the next section, this stands in contrast to the output from capacitive pick-off pressure sensors, for which the high output impedance creates significant challenges.

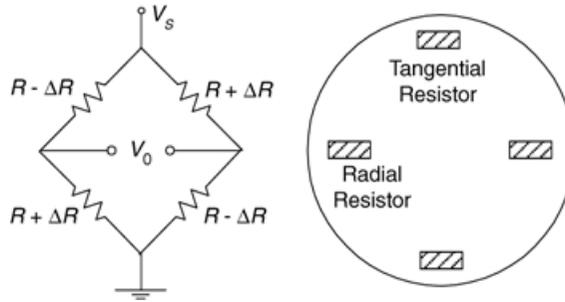

The resistors present a scaling limitation for the pressure sensors. As the length of a resistor is decreased, the resistance decreases and the power consumption rises, which is not favorable. As the width is decreased, minute variations that may occur because of nonideal lithography or other processing limitations will have a more significant impact on the resistance. These issues constrain how small a resistor can be made. Then, as the size of the diaphragm is reduced, the resistors will span a larger area between its perimeter and the center. Since the maximum stresses occur at these locations, a resistor that extends between them will be subject to stress averaging, and the sensitivity of the readout will be compromised. In addition, if the nominal values of the resistors vary, the two legs of the bridge become unbalanced, and the circuit presents a non-zero signal even when the diaphragm is undeflected. This offset varies with temperature and cannot be easily compensated because it is in general unsystematic.

## 25.3 Capacitive Pressure Sensors

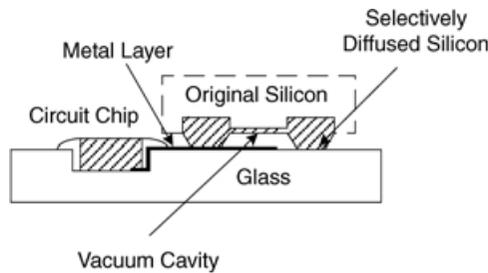

Capacitive pressure sensors were developed in the late 1970s and early 1980s. As indicated in Section 25.1, in these devices the flexible diaphragm serves as one electrode of a capacitor, whereas the other electrode is located on a substrate beneath it. As the diaphragm deflects in response to applied pressure, the average gap between the electrodes changes, leading to a change in the capacitance. The concept is illustrated in Figure 25.6.

**FIGURE 25.4** Longitudinal and transverse piezoresistive coefficients for p-type and n-type resistors on the surface of a (100) Si wafer. (From Kanda, Y. (1982) *IEEE Trans. Electron. Devices*, **29**, 64–70. With permission.)

**FIGURE 25.5** Schematic representation of Wheatstone bridge configuration (left) and placement of radial and tangential strain sensors on a circular diaphragm (right).

**FIGURE 25.6** Schematic of a pressure sensor fabricated on a glass substrate using a dopant-selective etch stop. (From Chau, H., and Wise, K. (1988) *IEEE Trans. Electron. Devices*, 35(12), 2355–2362. With permission.)

Although many fabrication schemes can be conceived, an attractive bulk micromachining approach is described in Chau and Wise (1988). Areas of a silicon wafer were first recessed, leaving plateaus that served as anchors for the diaphragm. Boron diffusion was then used to define the regions that would eventually form the structure. The top surface of the silicon wafer was then anodically bonded to a glass wafer that had been inlaid with a thin film of metal that served as the stationary electrode and provided lead transfer to circuitry. The undoped portions of silicon were finally dissolved in a dopant selective etchant such as ethylene diamine pyrocatechol (EDP). In order to maintain a low profile and small size, the interface circuit was hybrid-packaged into a recess in the same glass substrate, creating a transducer that was small enough to be located within a cardiovascular catheter of 0.5-mm outer diameter. Using a 2- $\mu\text{m}$ -thick,  $560 \times 280\text{-}\mu\text{m}^2$  diaphragm with a 2- $\mu\text{m}$  capacitor gap and a circuit chip 350  $\mu\text{m}$  wide, 1.4 mm long and 100  $\mu\text{m}$  thick, pressure resolution of  $<2$  mmHg was achieved [Ji et al., 1992].

The capacitive sensing scheme circumvents some of the limitations of piezoresistive sensing. For example, because the resistors do not have to be fabricated on the diaphragm, scaling down the device dimensions is easier because concerns about stress averaging and resistor tolerance are eliminated. In addition, the largest contributor to the temperature coefficient of sensitivity—the variation of  $\pi_{44}$ —is also eliminated. The full-scale output swing can be 100% or more, in comparison to about 2% for piezoresistive sensing. There is virtually no power consumption in the sense element as the dc current component is zero. However, capacitive sensing presents other limitations: The capacitance changes nonlinearly with diaphragm displacement and applied pressure. Even though the fractional change in the sense capacitance may be large, the absolute change is small and considerable caution must be exercised in designing the sense circuit. The output impedance of the device is large, which also affects the interface circuit design, and the parasitic capacitance between the interface circuit and the device output can have a significant negative impact on the readout, which means that the circuit must be placed in close proximity to the device in a hybrid or monolithic implementation. An additional concern is related to lead transfer and packaging. In the case of absolute pressure sensors the cavity beneath the diaphragm must be sealed in

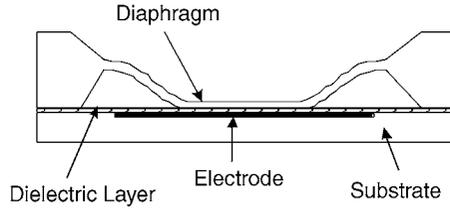

FIGURE 25.7 A touch mode capacitive pressure sensor.

vacuum. Transferring the signal at the counter electrode out of the cavity in a manner that retains the hermetic seal can present a substantial manufacturing challenge.

The capacitance between two parallel electrodes can be expressed as:

$$C = \frac{\epsilon_0 \epsilon_r A}{d} \quad (25.15)$$

where  $\epsilon_0$ ,  $\epsilon_r$ ,  $A$  and  $d$  are permittivity of free space ( $8.854 \times 10^{-14}$  F/cm), relative dielectric constant of material between the plates (which is unity for air), effective electrode area and gap between the plates, respectively. Since the gap is not uniform when the diaphragm deflects, finite element analysis is commonly used to compute the response of a capacitive pressure sensor. However, it can be shown that for deflections that are small compared to the thickness of the diaphragm, the sensitivity, which is defined as the fractional change in the capacitance per unit change in pressure, has the following proportionality [Chau and Wise, 1987]:

$$S_{\text{cap}} = \frac{\Delta C}{C \cdot \Delta P} \propto \frac{1 - \nu^2}{E} \frac{a^4}{h^3 g} \quad (25.16)$$

where  $g$  is the nominal gap between the diaphragm and the electrode, and the remaining variables represent the same quantities as for Eq. (25.3). Comparing to Eq. (25.13), which provides the fractional resistance change in a piezoresistive device, it is evident that capacitive devices have an increased dependence on  $a/h$ , the ratio of the radius to the thickness of the diaphragm. In addition, they are dependent on  $g$ , the capacitive gap. The sensitivity of capacitive pressure sensors is generally in the range of 1000 ppm/Torr, which is about  $10\times$  greater than piezoresistive pressure sensors. This is an important advantage, but it carries a penalty for linearity and dynamic range.

The dynamic range of a capacitive pressure sensor is conventionally perceived to be limited by the “full-scale” deflection, which is defined to exist at the point that  $\Delta C = C$ . However, in reality the capacitance keeps rising as the pressure increases even beyond the threshold at which the diaphragm touches the substrate beneath it. As the pressure increases, the contact area grows, extending the useful operating range of the device (Figure 25.7). As long as the electrode is electrically isolated from the diaphragm, such as by an intervening thin film of dielectric material, the sensor can continue to be used. This mode of operation is called “touch mode” [Cho et al., 1992; Ko et al., 1996]. Since most of the diaphragm may in fact be in contact with the substrate in this mode the output capacitance is relatively large. For example, a  $4\text{-}\mu\text{m}$ -thick  $p^{++}$  silicon diaphragm of  $1500 \times 447\text{-}\mu\text{m}^2$  area and a nominal capacitive gap of  $10.4 \mu\text{m}$  was experimentally shown to have a dynamic range of 120 psi in touch mode, whereas the conventional range was only 50 psi [Ko et al., 1996]. The concept of touch-mode operation exploits the fact that in a capacitive pressure sensor the substrate provides a natural over-pressure stop that can delay or prevent rupture of the diaphragm. This is a feature lacking in most piezoresistive pressure sensors.

One cause of temperature coefficients in capacitive pressure sensors is expansion mismatch between the substrate and diaphragm, which can be minimized by the proper choice of materials and fabrication sequence. For example, when a glass substrate is used, it is important to select one that is expansion-matched to the silicon. Hoya™ SD-2 is designed to be very closely matched to silicon, and #7740 Pyrex™

glass provides acceptable performance for a lower price. Naturally, the best results can be expected when the substrate material is the same as the diaphragm material. Anodic bonding of the silicon structure to a silicon-substrate wafer that was coated with 2.5 to 5  $\mu\text{m}$  of glass has been shown to produce devices with low TCO [Hanneborg and Ohlckers, 1990]. The typical TCO of silicon pressure sensors that use anodically bonded glass substrates is  $<100$  ppm/K. Since the sensitivity is in the range of 1000 ppm/Torr, the TCO can be stated as 0.1 Torr/K.

For absolute pressure sensors, the primary source of temperature sensitivity can be expansion of gas entrapped in the sealed reference cavity. This gas may come from an imperfect vacuum ambient during the sealing. If the gas is unreactive, this component can be estimated by the ideal gas equation. Another source of entrapped gas is out-diffusion from the cavity walls after sealing, which is more difficult to quantify [Henmi et al., 1994]. To some extent, this can be blocked by using a thin-film metal coating as a diffusion barrier [Cheng et al., 2001]. Various sealing methods have been developed based on the principle of creating a cavity by etching a subsurface sacrificial layer through a narrow access hole and then sealing off the access by depositing a thin film at a low pressure [Murakami, 1989]. The reactive sealing method reported by Guckel et al. (1987, 1990) provides some of the lowest sealed-cavity pressures. In this approach, chemical-vapor-deposited polysilicon is used as the sealant. A subsequent thermal anneal causes the trapped gas to react with the interior walls of the cavity, leaving a high vacuum.

Although appropriate for surface micromachined cavities, the thermal budget of the reactive sealing process that uses polysilicon is too high for devices that use glass substrates. A similar effect can be achieved with metal films called nonevaporable getters (NEG) which are suitable for use with glass wafers. In Henmi et al. (1994), the NEG used was a Ni/Cr ribbon covered with a mixture of porous Ti and Zr–V–Fe alloy. To achieve the best results it was initially heated to 300°C to desorb gas, following which it was sealed within the reference cavity and finally heated to 400°C to be activated. The final cavity pressure achieved was reported to be  $<10^{-5}$  Torr. It should be noted that gas entrapped in the sealed reference cavity changes pressure as the diaphragm is deflected and the cavity volume changed. This can lead to erroneous readings and a loss of sensitivity [Ji et al., 1992].

For capacitive pressure sensors, lead transfer to the sense electrode located within the sealed cavity has been a persistent challenge. For the type of device shown in Figure 25.6, in which the anodic bond must form a hermetic seal over the metal lead patterned on the glass substrate, the metal layer thickness may not exceed 50 nm [Lee and Wise, 1982]. In addition, a thin-film dielectric must be used to separate the silicon anchor from the lead. Epoxy is sometimes applied at the end of the fabrication sequence to strengthen the seal over the lead. However, this is not a favored solution, and alternatives have been developed. In one approach, a hole is etched or drilled in the substrate or in a rigid portion of the microstructure next to the flexible diaphragm, the lead is transferred through it, and then it is sealed with epoxy or metals [Wang and Esashi, 1997; Giachino et al., 1981]. The approach used by Wang and Esashi (1997) is shown in Figure 25.11. In another approach, subsurface polysilicon leads are used with the help of chemical–mechanical polishing to achieve a planar bonding surface that allows a hermetic seal [Chavan and Wise, 1997].

### 25.3.1 Design Variations

A number of variations of the conventional choices for structures and materials have been reported. These include ultra-thin dielectric diaphragms, bossed or corrugated diaphragms, double-walled diaphragms with embedded rigid electrodes and structures with sense electrodes located external to the sealed cavity.

Dielectric material compatible with silicon processing can be useful alternatives as structural materials for pressure sensors. One promising option is stress-compensated silicon nitride because it is chemically and mechanically stable. One concern about a larger and thinner diaphragm is high stress developed under applied pressure, which may cause device failure. However, the yield strength of silicon nitride is twice that of silicon. High sensitivities were reached by using a large and thin silicon nitride diaphragm of 2-mm diameter and 0.3- $\mu\text{m}$  thickness [Zhang and Wise, 1994b]. Silicon nitride is under high tensile

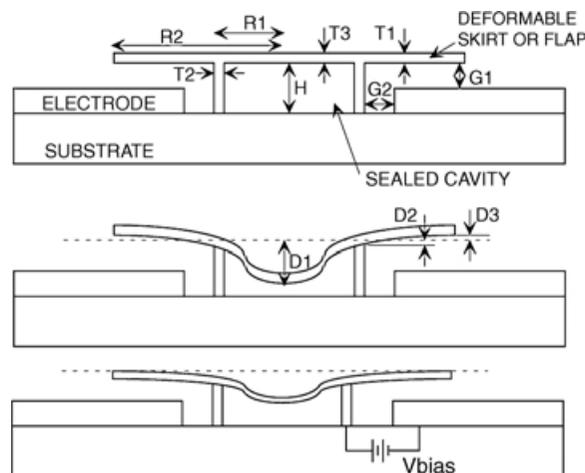

residual stress after low-pressure chemical vapor deposition (LPCVD), which reduces the diaphragm deflection. To compensate for this residual stress, a silicon dioxide layer, which creates compressive stress, is put between two silicon nitride layers (60 nm/180 nm/60 nm). To compensate for the nonlinear behavior due to large deflections, a 3- $\mu\text{m}$ -thick boss ( $\text{p}^+\text{Si}$ ) is located in the center of the diaphragm. Its diameter is 60% that of the diaphragm; a greater percentage lowers sensitivity, and a smaller percentage adversely affects linearity. The sensitivity has been shown to be 10,000 ppm/Pa (5 fF/mTorr), which is 10 $\times$  greater than the typical value for capacitive devices. The minimum resolution pressure was 0.1 mTorr. The TCO and TCS were, respectively, 910 ppm/K and  $-2900$  ppm/K. The dynamic range was  $>130$  Pa.

One issue of great importance to very small and very sensitive pressure sensors is noise. Many sources of noise, both electrical and mechanical, may contribute to the output signal. In general, these include Brownian motion from gas surrounding the diaphragm, noise from the sense capacitor (or resistor), electrostatic pressure variation from the sense circuit and electrical noise in the sense circuit itself [Chau and Wise, 1987].

Introducing corrugation into a pressure-sensor diaphragm allows longer linear travel and a larger dynamic range in capacitive pressure sensors. Corrugations can be manufactured with wet or dry etching. Residual stress in the diaphragm can result in bending when corrugations are present. The use of a boss in the center was shown to considerably improve this but causes a deflection in the opposite direction [Ding, 1992; Zhang and Wise, 1994a]. These papers presented development of bossed and corrugated structures manufactured under tensile, neutral and compressive stress. Both papers develop a square root dependence of deflection vs. pressure for unbossed, corrugated pressure sensors.

A differential capacitive pressure sensor consisting of a double-layer diaphragm with an embedded electrode was reported by Wang et al. (2000). One capacitor was formed between the upper diaphragm and middle electrode, and another between the electrode and lower diaphragm. The diaphragms were mechanically connected to each other and moved in the same direction, which was dependent on the pressure difference between the upper and lower surfaces. The advantage of this pressure sensor is that the cavity is sealed from the outside but still can generate a signal based on pressure difference. The diaphragm size was  $150 \times 150 \mu\text{m}^2$ , the thickness of the diaphragm was  $2 \mu\text{m}$  and the capacitor gaps were nominally  $1 \mu\text{m}$ .

Most masking steps in pressure sensors are consumed on electrical lead transfer from the inside of the vacuum cavity to the outside as shown in the previous devices. A pressure sensor that eliminates the problem of the sealed lead transfer by locating the pick-off capacitance outside the sealed cavity is illustrated in Figure 25.8 [Park and Gianchandani, 2000]. A skirt-shaped electrode extends outward from the periphery of the vacuum-sealed cavity, acting as the electrode that deflects under pressure. The stationary electrode is metal patterned on the substrate below this skirt. As the external pressure increases,

**FIGURE 25.8** Electrostatic attraction between the electrode and skirt opposes the deflection due to external pressure.

the center of the diaphragm deflects downwards, and the periphery of the skirt rises, reducing the pick-off capacitance. This deflection continues monotonically as the external pressure increases beyond the value at which the center diaphragm touches the substrate, so this device can be operated in touch mode for expanded dynamic range. To fabricate this a silicon wafer was first dry etched to the desired height of the cavity and then selectively diffused with boron to define the radius of the pressure sensor. The depth of the boron diffusion determined the eventual thickness of the structural layer. The silicon wafer was then flipped over and anodically bonded to a glass wafer that had been inlaid with a Ti/Pt metal that serves as the interconnect and provides the bond pads. The undoped Si was finally dissolved in EDP, leaving the pressure sensor on the glass substrate.

A single-crystal silicon pressure diaphragm using epitaxial deposition was reported by Mastrangelo (1995). The advantage of this kind of sensor is that it does not require bonding on glass as most p<sup>++</sup> silicon pressure sensors do, and the diaphragm stress condition and material properties are predictable, as single-crystal silicon provides more consistent performance than polysilicon.

### 25.3.2 Circuit Integration and Device Compensation

An interface circuit for capacitive pressure sensors which offers high sensitivity and immunity from parasitic capacitance is illustrated in Figure 25.9. This is basically a switched-capacitor charge integrator which utilizes a two-phase clock to compare the variable sense capacitor ( $C_X$ ) to a reference capacitor ( $C_R$ ) [Park and Wise, 1990]. A reset pulse initially nulls the output. Subsequently, when the clock switches, a charge proportional to the clock amplitude and the difference between the reference and variable capacitor is forced into the feedback capacitor  $C_F$ , producing an output voltage given by:

$$V_{out} = \frac{V_p(C_X - C_R)}{C_F} \tag{25.17}$$

Since this scheme measures the difference between two capacitors, it is unaffected by parasitic capacitance values that are common to both.

Capacitive pressure sensors offer numerous advantages to piezoresistive sensors, but they are highly nonlinear. Piezoresistive devices are more linear but are limited to about 0.5% of full scale (8 bits) when uncompensated. One of the first efforts at compensation of pressure sensors was by Crary et al. (1990). The compensation was provided with an off-chip computer. Two possible strategies would be to use polynomial fitting or full lookup tables. The authors used polynomial fitting, using stepwise regression. They characterized a piezoresistive polysilicon full-bridge membrane device over 153 fixed points, and temperature and pressure compensated the device. Before compensation, endpoint-to-endpoint nonlinearity was 29% of full scale. After compensation, the device was improved a quoted 4.4 bits.

One of the most highly integrated devices as of this writing was reported by Chavan and Wise (2000). The developed capacitive pressure sensor offered 15-bit resolution. It was unique in that the on-chip circuitry could interface with five different transducers, as it had a 3-bit multiplexer-transducer select register. It included programmable gain and offset circuitry to implement the circuitry into a variety of ranges and scales and had a buffered dc analog output. The system offered a calibration and operation

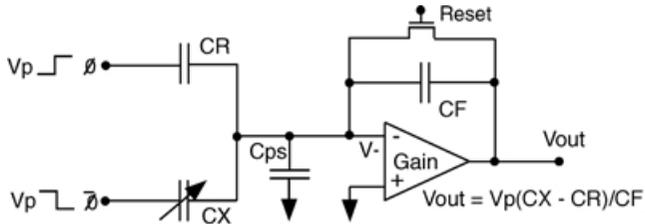

FIGURE 25.9 A switched capacitor charge integrator. (From Park, Y.E., and Wise, K.D., in *Microsensors*, R.S. Muller et al., Eds. (1990) IEEE Press, New York, pp. 329–333. With permission.)

mode and had external debugging pins. The finished array had five different transducers, covering a 300-Torr range. Due to the diameter dependence of capacitive sensors, the membrane diameter only varied 1000 to 1100  $\mu\text{m}$ . The membrane was 3.7/0.3- $\mu\text{m}$  Si-SiO<sub>2</sub> with a boss center. The fabrication was a 20-mask process, 15 for the on-device p-well circuitry, three for the transducers and two for the glass processing. The circuitry was fabricated in recessed cavities 2.5  $\mu\text{m}$  deep, and the transducers in 8- $\mu\text{m}$ -deep cavities, allowing the bonding anchors to be the highest points on the wafer. Then, a 2- $\mu\text{m}$ -thick level of polysilicon was deposited for electrical feedthroughs, followed by chemical-mechanical polishing, to make the device flat for bonding. The sensor was vacuum sealed, resulting in a 9.8- $\mu\text{m}$  deflection at atmosphere, leaving a 0.5- $\mu\text{m}$  gap and a resulting 8- to 10-pF capacitance. Ti/Pt/Au electrodes were used to getter the device. The sensor was measured with a three-stage programmable switched capacitor circuit (polysilicon reference capacitors). The front end was a differential charge integrator with a folded cascode amplifier. The operation was circuitry controlled so that a global sensor is used first, then the chip decides which transducer is used next to achieve maximum resolution. The clocking scheme used correlated double sampling, to lower the 1/f noise and amplifier offset.

## 25.4 Other Approaches

---

Several pressure sensor concepts that do not rely on capacitive and piezoresistive sensing have been developed. The motivation to pursue alternative approaches is typically driven by a unique application or by stringent requirements in a certain performance category. Resonant beam devices offer particularly high resolution and a pseudo-digital output. Closed-loop servo controlled devices offer a wider operating range. Tunneling devices offer high sensitivity, optical devices are ideal for harsh environments, and Pirani devices are well suited for vacuum applications.

### 25.4.1 Resonant Beam Pick-Off

Frequency measurement can be considerably more robust and accurate than the measurement of a resistor or capacitor. Resonating devices, therefore, will be more affected by the mechanical qualities than electrical qualities of the device. A common rule of thumb is that resonating devices can achieve ten times greater measurement accuracies than the more conventional capacitive and piezoresistive methods. In addition, because the output is naturally quantized, interfacing to a digital system can be easier.

Resonant devices make use of the fact that imparted strain on a resonating beam will change its effective spring constant, hence the resonating frequency. The typical resonating beam pressure sensor will incorporate end-clamped beams to detect the strain in a diaphragm which can be related to deformation as in piezoresistive sensing. The resonating beam may be driven by electrostatic, magnetic or even optical stimulus. The resonant frequency can be measured by these methods or by implanted piezoresistors on the beam itself.

One of the first commercialized devices was able to achieve accuracies better than 0.01% of the full-scale range [Ikeda et al., 1990]. This device utilized two resonating beams, one in the center of the diaphragm and one at the perimeter to achieve a differential signal (Figure 25.10). The beams were vacuum encapsulated through a fairly complex fabrication process using four levels of epitaxial growth. The cavity was evacuated to a pressure of 1 mTorr, which is allowed by the low pressures used in epitaxial growth processing. This allowed high Q factors of above 50,000 to be achieved for the beam. Temperature sensitivity of the device was limited by the thermal expansion of silicon, with a coefficient of  $-40$  ppm/K.

The beam was excited to resonance by driving an ac current through the resonating beam, and applying a dc magnetic field. The current was controlled by active feedback circuitry to keep the oscillation amplitude constant. The smaller resonance amplitude helps minimize second-order nonlinearities in the resonance, in particular hysteresis of the frequency response. The high accuracy that was a result of this design addressed the aerospace market, where the sensor has been commercialized.

Another resonating beam pressure sensor used a thin single-crystal silicon membrane [Peterson et al., 1991]. This was high-temperature fusion-bonded to a second wafer, which formed the square diaphragm

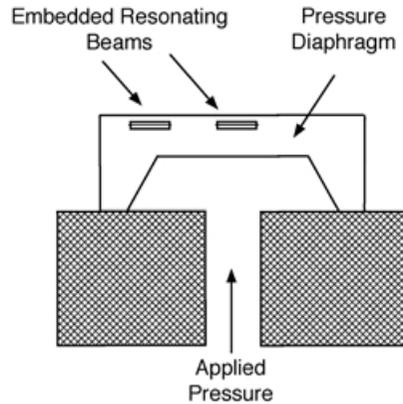

FIGURE 25.10 Schematic of a resonating beam pressure sensor.

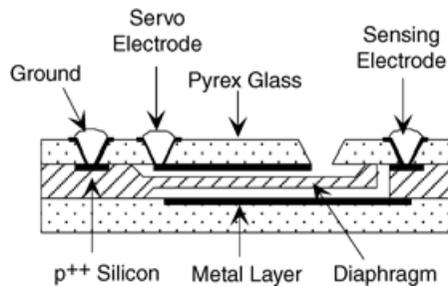

FIGURE 25.11 The structure of the electrostatic servo-controlled pressure sensor. (From Wang, Y., and Esashi, M. (1997) in *IEEE Int. Conf. on Solid-State Sensors and Actuators (Transducers '97)*, June, pp. 1457–1460. With permission)

of the pressure sensor. A single resonant beam was fabricated by etching two slots through the membrane. This beam was excited to resonance electrostatically by a voltage on the order of a few millivolts.

Burns et al. (1994) developed a unique resonant beam sensor that utilized a modulated laser beam as the driving mechanism of the resonator. This structure was developed with a single resonator on the membrane, however, a reference resonator can be located off the diaphragm to provide a differential output. The beam could also be driven electrostatically and was optimized to reduce secondary vibration modes. The cited sensitivity was 3880 counts per second per psi with a dynamic range of 0 to 10 psi. The temperature stability was 0.01 ppm per degree K, and the sensor operated with 12-V off-device circuitry. Compensation circuitry improved device linearity. The final noise variance was 0.2 to 0.4 Hz. One design strategy of the device was to select particular ratios of microbeam length to diaphragm diameter to optimize frequency sensitivity. Then the pressure sensor range was attained by varying diaphragm thickness, which allowed the same masks to be used for different models.

## 25.4.2 Servo-Controlled Pressure Sensors

When a measured signal from a pressure change is used for feedback control to restore the signal to its reference, the pressure sensor is called a *closed-loop pressure sensor*. This concept has been widely used in micromachined inertial sensors to increase sensitivity, linearity and dynamic range and can be beneficial to pressure sensors, as well. To implement this concept, an actuator is necessary to drive the pressure sensor. The most common choice for this purpose is an electrostatic actuator, because it is simple and easy to design and fabricate, although the actuation force is small.

In the structure shown in Figure 25.11, the Si diaphragm is suspended between two glass wafers on which the sensing and feedback electrodes are located [Wang and Esashi, 1997]. A perforation in one

glass wafer provides access to applied pressure. Lead transfer for the lower electrode is through the silicon wafer—this provides access to all the electrodes from the upper surface of the device. This device was fabricated by bulk silicon micromachining and required two glass wafers and one Si wafer. For 10-Torr (1.33-kPa) applied pressure, 70 V was applied to the electrostatic actuator.

A surface micromachined device that provided low-voltage operation was presented by Gogoi and Mastrangelo (1999). To accomplish this, the electrode area was designed to be 100× larger than the pressure diaphragm area to reduce the restoring voltage. The device has a 20- $\mu\text{m}$  × 20- $\mu\text{m}$  diaphragm, and 250- $\mu\text{m}$  × 250- $\mu\text{m}$  footprint area. The diaphragm as well as the feedback electrodes were made from polysilicon. The fabrication process required 15 masks, and the device was self-encapsulated, which can greatly simplify packaging. For 100-kPa applied pressure, the actuation voltage was less than 12 V.

To avoid structural complications and high operating voltage over a wide pressure range, another closed-loop pressure sensor has been devised [Park and Gianchandani, 2001]. In the proposed structure in Figure 25.8, the flexible diaphragm that deforms in response to applied pressure is not directly used for sensing. Instead, it is attached to a skirt-like external electrode which deflects *upward* as the diaphragm deflects *downward*. This movement is detected capacitively by a counter electrode located under it. For closed-loop operation, this setup permits deflection of the skirt to be balanced by a voltage bias on the sense electrode without an extra structural layer on the top of the diaphragm. Moreover, the concentric layout of the sealed cavity and the skirt permits the electrode to naturally occupy a larger area than the diaphragm, as preferred for electrostatic feedback. A point of distinction from other implementations is that in this feedback scheme the skirt, and not necessarily the diaphragm, is restored to its reference position. Low operating voltages are possible because there is no need to completely balance the pressure force, and the electrode is much more flexible than the diaphragm.

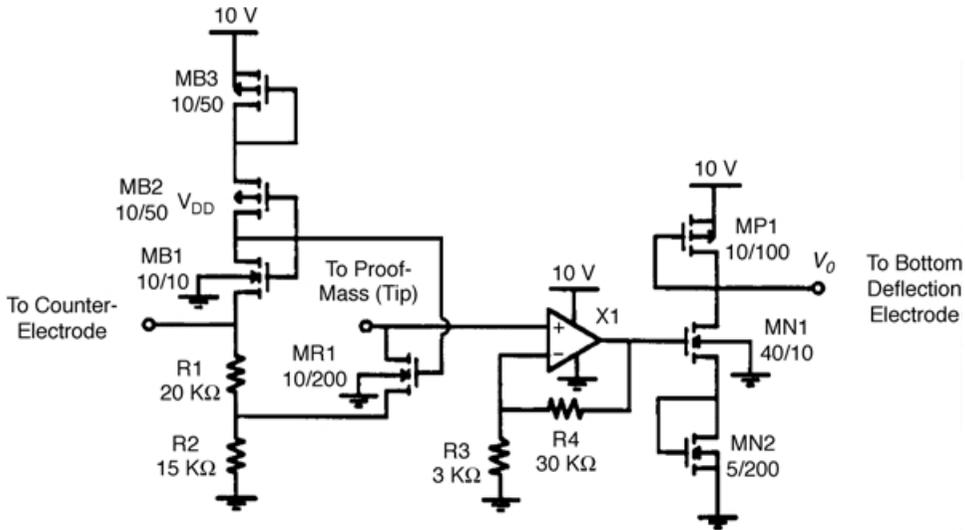

The closed-loop operation of the pressure sensor was demonstrated by varying the chamber pressure and setting the bias voltage to provide the capacitance that was measured at zero gauge pressure [Park and Gianchandani, 2001]. The applied voltage was varied from 31.2 to 73.2 V as the pressure was varied from 20 to 100 kPa, providing an average sensitivity of 0.516 V/kPa. Over this range, the response deviates from linearity by  $\leq 3.22\%$  of the full-scale output. The sensitivity can be electrically tuned by applying a bias to reduce the gap between the electrodes.

### 25.4.3 Tunneling Pick-Off Pressure Sensors

Certain applications require a particularly high sensitivity to pressure. High-sensitivity capacitive sensors require the fabrication of very thin and large-area pressure diaphragms in order to provide measurable deflection. However, tunneling current established between an electrode and the diaphragm can be used to measure nanometer scale deflections. This is because the tunneling current is an exponential function of the separation distance between the tunneling tip and counter electrode [Wickramasinghe, 1989]. One key advantage of this device is its ability to scale dimensions. A comparably sensitive device using traditional capacitive sensors would be quite large. In addition, fabrication yield is likely to be improved, as it would not require the fabrication of very thin and wide membranes.

Tunneling-based pressure sensors reported by Yeh and Najafi (1994) used two levels of silicon and one level of glass. The first silicon layer is fabricated as a cantilever beam with a tunneling tip, and the second silicon layer is fabricated as a thin pressure diaphragm. The glass substrate has a patterned metal electrode and is used to deflect the cantilever beam down using electrostatic forces. Two modes of operation are available. In the first mode, the diaphragm deflects with applied external pressure, and the tunneling current changes at a constant applied voltage. In the second closed-loop mode, the tunneling current is kept constant by applying an appropriate deflection voltage between the beam and deflection electrode. An increase of 10 V in either the deflection voltage or the tunneling voltage produces two orders of magnitude change in the tunneling current. Based on the beam deflection as a function of pressure, signal/pressure sensitivity was found to be 0.21 nA/mTorr.

Due to the exponential tunneling current, the dynamic range becomes limited to 1–10 mTorr in the open-loop mode. The range is significantly improved in closed-loop mode. The range limitation now

**FIGURE 25.12** Circuitry for tunneling-based sensor. (From Yeh, C. and Najafi, K. (1998) *J. MEMS*, March, 6–9. With permission.)

becomes the mechanical displacement limits of the device. Noise is a key issue in this device, as the measured quantity is in nanoamps, but for the same reason power consumption is uniquely small. Tunneling points can wear with time, so the long-term performance can drift. Tunneling electrodes, however, do not necessarily have to be tips and may be manufactured as flat electrodes.

Tunneling-based pressure sensors require special circuitry for their operation. Several circuits to operate these devices were presented by Yeh and Najafi (1998). One of the circuits tested is shown in Figure 25.12. Transistor MR1, a long NMOS, is biased in the linear region. As the tunneling current goes through MR1 its voltage increases roughly linearly. This is amplified  $10\times$  with the following noninverting amplifier and is inverted and buffered by the final stage. The final stage output controls the deflection electrode, which regulates the tunneling distance by deflecting a proof mass on a membrane. The final stage is a high-impedance output to prevent over-current should the proof mass and the deflection electrode contact. When MR1 is replaced with a diode, the current is exponential with the voltage across the diode, as the tunneling current is. This provides a deflection voltage that is linear with the gap distance. The final 10-V circuit is suitable for portable battery operation.

#### 25.4.4 Optical Pick-Off Pressure Sensors

Optical devices offer particular advantages in speed and remote sensing and may be utilized more in the future for specific niche applications. As the sensors can be addressed and read with light, they are potentially useful for hazardous environments. In areas that are flammable, remote or corrosive, it may not be practical to run electrical cabling.

A unique device was developed to measure surface pressure fluctuations. Measuring high-speed turbulent behavior on aeronautical surfaces requires remote sensing and good spatial and temporal resolution [Miller et al., 1997]. The objective for this application was to couple pressure fluctuations and mechanical vibrations. An array of pressure cavity devices was constructed that acts as Fabry–Perot interferometric etalons, in conjunction with an external near-infrared laser. The optical nature of the device allows no electrical connections to disturb the pressure fluctuations, as the device is interrogated with a laser externally. The device was fabricated with 0.55-mm-thick silicon-on-insulator (SOI) wafers, with a 55- $\mu\text{m}$ -thick upper layer, and a 0.4- $\mu\text{m}$ -thick buried  $\text{SiO}_2$  layer. The etalon cavities were formed by wet-etching the front surface down to the oxide layer using KOH. The buried oxide ensured an even

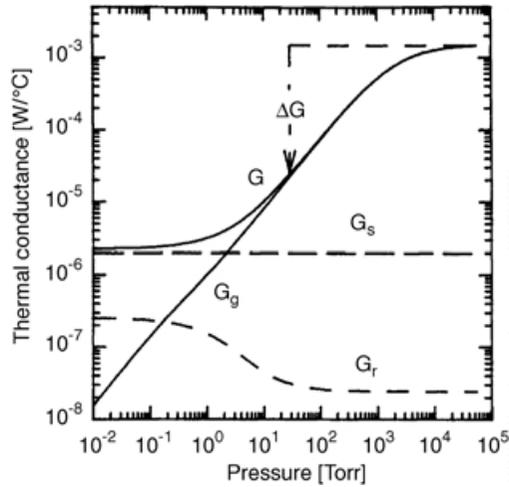

depth and a smooth reflective trench surface. A second SOI wafer was then bonded to it face to face. The silicon on the second wafer was then etched, forming a 55- $\mu\text{m}$ -thick diaphragm. A half-wave coating of  $\text{SiO}_2$  was deposited on the diaphragm. The formed etalons were 1000- $\mu\text{m}$  square, with an internal pressure of 0.8 atm. The device was interrogated with a 1.5- $\mu\text{m}$  wavelength laser, and interference patterns were observed with a video camera corresponding to quarter-wavelength deformations.

Various device concepts using optical sensing have been proposed by Greywall (1997). The devices are located at the end of an optical fiber and include a rigid substrate, followed by an evacuated or fixed-pressure air gap, followed by a flexible membrane. The device acts as a Fabry–Perot interferometer. The author defines a parameter,  $\beta$ , which is proportional to the square of the radius and inversely proportional to membrane stress and thickness and to the air/vacuum gap. The larger the  $\beta$ , the larger the midpoint displacement and therefore the larger the slope of reflectivity vs. pressure. As a consequence, larger  $\beta$  improves sensitivity but limits the range of operation. In this device concept, the optical intensity is the same for several values of pressure in some cases, as the gap can cycle through several multiples of quarter wavelengths. Luminous intensity can be a function of stray light leaking into the system, surface roughness of the device and the index of refraction of the medium being measured.

An in-line Fabry–Perot device was developed for use in pressure sensing of oil wells during the drilling process [Maron, 2000]. This sensor is categorized as an intrinsic Fabry–Perot interferometer, in that the fiberoptic waveguide has two mirrors internal to the fiber. The mirrors are partially transparent and act as an interferometer to light directed down the fiber. These sensors were packaged in a metal case, and they were able to measure peak pressures in the 15,000- to 30,000-Torr range, with resolution on the order of 300 Torr. These devices are in contrast to external Fabry–Perot interferometers, such as Greywall's, where at the end of the fiber is a flexible membrane that acts as the interferometer. The device reported by Kao and Taylor (1996) is a hybrid between the two, where a fiber with internal mirrors is epoxied to a pressure diaphragm and encapsulated in a cylindrical housing. The fiber is epoxied to the membrane, pulled under tension and connected to the other end of the sensor housing, which is sealed at a constant pressure. As the external pressure increases, the diaphragm deforms, and the optical length between the two mirrors changes accordingly. The fiber is interrogated with a laser, and Fabry–Perot interferometry is used to determine the optical distance. Modeling was done for the mechanics of the diaphragm, and the device was tested and found to be able to measure pressure from 1 to 100 Torr with a resolution of 0.4 Torr.

There are a few limited applications where the pressures are so high as to essentially preclude mechanical sensors. One application would be in a diamond anvil, where high-pressure physics experiments are conducted and pressures can reach the megabar range. These pressures are usually performed in very small volumes, and it is impractical to utilize any feedthroughs, so remote sensing is a must. A common sensor for this is a ruby crystal [Trzeciakowski et al., 1992]. The crystal is illuminated with a laser, and the very narrow fluorescent atomic excitation lines due to the chromium impurity shift to lower energies with pressure. The resolution is around 1 to 2 kbar, which is good for the Mbar range, but inadequate for lower ranges. Measuring pressure from the wavelength of atomic excitations offers advantages over intensity measurements, as roughness and reflection coefficients are no longer an issue. Spectral lines shift with pressure in many materials, but the effect is limited to fairly low (<77 K) temperatures due to phonon interaction. Intra-impurity transitions (as in ruby, due to the chrome) are not very sensitive to pressure.

Trzeciakowski (1992) constructed multiple quantum-well (MQW) structures using 10 or more consecutive GaAs/AlGaAs layers of 10-nm thickness which confine electrons and holes as excitons. The spectral lines shift in pressure similar to the energy gap in quantum-well-based materials. GaAs and AlGaAs emission can be excited with Ar, Kr and HeNe gas lasers, so the material is placed in the pressure chamber and externally stimulated with an off-the-shelf laser. Optical attenuation through several layers induce a temperature gradient from the absorbed light energy causing broadening of the lines. Better results were found in wider GaAs wells, with higher aluminum concentration in the AlGaAs regions. The heterostructure sample showed about 20 times the sensitivity of a ruby crystal with an accuracy cited at 0.02 kBar over a 40-kbar range. The temperature coefficient was about 40 bar/K.

**FIGURE 25.13** Thermal conductance as a function of pressure. (From Chou, B.C.S. and Shie, J.S. (1997) in *IEEE Int. Conf. on Solid-State Sensors and Actuators (Transducers '97)*, June, pp. 1465–1468. With permission.)

### 25.4.5 Pirani Sensors

Pirani sensors are vacuum sensors that utilize a temperature-sensitive resistor as a heating and sensing element to measure heat conduction across an air gap. This concept is widely used in conventional sensors, and micromachined versions have been reported [Chou and Shie, 1997]. Figure 25.13 illustrates thermal conductance as a function of pressure. The total thermal conductance,  $G$ , is a traditional S curve.  $G_s$  is the solid heat transfer-through leads and various contact points.  $G_r$  is radiative thermal conduction, and  $G_g$  is the gas heat conduction.

Gas heat conduction dominates radiative heat conduction above 1 Torr and is essentially linear with pressure up to a saturation point. Since constants such as solid conduction can be neglected, the thermal conduction is linear over some range of pressure. This range can be increased by minimizing the air gap across which the thermal conductivity is measured. Chao and Wise (2000) built a floating membrane  $50 \times 50 \mu\text{m}^2$  with plasma-enhanced chemical vapor deposition (PECVD) low-stress silicon nitride, followed by a 100-nm platinum film acting as a 200- $\Omega$  temperature-sensitive resistor. This was fabricated on top of a 0.3- $\mu\text{m}$ -thick polysilicon layer, which after being etched away exposed the air gap to the substrate. This was constructed as an element in a bridge-like circuit to measure temperature-dependent resistivity as a function of pressure. An identical platinum resistor located on the substrate served as a reference. The smaller air gap allowed an operating region from  $10^{-6}$  to  $10^4$  Torr, extending the upper limit into above-atmospheric-pressure regimes.

## 25.5 Conclusions

In this chapter, we have attempted to provide a perspective of the breadth and depth of developments in pressure sensors, which represent one of the richest applications of micromachining technology to date. Although most of the commercially available options use piezoresistive sense schemes, capacitive sensing has been a favorite research theme for a number of years, and other options have also emerged. Novel structures have been proposed to address special needs such as on-chip encapsulation and feedback control. Highly sensitive devices have been developed using thin-film dielectric diaphragms and by using tunneling current for sensing. Optical sensing appears to be particularly promising for applications in harsh environments. There is little doubt that this standard-bearer for the MEMS field will continue to evolve with exciting new structures and technologies in the future.

### 26.1 Introduction

---

During the last decade, microelectromechanical systems (MEMS) devices have had major impacts on both industrial and medical applications. Examples of the former group are accelerometers for automobile airbags, scanning electron microscope tips to image single atoms, micro-heat-exchangers for electronic cooling and micromirrors used for light-beam steering. Micropumping is useful for ink-jet printing and cooling of electronic equipment. Existing and prospective medical applications include reactors for separating biological cells, controlled delivery and measurement of minute amount of medication, pressure sensors for catheter tips and development of artificial pancreas. The concept of MEMS includes a variety of devices, structures and systems, and this chapter is limited to focus only on MEMS devices that generally can be categorized as microsensors and microactuators. Particularly, attention is directed toward microdevices used for turbulent-flow diagnosis and control.

MEMS are created using specialized techniques derived and developed from integrated (IC) technology in a process often called *micromachining*. A vast variety of sensors and actuators and several associated technologies for their fabrication exist today. However, three main technologies are usually distinguished when discussing micromachining: bulk micromachining, surface micromachining and micromolding. Bulk micromachining involves the different techniques that use simple, single-crystal, silicon wafer as structural material. Using anisotropic silicon etching and wafer bonding, three-dimensional structures such

as pressure sensors, accelerometers, flow sensors, micropumps and various resonators have been fabricated. This branch has been under development for more than 20 years and may now be considered a well-established technology.

In the second group, surface micromachining, the silicon substrate is used as support material, and thin films such as polysilicon, silicon dioxide and silicon nitride provide sensing elements and electrical interconnections as well as structural, mask and sacrificial layers. The basis of surface micromachining is sacrificial etching where freestanding, thin-film structures (polysilicon) are free-etched by lateral underlying sacrificial layer (silicon dioxide). Surface micromachining is very simple but powerful, and, despite the two-dimensional nature of this technique, various complex structures such as pressure sensors, micromotors and actuators have been fabricated.

The third group, micromolding (the LIGA technique), is more similar to conventional machining in concept. A metal mold is formed using lithographic techniques, which allow fine feature resolution. Typically, tall structures with submicrometer resolution are formed. Products created by micromolding techniques include thermally actuated microrelays, micromotors and magnetic actuators. In a rapidly growing field such as MEMS, numerous surveys on fabrication have been published and here we give only a few: Petersen (1982), Linder et al. (1992), Brysek et al. (1994), Diem et al. (1995) and Tien (1997). The books by Madou (1997) and Kovacs (1998) are valuable references, and the entire second part of this handbook focuses on MEMS design and fabrication. As mentioned, the emphasis in this chapter is on MEMS applications for turbulence measurements and flow control.

For more than 100 years, turbulence has been a challenge for scientists and engineers. Unfortunately, no simple solution to the “closure problem” of turbulence exists, so for the foreseeable future turbulence models will continue to play a crucial role in all engineering calculations. The modern development of turbulence models is basically directed toward applications to high-Reynolds-number flows ( $Re > 10^6$ ). This development will be a joint effort between direct numerical simulations of the governing equations and advanced experiments. However, an “implicit closure problem” is inherent in the experiments, as an increase in Reynolds number will automatically generate smaller length scales and shorter time scales, which both in turn require small and fast sensors for a correct resolution of the flowfield. MEMS offer a solution to this problem, as sensors with length and time scales on the order of the relevant Kolmogorov microscales can now be fabricated. Additionally, these sensors are produced with high accuracy at a relatively low cost per unit. For instance, MEMS pressure sensors can be used to determine fluctuating pressures beneath a turbulent boundary layer with a spatial resolution that is about one order of magnitude finer than what can be achieved with conventional transducers.

MEMS sensors can be closely spaced together on one chip, and such multisensor arrays are of significant interest when measuring correlations of fluctuating pressure and velocity and, in particular, for their applications in aeroacoustics. Moreover, the low cost and energy consumption per unit device will play a key role when attempting to cover a large macroscopic surface with sensors to study coherent structures. More elaborate discussion on turbulence and the closure problem can be found in textbooks in the field [e.g., Tennekes and Lumley, 1972; Hinze, 1975] or in surveys on turbulence modeling [e.g., Speziale, 1991; Speziale et al., 1991; Hallböck, 1993]. The role and importance of fluctuating pressures and velocities in aeroacoustics is well covered in the books by Goldstein (1976), Dowling and Ffowcs-Williams (1983) and Blake (1986).

Reactive flow control is another application where microdevices may play a crucial future role. MEMS sensors and actuators provide opportunities for targeting the small-scale coherent structures in macroscopic turbulent shear flows. Detecting and modulating these structures may be essential for a successful control of turbulent flows to achieve drag reduction, separation delay and lift enhancement. To cover areas of significant spatial extension, many devices are required that utilize small-scale, low-cost and low-energy-use components. In this context, the miniaturization, low-cost fabrication and low energy consumption of microsensors and microactuators are of utmost interest and promise a quantum leap in control-system performance. Combined with modern computer technologies, MEMS yield the essential matching of the length and time scales of the phenomena to be controlled. These issues and other aspects of flow control are well summarized in a number of reviews on reactive flow control [e.g., Wilkinson, 1990;

Gad-el-Hak, 1994; Moin and Bewley, 1994], and in the books by Gad-el-Hak et al. (1998) and Gad-el-Hak (2000). The topic is also detailed in Chapter 33 of this handbook.

In this chapter, we focus on specific applications of MEMS in fluid dynamics, namely to measure turbulence and to reactively control fluid flows in general and turbulent flows in particular. To place these applications in perspective, we start by giving a brief description of MEMS fabrication; the next section is devoted to a brief general introduction to turbulence, discussion on tools necessary for the analysis of turbulent flows and some fundamental findings made in turbulence. We pay specific attention to small scales, which are of significant interest both in turbulence measurements and in reactive flow control, and we discuss the spatial- and temporal-resolution requirements. MEMS sensors for velocities, wall-shear stress and pressure measurements are then discussed.

As compared to conventional technologies, an extremely small measuring volume can be achieved using MEMS-based velocity sensors. Most commonly, the velocity sensors are designed as hot-wires with the sensitive part made of polysilicon, but other principles are also available and these are elucidated and discussed.

A significant parameter for control purposes is the fluctuating wall-shear stress, as it determines the individual processes transferring momentum to the wall. MEMS offer a unique possibility for direct as well as indirect measurements of this local flow quantity. Different design principles of conventional and MEMS-based wall-shear-stress sensors are discussed together with methods for calibrating those sensors.

The discussion of pressure sensors is focused on measurements of the fluctuating pressure field beneath turbulent boundary layers. Some basic design criteria are given for MEMS pressure sensors and advantages and drawbacks are elucidated. Significant quantities such as rms values, correlations and advection velocities of pressure events obtained with MEMS sensors, yielding spatial resolution of 5 to 10 viscous units, are compared to conventional measurements.

In Section 26.5, we address a real challenge and a necessity for reactive flow-control, MEMS-based flow actuators. Our interest is focused on three-dimensional structures, and we discuss actuators working with the bilayer effect as a principle. Electrostatic and magnetic actuators operating through external forces are also discussed together with actuators operating with mechanical folding. We also summarize the one-layer structure technology and discuss the out-of-plane rotation technology that has been made possible with this method. In connection with the actuator section, we discuss in Section 26.6 MEMS-fabricated devices such as pumps and turbines. Finally, we present our concluding remarks and reflections on the future possibilities that can be achieved in turbulence measurements and flow control by using MEMS technology.

## 26.2 MEMS Fabrication

---

### 26.2.1 Background

MEMS can be considered as a logical step in the silicon revolution, which took off when silicon micro-electronics revolutionized the semiconductor and computer industries with the manufacturing of integrated circuits. An additional dimension is now being added by micromachines, as they allow the integrated circuit to break the confines of the electronic world and interact with the environment through sensors and actuators. This is a giant step, and it can be foreseen that MEMS will have in the near future the same impact on the society and economy as the IC has had since the early 1960s. The key element for the success of MEMS will be, as pointed out by Tien (1997), “the integration of electronics with mechanical components to create high-functionality, high-performance, low-cost, integrated microsystems.” In other words, the material silicon and the MEMS fabrication processes are crucial to usher in a new era of micromachines.

Silicon is a well-characterized material. It is strong, being essentially similar to steel in the modulus of elasticity, stronger than stainless steel in yield strength and exceeding aluminum in strength-to-weight ratio. Silicon has high thermal conductivity and a low bulk expansion coefficient, and its electronic properties are well defined and sensitive to stress, strain, temperature and other environmental factors. In addition,

the lack of hysteresis and the property of being communicative with electronic circuitry make silicon an almost perfect material for fabricating microsensors and microactuators for a broad variety of applications.

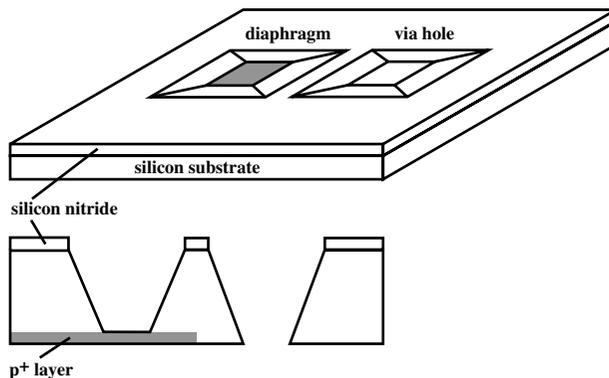

In MEMS fabrication, silicon can be chemically etched into various shapes, and associated thin-film materials such as polysilicon, silicon nitride and aluminum can be micromachined in batches into a vast variety of mechanical shapes and configurations. Several technologies are available for MEMS fabrication, but three main technologies are usually distinguished: bulk micromachining, surface micromachining and micromolding. An important characteristic of all micromachining techniques is that they can be complemented by standard IC batch-processing techniques such as ion implantation, photolithography, diffusion epitaxy and thin-film deposition. In this section, we will give a background of the three main technologies from a user viewpoint. Readers who are interested in more comprehensive information on fabrication are referred to more elaborate work in the field [e.g., Petersen, 1982; O'Connor, 1992; Bryzek et al., 1994; Tien, 1997; Madou, 1997; Kovacs, 1998]. Part II of this handbook also focuses on MEMS design and fabrication.

## 26.2.2 Microfabrication

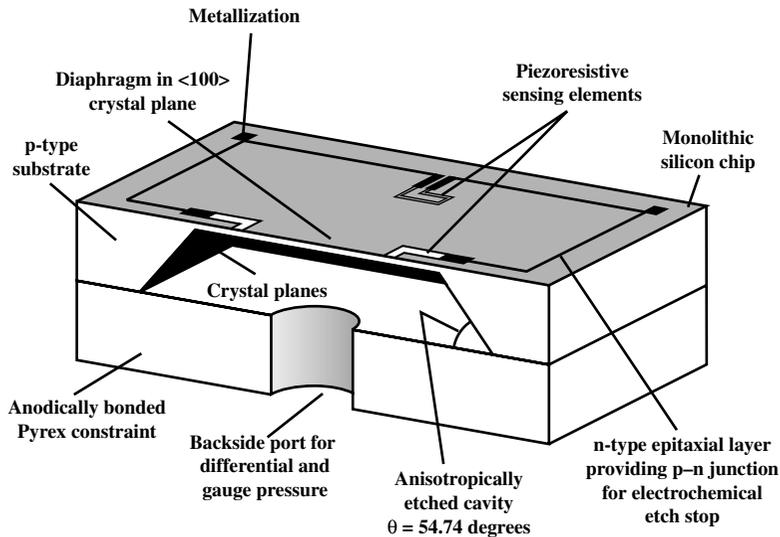

### 26.2.2.1 Bulk Micromachining

Bulk micromachining is the oldest technology for making MEMS. The technique has been used to fabricate sensors for about 20 years. The mechanical structures are created within the confines of a silicon wafer by selectively removing parts of the wafer material, and this is done by using orientation-dependent etching of single-crystal silicon substrate. Etch-stopping techniques and masking films are crucial in the bulk micromachining process. The etching can be either isotropic or anisotropic, or a combination of both. In isotropic etching, the etch rate is identical in all directions, while in anisotropic etching the etch rate depends on the crystallographic orientation of the wafer. Two commonly used etchants are ethylene diamine pyrocatechol (EDP) and an aqueous solution of potassium hydroxide (KOH). It is important to be able to stop the etching process at a precise location, and to do so etch-stopping techniques have been developed. One such method is based on the fact that heavily doped regions etch more slowly than undoped regions; hence, by doping a portion of the material, the etch process can be made selective. Another technique for etch stopping is electrochemical in nature and is based on the fact that etching stops upon encountering a region of different polarity in a biased p-n junction.

A good illustration of the various steps in the bulk microfabrication process is the following example. Tien (1997) has summarized the processing steps necessary for micromachining a hole and a diaphragm in a wafer, and this is shown in [Figure 26.1](#). Silicon nitride is used as an etch mask, as it is not etched

**FIGURE 26.1** Bulk micromachined structures, diaphragm and via hole in a silicon substrate. Deposited silicon nitride is the mask for the wet etch, and the doped silicon layer serves as an etch stop for the diaphragm formation. (From Tien, N.C. (1997) *Microscale Thermophys. Eng.*, 1, 275–292. Reproduced by permission of Taylor & Francis, Inc.)

**FIGURE 26.2** A bulk micromachined pressure sensor shown in cross section. The sensor contains a thin silicon diaphragm formed by etching the silicon wafer with alkaline hydroxide. The diaphragm deflection depends on pressure and is sensed by boron-doped piezoresistors. (From Bryzek, J. et al. (1994) *IEEE Spectrum*, 31, 20–31. © 1994 IEEE. With permission.)

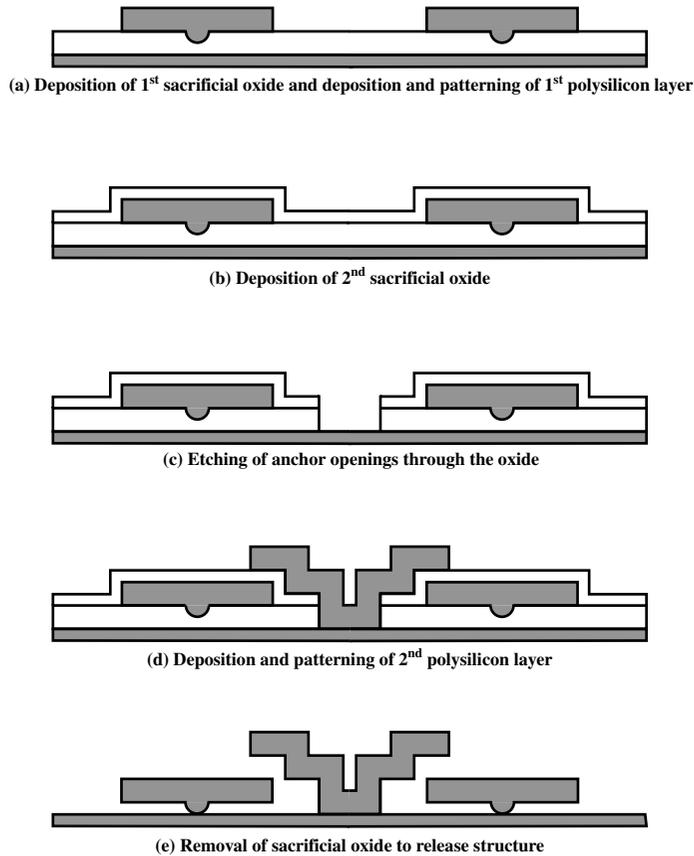

by either EDP or KOH. To stop the etch process at a specific location, and thereby form the diaphragm, a region heavily doped with boron is used. Holes and diaphragms, as shown in Figure 26.1, constitute the basis for many mechanical devices, such as, for example, pressure transducers which today are commercially available for measurements in the range of 60 Pa to 68 MPa.

The fabrication of a pressure transducer is straightforward, as has been summarized by Bryzek et al. (1994). As illustrated in Figure 26.2, the process starts with a silicon substrate that is polished on both sides. Boron-doped piezoresistors and both  $p^+$  and  $n^+$  enhancement regions are introduced by means of diffusion and ion implantation. Piezoresistors are the sensitive elements in pressure and acceleration sensors, as their resistance varies with stress and temperature, the latter being the unwanted part of the signal if the objective is to measure force. A thin layer of deposited aluminum or other metal creates the ohmic contacts and connects the piezoresistors into a Wheatstone bridge. Finally, the device side of the wafer is protected and the back is patterned to allow formation of an anisotropically etched diaphragm. After stripping and cleaning, the wafer is anodically bonded to Pyrex® and finally diced.

Bulk micromachining is the most mature of the micromachining technologies and constitutes the base for many microdevices such as silicon pressure sensors and silicon accelerometers. The fabrication process is straightforward and does not require much elaborate equipment, but the technique is afflicted with some severe, limiting drawbacks. Because the geometries of the structures are restricted by the aspect ratio inherent in the fabrication method, the devices tend to be larger than those made with other micromachining technologies. As a consequence of this, expensive silicon “real state” is wasted. Another drawback is the use of alkaline etchants, which unfortunately are not compatible with IC manufacturing. However, strategies to circumvent these drawbacks are available and details on such methods can be found in Bryzek et al. (1994) and Tien (1997).

### 26.2.2.2 Surface Micromachining

In contrast to bulk micromachining techniques, surface micromachining does not penetrate the wafer. Instead, thin-film materials are selectively added to and removed from the substrate during the processing. Polysilicon is used as the mechanical material, with sacrificial material such as silicon dioxide sandwiched between layers of polysilicon. Both materials are commonly deposited using low-pressure chemical vapor

**FIGURE 26.3** Polysilicon surface micromachining process for the fabrication of a slider with a central rail. (From Tien, N.C. (1997) *Microscale Thermophys. Eng.*, 1, 275–292. Reproduced by permission of Taylor & Francis, Inc.)

deposition (LPCVD). Both wet and dry etching are essential, and the sacrificial layers constitute the basis of surface micromachining.

To illustrate the processes necessary for surface micromachining, a simplified fabrication of a polysilicon slider with a central rail has been summarized by Tien (1997), and the basic steps are illustrated in Figure 26.3. Two layers of structural polysilicon and sacrificial oxide are needed for this design; Figure 26.3a illustrates the first sacrificial oxide layer and how the deposition and patterning of the first polysilicon layer have been completed. Figures 26.3b and c show the deposition of the second sacrificial oxide layer together with the free etching of the anchor openings through the oxide. The next step is the deposition and patterning of the second polysilicon layer, followed by removal of the sacrificial oxide used to release the structure. More details including used etchants, sacrificial layers and other “tricks” used in the fabrication process can be found in Tien (1997).

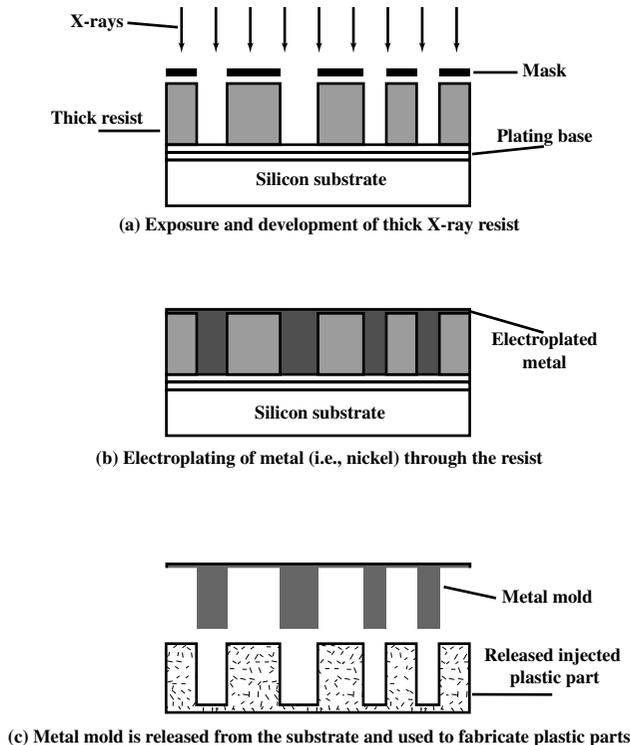

An essential advantage of surface micromachining is that there is no constraint on the miniaturization of the devices fabricated other than those raised by limitations in the lithography technology. Another important benefit is that structurally complex mechanical systems including freestanding or moveable parts can be created by stacking multiple layers of material. In addition, surface micromachining offers a high degree of compatibility with IC processing, an important trait assuming that the future success of MEMS will be linked to the integration of electronics with mechanical systems. The main drawback of surface micromachining is that it is a thin-film technology that creates essentially two-dimensional structures. However, this has been circumvented by creative designs [e.g., Pister et al., 1992; Tien et al., 1996a; 1996b]. We shall return to the issue of three-dimensional structures in the microactuators section.

### 26.2.2.3 Micromolding

Although the micromolding technique is more similar to conventional machining in concept, it should be discussed in connection with micromachining because it is capable of producing minute devices using advanced IC lithography. In this group, the LIGA process is the most common method and was introduced in the late 1980s by Ehrfeld et al. (1988). (LIGA is a German acronym for Lithographie, Galvanoformung, Abformung; in English, lithography, electroforming and molding). The method basically relies on forming a metal mold using lithographic techniques. To form the mold, a thick layer of photoresist placed on top of a conductive substrate is exposed and developed using X-ray lithography. As illustrated in Figure 26.4, the metal is then electroplated from the substrate through the openings in the photoresist. After removing the photoresist, the metal mold can be used for pouring low-viscosity polymers such as polyimide, polyimethyl metacrylate and other plastic resins. After curing, the mold is removed, leaving behind microreplicas of the original pattern. Products created by LIGA are three dimensional and include, for example, thermally actuated microrelays, micromotors, magnetic actuators, micro-optics and micro-connectors, as well as a host of micromechanical components such as joints, springs, bearings and gears.

An extension of the LIGA process, the SLIGA technique, gains another degree of design freedom by combining LIGA with the use of sacrificial layers. Keller and Howe (1995) have presented the HEXSIL, which also includes a sacrificial layer and creates polysilicon components. A drawback of the micromolding method is that the assembly of small parts and the integration of electronics with mechanical devices can be real challenges. Additionally, the X-ray equipment necessary for the fabrication is quite expensive.

To conclude this section, it is worth mentioning that much of what is known about the design of mechanical structures scales down to the microstructure level very nicely; however, the same cannot be said for the properties of materials moving from the bulk to the thin-film regimes. For instance, residual stresses within thin films can produce unwanted tension or compression within the microstructure.

**FIGURE 26.4** The basic LIGA process. (From Tien, N.C. (1997) *Microscale Thermophys. Eng.*, 1, 275–292. Reproduced by permission of Taylor & Francis, Inc.)

Microdefects can be ignored for thicknesses greater than 10  $\mu\text{m}$  but become important in the 1- $\mu\text{m}$  range, which is typical for surface micromachining. Finally, microfriction, surface tension and van der Waals forces can create undesired stiction or adhesion [e.g., Israelachvili, 1991].

## 26.3 Turbulent Flows

---

### 26.3.1 Introductory Remarks

For more than 100 years, turbulence has been a fascinating challenge to scientists in fluid mechanics. It is very easy to observe a turbulent flow and to form a picture of its nature by looking at, for instance, the plume of a smoke stack. Such visualization shows clearly that the turbulent flowfield contains numerous eddies of various size, orientation and intensity. The largest eddies have a spatial extension of approximately the same size as the width of the flowfield, while the smallest eddies are of the size where viscous effects become dominant and energy is transferred from kinetic into internal. To qualitatively analyze turbulent flowfields, the eddies are conveniently described by length, time and velocity scales.

In this section, we provide a general discussion on the classification of small and large length scales and their importance in analyzing and modeling turbulent flows. We find that the width of the wave-number spectrum is proportional to the Reynolds number in such a way that high  $Re$  generates smaller scales. Because turbulent flows are high-Reynolds-number flows, it is clear that a knowledge of scales, and in particular the small scales, is essential for the analysis and modeling of turbulence. MEMS offer through miniaturization of sensors and actuators unique opportunities to resolve, as well as to target for control, the smallest scales even at high  $Re$  and thus provide this essential information. The scale discussion here constitutes a cornerstone for the following sections, where we consider the use of MEMS sensors and actuators for measuring and controlling turbulence. For the benefit of readers new to turbulence, we start with a very gentle introduction to the subject, leading to simple ways for estimating typical scales and sensor requirements for a particular flow field.

### 26.3.2 Definition of Turbulence

During the century in which turbulence has been formally studied many different definitions have been contemplated. The first attempt to define turbulence was made in the late nineteenth century by Osborne Reynolds who simply stated that turbulence was a “sinuous motion.” Later, more comprehensive and detailed definitions have been given, and it is noteworthy that each definition commonly has been associated with the current fashion of approaching the closure problem of turbulence. Hence, the definition by G. I. Taylor in the 1930s had clear links to the statistical treatments of turbulence by Peter Bradshaw in the 1960s for hot-wire measurements and by Marcel Lesieur in the late 1980s for large-eddy and direct numerical simulations.

The most pragmatic definition is probably the one given by Tennekes and Lumley (1972), who provide not quite a definition but instead seven characteristics of turbulence. The authors stated that turbulence is irregular, or random, and this makes a deterministic approach impossible so in the analysis one must rely on statistical methods. Diffusivity is another crucial feature of turbulence, as it causes rapid mixing and increased rates of momentum, heat and mass transfer. Turbulent flows occur always at high Reynolds numbers which implies that they are always associated with small scales and complex interactions between the viscous and the nonlinear inertia terms in the equations of motion. All turbulent flows are three dimensional and are characterized by high levels of vorticity fluctuations. The viscous shear stresses perform deformation work, which increases the internal energy at the expense of the kinetic energy, meaning that all turbulent flows are strongly dissipative. If no energy is supplied, turbulent flows eventually decay. Under ordinary circumstances turbulence is a continuum phenomenon, so turbulent flows obey the continuum hypothesis, and the governing equations of fluid mechanics are applicable instantaneously. Even the smallest scales of a turbulent field are under normal conditions much larger than

any molecular length scale. Finally, turbulent flows are flows, and because all turbulent flows are unique no general solution to problems associated with turbulence is in sight. In spite of the latter statement, turbulent flows have many characteristics in common, and this fact is exploited in the following section dealing with methods of analysis.

### 26.3.3 Methods for Analyzing Turbulence

Turbulence is one of the unsolved problems in classical physics, and it is still almost impossible to make accurate quantitative predictions for turbulent flows without relying heavily on empirical data. This is basically due to the fact that no methodology exists for obtaining stochastic solutions to the nonlinear partial differential equations describing the instantaneous three-dimensional flow. Moreover, statistical studies of the equations of motion always lead to a situation where there are more unknowns than equations, the closure problem of turbulence. This can easily be derived and is shown in most textbooks in the field [e.g., Tennekes and Lumley, 1972; Hinze, 1975; Pope, 2000]. Excluding direct numerical simulations of the governing equations, which thus far have been used only for simple geometries and low Reynolds numbers, it can be stated that all computations, both scientific and engineering, of turbulent flows will even in the foreseeable future require experiment, modeling and analysis.

One powerful tool in the study of turbulent flows is dimensional analysis because it may be possible under certain conditions to argue that the structure of turbulence depends only on a few independent variables. Then, dimensional analysis dictates the relation between the dependent and independent variables, and the solution is known except for a numerical coefficient. An example where dimensional analysis has been successful is in the derivation of the region called the “inertial subrange” in the turbulence kinetic energy spectrum. Here the slope obeys the so-called  $-5/3$  law.

Because turbulent flows are characterized by high Reynolds numbers, it is reasonable to expect that a description of turbulence should behave properly as the Reynolds number approaches infinity. This method of analysis is called *asymptotic invariance* and has been successfully used in the development of the theory for turbulent boundary layers. In analyzing turbulence, the concept of local invariance or “self-preservation” is often invoked. This tool is powerful when the turbulent flow can be characterized as if it was controlled mainly by its immediate environment, and this situation occurs typically in the far downstream region of a wake, jet or free-shear layer. There, the time and length scales vary only slowly in the downstream direction, and if the turbulence time scales are sufficiently small it can be assumed that the flow has sufficient time to adjust to its gradually changing environment. The turbulence then is dynamically similar everywhere provided the average quantities are nondimensionalized with local length and time scales.

More details on the physics of turbulence can be found in classical textbooks in the field [Tennekes and Lumley, 1972; Hinze, 1975; Monin and Yaglom, 1975; Townsend, 1976]. There are also many good modern books available on the subject [McComb, 1990; Lesieur, 1991; Holmes et al., 1996; Pope, 2000]. The important point here is that almost all methods for analyzing turbulence are heuristic and are not derived from first principles; therefore, detailed measurements of flow quantities will continue to be an essential component of the arsenal of attacks on the turbulence problem. In this context, MEMS-based sensors have widened the horizon of experiments and can be used for measuring turbulence reliably and inexpensively at high Reynolds numbers.

### 26.3.4 Scales

As mentioned, turbulence is a high-Reynolds-number phenomenon that is characterized by the existence of numerous length and time scales. The spatial extension of the length scales is bounded from above by the dimensions of the flowfield and from below by the diffusive and dissipative action of the molecular viscosity. If we limit our interest to shear flows, which are basically characterized by two large length scales, one in the streamwise direction (the convective or longitudinal length scale) and the other perpendicular to the flow direction (the diffusive or lateral length scale), we obtain a more well-defined problem.

Moreover, at sufficiently high Reynolds numbers the boundary layer approximation applies and it is assumed that there is a wide separation between the lateral and the longitudinal length scales. This leads to some attractive simplifications in the equations of motion—for instance, the elliptical Navier-Stokes equations are transferred to the parabolic boundary-layer equations [e.g., Hinze, 1975]. So in this approximation, the lateral scale is approximately equal to the extension of the flow perpendicular to the flow direction (the boundary-layer thickness), and the largest eddies typically have this spatial extension.

The large eddies are most energetic and play a crucial role both in the transport of momentum and contaminants. A constant energy supply is needed to maintain the turbulence, and this energy is extracted from the mean flow into the largest most energetic eddies. The lateral length scale is also the relevant scale for analyzing this energy transfer. However, there is an energy destruction in the flow due to the action of the viscous forces (the dissipation), and for the analysis of this process other smaller length scales are needed.

As the eddy size decreases, viscosity becomes a more significant parameter, as one property of viscosity is its effectiveness in smoothing out velocity gradients. The viscous and the nonlinear terms in the momentum equation counteract each other in the generation of small-scale fluctuations. While the inertial terms try to produce smaller and smaller eddies, the viscous terms check this process and prevent the generation of infinitely small scales by dissipating the small-scale energy into heat. In the early 1940s, the universal equilibrium theory was developed by Kolmogorov (1941a; 1941b). One cornerstone of this theory is that the small-scale motions are statistically independent of the relatively slower large-scale turbulence. An implication of this is that the turbulence at the small scales depends only on two parameters—namely, the rate at which energy is supplied by the large-scale motion and the kinematic viscosity. In addition, it is assumed in the equilibrium theory that the rate of energy supply to the turbulence should be equal to the rate of dissipation. Hence, in the analysis of turbulence at small scales, the dissipation rate per unit mass  $\varepsilon$  is a relevant parameter together with the kinematic viscosity  $\nu$ . Kolmogorov (1941a; 1941b) used simple dimensional arguments to derive length, time and velocity scales relevant for the small-scale motion, given respectively by:

$$\eta = \left( \frac{\nu^3}{\varepsilon} \right)^{1/4} \quad (26.1)$$

$$\tau = \left( \frac{\nu}{\varepsilon} \right)^{1/2} \quad (26.2)$$

$$v = (\nu\varepsilon)^{1/4} \quad (26.3)$$

These scales are accordingly called the *Kolmogorov microscales*, or sometimes the inner scales of the flow. As they are obtained through a physical argument, these scales are the smallest scales that can exist in a turbulent flow and they are relevant for both free-shear and wall-bounded flows.

In boundary layers, the shear-layer thickness provides a measure of the largest eddies in the flow. The smallest scale in wall-bounded flows is the viscous wall unit, which will be shown below to be of the same order as the Kolmogorov length scale. Viscous forces dominate over inertia in the near-wall region, and the characteristic scales there are obtained from the magnitude of the mean vorticity in the region and its viscous diffusion away from the wall. Thus, the viscous time scale  $t_v$  is given by the inverse of the mean wall vorticity:

$$t_v = \left[ \left. \frac{\partial \bar{U}}{\partial y} \right|_w \right]^{-1} \quad (26.4)$$

where  $\bar{U}$  is the mean streamwise velocity. The viscous length-scale  $\ell_v$  is determined by the characteristic distance by which the (spanwise) vorticity is diffused from the wall, and is thus given by:

$$\ell_v = \sqrt{\nu t_\tau} = \sqrt{\frac{\nu}{\partial \bar{U} / \partial y|_w}} \quad (26.5)$$

where  $\nu$  is the kinematic viscosity. The wall velocity-scale (so-called friction velocity,  $u_\tau$ ) follows directly from the above time and length scales:

$$u_\tau = \frac{\ell_v}{t_\tau} = \sqrt{\nu \frac{\partial U}{\partial y}|_w} = \sqrt{\frac{\tau_w}{\rho}} \quad (26.6)$$

where  $\tau_w$  is the mean shear stress at the wall, and  $\rho$  is the fluid density. A wall unit implies scaling with the viscous scales, and the usual  $( )^+$  notation is used; for example,  $y^+ = y/\ell_v = yu_\tau/\nu$ . In the wall region, the characteristic length for the large eddies is  $y$  itself, while the Kolmogorov scale is related to the distance from the wall  $y$  as follows:

$$\eta^+ = \frac{\eta u_\tau}{\nu} \approx (\kappa y^+)^{1/4} \quad (26.7)$$

where  $\kappa$  is the von Karman constant ( $\approx 0.41$ ). As  $y^+$  changes in the range of 1 to 5 (the extent of the viscous sublayer),  $\eta$  changes from 0.8 to 1.2 wall units.

We now have access to scales for the largest and smallest eddies of a turbulent flow. To continue our analysis of the cascade energy process, it is necessary to find a connection between these diverse scales. One way of obtaining such a relation is to use the fact that at equilibrium the amount of energy dissipating at high wavenumbers must equal the amount of energy drained from the mean flow into the energetic large-scale eddies at low wavenumbers. In the inertial region of the turbulence kinetic energy spectrum, the flow is almost independent of viscosity and, because the same amount of energy dissipated at the high wavenumbers must pass this “inviscid” region, an inviscid relation for the total dissipation may be obtained by the following argument. The amount of kinetic energy per unit mass of an eddy with a wavenumber in the inertial sublayer is proportional to the square of a characteristic velocity for such an eddy,  $u^2$ . The rate of transfer of energy is assumed to be proportional to the reciprocal of one eddy turnover time,  $u/\ell$ , where  $\ell$  is a characteristic length of the inertial sublayer. Hence, the rate of energy that is supplied to the small-scale eddies via this particular wavenumber is of order  $u^3/\ell$ , and this amount of energy must be equal to the energy dissipated at the highest wavenumber, expressed as:

$$\varepsilon \approx \frac{u^3}{\ell} \quad (26.8)$$

Note that this is an inviscid estimate of the dissipation, as it is based on large-scale dynamics and does not either involve or contain viscosity. More comprehensive discussion of this issue can be found in Taylor (1935) and Tennekes and Lumley (1972). From an experimental perspective, this is a very important expression as it offers one way of estimating the Kolmogorov microscales from quantities measured in a much lower wavenumber range.

Because the Kolmogorov length and time scales are the smallest scales occurring in turbulent motion, a central question will be how small these scales can be without violating the continuum hypothesis. By looking at the governing equations, it can be concluded that high dissipation rates are usually associated with large velocities, and this situation is more likely to occur in gases than in liquids so it would be sufficient to show that for gas flows the smallest turbulence scales are normally much larger than the

molecular scales of motion. The relevant molecular length scale is the mean free path,  $\Lambda$ , and the ratio between this length and the Kolmogorov length scale,  $\eta$ , is the microstructure Knudsen number and can be expressed as [see Corrsin, 1959]:

$$Kn = \frac{\Lambda}{\eta} \approx \frac{Ma^{1/4}}{Re} \quad (26.9)$$

where the turbulence Reynolds number  $Re$  and the turbulence Mach number  $Ma$  are used as independent variables. It is obvious that a turbulent flow will interfere with the molecular motion only at a high Mach number and low Reynolds number, a very unusual situation occurring only in certain gaseous nebulae. (Note that in microduct flows and the like, the  $Re$  is usually too small for turbulence to even exist, so the issue of turbulence Knudsen number is moot in those circumstances even if rarefaction effects become strong.) Thus, under normal conditions the turbulence Knudsen number falls in the group of continuum flows. Noteworthy, however, is that measurements using extremely thin hot-wires, small MEMS sensors or flows within narrow MEMS channels can generate values in the slip-flow regime and even beyond, and this implies, for instance, that the no-slip condition may be questioned.

### 26.3.5 Sensor Requirements

The ultimate goal of all measurements in turbulent flows is to resolve both the largest and smallest eddies that occur in the flow. At the lower wavenumbers, the largest and most energetic eddies occur, and normally there are no problems associated with resolving these eddies. Basically, this is a question of having access to computers with sufficiently large memory for storing the amount of data acquired from a large number of distributed probes, each collecting data for a time period long enough to reduce the statistical error to a prescribed level. However, at the other end of the spectrum, both the spatial and the temporal resolutions are crucial, putting severe limitations on the sensors to be used. It is possible to obtain a relation between the small and large scales of the flow by substituting the inviscid estimate of the total dissipation rate, Eq. (26.8), into the expressions for the Kolmogorov microscales, Eqs. (26.1) to (26.3); thus,

$$\frac{\eta}{\ell} \approx \left(\frac{u\ell}{\nu}\right)^{3/4} = Re^{3/4} \quad (26.10)$$

$$\frac{\tau u}{\ell} \approx \left(\frac{u\ell}{\nu}\right)^{-1/2} = Re^{-1/2} \quad (26.11)$$

$$\frac{\nu}{u} \approx \left(\frac{u\ell}{\nu}\right)^{-1/4} = Re^{-1/4} \quad (26.12)$$

where  $Re$  is the Reynolds number based on the speed of the energy containing eddies  $u$  and their characteristic length  $\ell$ . Because turbulence is a high-Reynolds-number phenomenon, these relations show that the small length, time and velocity scales are much less than those of the larger eddies, and that the separation in scales widens considerably as the Reynolds number increases. Moreover, this also implies that the assumptions made on the statistical independence and the dynamical equilibrium state of the small structures will be most relevant at high Reynolds numbers. Another interesting conclusion that can be drawn from the above relations is that if two turbulent flow fields have the same spatial extension (i.e., same large scale) but different Reynolds numbers, there would be an obvious difference in the small-scale structure in the two flows. The low-Reynolds-number flow would have a relatively coarse small-scale structure, while the high-Reynolds-number flow would have much finer small eddies.

To spatially resolve the smallest eddies, sensors approximately the same size as the Kolmogorov length scale for the particular flow under consideration are needed. This implies that as the Reynolds number increases smaller sensors are required. For instance, in the self-preserving region of a plane-cylinder wake at a modest Reynolds number, based on the cylinder diameter of 1840, the value of  $\eta$  varies in the range of 0.5 to 0.8 mm [Aronson and Löfdahl, 1994]. For this case, conventional hot-wires can be used for turbulence measurements. However, an increase in the Reynolds number by a factor of ten will yield Kolmogorov scales in the micrometer range and call for either extremely small conventional hot-wires or MEMS-based sensors. Another illustrating example of the Reynolds number effect on the requirement of small sensors is a simple two-dimensional, flat-plate boundary layer. At a momentum thickness Reynolds number of  $Re_\theta = 4000$ , the Kolmogorov length scale is typically of the order of 50  $\mu\text{m}$ , and in order to resolve these scales it is necessary to have access to sensors that have a characteristic active measuring length of the same spatial extension.

Severe errors will be introduced in the measurements by using sensors that are too large, as such a sensor will integrate the fluctuations due to the small eddies over its spatial extension, and the energy content of these eddies will be interpreted by the sensor as an average “cooling.” When measuring fluctuating quantities, this implies that these eddies are counted as part of the mean flow and their energy is “lost.” The result will be a lower value of the turbulence parameter, and this will wrongly be interpreted as a measured attenuation of the turbulence [Ligrani and Bradshaw, 1987]. However, because turbulence measurements deal with statistical values of fluctuating quantities, it may be possible to loosen the spatial constraint of having a sensor of the same size as  $\eta$ , to allow sensor dimensions slightly larger than the Kolmogorov scale—say, on the order of  $\eta$ .

For boundary layers, the wall unit has been used to estimate the smallest necessary size of a sensor for accurately resolving the smallest eddies. For example, Keith et al. (1992) state that 10 wall units or less is a relevant sensor dimension for resolving small-scale pressure fluctuations. Measurements of fluctuating velocity gradients, essential for estimating the total dissipation rate in turbulent flows, are another challenging task. Gad-el-Hak and Bandyopadhyay (1994) argue that turbulence measurements with probe lengths greater than the viscous sublayer thickness (about 5 wall units) are unreliable, particularly near the surface. Many studies have been conducted on the spacing between sensors necessary to optimize the formed velocity gradients [see Aronson et al., 1997, and references therein]. A general conclusion from both experiments and direct numerical simulations is that a sensor spacing of 3 to 5 Kolmogorov lengths is recommended. When designing arrays for correlation measurements the spacing between the coherent structures will be the determining factor. For example, when studying the low-speed streaks in a turbulent boundary layer, several sensors must be situated along a lateral distance of 100 wall units, the average spanwise spacing between streaks. All this requires quite small sensors, and many attempts have been made to meet these conditions with conventional sensor designs. However, in spite of the fact that conventional sensors such as hot-wires have been fabricated in the micrometer-size range (for their diameter but not their length), they are usually handmade, difficult to handle and too fragile, and it is here that MEMS technology has really opened a door for new applications.

It is clear from the above that the spatial and temporal resolutions for any probe to be used to resolve high-Reynolds-number turbulent flows are extremely tight. For example, both the Kolmogorov scale and the viscous length scale change from a few microns at the typical field Reynolds number—based on the momentum thickness—of  $10^6$  to a couple of hundred microns at the typical laboratory Reynolds number of  $10^3$ . MEMS sensors for pressure, velocity, temperature and shear stress are at least one order of magnitude smaller than conventional sensors [Löfdahl et al., 1994a; 1994b; Ho and Tai, 1998]. Their small size improves both the spatial and temporal resolutions of the measurements, typically a few microns and few microseconds, respectively. For example, a micro-hot-wire (called a *hot-point*) has very small thermal inertia, and the diaphragm of a micro-pressure-transducer has correspondingly fast dynamic response. Moreover, the extreme miniaturization and low energy consumption of microsensors make them ideal for monitoring the flow state without appreciably affecting it. Also, literally hundreds of microsensors can be fabricated on the same silicon chip at a reasonable cost, making them well suited for distributed measurements and control. The UCLA/Caltech team [Ho and Tai, 1996; 1998, and references therein]

has been very effective in developing many MEMS-based sensors and actuators for turbulence diagnosis and control.

In the next section we focus our attention on sensors used for measurements in turbulent flows. Specifically, we discuss sensors for velocity, pressure and wall-shear stress, quantities that so far have been difficult to measure and for which the introduction of MEMS has created a completely new perspective.

## 26.4 Sensors for Turbulence Measurements and Control

---

### 26.4.1 Introductory Remarks

By definition, a transducer is a device actuated by power from one system that supplies power, usually in another form, to a second system. Hence, in an electromechanical transducer one connection to the environment typically conducts electrical energy and another conducts mechanical energy. Microphones, loudspeakers, strain gauges and electric motors are examples of electromechanical transducers, which in turn may be categorized into sensors and actuators. A sensor is a device that responds to physical stimulus such as velocity, pressure and temperature and transmits a resulting impulse for either measurement or control purposes. The output of a sensor may depend on more than one variable. Ideally, the sensor monitors the state of a system without affecting it, while an actuator operates on the system the other way around: It imposes a state without regard to the system load.

Typically, a sensor converts the physical parameter to be measured into an electrical signal, which is subsequently analyzed and interpreted. The studied physical parameters are usually classified into different groups, such as chemical, mechanical and thermal signals, and the transducer or sensor “helps” the electronic to “see,” “hear,” “smell,” “taste” or “touch.” In many applications, a sensor can be divided into a sensing part and a converting part. For instance, for a piezoresistive pressure sensor, the sensing part is the deflecting diaphragm and the converting part is the piezoresistor, which converts the deflection of the diaphragm into an electrical signal. It is generally more difficult to control a system than to monitor it, and in the last decade it has been more challenging for scientists and engineers to design and build microsensors than microactuators. As a consequence, progress in sensors lags behind that in actuators.

### 26.4.2 Background

A typical MEMS sensor is well below 1 mm in size, and at least one order of magnitude smaller than traditional sensors used to measure instantaneous flow quantities such as velocity, pressure and temperature. The small spatial extension implies that both the inertial mass and the thermal capacity are reduced which make these sensors suited for measurements of flow quantities in high-Reynolds-number turbulent flows where both high-frequency response and fine spatial resolution are essential. For instance, pressure and velocity sensors with, respectively, diaphragm side length and wire length of less than 100  $\mu\text{m}$  are in use today. MEMS sensors are not handmade but are produced by photolithographic methods, implying that each unit is fabricated to extremely low tolerance and at low cost. (Normally the fabrication of a prototype sensor, the first batch, is very costly, but once the fabrication principle has been outlined the unit cost drops dramatically.) The latter trait makes it possible to use a large number of sensors to cover large areas/volumes of the flowfield. This in turn makes it feasible to study coherent structures and to effectively execute reactive control for turbulent shear flows. An additional important advantage of microfabrication is that it enables packing of sensors in arrays on the same silicon chip. A major difficulty, however, is that the leads of each sensor have to be connected to an external signal-conditioning instrument; also, the handling of numerous signal paths is tedious and they occupy a large portion of the precious surface area of the chip. For example, Ho and Tai (1998) state that their array of wall-shear-stress sensors containing 85 elements occupies 1% of the area, while the leads take about 50% of the surface. However, current research is attempting to solve this problem.

In this section, we look at MEMS-based sensors for use in turbulence measurements and reactive flow-control applications. In particular, we review the state of the art of microsensors used to measure the

instantaneous velocity, wall-shear stress and pressure, which we deem as quantities of primary importance in turbulence diagnosis and control. For each group, we give a general background, design criteria and calibration procedure and provide examples of measurements conducted with MEMS-based sensors. When possible, we compare the results to conventional measurements. Each subsection concludes with brief remarks on future prospects.

## 26.4.3 Velocity Sensors

### 26.4.3.1 Background

Turbulence is one of the unsolved problems of classical physics, and it is almost impossible to make predictions for turbulent flows without relying heavily on empirical data. Because turbulence obeys the continuum hypothesis, the governing equations are known and an analysis of these equations shows that mean velocities, higher order moments of fluctuating velocities and products of gradients of fluctuating velocities are needed for future development of turbulence models. To this end, thermal anemometers have been the most significant tool for measuring these quantities. The introduction of MEMS has extended the range of applicability of the thermal anemometer and has provided incentives for conducting new measurements in high-Reynolds-number flows. This progress is basically achieved by the increased spatial and temporal resolutions that are feasible through the miniaturization and formation of sensor arrays.

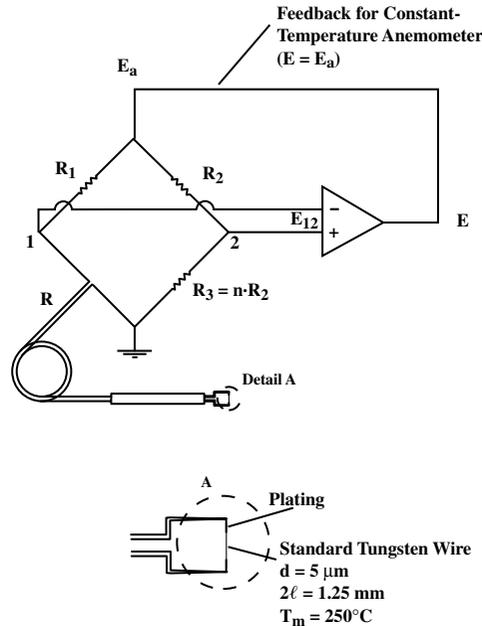

According to King (1914), the first experiments using thermal anemometers were conducted already in 1902, but otherwise the work of King (1915; 1916) on the design of hot-wires and on the theory of heat convection from cylinders is considered the starting point for the era of thermal anemometry research. Early experiments were usually limited to measurements of mean velocities. In the late 1920s, however, the emphasis shifted toward measurements of fluctuating velocities [e.g., Dryden and Kuethé, 1930]. Since then, numerous papers in the field describe measurements that have been conducted using thermal anemometry with hot-wires or hot-films as sensing elements. Many researchers have made significant contributions to thermal anemometry and should be given credit in any complete review of the subject; however, here we focus only on the advantages gained from MEMS for improving measurements with current thermal anemometry. For a literature review of conventional hot-wires, the reader is referred to the survey papers by Comte-Bellot (1976), Freymuth (1983; 1992) and Fingerson and Freymuth (1977) and to the books by Hinze (1975), Lomas (1986) and Perry (1982).

In this section, we recall the principle of thermal anemometry for velocity measurements and summarize the characteristics of hot-wire sensors operated in a constant-temperature circuit. Because the governing equations of thermal anemometry are the same whether the sensor is a conventional hot-wire or a MEMS-based probe, we discuss these equations for one, two and three sensors and remark on their applicability for MEMS. We provide an overview of current MEMS-based sensors used for velocity measurements and discuss the results of experiments conducted with these probes. Finally, the section ends with the future outlook for MEMS velocity sensors.

### 26.4.3.2 Thermal-Sensor Principle

For our purpose, we may consider the thermal anemometer as a device used for measuring significant quantities for turbulence diagnosis and for reactive flow control. The sensors used are small, conducting elements which are heated by an electric current and cooled by the flow. All modes of heat transfer are present but forced convection is usually the dominant mode. From the temperature, or rather resistance, attained by the sensor, it is possible to gain the desired information on the instantaneous velocity vector. In order to thoroughly investigate a turbulent flowfield, usually more than one sensor is needed and multisensor arrangements are commonly used in measurements forming the base for development of turbulence models.

The generally small sensor size yields a good spatial resolution and frequency response [Freymuth, 1977], making thermal anemometry especially suited for studying flow details in turbulent flows. A simple thermal anemometer is shown schematically in [Figure 26.5](#). The minute resistor mounted between two

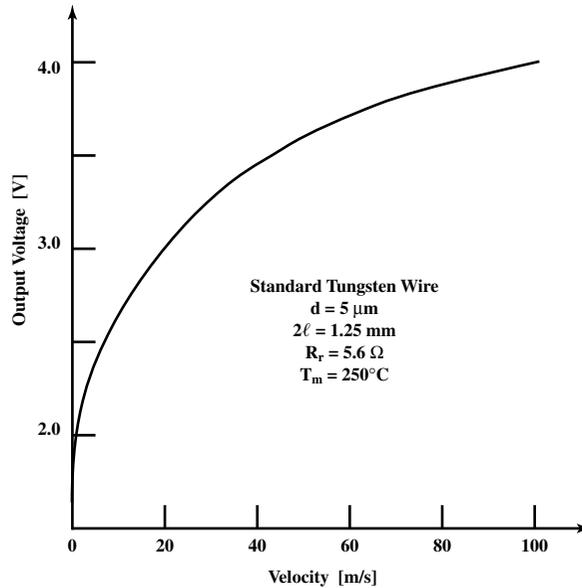

**FIGURE 26.5** Basic elements of a hot-wire anemometer. (From Fingerson, L.M., and Freymuth, P. (1977) in *Fluid Mechanics Measurements*, 2nd ed., R.J. Goldstein, Ed., Taylor & Francis, Washington, D.C., pp. 115–173. Reproduced by permission of Routledge, Inc.)

prongs constitutes the sensing part and forms one arm in a Wheatstone bridge. For moderate temperature changes, the hot-wire resistance changes linearly with its temperature:

$$R = R_r[1 + \alpha(T_m - T_r)] \quad (26.13)$$

where  $R_r$  is the resistance at the reference temperature  $T_r$ ,  $T_m$  is the mean sensor temperature along its length and  $\alpha$  is the temperature coefficient of resistance. The latter value is critical, because if the hot-wire sensor did not vary in resistance with temperature there would be no signal from a thermal anemometer. The ambient fluid temperature  $T_a$  is often used as reference temperature  $T_r$ , and the value of  $\alpha$  depends on the reference temperature used.

The Wheatstone bridge arrangement shown in Figure 26.5 is designed so that resistance  $R_1$  is large compared to that of the sensor. Then, current  $I$  through the hot-wire is nearly constant. This implies that any increase in heat transfer from the hot-wire to its surrounding will cause the sensor to cool, and this in turn will decrease the hot-wire resistance  $R$  (a decrease in the voltage  $E_{12}$  and a decrease in the amplifier output  $E$ ). A decrease in heat transfer between sensor and fluid will have the opposite effect and create an increase in  $E$ . Without the feedback amplifier, the principle scheme shown in Figure 26.5 is basically an uncompensated, constant-current, hot-wire anemometer, and this kind of system was dominate in the infancy of the thermal anemometer era. Since then, advances have taken place in hot-wire fabrication, electronic control circuits and data acquisition. The result is that the constant-current operation of thermal sensors has been largely replaced by the constant-temperature operation, which offers much better stability and frequency response through high-gain feedback amplifiers. Stability criteria and techniques for checking the frequency response are now well understood for constant-temperature systems, and the introduction of digital techniques have significantly expanded the capabilities for analyzing the resulting data. Today, the nonlinear output is no longer a limitation; correlations, power spectra and amplitude probability distributions are all readily obtainable.

**FIGURE 26.6** Typical calibration curve for a hot-wire anemometer. (From Fingerson, L.M., and Freymuth, P. (1977) in *Fluid Mechanics Measurements*, 2nd ed., R.J. Goldstein, Ed., Taylor & Francis, Washington, D.C., pp. 115–173. Reproduced by permission of Routledge, Inc.)

### 26.4.3.3 Calibration

A calibration curve is usually obtained by measuring a number of distinct velocities in a nearly inviscid flow—for example, in the freestream outside a boundary layer. A Pitot tube is used as standard for the velocity, and at the same time the output voltage of the anemometer is recorded. A typical calibration curve for a single hot-wire is shown in Figure 26.6. As is evident, this curve shows a nonlinear output with the velocity and a sensitivity decrease as the velocity increases. However, the sensitivity as a percentage of reading stays nearly constant which makes the hot-wire anemometer useful over a wide range of velocities. Under normal conditions the hot-wire is calibrated in a well-defined flow. Today the nonlinearity of the sensor characteristics is not a major constraint and many different transfer functions and cooling laws are available [e.g., Perry, 1982].

Once the calibration curve is obtained, good measurements in the unknown environment can be made directly provided that the fluid temperature, composition and density are the same as those during the calibration. In addition, it is assumed that the turbulence intensity is small (say, less than 15% of the mean velocity) and that the flow is incompressible. Once these conditions are fulfilled, the single hot-wire can be used to measure the streamwise mean and fluctuating velocities. Today, most modern laboratories use fast analog-to-digital converters (ADCs), implying that all the above functions, including the linearization, are performed with high accuracy employing digital computers.

### 26.4.3.4 Hot-Wire Sensors

In the design of hot-wire sensors one has to deal with many compromises. For example, the length and diameter are optimizations between several conflicting criteria. Concerning the hot-wire length, a short sensor is desired to maximize the spatial resolution and minimize the aerodynamic stress. However, a long sensor is desired to minimize conduction losses to the support, provide more uniform temperature distribution and reduce prong interference. Regarding the sensor diameter, a small diameter is desired to eliminate output noise due to separated flow around the sensor, to maximize the frequency response of the wire due to thermal inertia, to create higher heat transfer coefficient, to maximize the spatial resolution and to improve the signal-to-noise ratio at high frequencies. On the other hand, the solidity

of the wire is essential, and a large diameter is desirable to increase the probe strength and to reduce contamination effects due to particles in the fluid.

For research work, typical values of the traditional wire diameter are in the range of 2.5 to 5  $\mu\text{m}$ , and the wire length-to-diameter ratios are usually in the range of  $100 < \ell/d < 600$ . The choice of wire material is also a compromise. Tungsten, platinum and platinum–iridium are common hot-wire materials. Tungsten is desirable because of its high temperature coefficient of resistance and high strength. Platinum is available in small diameters, has good temperature coefficients of resistance and does not oxidize. Platinum–iridium is a wire that does not oxidize and has good strength, but unfortunately it has a low temperature coefficient of resistance. The article by Fingerson and Freymuth (1977) contains an elaborate section on wire materials and summarizes the properties of the most commonly used materials. An analytical relation between the flow velocity and anemometer output is desirable when physically interpreting the heat-transfer process in complex flow situations not covered by the calibration and when correcting for various sources of error and approximations. For a constant-temperature anemometer, the heat transfer from the sensor to its environment,  $Q$ , can be expressed in terms of the anemometer output voltage  $E$  as follows:

$$Q = \frac{E^2 R}{(R + R_1)} = \phi + K \quad (26.14)$$

where  $R$  represents the resistance of the sensor only. The rate of heat transfer,  $Q$ , is equal to the electrical power input to the sensor and consists of two parts: convective heat transfer,  $\phi$ , between the heated portion of the sensor and the flowing fluid and conductive heat transfer,  $K$ , between the heated portion of the sensor and its support prongs. Our aim is now to establish a relation between the heat transfer, or electrical power input, and the flow velocity. Bremhorst and Gilmore (1976) concluded that the static- and dynamic-calibration coefficients agree to within 3% for the velocity range of 3 to 32 m/s. Based on this, and neglecting radiation, we can for the stationary case focus our interest on  $\phi$ , which can be expressed as:

$$\phi = Nu \times 2\pi\ell\kappa_f(T_m - T_a) \quad (26.15)$$

where  $Nu$  is the Nusselt number,  $\equiv h_c d / \kappa_f$ , where  $d$  is the sensor diameter,  $h_c$  is the coefficient of convective heat transfer and  $\kappa_f$  is the fluid thermal conductivity at  $T_f = (T_m + T_a)/2$ , where  $T_m$  is the mean cylinder temperature,  $T_a$  is the ambient fluid temperature and  $2\ell$  is the length of the sensitive portion of the wire.

The main problem now is to find a representative expression of Nusselt number in terms of fluid and sensor parameters. General expressions of this quantity can be found in Hinze (1975), Perry (1982) and Fingerson and Freymuth (1977). Fortunately, most applications permit a reduction of the parameters needed, and a commonly used simplified expression is

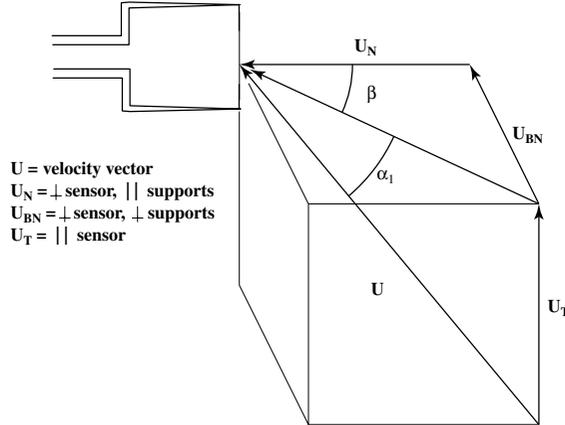

$$Nu = A + B Re^{0.5} \quad (26.16)$$

where  $A$  and  $B$  are constants determined through the calibration, and  $Re$  is the Reynolds number based on the wire diameter and the speed being measured. This is a very useful expression for ordinary measurements, and its only drawback is that it does not represent the  $Nu$  number over a wide range of velocities. More elaborate expressions have, however, been proposed by, for example, Collis and Williams (1959):

$$Nu = (A + B Re^n) \left(1 + \frac{\alpha_T}{2}\right)^{0.17} \quad (26.17)$$

where  $\alpha_T$  is the overheat ratio, and also by Kramers (1946):

$$Nu = 0.42 Pr^{0.26} + 0.57 Pr^{0.53} Re^{0.50} \quad (26.18)$$

**FIGURE 26.7** Velocity components relative to a hot-wire sensor. (From Fingerson, L.M., and Freymuth, P. (1977) in *Fluid Mechanics Measurements*, 2nd ed., R.J. Goldstein, Ed., Taylor & Francis, Washington, D.C., pp. 115–173. Reproduced by permission of Routledge, Inc.)

where  $Pr$  is the Prandtl number. The latter expression covers the ranges  $0.71 < Pr < 525$  and  $2 < Nu < 20$  and can be used even when the fluid is water.

A discussion on parameters neglected in the general expression can be found in the references cited above. Noteworthy is the fact that the ambient temperature, wire aspect ratio and conduction to wire supports have a large influence on the Nusselt number. Additionally, the Knudsen number (defined in the turbulence section) has been shown to be crucial in measurements using fine wires and small MEMS devices. In the next section, we consider the important issue of the angular dependence of the heat transfer, and the equations necessary for measurement of one, two and three velocity components.

### 26.4.3.5 Mean and Fluctuating Velocities

Figure 26.7 illustrates the instantaneous velocity components sensed by a hot-wire element. The simplest analytical expression for the angular sensitivity for an infinitely long wire is the so-called “cosine law”:

$$U_{eff} = U \cos \alpha_1 \quad (26.19)$$

where  $U_{eff}$  is the effective cooling velocity past the sensor. This equation essentially states that the velocity component along the wire ( $U \sin \alpha_1$ ) has no cooling effect, and that the sensor is rotationally symmetrical in both construction and response. However, the real hot-wire has a finite length and the velocity component parallel to the sensor must be considered. Therefore, Champagne (1965) suggested an extended expression for the effective velocity:

$$U_{eff} = U \sqrt{\cos^2 \alpha_1 + k_T^2 \sin^2 \alpha_1} \quad (26.20)$$

where  $k_T$  is an empirically determined factor which varies as a function of both  $\alpha_1$  and the velocity. Champagne (1965) found that  $k_T$  decreases nearly linearly with  $\ell/d$  from a value of  $k_T = 0.2$  at  $\ell/d = 200$ , to zero at  $\ell/d = 600$ – $800$ . Clearly, a large-aspect-ratio sensor decreases the influence of the velocity component along the wire. Comte-Bellot et al. (1971) have shown that aerodynamic effects from both support needles and probe body must be considered, and Jörgensen (1971) has suggested a cooling law to take these effects into account:

$$U_{eff} = \sqrt{U_N^2 + k_T^2 U_T^2 + k_N^2 U_{BN}^2} \quad (26.21)$$

where  $U_{BN}$  is the velocity perpendicular to both sensor and supporting prongs. The value of  $k_N$  can range from 1.0 to 1.2, depending on the design of probe support and needles [Drubka et al., 1977]. It is important to note that neither  $k_T$  nor  $k_N$  can be considered as constants for all angles and velocities. The cooling laws are basically methods for calibrating a hot-wire. More elaborate computer-oriented cooling-law relations have been presented. For example, Lueptov et al. (1988) have suggested the so-called “lookup” table, where a direct transfer of voltages into velocities and angles of attack is conducted.

It is common practice to use a single hot-wire probe perpendicular to the flow direction to measure the time-averaged velocity  $\bar{U}$  and corresponding fluctuating velocity mean-square  $\bar{u}^2$ . In Figure 26.7, the wire is oriented with the prongs in the streamwise direction so that  $U_N = U_1$ ,  $U_T = U_2$ , and  $U_{BN} = U_3$ , where  $U_1$ ,  $U_2$  and  $U_3$  are the orthogonal components of the velocity vector  $U$ . The effective instantaneous cooling velocity can then be expressed as:

$$U_{eff} = \sqrt{U_1^2 + k_T^2 U_2^2 + k_N^2 U_3^2} \quad (26.22)$$

If the mean flow is in the  $U_1$  direction and if Reynolds decomposition is introduced, then the mean velocities  $\bar{U}_2 = \bar{U}_3 = 0$ , and the effective cooling velocity may be expressed as:

$$U_{eff} = \sqrt{(\bar{U}_1 + u_1)^2 + k_T^2 u_2^2 + k_N^2 u_3^2} \quad (26.23)$$

Because  $k_T$  is small and  $k_N \approx 1$ , we can write:

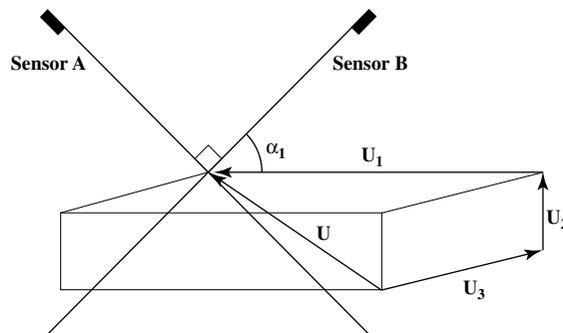

$$U_{eff} = \sqrt{(\bar{U}_1 + u_1)^2 + u_3^2} \quad (26.24)$$

If it is further assumed that  $u_3$  is small, then:

$$\bar{U}_{eff} = \bar{U}_1 = \bar{U} \quad (26.25)$$

$$\sqrt{\bar{u}_1^2} = \sqrt{\bar{u}^2} \quad (26.26)$$

Two velocity components can be measured with a cross hot-wire or by rotating a single probe and taking several sequential measurements [Fujita and Kovaszny, 1968]. Three velocity components can be measured with a triple hot-wire or by rotating a cross hot-wire. Figure 26.8 shows a cross wire with two

**FIGURE 26.8** Configuration of a cross hot-wire sensor. (From Fingerson, L.M., and Freymuth, P. (1977) in *Fluid Mechanics Measurements*, 2nd ed., R.J. Goldstein, Ed., Taylor & Francis, Washington, D.C., pp. 115–173. Reproduced by permission of Routledge, Inc.)

sensors  $A$  and  $B$  located so that they are sensitive to  $U_2$ . The effective cooling velocities of the two sensors can be expressed as:

$$U_{A,eff}^2 = (U_1 \cos \alpha_1 - U_2 \sin \alpha_1)^2 + k_T^2 (U_1 \cos \alpha_1 + U_2 \sin \alpha_1)^2 + k_N^2 U_3^2 \quad (26.27)$$

$$U_{B,eff}^2 = (U_1 \sin \alpha_1 + U_2 \cos \alpha_1)^2 + k_T^2 (U_1 \cos \alpha_1 - U_2 \sin \alpha_1)^2 + k_N^2 U_3^2 \quad (26.28)$$

If the coordinates are selected so that the mean velocity  $\bar{u}_3 = 0$ , and if it is assumed once again that the sensors are sufficiently long, then  $k_T \rightarrow 0$ ,  $k_N \rightarrow 1$ , and Eqs. (26.27) and (26.28) are reduced to:

$$U_{A,eff}^2 = (U_1 \cos \alpha_1 - U_2 \sin \alpha_1)^2 + u_3^2 \quad (26.29)$$

$$U_{B,eff}^2 = (U_1 \sin \alpha_1 + U_2 \cos \alpha_1)^2 + u_3^2 \quad (26.30)$$

Assuming that  $u_3$  is small and that the sensors are oriented so that  $\alpha_1 = 45^\circ$ , the streamwise and normal velocities are then expressed, respectively, as:

$$U_1 = \frac{1}{\sqrt{2}}(U_{A,eff} + U_{B,eff}) \quad (26.31)$$

$$U_2 = \frac{1}{\sqrt{2}}(U_{A,eff} - U_{B,eff}) \quad (26.32)$$

It is a common practice to orient the wire in the mean flow direction so that  $\bar{U}_2 = 0$ . In this case, the expressions for the mean velocity and Reynolds stresses are

$$\bar{U} = \frac{1}{\sqrt{2}}(U_{A,eff} + U_{B,eff}) \quad (26.33)$$

$$\bar{u}_1^2 = \frac{1}{2}(u_{A,eff} + u_{B,eff})^2 \quad (26.34)$$

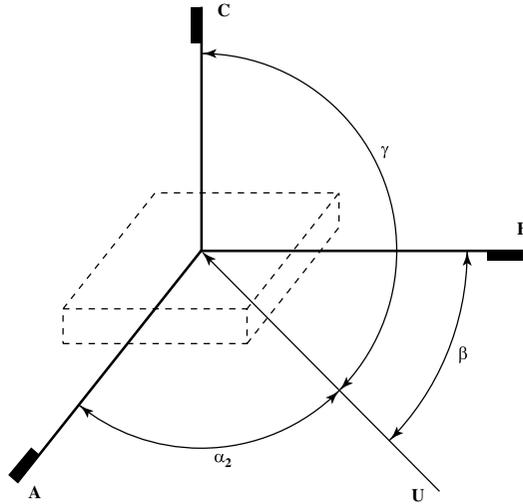

$$\bar{u}_2^2 = \frac{1}{2}(u_{A,eff} - u_{B,eff})^2 \quad (26.35)$$

$$\overline{u_1 u_2} = \frac{1}{2} \overline{(u_{A,eff} + u_{B,eff})(u_{A,eff} - u_{B,eff})} \quad (26.36)$$

Equations (26.34) to (26.36) are the fundamental relations used in most cross hot-wire measurements. As mentioned earlier, more information about the flowfield can be obtained if all three velocity components are measured. This can, for instance, be done as shown schematically in [Figure 26.9](#) by adding a third sensor  $C$  whose axis is at an angle  $\alpha_3$  to  $U_1$  and in the  $(U_1 U_3)$  plane. The effective cooling velocity of the third wire will then be

$$U_{C,eff}^2 = (U_1 \sin \alpha_3 + U_3 \cos \alpha_3)^2 + k_T^2 (U_1 \cos \alpha_3 - U_3 \sin \alpha_3)^2 + k_N^2 U_2^2 \quad (26.37)$$

Together with the equations for the cross hot-wire we have three equations and three unknowns, so the instantaneous velocity vector can be determined. Once the instantaneous components are available, all turbulence parameters can be calculated. Again, the equations can be simplified if the sensors are sufficiently

$$U_{A,\text{eff}}^2 = U^2(\sin^2\alpha_2 + k^2\cos^2\alpha_2)$$

$$U_{B,\text{eff}}^2 = U^2(\sin^2\beta + k^2\cos^2\beta)$$

$$U_{C,\text{eff}}^2 = U^2(\sin^2\gamma + k^2\cos^2\gamma)$$

$$U^2 = \frac{U_A^2 + U_B^2 + U_C^2}{2 + k^2}$$

**FIGURE 26.9** Direction sensitivity of a triple hot-wire sensor. (From Fingerson, L.M., and Freymuth, P. (1977) in *Fluid Mechanics Measurements*, 2nd ed., R.J. Goldstein, Ed., Taylor & Francis, Washington, D.C., pp. 115–173. Reproduced by permission of Routledge, Inc.)

long so that  $k_T \rightarrow 0$  and  $k_N \rightarrow 1$ , and if the sensors are oriented so that  $\bar{U}_2 = \bar{U}_3 = 0$ , and  $\alpha_1 = \alpha_2 = 45^\circ$ . The simplified equations are given below and were used by Fabris (1978) to make three-component velocity measurements:

$$U_{A,\text{eff}}^2 = U^2(\sin^2\alpha_2 + k^2\cos^2\alpha_2) \quad (26.38)$$

$$U_{B,\text{eff}}^2 = U^2(\sin^2\beta + k^2\cos^2\beta) \quad (26.39)$$

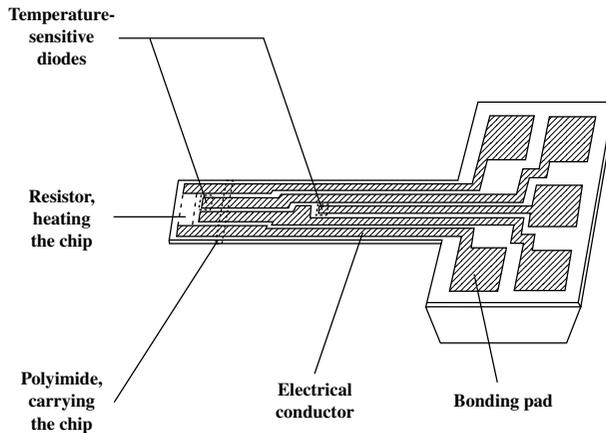

$$U_{C,\text{eff}}^2 = U^2(\sin^2\gamma + k^2\cos^2\gamma) \quad (26.40)$$

$$U^2 = \frac{U_A^2 + U_B^2 + U_C^2}{2 + k^2} \quad (26.41)$$

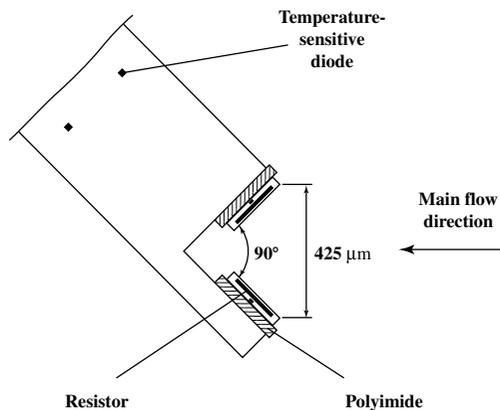

All the equations developed in this section for velocity measurements using one, two and three hot-wires are used in the same way when making velocity measurements using MEMS-based sensors. Few variants of the thermal principle for velocity measurements are used in microsensors, and these are discussed in the next section.

#### 26.4.3.6 MEMS Velocity Sensors

Because turbulence is a high-Reynolds-number phenomenon with small length and time scales, it is generally preferred that sensors used to measure instantaneous quantities have a small physical size. Although it is true that conventional hot-wires with sensor diameter in the micrometer range have been reported

**FIGURE 26.10** Schematic of a single-wire MEMS sensor consisting of three parts: the base plate  $1.5 \times 1.0 \times 0.3$  mm, the silicon beam  $1.6 \times 0.4 \times 0.03$  mm, and the chip  $0.4 \times 0.3 \times 0.03$  mm. (From Löfdahl, L. et al. (1992) *Exp. Fluids*, **12**, 391–393. © 1992 Springer-Verlag. With permission.)

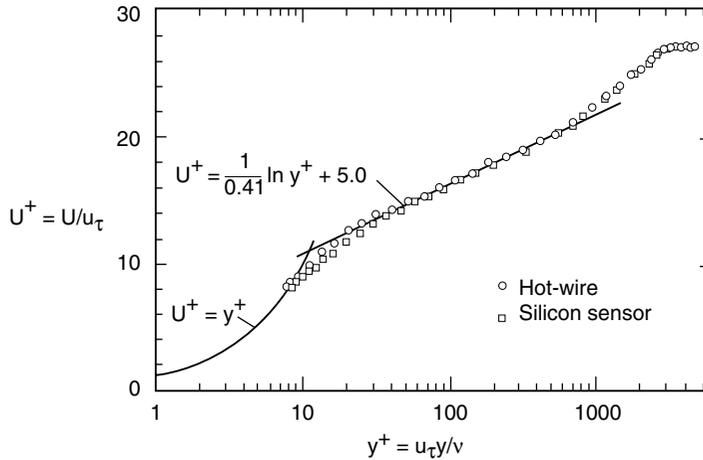

**FIGURE 26.11** Double chip sensor for the determination of fluctuating velocity correlations. (From Löfdahl, L. et al. (1992) *Exp. Fluids*, **12**, 391–393. © 1992 Springer-Verlag. With permission.)

in the literature, these wires are usually very fragile, expensive and handmade. Conventional velocity sensors are difficult to use and not feasible to employ in large numbers. MEMS sensors are not afflicted with these drawbacks, and as is clear from earlier discussion are well suited to being fabricated in dense arrays at a moderate cost.

The first MEMS-based sensor for the determination of mean velocities and turbulence intensities was presented by Löfdahl et al. (1992). A schematic drawing of this sensor is depicted in Figure 26.10. Different overheat ratios and length-to-width ratios of the sensor were used: 4/3, 5/1 and 10/1. The principle of operation is very similar to that used in conventional hot-wires, but some deviations are important to note. Instead of using a bridge balance, the operation relies on a voltage difference which is formed between two temperature-sensitive p–n junction diodes. The “hot” diode monitors the temperature of the chip, which is electrically heated by an integrated resistor and cooled by the flow. The “cold” diode, which is positioned on the beam as shown in Figure 26.10, adjusts the set overheat ratio relative to the ambient air temperature. Thus, the power dissipated in the heated resistor is a measure of the instantaneous flow velocity.

Both single and double chip sensors were fabricated by Löfdahl et al. (1992), and Figure 26.11 shows the perpendicular arrangement of two heated sensors for measuring two velocity components. The performance

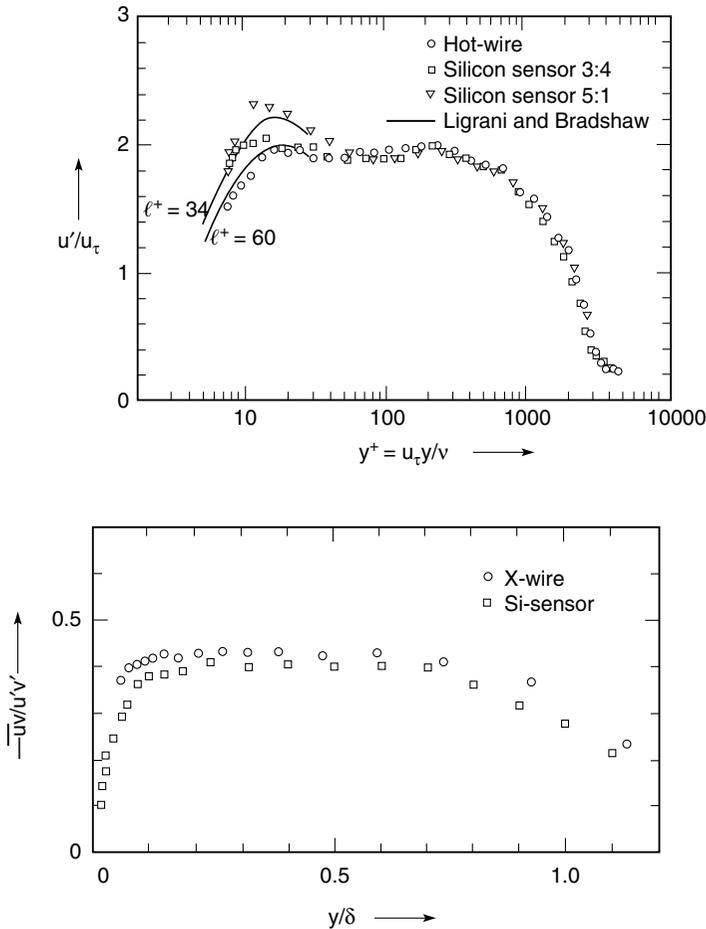

**FIGURE 26.12** Typical mean velocity profile measured with a MEMS sensor and a conventional single hot-wire. Here,  $U/u_\tau = f(u_\tau y/\nu)$ , where  $u_\tau$  is the friction velocity. (From Löfdahl, L. et al. (1992) *Exp. Fluids*, 12, 391–393. © 1992 Springer-Verlag. With permission.)

of this micro-velocity-sensor was tested in a two-dimensional, flat-plate boundary layer at a Reynolds number based on distance from the leading edge of  $4.2 \times 10^6$ . Figure 16.12 compares the mean velocity profile in a turbulent boundary layer as measured with a conventional and MEMS-based sensor. The microsensors measured mean velocities with the same accuracy as a corresponding conventional hot-wire. Moreover, it was also demonstrated that the microsensors had spatial and temporal resolutions that made it suited for turbulence measurements. Figure 26.13 shows the streamwise turbulence intensity and the Reynolds stress as measured by a conventional X-wire and by two silicon microsensors. The MEMS-based sensors operated with good resolution even when the temperature of the heated part was reduced considerably. A clear drawback of this micro-hot-film is the proximity of the heated part of the sensor to the surface of the chip, rendering the probe insensitive to changes in flow direction. This makes the silicon sensor unsuited for use in three-dimensional flows where the primary flow direction is not known *a priori*.

Jiang et al. (1994) presented a MEMS-based velocity sensor with the hot-wire freestanding in space without any nearby structures, so that cooling velocities can be determined in the same way as with a conventional hot-wire. Their sensor is shown in Figure 26.14 and has a polysilicon hot-element that is greatly reduced in size, typically about  $0.5 \mu\text{m}$  thick,  $1 \mu\text{m}$  wide, and  $10\text{--}160 \mu\text{m}$  long. The dynamic performance and sensitivity of this sensor have been tested. A heating time of  $2 \mu\text{s}$  and a cooling time of  $8 \mu\text{s}$  for the  $30\text{-}\mu\text{m}$ -long sensor in constant-current mode have been achieved. For constant-temperature operation, a time constant of  $0.5 \mu\text{s}$  for the  $10\text{-}\mu\text{m}$ -long sensor has been recorded. The corresponding cut-off frequency is  $1.4 \text{ MHz}$ . The calibration curves of a  $20\text{-}\mu\text{m}$ -long micro-hot-wire at two different angles are shown in Figure 26.15. The average sensitivity was found to be  $20 \text{ mV/m/s}$  at an input current of  $0.5 \text{ mA}$ . No turbulence measurements have been reported using this sensor. Noteworthy is that the silicon hot-wires have a trapezoidal cross section, which might cause severe uncontrolled errors in turbulence measurements.

A severe drawback of commercially available triple hot-wire probes is the large measuring volume, typically a sphere with a diameter of  $3 \text{ mm}$ . This is far too large to be acceptable for turbulence measurements at realistic Reynolds numbers. Ebefors et al. (1998) have presented a MEMS-based triple-hot-wire sensor, shown schematically in Figure 26.16. The x- and y-hot-wires are located in the wafer plane while the z-wire is rotated out of the plane using a radial polyimide joint. The silicon chip size is  $3.5 \times 3.0 \times 0.5 \text{ mm}^3$ , and the three wires are each  $500 \times 5 \times 2 \mu\text{m}^3$ . The sensor is based on the thermal anemometer principle, and the polyimide microjoint technique is used to create a well-controlled,

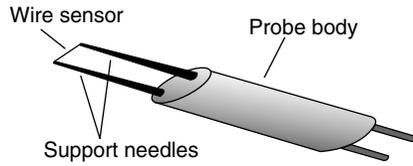

**FIGURE 26.13** Streamwise velocity fluctuation (top plot), and turbulent shear stress (bottom plot) measured with MEMS sensors and conventional hot-wires. (From Löfdahl, L. et al. (1992) *Exp. Fluids*, **12**, 391–393. © 1992 Springer-Verlag. With permission.)

out-of-plane rotation of the third wire. The time constant of the hot-wire resistance change caused by heating without any flow was measured, and the cooling and heating time constants were found to be 120 and 330  $\mu\text{s}$ , respectively. By operating the sensor at a constant temperature, these response times can be improved. Only some very preliminary velocity measurements have been conducted with this sensor in channel flow.

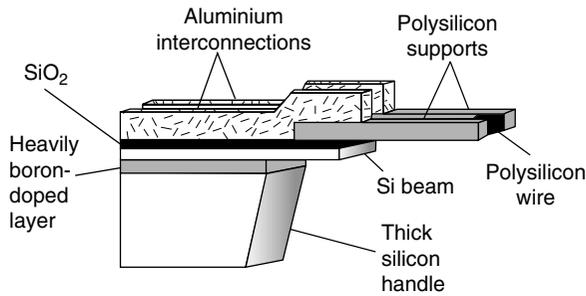

### 26.4.3.7 Outlook for Velocity Sensors

MEMS velocity sensors are superior to conventional hot-wires in the sense that they can be reduced in size to the order of microns. This is of course an important advantage, but for velocity measurements it is presumably the MEMS properties of accurate fabrication at a low unit cost that are even more relevant. For engineering purposes this means that velocity sensors, which may not necessarily be extremely small, can be used for controlling and optimizing system performance. Due to the low price per unit, numerous control points can be sensed, which is of utmost importance, for instance, in controlling room ventilation.

In turbulence research, small sensors are required for correct interpretation of the flow phenomena; here, the most significant advantage of the MEMS sensors is that they can be spaced close together and fabricated in arrays for studies of coherent structures in the flow. In particular, further development of devices for measuring the instantaneous, three-dimensional velocity using, for example, the triple-hot-wire presented

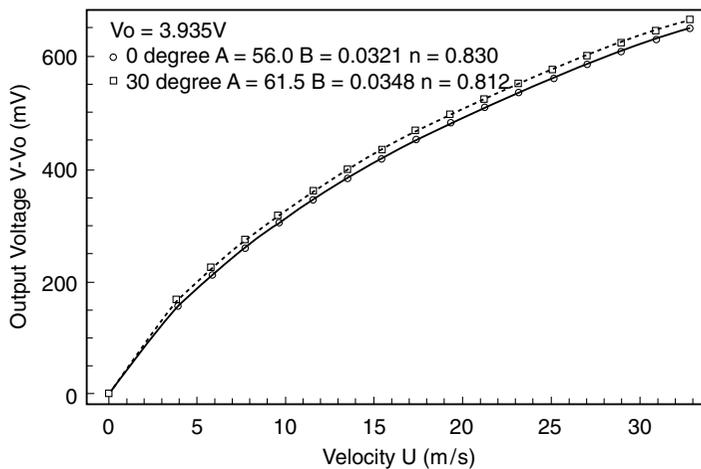

Conventional Hot-Wire

Micromachined Hot-Wire

**FIGURE 26.14** Structure of hot-wire probes: (a) conventional hot-wire, (b) micromachined hot-wire. (From Jiang, F. et al. (1994) in *Solid-State Sensor and Actuator Workshop*, Hilton Head, SC. © 1994 IEEE. With permission.)

**FIGURE 26.15** Calibration curves of a 20- $\mu$ m-long, MEMS-based hot-wire sensor at two different angles. (From Jiang, F. et al. (1994) in *Solid-State Sensor and Actuator Workshop*, Hilton Head, SC. © 1994 IEEE. With permission.)

by Ebefors et al. (1998) would be of great interest. Further miniaturization of this sensor and positioning of each sensor in closely spaced arrays would offer the possibility of measuring flow events, both in the direction normal to the surface and in the spanwise direction. An integration of such sensor arrays with arrays of pressure transducers would be beneficial in instantaneous mapping of the flowfield for studies of coherent structures. Combined with proper actuators, MEMS-based velocity sensors can be used for effective reactive control of difficult-to-tame turbulent shear flows.

## 26.4.4 Wall-Shear-Stress Sensors

### 26.4.4.1 Background

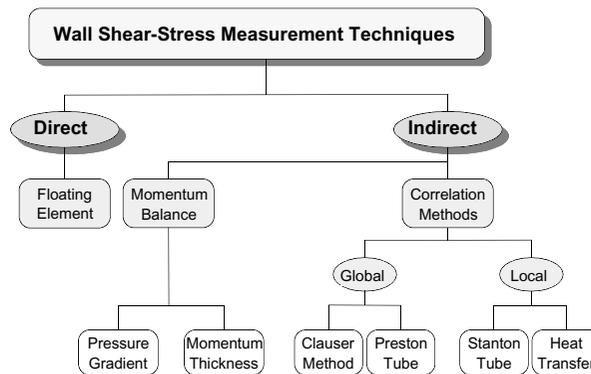

From scientific and engineering perspectives, the wall-shear stress is an essential quantity to compute, measure or infer in a wall-bounded turbulent flow. Time-averaged values of this quantity are indicative of the global state of the flow along a surface and can be used to determine body-averaged properties such as skin-friction drag. The time-resolved part of the wall-shear stress is a measure of the unsteady structures in the flow which are responsible for the individual momentum transfer events and is an indicator of the coherent portion of the turbulence activities. Spatially distributed values of the instantaneous wall-shear stress can be used in a feedforward or feedback control loop to effect beneficial changes in the boundary layer. The majority of wall-shear-stress studies conducted rely on the premise that the mean velocity-gradient and the heat-transfer rate near or at the wall are both proportional to the wall-shear stress. The former relation was established already by the early 1920s by Stanton et al. (1920), and the latter a few years later by Leveque (1928).

During the last few decades, numerous experiments have been conducted where measurements of wall-shear stress have been the kernel. The success of those endeavors depends basically on the complexity of the flow, the geometry of the solid boundaries and the limitations of the measuring device used. Some facts have been established, such as the wall-shear-stress distribution along flat plates and simple bodies of revolution, but in general our knowledge of wall-shear stress and in particular its fluctuating component is limited. An explanation of this is that it is both difficult and cumbersome to measure wall-shear stress. In general it is a parameter of small magnitude, and some typical values can be of interest to keep in mind for the following discussion. A submarine cruising at 30 km/hr has an estimated value of the shear stress of about 40 Pa; an aircraft flying at 420 km/hr, 2 Pa; and a car moving at 100 km/hr, 1 Pa. Such small forces per unit area put heavy demands on the resolution of the measuring devices used. Those estimates are approximate and were obtained by Munson et al. (1990), who treated the body as a collection of parts; for instance, the drag of an aircraft was approximated by adding the drag contributions produced by wings, fuselage, tail, etc.

Many different methods for the determination of wall-shear stress have been developed, and the required spatial and temporal resolutions are specific for each application and environment. In laminar flows, the sensors must be capable of measuring the time-averaged shear stress, while in turbulent flows both the mean shear and its fluctuating component are of interest. An attempt to classify the techniques available for wall-shear-stress measurements was made by Haritonidis (1989), who divided the technologies into direct

**TABLE 26.1** Operation and Detection Principle of Silicon Micromachined Wall-Shear-Stress Sensors

Author	Operation	Detection Principle	Active Sensor Area (mm <sup>2</sup> )
Oudheusden and Huijsing (1988)	Thermal	Thermopile	4 × 3
Schmidt et al. (1988)	Floating element	Capacitive	0.5 × 0.5

**FIGURE 26.17** Classification of wall-shear-stress measurements techniques. (Adapted from Haritonidis, 1989.)

or indirect methods, depending upon whether the method measures the wall-shear stress directly or infers it from other measured properties. Figure 26.17 shows a bird's eye view of Haritonidis' classification. Because the number of different methods is enormous, it is out of the scope of this chapter to review each technique but a trend common to all measurements and methods can be highlighted. Since the mid-1950s, the evolution of the probes used has been directed toward utilizing smaller and smaller sensors in order to improve the accuracy, flexibility and resolution. Several review papers describe shear-stress sensors and discuss in detail the merits and drawbacks of the methods used in a vast variety of flow situations. To cite a few, Winter (1977) gives a comprehensive review of available conventional methods and a good discussion of measurements in turbulent flows. Haritonidis (1989) summarizes conventional methods and introduces the first micromachined wall-shear-stress sensor. Hakkinen (1991) lists the merits and drawbacks of conventional techniques. More recently, Hanratty and Campbell (1996) discuss the relevant experimental issues associated with the use of various wall-shear-stress sensors.

A major problem faced in wall-shear-stress measurements is that conventional fabrication of sensors and balances allows only a certain degree of miniaturization, as these devices are more or less handmade. Spatial and temporal resolutions better than what conventional probes can provide are needed in typical turbulence studies and reactive flow control. MEMS has the potential of circumventing the conventional sensor limitations, as microfabrication offers a high degree of miniaturization and associated increased resolution together with the fact that the sensors are not handmade, implying that each unit is fabricated to extremely low tolerance at reasonable cost. Table 26.1 lists the operation and detection principles as well as the sensor area of some recently developed MEMS-based shear-stress probes.

A glance at the classification scheme of Figure 26.17 shows that the floating-element principle and the heat-transfer method (or more correctly thermal-element method) are both well suited for MEMS fabrication. Figure 26.18 shows a schematic of the principle of operation of the two methods. The thermal-element method relies on measuring the amount of energy necessary for keeping a wall-mounted, electrically heated resistor at constant temperature, despite a time-dependent, convective heat transfer to

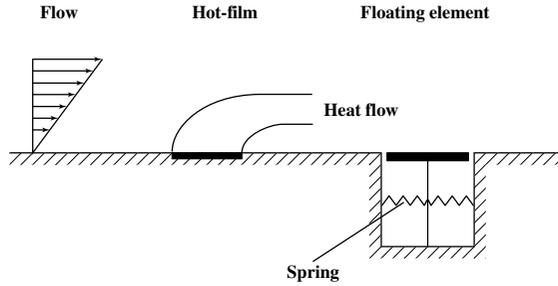

FIGURE 26.18 Wall-shear-stress sensors of the hot-film and floating-element type.

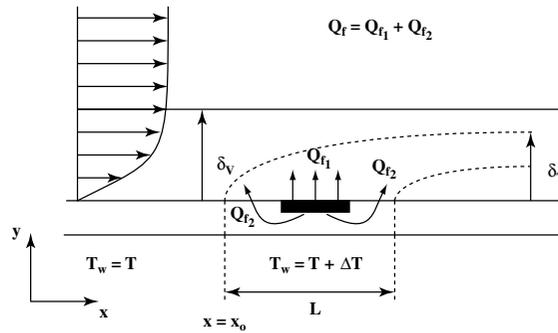

FIGURE 26.19 An illustration of a surface mounted hot-film.

the flow. A high freestream velocity yields steep velocity and temperature gradients at the heated surface and thereby a good cooling, which requires more energy, while the opposite is true for a low freestream velocity. In the floating-element principle, a flush-mounted wall-element, moveable in the plane of the wall-shear stress, is displaced laterally by the tangential viscous force and this movement can be measured using resistive, capacitive or optical detection principles.

In the following eight sections, we describe the principles of the thermal sensor and the floating element, as both strategies are particularly suited for measurements of fluctuating wall-shear stress as well as for MEMS fabrication. In the description of the thermal-sensor method, we briefly recall the classical equations, and based on these we highlight possible uncertainties and sources of errors in measuring instantaneous wall-shear stress. For the floating-element method, we discuss the general principle and pitfalls associated with steady and time-dependent measurements. For both principles we review current MEMS-based sensors. Because calibration is a crucial part of wall-shear-stress measurements, particularly in the determination of fluctuating quantities, we summarize some common calibration methods and discuss possibilities for dynamic calibration. Finally, we provide an outlook for the use of MEMS-based wall-shear-stress sensors for future turbulence studies and flow control.

#### 26.4.4.2 Thermal-Sensor Principle

The thermal or hot-film sensor benefits from the fact that the heat transfer from a sufficiently small heated surface depends only on the flow characteristics in the viscous region of the boundary layer. A schematic drawing of a thermal sensor is depicted in Figure 26.19. The hot-film gauge consists of a thin metallic film positioned into a substrate. Usually the gauge forms one part of a Wheatstone bridge, and an electric current is passed through the film in order to maintain it at a constant temperature as heat is continuously being transferred from the film to the moving fluid. The ohmic heating in the device  $q_w$  is transferred both to the fluid and to the surrounding substrate. This can be expressed as:

$$q_w = q_T + q_C \tag{26.42}$$

where  $q_T$  represents the heat transferred to the fluid directly from the heated surface and indirectly through the heated portion of the substrate, and  $q_C$  represents the heat lost to the substrate. If the flow is steady and laminar and if the streamwise pressure gradient can be neglected, the resulting heat-transfer rate to the fluid  $q_T$  has been shown to be related to the wall-shear stress according to the classical relation:

$$\tau_w \propto q_T^3 \quad (26.43)$$

This expression has been derived by many researchers [e.g., Ludwig, 1950; Liepmann and Skinner, 1954; Bellhouse and Schultz, 1966]. However, this simple relation breaks down in unsteady and turbulent flows as has been pointed out by Bellhouse and Schultz (1966). In a turbulent environment, most assumptions made in the derivation are violated and the heat conduction to the substrate changes instantaneously. In spite of this, we will use an extended version of Equation (26.43) to illustrate the assumptions made and to pinpoint possible pitfalls in using hot-film gauges for fluctuating wall-shear-stress measurements. In the following argument, we will follow a path outlined by Bellhouse and Schultz (1966) and later by Menendez and Ramaprian (1985), who derived the extended version for boundary-layer flows subjected to a periodic freestream velocity of the form:

$$U_a(t) = U_o(1 + \varepsilon \sin \omega t) \quad (26.44)$$

where  $\omega$  is the angular frequency of the oscillation,  $U_o$  is the mean freestream velocity, and  $\varepsilon$  is the relative amplitude of the oscillation. The derivation below is strongly abbreviated, and the reader is referred to Menendez and Ramaprian (1985) for a more elaborate version. The problem to be considered is shown in Figure 26.19. A thermal boundary layer develops within a turbulent boundary layer over a heated film having an effective streamwise length  $L$ . The thermal boundary layer is produced by a sudden jump in the surface temperature, from a constant value equal to the ambient temperature  $T_a$  to the higher constant value  $T_w$  at the location  $x = x_o$ . It is assumed that the thermal boundary layer is totally embedded in the viscous region, so effects of turbulent diffusion can be neglected. A relation between the local wall-shear stress  $\tau_w$  and the heat-transfer rate from the wall to the fluid  $q_T$  is derivable from the first law of thermodynamics. For a two-dimensional flow, neglecting dissipation and compressibility effects and applying the usual boundary-layer approximation, the energy equation reads:

$$\frac{\partial T}{\partial t} + U \frac{\partial T}{\partial x} + V \frac{\partial T}{\partial y} = \frac{\kappa_f}{\rho c_p} \frac{\partial^2 T}{\partial y^2} \quad (26.45)$$

where  $T(x, y, t)$  is the desired temperature distribution;  $t$  is time;  $U$  and  $V$  are the velocity components along the coordinates  $x$  and  $y$ , respectively; and  $\rho$ ,  $\kappa_f$  and  $c_p$  are, respectively, the fluid density, thermal conductivity and specific heat. Using the equation of continuity and integrating Eq. (26.45) across the thermal boundary layer up to a point  $y = y_e$  beyond the edge of the thermal boundary layer, we get:

$$\frac{\partial}{\partial t} \int_0^{y_e} (T - T_o) dy + \frac{\partial}{\partial x} \int_0^{y_e} U(T - T_e) dy = -\frac{1}{\rho c_p} q_w \quad (26.46)$$

where  $T_e$  is the temperature at the edge of the thermal boundary layer. It is now assumed that within the viscous region where the thermal boundary layer resides, inertial effects can be neglected. The velocity profile can be approximated by:

$$U = \frac{\tau_w}{\mu} y + \frac{1}{2\mu} \left( \frac{\partial p}{\partial x} \right) y^2 \quad (26.47)$$

where  $p$  is the pressure, and  $\mu$  is the dynamic viscosity of the fluid. It is further assumed that the temperature distribution in the thermal boundary layer is self-similar at any instant of time and that the thermal boundary

layer thickness  $\delta_T$  can be expressed as follows:

$$\frac{T - T_e}{T_w - T_e} = f(\xi, t) \quad (26.48)$$

$$\frac{\delta_T(x, t)}{\delta_T(x_o + L, t)} = \left[ \frac{x - x_o}{L} \right]^n \quad (26.49)$$

where  $\xi \equiv y/\delta_T$  is the similarity coordinate, and  $n$  is an unknown exponent which can in general depend on time. After some algebra and assuming  $n$  is independent of time, an expression for the local wall-shear stress at  $x = x_o + L$  is obtained as a function of the heat-transfer rate from the wall to the fluid:

$$\tau_w = (A_1 q_w^3) + A_2 \frac{\cos \omega t}{q_w} + A_3 \frac{\partial q_w}{\partial t} \quad (26.50)$$

where

$$A_1 \equiv \frac{\mu L}{(1 - n) a \rho c_p \kappa^2 (\Delta T_o)^3} \quad (26.51)$$

$$A_2 \equiv \frac{b \kappa (\Delta T_o) a \rho \epsilon \omega U_o}{2a} \quad (26.52)$$

$$A_3 \equiv \frac{\mu L c}{(1 + n) a \kappa (\Delta T_o)} \quad (26.53)$$

In these expressions, the “shape parameters,”  $a$ ,  $b$  and  $c$ , are basically functions of the streamwise coordinate  $x$ . According to Menendez and Ramaprian (1985), Eq. (26.50) can be regarded as the basic relationship between the instantaneous value of the wall-shear stress and the wall heat flux. By taking the ensemble average of Eq. (26.50) over a large number of cycles and assuming that the turbulent fluctuations are small, a linearized expression for the periodic wall-shear stress is obtained.

To summarize, the classical expression, Eq. (26.43), gives a relation between the wall-shear stress and the heat transfer from the wall. This expression assumes steady, laminar, zero-pressure-gradient flow and is not valid in a turbulent environment. Menendez and Ramaprian (1985) have derived an extended version of Eq. (26.43) valid for a periodically fluctuating freestream velocity, Eq. (26.50). The latter relation contains, however, some assumptions that are questionable for turbulent flows. For instance, in the thermal boundary layer it is assumed that the temperature distribution is self-similar and that the local thickness varies linearly. These assumptions are relevant for a streamwise velocity oscillation and a weak fluctuation, but certainly not in a turbulent flow that is strongly unstable in all directions. Following a brief look at available calibration methods, we discuss the spatial and temporal resolutions of wall-mounted hot-films together with some MEMS-based sensors for wall-shear-stress determination.

### 26.4.4.3 Calibration

Several methods and formulas are in use for calibrating hot-film shear probes operated in the constant-temperature mode, and the choice of method depends on flow conditions and sensor used. In this section, two static calibration methods are discussed. Both are based on the theoretical analysis leading to the relation between rate of heat transfer and wall-shear stress, as discussed in the previous section. The challenge is, of course, to be able to use the shear-stress sensor in a turbulent environment.

If a laminar flow facility is used to calibrate the wall-shear-stress sensor, then Eq. (26.43) can be rewritten more conveniently in time-averaged form:

$$\overline{\tau_w}^{1/3} = A\overline{e^2} + B \quad (26.54)$$

where  $\overline{\tau_w}$  is the desired mean wall-shear stress,  $\overline{e^2}$  is the square of the mean output voltage, and  $A$  and  $B$  are calibration constants. The term  $B$  represents the heat loss to the substrate in a quiescent surrounding, and this procedure is similar to a conventional calibration of a hot-wire [King, 1916]. However, a laminar flow is often difficult to realize in the desired range of turbulence wall-shear stress, and it is more practical to calibrate without moving the sensor between calibration site and measurement site. In that case, the calibration is made in a high-turbulence environment and the high-order moments of the voltage must also be considered.

Ramaprian and Tu (1983) proposed an improved calibration method, and the instantaneous version of Eq. (26.54), can be rewritten and time-averaged to give:

$$\overline{\tau_w} = \overline{(Ae^2 + B)^3} = A^3\overline{e^6} + 3A^2B\overline{e^4} + 3AB^2\overline{e^2} + B^3 \quad (26.55)$$

This can be rewritten as:

$$\overline{\tau_w} = C_6\overline{e^6} + C_4\overline{e^4} + C_2\overline{e^2} + C_0 \quad (26.56)$$

where the  $C_s$  are the new calibration constants. The high-order moments of the voltage can easily be calculated with a computer, but care must be taken that they are fully converged. The relation between  $e$  and  $\tau_w$  can also be represented by a full polynomial function, so if the frequency response of the sensor is sufficiently flat, it is possible to write:

$$\overline{\tau_w} = C_0 + C_1\overline{e} + C_2\overline{e^2} + \dots + C_M\overline{e^N} \quad (26.57)$$

where  $M$  is the number of calibration points and  $N$  is the order of the polynomial above. A system of linear equations is obtained where the calibration coefficients can be computed by a numerical least-square method. The mean wall-shear stress on the left-hand side of Eq. (26.57) can be measured with, for example, a Preston tube using the method of Patel (1965). The second calibration technique described here is called “stochastic” calibration by Breuer (1995), who also demonstrated that the validity of the calibration polynomial may extend well beyond the original calibration range, although this requires careful determination of the higher order statistics as well as a thorough understanding of the sensor response function.

The experiments of Bremhorst and Gilmore (1976) showed that the static and dynamic calibration coefficients for hot-wires agree to within a standard error of 3% for the velocity range of 3 to 32 m/s. Thus, they recommend the continued use of static calibration for dynamic measurements. As pointed out in the previous section, this is not true for a wall-mounted hot-film. One solution to this problem may be to calibrate the hot-film in pulsatile laminar flow with a periodic freestream velocity  $U_a(t)$ , and make use of the Menendez and Ramaprian’s formula, Eq. (26.50):

$$\overline{\tau_w} = (A\overline{e^2} + B)^3 + \frac{c_1}{A\overline{e^2} + B} \frac{dU_a}{dt} + c_2A \frac{d\overline{e^2}}{dt}$$

to obtain the additional calibration constants  $c_1$  and  $c_2$ . This step is necessary in order to characterize the gauge dynamic response at relatively high frequencies. The constants  $A$  and  $B$  are obtained from a steady-state calibration.

One difficulty in performing a dynamic calibration is generating a known sinusoidal wall-shear-stress input. Bellhouse and Rasmussen (1968) and Bellhouse and Schultz (1966) achieved this in two different ways. One method is to mount the hot-film on a plate which can be oscillated at various known frequencies and amplitudes. The main drawback to this arrangement is the limited amplitudes and frequencies that can be achieved when attempting to vibrate a relatively heavy structure. An alternative strategy is to generate the shear-stress variations by superimposing a monochromatic sound field of different frequencies on a steady, laminar flowfield. A hot-wire close to the wall can be used as a reference.

#### 26.4.4.4 Spatial Resolution

Equation (26.50) is an extended version of Eq. (26.43), and by assuming a steady flow and zero-pressure-gradient in the streamwise direction it reduces to the classical formula. The latter expression can be used to estimate the effective streamwise length of a hot-film:

$$\tau_w = -A_1 q_w^3 \quad (26.58)$$

By assuming a stepwise temperature variation and introducing the average heat flux  $\overline{q_w}$  over the heated area which is assumed to have a streamwise length  $L$ , the desired relation reads:

$$\overline{q_w} = 0.807 \kappa_f \Delta T_w Pr^{1/3} \left( \frac{\tau_w}{L \nu \mu} \right) \quad (26.59)$$

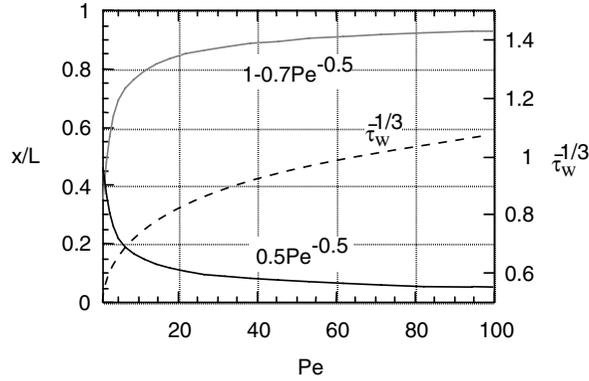

It is convenient to rewrite the above expression in a nondimensional form, and in doing so we keep  $L$  explicit:

$$\overline{Nu} \equiv \frac{h_c L}{\kappa_f} = 0.807 (Pr L^{+2})^{1/3} \quad (26.60)$$

where  $\overline{Nu}$  is the Nusselt number averaged over the heated area,  $L^{+}$  is the streamwise length of the heated area normalized with the viscous length-scale  $\nu/u_\tau$ , and  $h_c$  is the convective heat-transfer coefficient. This equation has been derived for flows with pressure gradient by Brown (1967). The dimensionless sensor length  $L^{+}$  is a crucial parameter when examining the assumptions made.

The lower limit on  $L^{+}$  is imposed by the boundary-layer approximation, as there is an abrupt change of temperature close to the leading and trailing edge zones of the heated strip where the neglected diffusive terms in Eq. (26.45) become significant. Tardu et al. (1991) have conducted a numerical simulation of the heat transfer from a hot-film, and found a peak of the local heat transfer at the leading and trailing edges. They conclude that if the hot-film is too narrow, the heat transfer would be completely dominated by these edge effects. Ling (1963) has studied the same problem in a numerical investigation and concludes that the diffusion in the streamwise direction can be neglected if the Péclet number is larger than 5000. (The Péclet number here is defined as the ratio of heat transported by convection and by molecular diffusion,  $Pe = Pr L^{+2}$  [see Brodkey, 1967]). Pedley (1972) concludes that, provided  $0.5 Pe^{-0.5} < x/L < (1 - 0.7 Pe^{-0.5})$ , there exists a central part of the hot-film where the boundary-layer solution predicts the heat transfer within 5%. Figure 26.20 shows the relation proposed by Pedley (1972), and it can be seen that the heat transfer is correctly described over a large part of the hot-film area, but as the Péclet number decreases, the influence from the diffusive terms must be considered. For Péclet numbers larger than 40, the heat transfer is correctly described by more than 80% of the heated area.

The upper limit of  $L^{+}$  is crucial, as there the hot-film thermal boundary layer may not be entirely submerged in the viscous sublayer. Equation (26.58) has been included in Figure 26.20, and it can be seen that Péclet numbers larger than 40 correspond approximately to  $\overline{\tau_w}^{1/3} > 0.95$ . A relatively simple calculation of the upper limit of  $L^{+}$  can then be made by assuming that the viscous sublayer is about five viscous units, and this yields an upper limit of  $L^{+}$  which for air can be estimated to be approximately 47.

**FIGURE 26.20** Pedley's (1972) relation showing the region of validity of the boundary-layer solution as a function of Péclet number. In the area in between the two continuous curves, the boundary-layer approximation predicts the heat transfer accurately to within 5% of the correct value. (From Pedley, T.J. (1972) *J. Fluids Eng.*, 55, pp. 329–357. With permission.)

In summary, then, it can be concluded that the streamwise extent of the hot-film cannot be too small; otherwise, the boundary-layer approximations made are not applicable. On the other hand, a sensor that is too large will cause the thermal boundary layer to grow beyond the viscous region. Additionally, the spatial resolution will be adversely affected if the sensor is too large, as the smallest eddies imposed by the flow structures above the wall will then be integrated along the sensor length.

#### 26.4.4.5 Temporal Resolution

The temporal resolution of the thermal probe is affected by the different time constants of the hot-film and the substrate. The hot-film usually has a much shorter time constant than the substrate. The higher the percentage of the total heat that leaks into the substrate, the lower is the sensitivity of the device to shear-stress fluctuations, and this changes the sensor characteristics sufficiently to invalidate the static calibration made. An example of this phenomenon is given by Haritonidis (1989), who showed that a hot-film sensor in a fluctuating wall-shear-stress environment will respond quickly to the instantaneous shear stress, while the substrate due to its much larger thermal inertia will react slowly. Haritonidis (1989) also showed that the ratio of the fluctuating sensitivity  $S_f$  to the average sensitivity  $S_a$  can be related to the ratio of the effective lengths under dynamic and static conditions:

$$\frac{S_f}{S_a} = \left(\frac{L_f}{L_a}\right)^{2/3} < 1 \quad (26.61)$$

where  $L_a$  is the average effective length during static calibration, and  $L_f$  is the effective length during dynamic calibration. Due to this, the hot-film becomes less sensitive to shear-stress fluctuations at higher frequencies and the static calibration in a laminar flow will not give a correct result. These length scales can be considerably larger than the probe true extent. For example, Brown (1967) reported that the effective length scale from a static calibration was about twice the physical length.

Both the substrate material and the amount of heat lost to the substrate are crucial when determining the temporal or frequency response of the hot-film sensor. At low frequencies, the thermal waves through the substrate and into the fluid are quasi-static, which means that the fluctuating sensitivity of the hot-film is determined by the first derivative of the static calibration curve. In this range, which is of the order of a couple of cycles per second, the heat transfer through the substrate responds without time lag to wall-shear-stress fluctuations. Basically, this frequency range does not cause any major problems.

For the high-frequency range at the other end of the spectrum, it is possible to estimate the substrate role by considering the propagation of heat waves through a semi-infinite solid slab subjected to periodic temperature fluctuations at one end. This has been reported by Blackwelder (1981) who compared the

wavelength of the heat wave to the hot-film length. He showed that the amplitude of the thermal wave would attenuate to a fraction of a percent over a distance equal to its wavelength. A relevant quantity to consider in this context turned out to be the ratio of the wavelength to the length of the substrate, as this is an indication of the extent to which the substrate will partly absorb heat from the heated surface and partly return it to the flow. Haritonidis (1989) computed this ratio for a number of fluids and films and the main conclusion drawn is that at high frequencies the substrate would not participate in the heat-transfer process. However, this conclusion should be viewed with some caution, as the frequencies studied were the highest that could be expected in a wall flow.

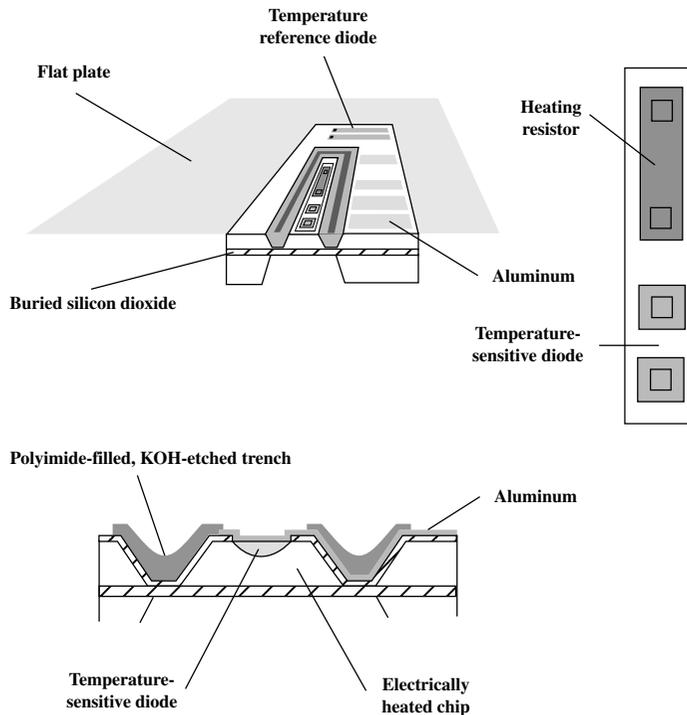

The most difficult problem occurs for frequencies in the intermediate range, resulting in a clear substrate influence and an associated deviation from the static calibration. Hanratty and Campbell (1996) showed that damping by the thermal boundary layer for pipe flow turbulence is important when:

$$[L^{+2}(5.65 \times 10^{-2})^3 Pr]^{1/2} \leq 1 \quad (26.62)$$

For  $Pr = 0.72$ , this requires the dimensionless length in the streamwise direction  $L^+$  to be less than 90. For turbulence applications, this is most disturbing, as it is in this frequency range where the most energetic eddies are situated. The primary conclusion to be reached from this discussion is that all wall-shear-stress measurements in turbulent flows require dynamical calibration of the hot-film sensor.

#### 26.4.4.6 MEMS Thermal Sensors

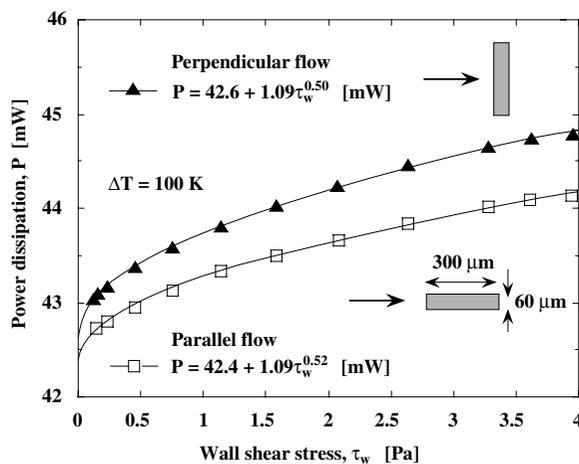

Kälvesten (1996) and Kälvesten et al. (1996b) have developed a MEMS-based, flush-mounted, wall-shear-stress sensor that relies on the same principle of operation as the micro-velocity-sensor presented by Löfdahl et al. (1992). The shear sensor is based on the cooling of a thermally insulated, electrically heated part of a chip. As depicted in Figure 26.21, the heated portion of the chip is relatively small,  $300 \times 60 \times 30 \mu\text{m}^3$ ,

**FIGURE 26.21** Flush-mounted wall-shear-stress sensor: (a) schematic cross section, (b) top view. (From Kälvesten, E. (1996) *Pressure and Wall Shear Stress Sensors for Turbulence Measurements*, Royal Institute of Technology, TRITA-ILA-9601, Stockholm, Sweden. © 1996 IEEE. With permission.)

**TABLE 26.2** Some Calculated and Measured Characteristics of the MEMS-Based Wall-Shear-Stress Sensors Fabricated by Kälvesten et al. (1994)

	Theory		Measurements	
	300 × 60	1200 × 600	300 × 60	1200 × 600
Heated chip top area, $A = w \times \ell$ ( $\mu\text{m}^2$ )	300 × 60	1200 × 600	300 × 60	1200 × 600
Heated chip thickness, $h$ ( $\mu\text{m}$ )	30	30	30	30
Thermal conduction conductance, $G_c$ ( $\mu\text{W}/\text{K}$ )	372	510	426	532
Thermal convection conductance, $G_f$ ( $\mu\text{W}/\text{K}$ ):				
Perpendicular configuration at 50 m/s	6.7	207	21.0	231
Parallel configuration at 50 m/s	5.6	192	17.3	160
Thermal capacity ( $\mu\text{J}/\text{K}$ )	1.2	37	—	—
Thermal time constant at zero flow (ms)	3	72	6	55
Time response (electronic feedback) ( $\mu\text{s}$ )	—	—	25	—

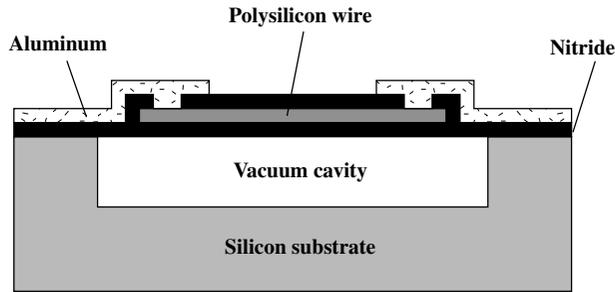

**FIGURE 26.22** Total steady-state power dissipation calibration as a function of the wall-shear stress for two different probe orientations. (From Kälvesten, E. (1996) *Pressure and Wall Shear Stress Sensors for Turbulence Measurements*, Royal Institute of Technology, TRITA-ILA-9601, Stockholm, Sweden. © 1996 IEEE. With permission.)

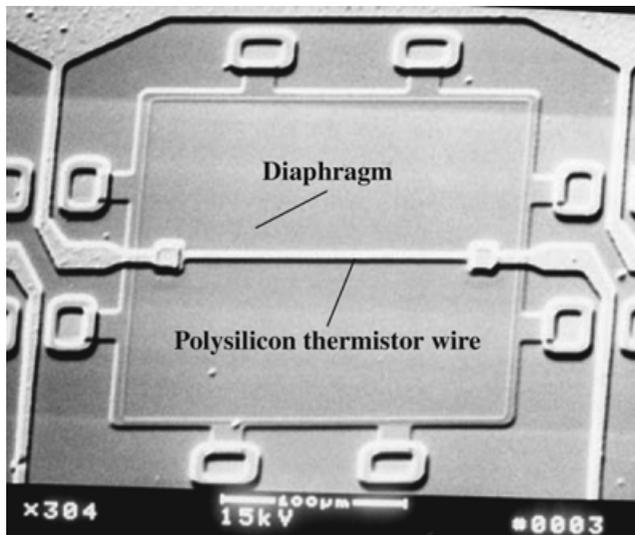

and is thermally insulated by polyimide-filled, KOH-etched trenches. The rectangular top area, with a ratio of side length to side length of 5:1, yields a directional sensitivity for the measurements of the two perpendicular in-plane components of the fluctuating wall-shear stress. Due to the etch properties of KOH, the 30- $\mu\text{m}$ -deep, thermally insulating trenches have sloped walls with a bottom and top width of about 30  $\mu\text{m}$ . The sensitive part of the chip is electrically heated by a polysilicon piezoresistor and its temperature is measured by an integrated diode. For the ambient temperature, a reference diode is integrated on the substrate chip, far away from the heated portion of the chip. (Note that for backup two hot diodes and two cold diodes are fabricated on the same chip.)

Kälvesten (1996) performed a static wall-shear-stress calibration in the boundary layer of a flat plate. A Pitot tube and a Clauser plot were used to determine the time-averaged wall-shear stress. The power consumed to maintain the hot part of the sensor at a constant temperature was measured, and Figure 26.22 shows the data for two different probe orientations. For a step-wise increase of electrical power, the response time was about 6 ms, which is double the calculated value. This response was considerably shortened to 25  $\mu\text{s}$  when the sensor was operated in a constant-temperature mode using feedback electronics. Table 26.2 lists some calculated and measured characteristics of the Kälvesten MEMS-based wall-shear-stress sensor.

Jiang et al. (1994; 1996) have developed an array of wall-shear-stress sensors based on the thermal principle. The primary objective of their experiment was to map and control the low-speed streaks in

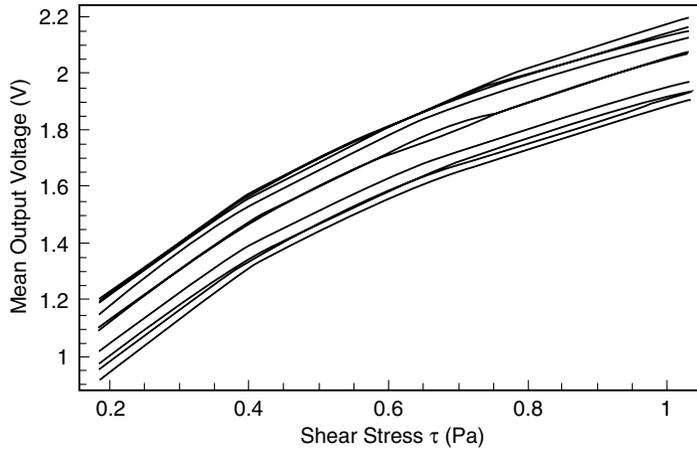

**FIGURE 26.23** Cross-sectional structure of a single shear-stress sensor. (From Jiang, F. et al. (1997) in *Proc. IEEE MEMS Workshop (MEMS '97)*, pp. 465–470. © 1997 IEEE. With permission.)

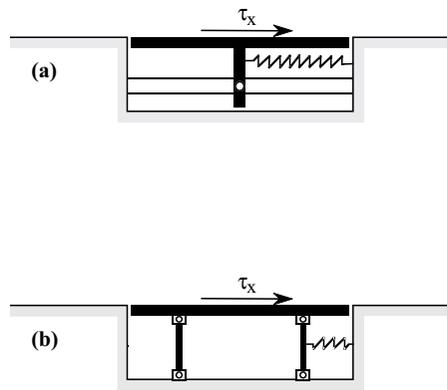

**FIGURE 26.24** SEM photo of a single wall-shear-stress sensor. (From Jiang, F. et al. (1997) in *Proc. IEEE MEMS Workshop (MEMS '97)*, pp. 465–470. © 1997 IEEE. With permission.)

the wall region of a turbulent channel flow. Therefore, to properly capture the streaks, each sensor was made smaller than a typical streak width. For a Reynolds number based on the channel half-width and centerline velocity of  $10^4$ , the streaks are estimated to be about 1 mm in width, so each sensor was designed to have a length less than 300  $\mu\text{m}$ . [Figure 26.23](#) shows a schematic of one of Jiang et al.'s sensors. It consists of a diaphragm with a thickness of 1.2  $\mu\text{m}$  and a side length of 200  $\mu\text{m}$ . The polysilicon resistor wire is located on the diaphragm and is 3  $\mu\text{m}$  wide and 150  $\mu\text{m}$  long. Below the diaphragm there is a 2- $\mu\text{m}$ -deep vacuum cavity so that the device will have a minimal heat conduction loss to the substrate. When the wire is heated electrically, heat is transferred to the flow by heat convection, resulting in an electrically measurable power change that is a function of the wall-shear stress. [Figure 26.24](#) shows a photograph of a portion of the  $2.85 \times 1.00\text{-cm}^2$  streak-imaging chip, containing just one probe. The sensors were calibrated in a fully developed channel flow with known average wall-shear-stress values. [Figure 26.25](#) depicts the calibration results for ten sensors in a row. The output of these sensors is sensitive to the fluid temperature, and the measured data must be compensated for this effect. Measurements of the fluctuating wall-shear stress using the sensor of Jiang et al. (1997) have been reported by Österlund (1999) and Lindgren et al. (2000).

**FIGURE 26.25** Calibration curves of 10 different sensors in an array. (From Jiang, F. et al. (1997) in *Proc. IEEE MEMS Workshop (MEMS '97)*, pp. 465–470. © 1997 IEEE. With permission.)

(1989) in *Advances in Fluid Mechanics Measurements*, M. Gad-el-Hak, Ed., Springer-Verlag, Berlin, pp. 229–261. © 1989 Springer-Verlag. With permission.)

### 26.4.4.7 Floating-Element Sensors

The floating-element technique is a direct method for sensing skin friction, which means a direct measurement of the tangential force exerted by the fluid on a specific portion of the wall. The advantage of this method is that the wall-shear stress is determined without having to make any assumptions either about the flowfield above the device or about the transfer function between the wall-shear stress and the measured quantity. The sensing wall-element is connected to a balance which determines the magnitude of the applied force. Basically, two arrangements are distinguished to accomplish this: either direct measurement of the distance the wall-element is moved by the wall-shear stress, so-called displacement balance, or measurement of the force required to maintain the wall element at its original position when actuated on by the wall-shear stress, the null balance.

The principle of a floating-element balance is shown in [Figure 26.26](#). In spite of the fact that the force measurement is simple, the floating-element principle is afflicted with some severe drawbacks which strongly limit its use, as has been summarized by Winter (1977). It is difficult to choose the relevant size

**FIGURE 26.27** Schematic of the MEMS floating-element balance of Schmidt et al. (From Schmidt et al. (1988) *IEEE Trans. Electron. Devices* 35, pp. 750–757. © 1988 IEEE. With permission.)

of the wall element, in particular, when measuring small forces and in turbulence applications. Misalignments and the gaps around the element, especially when measuring small forces, are constant sources of uncertainty and error. Effects of pressure gradients, heat transfer and suction/blowing cause large uncertainties in the measurements, as well. If the measurements are conducted in a moving frame of reference, effects of gravity, acceleration and large transients can also severely influence the results. Haritonidis (1989) discussed the mounting of floating-element balances and errors associated with the gaps and misalignments. In addition, floating-element balances fabricated with conventional techniques have in general poor frequency response and are not suited for measurements of fluctuating wall-shear stress. To summarize, the idea of direct force measurements by a floating-element balance is excellent in principle, but all the drawbacks taken together make them difficult and cumbersome to work with in practice. It was not until the introduction of microfabrication in the late 1980s that floating-element force sensors experienced revitalized interest, particularly for turbulence studies and reactive flow control.

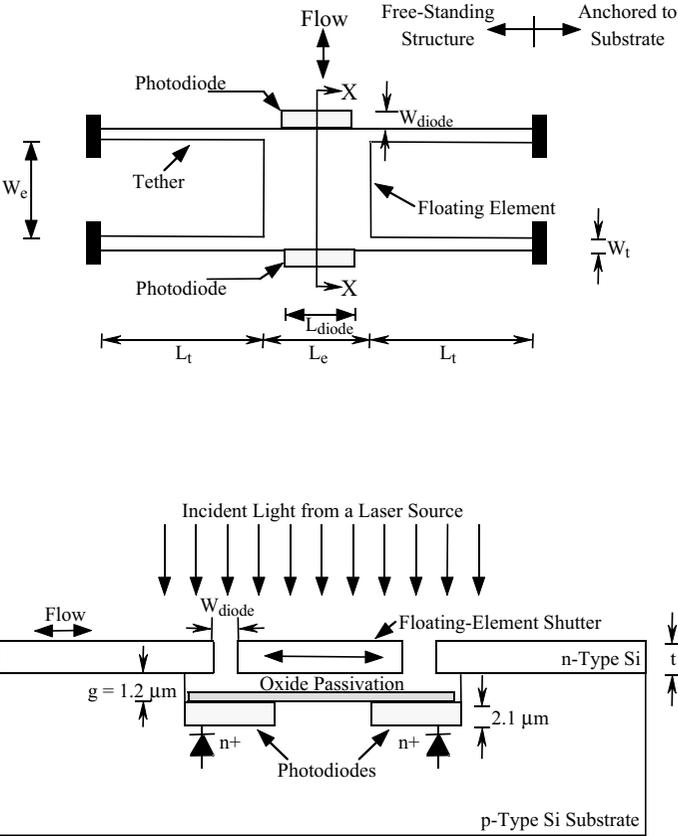

#### 26.4.4.8 MEMS Floating-Element Sensors

Schmidt et al. (1988) were the first to present a MEMS-based floating-element balance for operation in low-speed turbulent boundary layers. A schematic of their sensor is shown in [Figure 26.27](#). A differential capacitive sensing scheme was used to detect the floating-element movements. The area of the floating element used was  $500 \times 500 \mu\text{m}^2$ , and it was suspended by four tethers which acted both as supports and restoring springs. The floating element had a thickness of  $30 \mu\text{m}$ , and was suspended  $3 \mu\text{m}$  above the silicon substrate on which it was fabricated. The gap on either side of the tethers and between the element and surrounding surface was  $10 \mu\text{m}$ , while the element top was flush with the surrounding surface within  $1 \mu\text{m}$ . The element and its tethers were made of polyimide, and the sensor was designed to have a bandwidth of 20 kHz. A static calibration of this force gauge indicated linear characteristics, and the sensor was able to measure a shear stress as low as 1 Pa. However, the sensor showed sensitivity to electromagnetic interference due to the high-impedance capacitance used, and drift problems attributed to water-vapor absorption by the polyimide were observed. No measurements of fluctuating wall-shear

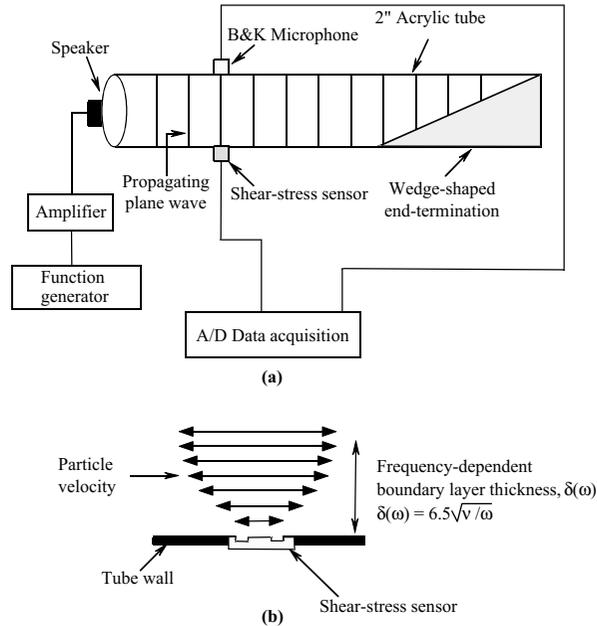

stress were made, as the signal amplitude available from the device itself was too low in spite of the fact that the first-stage amplification was fabricated directly on the chip.

Since the introduction of Schmidt et al.'s sensor, other floating-element sensors based on transduction, capacitive and piezoresistive principles have been developed [Ng et al., 1991; Goldberg et al., 1994; Pan et al., 1995]. Ng et al.'s sensor was small and had a floating element of size  $120 \times 40 \mu\text{m}^2$ . It operated on a transduction scheme and was basically designed for polymer-extrusion applications so it operated in the shear stress range of 1 to 100 kPa. Goldberg et al.'s sensor has a larger floating element size,  $500 \times 500 \mu\text{m}^2$ . It has the same application and the same principle of operation as Ng et al.'s balance. Neither of these two sensors is of interest in turbulence and flow-control applications, as their sensitivities are far too low. The capacitive floating-element sensor of Pan et al. (1995) is a force-rebalance device designed for wind-tunnel measurements and is fabricated using a surface micromachining process. Unfortunately, this particular fabrication technique can lead to nonplanar floating-element structures. The sensor has only been tested in laminar flow, and no dynamic response of this device has been reported.

Padmanabhan (1997) presented a floating-element wall-shear-stress sensor based on optical detection of instantaneous element displacement. The probe is designed specifically for turbulent boundary layer research and has a measured resolution of 0.003 Pa and a dynamic response of 10 kHz. A schematic illustrating the sensing principle is shown in Figure 26.28. The sensor is comprised of a floating element suspended by four support tethers. The element moves in the plane of the chip under the action of wall-shear stress.

**FIGURE 26.28** Schematic of the floating-element balance of Padmanabhan (1997). (From Padmanabhan, A. (1997) Silicon Micromachined Sensors and Sensor Arrays for Shear-Stress Measurements in Aerodynamic Flows, Ph.D. thesis, Department of Aeronautics and Astronautics, Massachusetts Institute of Technology, Cambridge, MA. © 1997 IEEE. With permission.)

**FIGURE 26.29** An acoustic plane-wave tube for the calibration of a floating-element shear sensor: (a) overall experiment setup and (b) probe region.

Two photodiodes are placed symmetrically underneath the floating element, at the leading and trailing edges, and a displacement of the element causes a “shuttering” of the photodiodes. Under uniform illumination from above, the differential current from the photodiodes is directly proportional to the magnitude and sign of shear stress. Analytical expressions were used to predict the static and dynamic response of the sensor, and based on the analysis two different floating-element sizes were fabricated,  $120 \times 120 \times 7 \mu\text{m}^3$  and  $500 \times 500 \times 7 \mu\text{m}^3$ . The device has been calibrated statically in a laminar flow over a stress range of four orders of magnitude, 0.003–10 Pa. The gauge response was linear over the entire range of wall-shear stress. The sensor also showed good repeatability and minimal drift.

A unique feature of the shear sensor described above is that its dynamic response has been experimentally determined to 10 kHz. Padmanabhan (1997) described how oscillating wall-shear stress of a known magnitude and frequency can be generated using an acoustic plane-wave tube. A schematic of the calibration experiment is shown in Figure 26.28. The set-up is comprised of an acrylic tube with a speaker/compression driver at one end and a wedge-shaped termination at the other end. The latter is designed to minimize reflections of sound waves from the tube end and thereby set up a purely traveling wave in the tube. A signal generator and an amplifier drive the speaker to radiate sound at different intensities and frequencies. At some distance downstream, the waves become a plane and at this location a condenser microphone, which measures the fluctuating pressure, and the shear-stress sensor are mounted. The flowfield inside the plane-wave tube is very similar to a classical fluid dynamics problem—the Stokes second problem. The only difference is that instead of an oscillating wall with a semi-infinite stationary fluid, the plane-wave tube has a stationary wall and oscillating fluid particles far away from the wall. Solutions to the Stokes problem can be found in many textbooks [Brodkey, 1967; Sherman, 1990; White, 1991]. Padmanabhan (1997) converted the boundary conditions and derived corresponding analytical expression for the plane-wave tube. The analytical solution of the fluctuating wall-shear stress was compared to the measured output of the shear-stress sensor as a function of frequency and a transfer function of the sensor was determined. As expected, the measured shear stress showed a square-root dependence on frequency.

### 26.4.4.9 Outlook for Shear-Stress Sensors

Because coherent structures play a significant role in the dynamics of turbulent shear flows, the ability to control these structures will have important technological benefits such as drag reduction, transition control, mixing enhancement and separation delay. In particular, the instantaneous wall-shear stress is of interest for reactive control of wall-bounded flows to accomplish any of those goals. An anticipated scenario to realize this vision would be to cover a fairly large portion of a surface (for instance, parts of an aircraft wing or fuselage) with sensors and actuators. Spanwise arrays of actuators would be coupled with arrays of wall-shear-stress sensors to provide a locally controlled region. The basic idea is that sensors upstream of the actuators detect the passing coherent structures, and sensors downstream of the actuators provide a performance measure of the control. Fast, small and inexpensive wall-shear-stress sensors like the microfabricated thermal or floating-element sensors discussed in this section would be a necessity in accomplishing this kind of futuristic control system. Control theory, control algorithms and the use of microsensors and microactuators for reactive flow control are among the topics discussed in several chapters of this handbook.

As mentioned in the introduction, the fluctuating wall-shear stress is an indicator of the turbulence activity of the flow. In the ongoing development of existing turbulence models for application in high-Reynolds-number flows, absolute values of the fluctuating wall-shear stress are of significant interest. To accomplish this kind of measurement, reliable methods for conducting dynamical calibration of wall-shear-stress sensors are needed and must be developed. The calibration method of Padmanabhan (1997) is of interest and other strategies are likely to develop in the future. Another intriguing possibility that would be challenging is to design a microsensor where the dynamic effects of the gauge could be controlled in such a way that only a static calibration of the sensor would be adequate.

## 26.4.5 Pressure Sensors

### 26.4.5.1 Background

In turbulence modeling, flow control and aeroacoustics, the fluctuating wall pressure beneath a wall-bounded flow is a crucial parameter. By measuring this random quantity much information can be gleaned about the boundary layer itself without disturbing the interior of the flow. The fluctuating wall-pressure is coupled via a complex interaction to gradients of both mean-shear and velocity fluctuations as described by the transport equations for Reynolds stresses [Tennekes and Lumley, 1972; Hinze, 1975; Pope, 2000].

The characteristics of the fluctuating wall-pressure field beneath a turbulent boundary layer have been extensively studied in both experimental and theoretical investigations, and reviews of earlier work may be found in Blake (1986), Eckelmann (1990) and Keith et al. (1992). However, from the experimental perspective, knowledge of pressure fluctuations is far from being as comprehensive as that of velocity fluctuations, as there is a lack of a generally applicable pressure-measuring instrument that can be used in the same wide variety of circumstances as the hot-wire anemometer. In spite of this, some general facts have been established for wall-pressure fluctuations—for example, the order of magnitude of the root-mean-square (rms) value, the general shape of the power spectra and the space–time correlation characteristics [Harrison, 1958; Willmarth and Wooldridge, 1962; Bull, 1967; Bull and Thomas, 1976; Schewe, 1983; Blake, 1986; Lauchle and Daniels, 1984; Farabee and Casarella, 1991].

A clear shortcoming in many of the experiments designed to measure pressure fluctuations is the quality of the data. In the low-frequency range, the data may be contaminated by facility-related noise, while in the high-frequency range the spatial resolution of the transducers limits the accuracy. The former difficulty is usually circumvented by noise-cancellation techniques [Lauchle and Daniels, 1984] or by using a free-flight glider as an experimental platform. This problem may not be considered as a major obstacle today. At the other end of the spectrum, the spatial-resolution problem is more difficult to handle. The main criticism raised is that in many experiments the size of the pressure transducer used has been far too large in relation to the thickness of the boundary layer in context, let alone in relation to the characteristic small scale. The ultimate solution is of course to use small sensors, but testing in

tunnels containing fluids with high viscosity—to increase the viscous length scale in the flow—has been conducted. Using highly viscous fluids creates its own set of problems. Very specialized facilities and instrumentation are needed when oil or glycerin, for example, are used as the working fluid. An oil tunnel is expensive to build and to operate. Moreover, the Reynolds numbers achieved are generally low, and it is not clear how to extrapolate the results to higher Reynolds number flows [Gad-el-Hak and Bandyopadhyay, 1994].

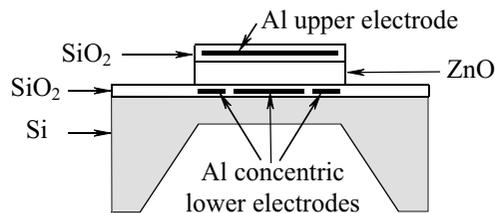

Pinhole microphones have also been utilized in an attempt to improve the sensor's spatial resolution. Unfortunately, results from this type of arrangement are in general questionable, and to this end the use of pinhole microphones must be considered an open question. Bull and Thomas (1976) concluded that the use of pinhole sensors in air may lead to severe errors in the measured spectra, while Farabee (1986), Gedney and Leehey (1989) and Farabee and Casarella (1991) all claim that the pinhole sensors are most effective for wall-pressure measurements.

Based on the above arguments, it seems then that the only realistic solution to improve measurements of fluctuating wall pressure is to use small sensors. For this reason microfabrication offers a unique opportunity for reducing the diaphragm size by at least one order of magnitude. MEMS also provides an opportunity to fabricate inexpensive, dense arrays of pressure sensors for correlation measurements and studies of coherent structures in turbulent boundary layers. In this section, we describe the basic principles used for MEMS-based pressure sensors/transducers/microphones. We look specifically at the design of pressure sensors utilizing the piezoresistive principle, which is particularly suited for measurements of wall-pressure fluctuations in turbulent flows. The section also contains a summary of measurements conducted with MEMS pressure sensors and when possible a comparison to conventional data. Finally, we provide an outlook for the use of MEMS-based pressure sensors for turbulence measurements and flow control.

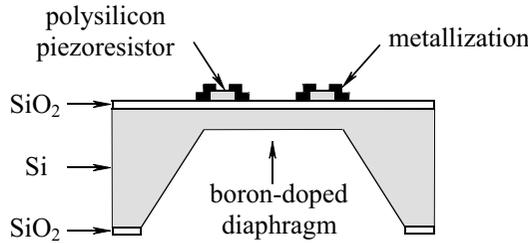

#### 26.4.5.2 Pressure-Sensor Principles

Many different methods have been advanced for the detection of pressure fluctuations. The principles available are based on detecting the vibrating motion of a diaphragm using piezoelectric, piezoresistive and capacitive techniques. These principles were already known at the beginning of the twentieth century, but the introduction of photolithographic fabrication methods during the last two decades has provided strong impetus as this technology offers sensors fabricated to extremely low tolerance, increased resolution due to a high degree of miniaturization and low unit-cost. This method of fabrication is also compatible with other IC techniques so electronic circuitry such as preamplifiers can be integrated close together with the sensor, an important factor for improving pressure sensor performance. Here we will give a short background of the above-mentioned principles for pressure sensor operations. In the description we use the word *microphone* for a device whereby sound waves are caused to generate an electric current for the purpose of transmitting or recording sound.

A piezoelectric sensor consists of a thin diaphragm, which is either fabricated in a piezoelectric material or mechanically connected to a cantilever beam consisting of two layers of piezoelectric material with opposite polarization. A vertical movement of the diaphragm causes a stress in the piezoelectric material and generates an electric output voltage. Royer et al. (1983) presented the first MEMS-based piezoelectric sensor, shown in [Figure 26.30](#). This sensor consists of a 30- $\mu\text{m}$ -thick silicon diaphragm with a diameter

**FIGURE 26.30** Cross-sectional view of a piezoelectric silicon microphone. (From Royer, M. et al. (1983) *Sensors and Actuators A*, 44, 1–11. © 1983 IEEE. With permission.)

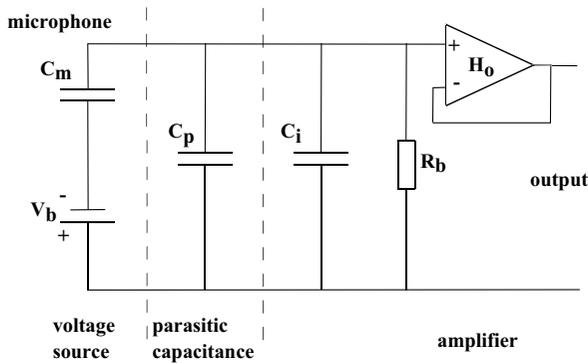

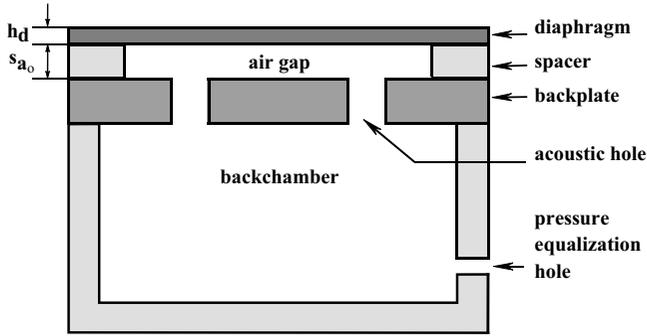

**FIGURE 26.31** Cross-sectional view of a piezoresistive silicon microphone. (From Schellin, R. and Hess, G. (1992) *Sensors and Actuators A*, **32**, 555–559. © 1992 IEEE. With permission.)

of 3 mm. On top of the diaphragm a layer of 3- to 5- $\mu\text{m}$  ZnO was deposited, sandwiched between two SiO<sub>2</sub> layers that contained the upper and lower aluminum electrodes. The sensor can be provided with an integrated preamplifier and is basically used for microphone applications. A sensitivity of 50 to 250  $\mu\text{V}/\text{Pa}$  and a frequency response in the range of 10 Hz to 10 kHz (flat within 5 dB) were recorded. Other researchers have presented similar piezoelectric silicon microphones [Kim et al., 1991; Kuhnel, 1991; Schellin and Hess, 1992; Schellin et al., 1995], and the sensitivities of these microphones were in the range of 0.025 to 1 mV/Pa. However, applications of the piezoelectric microphone to turbulence measurements are strongly limited because of its high noise level, which has been found to be in the range of 50 to 72 dB(A)SPL. These noise levels are most commonly measured using an A-weighted filter, in dBs relative to  $2 \times 10^{-5}$  Pa, which is the lowest sound level detectable by the human ear. The A-weighted filter corrects for the frequency characteristics of the human ear and provides a measure of the audibility of the noise.

A piezoresistive sensor consists of a diaphragm which is usually provided with four piezoresistors in a Wheatstone bridge configuration. One common arrangement is to locate two of the gauges in the middle and two at the edge of the diaphragm. When the diaphragm deflects, the strains at the middle and at the edge of the diaphragm would have opposite signs, causing an opposite effect on the piezoresistive gauges. The most important advantage of this detection principle is its low output-impedance and its high sensitivity. The main drawback is that the piezoresistive material is sensitive to both stress and temperature. Unfortunately, this gives the piezoresistive sensor a strong temperature dependency. Schellin and Hess (1992) presented the first MEMS-fabricated piezoresistive sensor, which is shown in Figure 26.31. This particular sensor was used as a microphone and had a diaphragm made of 1- $\mu\text{m}$ -thick, highly boron-doped silicon with an area of 1 mm<sup>2</sup>. The diaphragm was equipped with a 250-nm-thick, p-type polysilicon resistors, which were isolated from the diaphragm by a 60-nm silicon dioxide layer. Using a bridge supply voltage of 6 V, this transducer showed a sensitivity of 25  $\mu\text{V}/\text{Pa}$  and a frequency response in the range of 100 Hz to 5 kHz (+3 dB). However, the sensitivity was lower than expected by a factor of 10, which was explained by the initial static stress in the highly boron-doped silicon diaphragm. To improve the sensitivity of the piezoresistive sensor, various diaphragm materials have been explored such as polysilicon and silicon nitride [Guckel, 1987; Sugiyama et al., 1993].

Most MEMS-fabricated pressure sensors are based on the capacitive detection principle, and a vast majority of these sensors are used as microphones. Figure 26.32 shows a cross-sectional view of such a condenser microphone together with the associated electrical circuit. The latter must be included in the discussion, as the preamplifier is a vital part of determining the sensitivity of the capacitive probe. Basically, a condenser microphone consists of a backchamber (with a pressure-equalizing hole), a backplate (with acoustic holes), a spacer and a diaphragm covering the air gap created by the spacer located on the backplate. The condenser  $C_m$  and a dc-voltage source  $V_b$  constitute the sensing part of the microphone. Fluctuations in the flow pressure field above the diaphragm cause it to deflect which in turn changes the capacitance  $C_m$ . These changes are amplified in the preamplifier  $H_o$  which acts as an impedance converter with a bias resistor  $R_b$  and an input capacitance  $C_i$ . In this figure,  $C_p$  is a parasitic capacitance which is of interest when determining the microphone attenuation. In discussing the sensitivity

**FIGURE 26.32** Cross-sectional view of a condenser microphone. The microphone is connected to an external dc bias voltage source and loaded by a parasitic capacitance, bias resistor and a preamplifier with an input capacitance. (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

of a capacitive sensor, the open-circuit sensitivity is a relevant quantity and is considered to consist of two components, namely the mechanical sensitivity  $S_m$  and the electrical sensitivity  $S_e$ . The total sensitivity is a weighted value of both. The former sensitivity  $S_m$  is defined as the increase of the diaphragm deflection  $dw$  resulting from an increase in the pressure  $dp$  acting on the microphone:

$$S_m = \frac{dw}{dp} \quad (26.63)$$

From [Figure 26.32](#) we obtain the relation  $dw = -ds_{a_0}$ , where  $s_{a_0}$  is the thickness of the air gap between the diaphragm and the backplate. The electrical sensitivity of the microphone is given by the change in the voltage across the air gap  $dV$  resulting from a change in the air-gap thickness  $ds_{a_0}$ . Thus,

$$S_e = \frac{dV}{ds_{a_0}} \quad (26.64)$$

The quasi-static, open-circuit sensitivity  $S_{\text{open}}$  of a condenser microphone may be defined as  $S_{\text{open}} = -S_m S_e$ . The output signal  $e_m$  can then be expressed as

$$e_m = S_m S_e p \quad (26.65)$$

where  $p$  is the fluctuating pressure. For details of this derivation, see Scheeper et al. (1994).

Hohm (1985) presented the first electret microphone based on MEMS technology. The backplate, 1-cm × 1-cm silicon, was provided with one circular acoustic hole with a diameter of 1 mm. A 2- $\mu$ m-thick SiO<sub>2</sub> layer was used as an electret and was charged to about 350 V. The diaphragm was a metallized 13- $\mu$ m-thick foil with a diameter of 8 mm. Later, polymer foil diaphragms were used in condenser microphones by Sprenkels (1988) and Murphy et al. (1989). In these microphones, the fabrication was made more compatible with standard thin-film technology. Bergqvist and Rudolf (1991) showed that MEMS-fabricated microphones can achieve a high sensitivity. For example, microphones with a 2-cm × 2-cm diaphragm had an open-circuit sensitivity in the range of 1.4 to 13 mV/Pa. In these microphones, diaphragms with thickness of 5 to 8  $\mu$ m were fabricated using an anisotropic etching in a KOH solution and by applying an electrochemical etch stop. More details on the design and performance of the capacitive pressure sensors can be found in Scheeper et al. (1994).

An overview of the most significant dimensions, measured sensitivity, noise level and high-frequency response of first-generation MEMS pressure sensors is provided in Table 26.3. Inspecting the data, the following remarks can be made. The piezoelectric sensors seem to have the highest noise levels. Although simple in design, they have fairly low sensitivity and relatively large spatial extension of their diaphragms. The piezoresistive sensors seem to be most flexible, as the major advantage of locating piezoresistive gauges on a diaphragm is the high sensitivity accomplished with this arrangement. The drawback is the high temperature sensitivity, although this problem can be circumvented by a Wheatstone bridge arrangement of the gauges. The capacitive sensors are most common, as these sensors hold the largest commercial interest and are mainly designed to operate in conventional microphone applications such as music and human communications with pressure amplitudes as low as 20  $\mu$ Pa. The capacitive sensors have relatively large spatial extension and are commonly equipped with on-chip electronics for signal amplification. This implies a reduction of the noise levels but unfortunately also yields a very complex fabrication process.

The main advantages of the capacitive sensors are their high sensitivity to pressure and low sensitivity to temperature. Their primary disadvantages are the relatively large diaphragm areas and the decreased sensitivity for high frequencies due to the air-streaming resistance of the narrow air gap inherent in the principle.

### 26.4.5.3 Requirements for Turbulent Flows

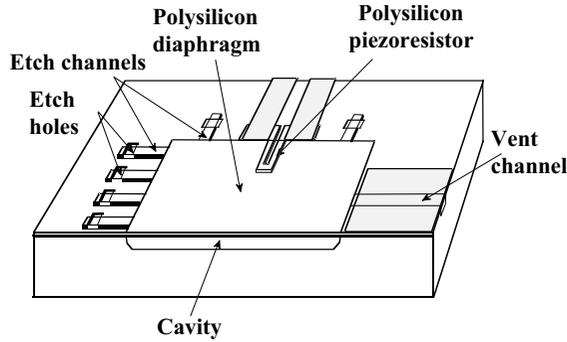

There is no simple way to calculate the required pressure range of a sensor for turbulence and flow-control applications. Tennekes and Lumley (1972) estimate the fluctuating pressure to be a weighted integral of the Reynolds stresses, so its length scales should in general be larger than those of the velocity fluctuations. Moreover, it is plausible to assume that the order of magnitude of the fluctuating pressure would not be less than the Reynolds stresses, giving a good hint as to the intensity of the fluctuating pressure. This intensity, of course, depends strongly on the particular flow under consideration, but for a typical flat-plate boundary layer at, say,  $Re_0 = 4000$ , this implies that the fluctuating pressure rms would be of the order of 10 Pa. Higher Reynolds numbers yield higher magnitudes of the fluctuating wall pressure. As compared to other applications, where the fluctuating pressure has a major interest, as, for example, in combustion processes, the pressure magnitudes in incompressible turbulent flows are extremely small. There is also a spatial constraint in the sensor design. For the same boundary layer considered here, we have a Kolmogorov length scale of about 50  $\mu\text{m}$ , requiring a diaphragm size in the range of 100 to 300  $\mu\text{m}$ . The required temporal resolution of the pressure sensor is probably the easiest to estimate as we have access to good turbulence kinetic energy spectra and these show that the energy content in the flow above 10 kHz is almost negligible. Based on these physical arguments, a frame for the design of a pressure transducer for turbulence applications can be established; namely, the sensor should have a pressure sensitivity of  $\pm 10$  Pa, a diaphragm size of 100  $\mu\text{m}$ , and flat frequency characteristics in the range of 10 Hz to 10 kHz. Of course, the signal-to-noise ratio must be sufficiently high so that an ordinary data acquisition can be made.

A critical scrutiny of the different principles for designing a pressure sensor shows that the most suitable principle for turbulence applications is the piezoresistive, as the required spatial and temporal resolutions can easily be achieved, a simple fabrication in MEMS is possible, and the temperature drift can be controlled. In the next section, we outline the design procedure of such a piezoresistive pressure transducer for turbulence and flow control applications.

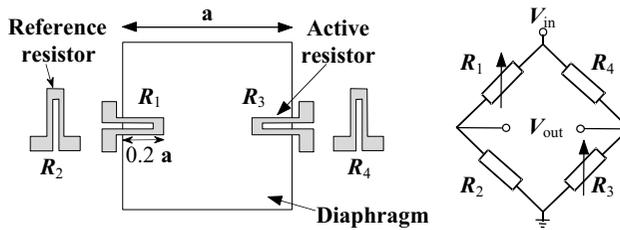

### 26.4.5.4 Piezoresistive Pressure Sensors

Micromachined piezoresistive pressure sensors were introduced on the market already in the late 1950s by companies such as Kulite, Honeywell and MicroSystems. These early transducers were all very simple devices and typically the piezoresistive gauges were glued by hand onto the diaphragm. As the technology developed, more advanced fabrication methods were introduced, and today pressure transducers are all fabricated using batch-processing technologies and no hand assembly is required. A large variety of different pressure transducers are available commercially and the range of applications is very wide, spanning from relatively slow but stable tools for meteorological observations to sensors used to optimize rapid combustion processes. However, an examination of these commercial sensors with turbulence and control applications in mind will show that very few, almost none, can yet be applied for these specific purposes. If the sensors have either a frequency response or sensitivity that is acceptable, then the sensing area is far too large and the necessary spatial resolution is not fulfilled. Or, vice versa, if the diaphragm size is acceptable—which is very rare—then either the frequency response or the sensitivity is far too low for the fulfillment of, respectively, the required temporal resolution or an acceptable signal-to-noise ratio. Moreover, a literature review will confirm this statement, and the sensors of [Table 26.3](#) are the ones that are fabricated using MEMS technology and fall in the range of interest for turbulence and flow-control applications.

Based on the earlier mentioned criteria, it may be concluded that a piezoresistive sensor for turbulence applications should be fabricated with a diaphragm size of  $100 \times 100 \times 0.4 \mu\text{m}$ . In order to give the pressure sensor the necessary sensitivity, the diaphragm must be very thin, and the air gap behind the diaphragm

**FIGURE 26.33** Isometric view of a pressure sensor/microphone for turbulence applications. The diaphragm side-length is  $100\ \mu\text{m}$  and its thickness is  $0.4\ \mu\text{m}$ . (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

**FIGURE 26.34** Top view of the piezoresistor layout with the electrical Wheatstone bridge configuration. (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

(the cavity) must be relatively deep (say,  $4\ \mu\text{m}$ ) to reduce the air stiffening effect. For equalization of the static pressure between the cavity and the ambient, a narrow vent channel with a length of  $3\ \text{mm}$  and a cross section of  $5 \times 0.1\ \mu\text{m}$  must be included in the design. An isometric view of an acoustic sensor built to those specifications by Kälvesten (1994) is shown in Figure 26.33.

When a diaphragm is deflected by a pressure load, stress is induced in the diaphragm and this should be detected by piezoresistive strain gauges located at appropriate positions on the diaphragm. Noting that the geometrical piezoresistive effect in semiconductors can be neglected, the general relation between the relative change of resistance and the strain components in the longitudinal (streamwise),  $\langle \epsilon_L \rangle$ , and transverse (spanwise),  $\langle \epsilon_T \rangle$ , directions can, according to Guckel (1991), be expressed as:

$$\frac{\Delta R}{R} = G_{par} \langle \epsilon_L \rangle + G_{per} \langle \epsilon_T \rangle \quad (26.66)$$

where  $G_{par}$  and  $G_{per}$  are the longitudinal and transverse gauge factors. The pressure sensors fabricated by Kälvesten (1994) use two active strain gauges positioned at the points of maximum stress of the diaphragm (i.e., at the middle of the edges of the diaphragm), and the other two are integrated beside the diaphragm to serve as passive reference gauges (see Figure 26.34). This arrangement makes it possible to connect them in a half-active Wheatstone bridge for high pressure and low temperature sensitivity.

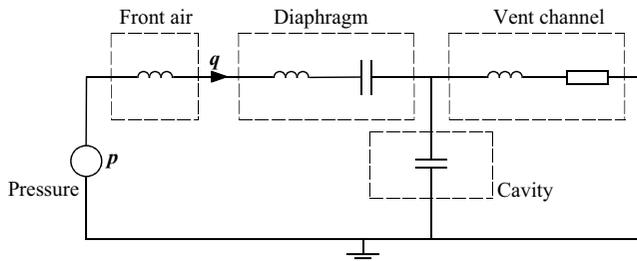

The expected theoretical acoustical pressure sensitivity,  $S$ , for small pressure amplitudes has been derived by Kälvesten (1994) and reads:

$$S = \frac{1}{V_{in}} \frac{\partial V_{out}}{\partial p} \approx \frac{0.077 G_{par} (1 - \mu^2)}{\left( \frac{Et^2}{a^2} + \frac{3(1 + \mu)E\epsilon_o}{4\pi} + \frac{\alpha^{-1}(1 - \mu^2)a^2}{16\pi^2 td} \right)} \quad (26.67)$$

**TABLE 26.4** Some Calculated and Measured Characteristics of the MEMS-Based Microphone Fabricated by Kälvesten (1994)

	Theory		Measurements	
Diaphragm side length, $a$ ( $\mu\text{m}$ )	100	300	100	300
Diaphragm thickness, $t$ ( $\mu\text{m}$ )	0.4	0.4	0.4	0.4
Lower frequency limit (Hz)	$2 \times 10^{-3}$	$5 \times 10^{-6}$	$10^a$	$10^a$
Upper frequency limit (Hz)	1310	894	$25^a$	$25^a$
Acoustical sensitivity at 10 V ( $\mu\text{V}/\text{Pa}$ )	1.0	0.2	0.9	0.3
Static sensitivity at 10 V ( $\mu\text{V}/\text{Pa}$ )	1.7	2.2	1.2	1.4
Noise (A-weighted) (dB(A))	—	—	$\approx 90$	$\approx 90$

<sup>a</sup> Limits set by the calibration measurement setup.

**FIGURE 26.35** An electrical analogy describing the equivalent acoustical circuit of the pressure sensor/microphone. (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

where  $V_{in}$  and  $V_{out}$  are, respectively, the bridge supply and output voltages;  $p$  is the pressure acting on the diaphragm;  $\alpha$  is the isothermal compressibility coefficient of air;  $d$  is the cavity depth; and  $G_{par}$  is the longitudinal gauge factor of the polysilicon piezoresistor. For the polysilicon diaphragm,  $\mu$  is the Poisson's ratio,  $E$  is the Young's modulus,  $\epsilon_0$  is the built-in strain,  $a$  is the side length, and  $t$  is the thickness. Assuming a linear diaphragm deflection, this equation can be used to derive the static pressure sensitivity of the sensor. In doing so it is necessary to assume a vacuum-sealed cavity by setting the third term of the denominator (air-gap compressive forces) to zero; see Rossi (1988). Table 26.4 compares the measured and calculated characteristics of the microphone developed by Kälvesten (1994).

A piezoresistive sensor is a combination of mechanical (the small and thin diaphragm), acoustical (the air-gap cavity, the air in the front of the diaphragm and the narrow vent channel) and electrical (polysilicon piezoresistors) elements. In order to optimize the dimensions of the sensor, an electrical analogy model is very useful for the task; see Rossi (1988). The important advantage of this analogy—from which the microphone frequency response and the diaphragm center deflection can be derived—is that it allows a good overview of even very complex systems. The analog model relies on the fact that there is a relationship between the geometry of the mechano-acoustical elements and their equivalent electrical impedance. Hence, pressure  $p$  ( $\text{N}/\text{m}^2$ ) is equivalent to voltage; flow rate  $q$  ( $\text{m}^3/\text{s}$ ), to current; and acoustic mass  $M$  ( $\text{kg}/\text{m}^4$ ), to inductance. Damping in the system, which is due to the viscosity of the gas, is described by resistances  $R$  ( $\text{N s}/\text{m}^5$ ) and capacitors  $C$  ( $\text{m}^5/\text{N}$ ). These quantities then describe the diaphragm flexibility and the gas compressibility. However, a limitation of this “equivalent circuit method” is that analytical expressions for the equivalent electrical impedance are available only for simple mechanical and acoustical structures. One possibility for the derivation of the equivalent impedance is demonstrated in Kälvesten (1994) and Kälvesten et al. (1995; 1996a), where an energy method is used for the calculation of the energy and power contributions of the different elements. These expressions are then identified as equivalent electrical impedance. Figure 26.35 shows a simplified circuit diagram of their microphone.

The piezoresistive pressure probe fabricated by Kälvesten (1994) has perhaps the smallest diaphragm built specifically for turbulence diagnosis. Its spatial resolution is adequate to measure the small scales,

and the small diaphragm has a correspondingly high resonance frequency which leads to a wide frequency bandwidth. The main drawbacks of this small sensor are its relatively low acoustical sensitivity and high equivalent noise level. It should be noted, however, that for turbulence applications, the pressure is of the order of 1 Pa, while pressure amplitudes as low as 20  $\mu\text{Pa}$  are encountered in human communication and music applications.

The frequency characteristics of Kälvesten's pressure sensor/microphone were determined by using a Bruel & Kjaer, Type 4226, closed coupler with a built-in reference microphone at a sound pressure level of 114 dB. All measurements were performed for a bridge supply voltage of 10 V and show acoustical sensitivities of about 0.9 and 0.3  $\mu\text{V}/\text{Pa}$  for diaphragm side lengths of, respectively, 100 and 300  $\mu\text{m}$ . The deviations from the theoretical estimates for the acoustical sensitivities can be explained by the approximations made in the sensitivity calculation and the uncertainty of the level of the built-in stresses in the polysilicon diaphragm. As can be seen from Table 26.4, and as is further elucidated in Kälvesten et al. (1995; 1996a), the required frequency range for turbulence applications of  $10 \text{ Hz} < f < 10 \text{ kHz}$  is safely covered by the theoretical range of about  $1 \text{ Hz} < f < 1 \text{ MHz}$ . The noise levels of the sensors are nearly the same for the two sensor versions, corresponding to an acoustic level of about 90 dB(A). More details on this sensor can be found in Kälvesten (1994) and Löfdahl et al. (1996).

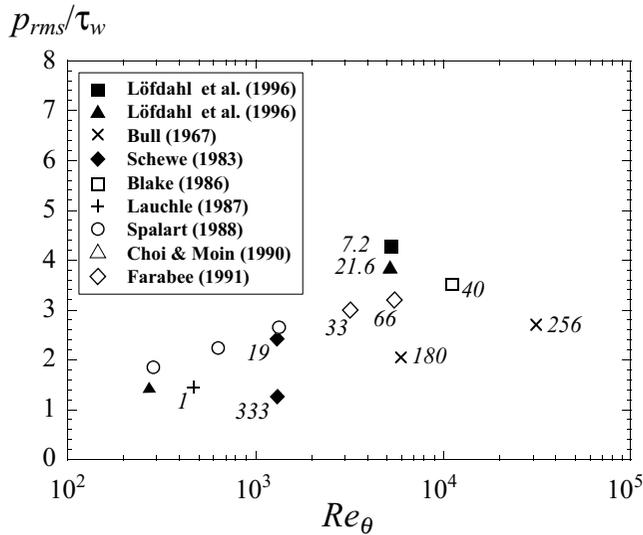

#### 26.4.5.5 MEMS Pressure Sensors

Genuine MEMS sensors for turbulence measurements were not introduced until the 1990s, so very few reliable measurements for studying wall-pressure fluctuations beneath turbulent boundary layers have been conducted. Otherwise, many MEMS devices have been launched, but fluid dynamics verification of these devices has been made at a surprisingly low level, typically in some undefined channel or pipe flow.

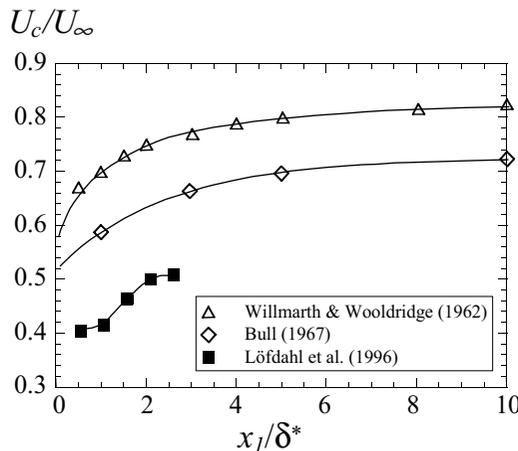

Schellin et al. (1995) presented a subminiature microphone based on the piezoresistive effect in polysilicon using only one chip. This sensor was classified as an acoustical sensor fabricated with a complementary metal oxide semiconductor (CMOS) process and standard microfabrication technology. The diaphragm area was  $1 \text{ mm}^2$  and the sensitivity was 0.025 mV/Pa at 6 V, so for turbulence application this sensor is a bit on the large side as well as too insensitive. The frequency response was determined to be flat from 100 Hz to 5 kHz. Unfortunately, no fluid dynamics measurements have been reported with this sensor.

Kälvesten (1994), Kälvesten et al. (1995; 1996a) and Löfdahl et al. (1996) have designed, fabricated and used a silicon-based pressure transducer for studies focused on the high-frequency portion of the wall-pressure spectrum in a two-dimensional, flat-plate boundary layer. The momentum thickness Reynolds number in their study was  $Re_\theta = 5072$ . A large value of the ratio between the boundary layer thickness  $\delta$  and the diaphragm side-length  $d$  was used. The side lengths of the diaphragm were 100  $\mu\text{m}$  ( $d^+ = 7.2$ ) and 300  $\mu\text{m}$  ( $d^+ = 21.6$ ). This gives a ratio of the boundary-layer thickness to the diaphragm side length of the order of 240 and a resolution of eddies with wavenumbers less than 10 viscous units. Power spectra were measured for the frequency range  $13 \text{ Hz} < f < 13 \text{ kHz}$ , and these were scaled in outer and inner variables. A clear overlap region between the mid- and high-frequency parts of the spectrum was found, and in this region the slope was estimated to be  $\omega^{-1}$ . For the high-frequency region, the slope was proportional to  $\omega^{-5}$ . The normalized rms pressure fluctuations was shown to depend strongly on the dimensionless diaphragm size with an increase connected to the resolution of the high-frequency region as shown in Figure 26.36. Classical data in the field are also plotted in the same figure for comparison.

Correlation measurements in both the longitudinal and transverse directions were performed by Löfdahl et al. (1996). Longitudinal space-time correlations, including the high-frequency range, indicated an advection velocity of the order of half the freestream velocity as can be seen in Figure 26.37. In this figure,  $U_c$  is the advection velocity,  $U_\infty$  is the freestream velocity,  $x_1$  is the streamwise distance between two probes, and  $\delta^*$  is the local displacement thickness. The advection velocities computed by Löfdahl et al. (1996) are consistently lower than those obtained by Willmarth and Wooldridge (1962) and Bull (1967). A broad-band filtering of the longitudinal correlation confirmed that the high-frequency part of the

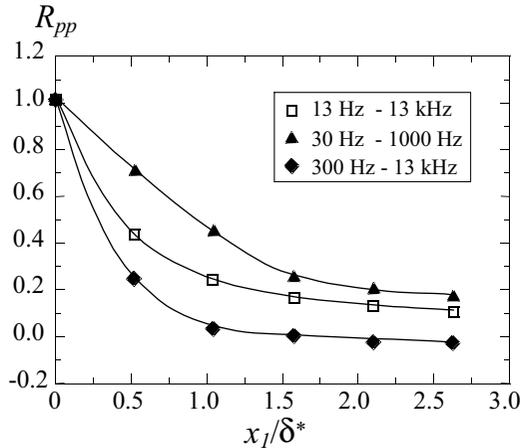

**FIGURE 26.36** Dependence of normalized rms pressure fluctuations on Reynolds number; uncertainty is less than 10%. The numbers next to selected data points indicate the diaphragm side length in wall units. (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

**FIGURE 26.37** Local advection velocity of the pressure producing eddies for various frequency ranges; uncertainty is less than 10%. (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

spectrum is associated with the smaller eddies from the inner part of the boundary layer, resulting in a reduction of the correlation, as shown in Figure 26.38.

Miller et al. (1997) designed, fabricated and tested a unique micromachined sensor array for making optical measurements of surface-pressure distributions. Each sensor element consists of a Fabry–Perot etalon fabricated from single-crystal silicon. Illuminating the sensor array with a near-infrared, tunable, diode laser and detecting the reflected light intensity with an infrared camera allow remote, simultaneous reading of the reflected signals from the entire sensor array. The results obtained demonstrate the basic feasibility of optically measuring surface pressure using micromachined Fabry–Perot pressure sensor arrays. Future work in this context will concentrate on demonstrating temporally resolved pressure measurements. This technology is interesting, as it offers the possibility of putting the arrays on curved surfaces.

**FIGURE 26.38** Longitudinal spatial correlation of the pressure fluctuations in three frequency ranges:  $30 \text{ Hz} < f < 1000 \text{ Hz}$ ;  $300 \text{ Hz} < f < 13 \text{ kHz}$ ; and  $13 \text{ Hz} < f < 13 \text{ kHz}$ . Momentum thickness Reynolds number is  $Re = 5072$ . (From Löfdahl, L. et al. (1996) *J. Fluids Eng.*, **118**, 457–463. With permission.)

### 26.4.5.6 Outlook for Pressure Sensors

MEMS pressure transducers have certainly opened many doors to formulating relationships between wall pressure and turbulence. In this section, we will focus on some issues that should be possible to sort out in the near future by further miniaturization and array arrangements of pressure transducers. The Reynolds number effect on the rms values of the wall pressure is one key issue. The data shown in Figure 26.36 seem to suggest a trend that is also depicted schematically in the figure; that is, they come from a family of  $d^+$ . In a review of Reynolds number effects, Gad-el-Hak and Bandyopadhyay (1994) concluded that meaningful trends in the inner layer can be extracted only when the sensors are of the order of the viscous sublayer thickness. At all Reynolds numbers in the figure, the asymptotic values are reached by sensors approaching the size  $d^+ = 5$ , and the slope of the family of  $d^+$  lines drops as  $d^+$  values are increased, indicating a decreasing sensitivity of sensors to Reynolds number effects. It should be noted that the data shown in Figure 26.36 come from various sources with varying degrees of background noise, differences in data acquisition and corrections applied and different inherent errors in the sensors and instrumentation. Hence, the uncertainties in each dataset are different and probably not known accurately. There are also gaps in the data, so a useful contribution would be a systematic variation of the sensor dimension and Reynolds number so the data of Figure 26.36 could be completed.

Using arrays of wall-pressure sensors will offer the possibilities of more extensive studies of space-time correlations of pressure fluctuations. The primary contribution of the small transducers is that the eddies of the flowfield can be resolved with a spatial resolution of about five viscous units (i.e., the thickness of the viscous sublayer). Based on the measured correlations it is possible to examine the advection velocities of the different wavenumbers. It has earlier been shown [e.g., Bull, 1967] that the advection velocities of the turbulent eddies based on broad- and narrow-band frequency analysis approach 80% and 60%, respectively, of the freestream velocity. This can be questioned, as in all earlier investigations sensors that were too large have been used. In other words, the ratio between the boundary layer thickness and the characteristic dimension of the sensor has been too low. With MEMS sensors, about ten times larger values of this ratio can be achieved as compared with conventional sensors.

Having access to well-designed pressure-sensor arrays, the advection velocities for the different wavenumbers can be determined. Such data also offer the possibility of examining whether or not the structures are produced by pressure sources inside the boundary layer with a wide range of advection velocities. The so-called “two family” concept suggested by Bull (1967) can then be scrutinized. It was claimed by Bull (1967) that one family of high-wavenumber components was associated with the turbulent motion in the

constant-stress layer. Those components were longitudinally coherent for times proportional to the time needed for structures to be advected distances equal to their wavelengths and laterally coherent over distances proportional to their own wavelengths. The other wavenumber family was associated with large-scale eddy motion in the boundary layer and loses coherence as a group independent of the wavelength. To this end, it has not been possible to question the Bull's hypothesis mainly because of the lack of small pressure transducers and associated arrays.

The concepts discussed above in relation to MEMS-based pressure sensors are all key issues and significant to aeroacoustics, energy transport in vibrating structures interacting with turbulent flows, turbulence modeling of the PVC terms and last but certainly not least to reactive control of the flow.

## **26.5 Microactuators for Flow Control**

---

### **26.5.1 Background on Three-Dimensional Structures**

It has recently been suggested by Busch-Vishniac (1998) that it is generally more difficult to control a system than to monitor it. For reactive control, the state of the system at a point or points in space-time must be monitored then accordingly made to change by a suitable actuation process. In the last decade it has been more challenging for scientists and engineers to design and build microsensors than microactuators; as a consequence, the progress in sensors has been left behind that for actuators. In this section, the terse coverage of microactuators relative to that of microsensors is a reflection of the relative progress in the two fields.

To reactively control a flowfield to reduce the drag, for example, it is necessary to develop specific actuators. Most conveniently the actuators should be flush-mounted on the body and aimed to influence near-wall phenomena, which in turbulent flows are dominated by small scales. To actuate these scales, it is required that the spatial extent of the actuator be of the same order as the small scales. As mentioned, the small scales decrease in spatial extension as the Reynolds number increases so sensor/actuator miniaturization is crucial for most field applications of the targeted control idea. In addition, the actuators are commonly intended to operate in a feedback loop with sensors on an extremely short time scale, implying that the operation of small actuators must additionally be very fast. Other constraints of control actuators are that they should yield minimal pressure drag especially when not in use and that they should be fabricated in large numbers at low cost so large portions of drag-inducing surfaces may be covered. Additionally, the actuator must be able to apply a significant disturbance to the flow while expending little energy when in operation. Finally, the sensor/actuator system must be able to withstand the typically harsh field environment. Taken together, it can be seen that the design of actuators for reactive flow control constitutes a real challenge.

Numerous devices for actuating a variety of flowfields have been advanced during the last few years. This has mostly been motivated by the quest to achieve efficient reactive control of turbulent flows. Wiltse and Glezer (1993) originated an interesting path when they used piezoelectric-driven cantilevers as flow-control actuators to beneficially affect free-shear layers. Following the idea of Wiltse and Glezer (1993), Jacobson and Reynolds (1995) designed an actuator that has the piezoelectric cantilever mounted flush with a boundary layer surface. The cantilever was oriented in the streamwise direction and fixed to the wall at its upstream end and could flex out into the flow and down into a cavity in the wall. The under-cantilever cavity was filled with fluid that was connected to the flow through the gaps on the sides and at the tip of the cantilever. Hence, when the cantilever flexed into the cavity, it forced fluid out of the cavity into the external flow, and when the cantilever flexed out of the cavity, fluid was drawn into the cavity from the external flow. Neither Wiltse and Glezer (1993) nor Jacobson and Reynolds (1995) used MEMS technology to fabricate their actuators, but the main conclusion drawn in Jacobson and Reynolds (1995) was that future actuators must be MEMS-based in order to match the relevant scales of turbulent flows.

The major challenge in designing MEMS-based actuators is that a motion perpendicular to the plane of the surface is needed to influence selective flow structures. It is implicitly complex to accomplish this,

as micromachining and MEMS devices are basically two-dimensional structures. Some kind of quasi-three-dimensional structures have been fabricated using bulk and surface micromachining (see, for example, the passive cantilever structures developed by Bandyopadhyay, 1995). While these techniques usually have good resolution in the surface plane, in the direction normal to this plane the resolution is less impressive. Genuine three-dimensional structures can be achieved by using the so-called out-of-plane rotation of microstructures. A major advantage of this method is that it utilizes conventional high-resolution surface lithography and thus simultaneously provides access to the third dimension. A number of techniques based on out-of-plane rotation or folding of silicon microstructures have been advanced, and in this section we present the characteristics of some of these three-dimensional methods which may form a base for future development of MEMS actuators for reactive flow control. Actuating mechanisms based on the bilayer effect, electrostatic or electromagnetic forces, mechanical folding and one-layer structures are presented and discussed. The section will conclude with a brief look at some recently developed microturbomachines whose primary applications may be in fields other than flow control.

### 26.5.2 The BiLayer Effect

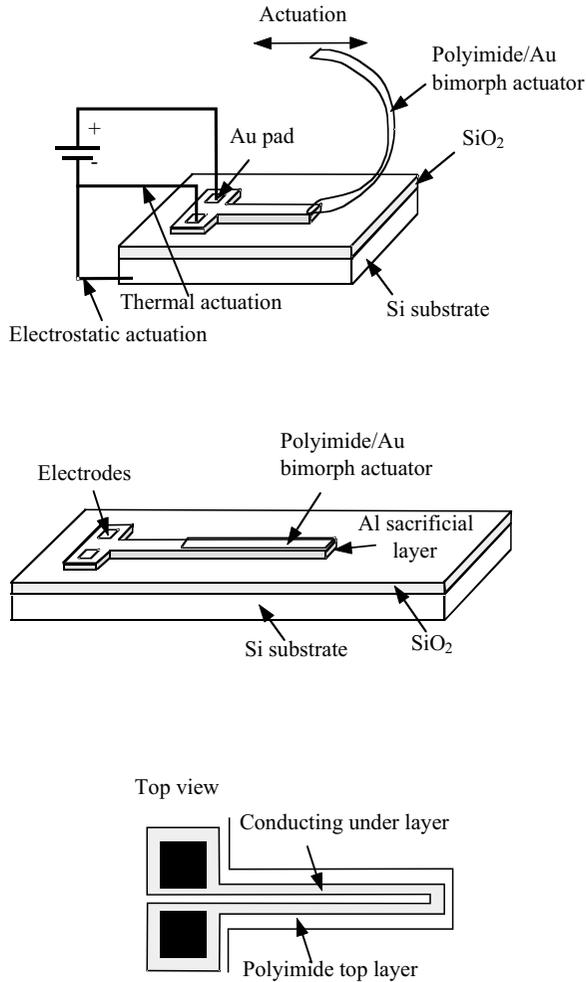

Out-of-plane rotation of microstructures can be achieved by controlled stress engineering in sandwiched structures, the bilayer effect method. The volume change between the two different materials used is the key to controlling the rotation, and several methods are available for this. A significant advantage of this technique is that the microstructure is self-assembled, so no external manipulators are needed to raise the structure out of plane. However, because the bilayer effect is based on the volume change of different materials, the rotation is limited to a fairly large radius of curvature which for certain applications is certainly a severe drawback.

It has been more than 70 years since Timoshenko (1925) presented the basic theory for bending sandwiched structures that consist of two materials with different coefficients of thermal expansion, the bimetal effect. By heating a bimetal cantilever, controlled bending can be achieved and this has been studied by, for example, Riethmuller and Benecke (1988) and Ataka et al. (1993), who used different standard IC materials. Commonly aluminum, chromium or gold, all having relatively high coefficients of thermal expansion, are used in combinations with silicon, polysilicon, silicon dioxide or silicon nitride, which all have low thermal expansion coefficients. As mentioned, the drawback of the bilayer method is that the bending radii are always large, and very thin and fragile structures are needed to reduce the radius of curvature. This pitfall reduces the impact of this particular technology.

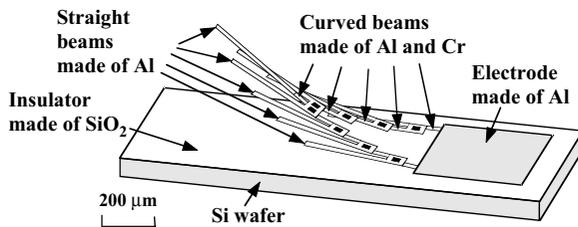

Figure 26.39 illustrates a surface-micromachined actuator achieved by utilizing the large residual stress between two different polyimide films. The out-of-plane curling can be controlled either with thermal actuation using an integrated heater and the bimetal effect or by electrostatic actuation [Elwenspoek et al., 1992; Lin et al., 1995]. The electrostatic actuation requires unfortunately relatively high driving voltage. To circumvent this, Yasuda et al. (1997) have proposed using a serial connection of several bending actuators as depicted in Figure 26.40.

Smela et al. (1995) have shown that when a conjugated or conducting polymer is changed from insulating to metallic by applying a small voltage, the volume of the polymer is changed. A bilayer structure consisting of the polymer and a gold layer will curl, and this can be used as a hinge. Large reversible bending angles with small radii of curvature can be obtained with this technique. However, the price to pay is that the tuning requires an electrolyte which normally is not compatible with sensor applications. The polymer material is also more unstable than conventional integrated circuit materials and has a large potential for degradation.

Volume changes that result in bending can be achieved by using controlled heating to obtain a phase change in a material, so-called shape memory alloys (SMAs); see Otsuka (1995). An integrated heater is used to obtain the phase transformation of the SMA. Additionally, volume changes can also be obtained by applying a voltage over a piezoelectric material deposited on a thin cantilever. When such material expands, the cantilever bends and it is possible to obtain a voltage-controlled, out-of-plane rotation. Unfortunately, both the SMA and piezoelectric techniques give relatively large bending radii.

**FIGURE 26.39** Surface micromachined three-dimensional structures using a bimorph structure consisting of two different polyimides with different thermal expansion coefficients. Control of the out-of-plane rotation can be obtained either with integrated gold heater or by electrostatic forces. (From Lin, G. et al. (1995) in *Technical Digest, Eighth Int. Conf. on Solid-State Sensors and Actuators (Transducers '95 and Eurosensors 9)*, June 25–29, Stockholm, Sweden, pp. 416–419. © 1995 IEEE. With permission.)

Electrostatic forces obtained through an applied voltage between the serially connected beams and the Si wafer are used to control the out-of-plane rotation. (From Yasuda, T. et al. (1997) in *Proc. IEEE Tenth Int. Workshop MEMS (MEMS '97)*, January 26–30, Nagoya, Japan. © 1997 IEEE. With permission.)

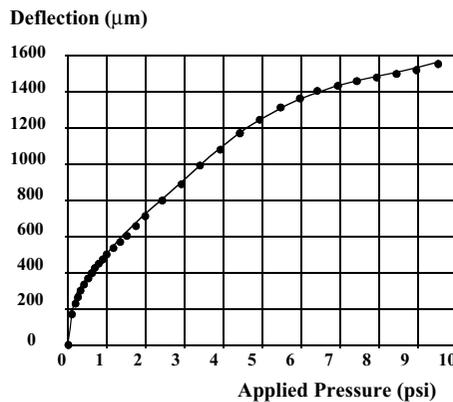

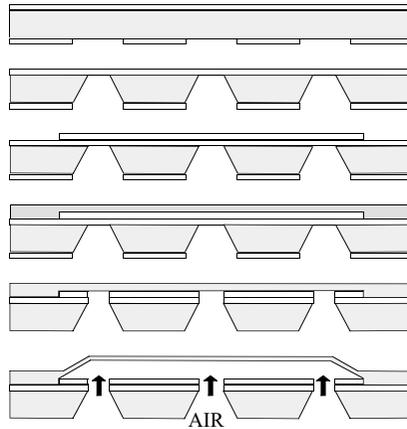

### 26.5.3 Electrostatic and Magnetic External Forces

The most straightforward way of bending a structure is simply to apply an active force on the structure. Different forces can be used to repel or attract freestanding structures so that they bend out of the wafer plane. Both electrostatic and magnetic forces have been utilized. Electrostatic actuators are easy to fabricate, but their operation is limited by small force and displacement outputs. The electromagnetic actuators are, on the other hand, more robust and can be used when larger forces and displacements are required—for example, for separation control or drag reduction. MEMS-based electrostatic actuators have been used to control aerodynamic instabilities. Huang et al. (1996) used an electrostatic actuator to control screech in high-speed jets. With the design of a 70- $\mu\text{m}$  peak-to-peak displacement at the resonant frequency of 5 kHz, it has been shown that disturbances in the jet can be suppressed. Figure 26.41 illustrates the external-force principle using a permanent magnet to achieve an out-of-plane rotation [Liu et al., 1995]. Miller et al. (1996) used a microelectromagnetic flap with a 30-turn copper coil and a layer of permalloy on a 4-mm  $\times$  4-mm silicon plate to obtain a 2-mm tip motion of the actuator. These devices have been shown to be effective for changing the location of flow separation [Liu et al., 1995] and to achieve drag reduction [Tsao et al., 1994; Ho et al., 1997].

To summarize, it may be stated that the electrostatic actuators seem simple to fabricate, however, their operations are limited by small force and displacement outputs. The electromagnetic actuators are more robust and can be used when larger forces and displacements are required (e.g., for separation control or drag reduction). Promising results were reported by Yang et al. (1997), who used thermopneumatic

**FIGURE 26.41** Three-dimensional actuation achieved by applying external magnetic forces. (From Liu, C. et al. (1995) in *Technical Digest, Eighth Int. Conf. on Solid-State Sensors and Actuators (Transducers '95 and Eurosensors 9)*, June 25–29, Stockholm, Sweden, pp. 328–331. © 1995 IEEE. With permission.)

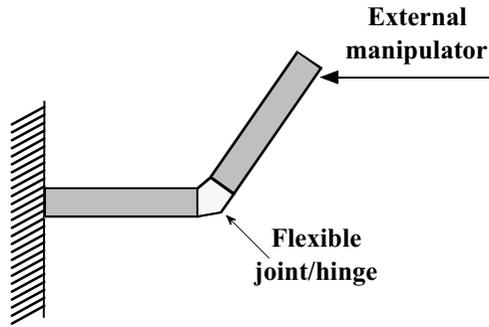

**FIGURE 26.42** Steps involved in fabricating a microballoon actuator (top figure), and applied pressure vs. deflection (bottom plot) for a  $2.3 \times 6.6$ -mm balloon actuator. actuators or microballoons. Typically, these actuators have a heater in a cavity covered by a diaphragm, and when the fluid inside the cavity is heated a significant pressure rise is achieved. This causes a deflection of the diaphragm and for silicon rubber diaphragms more than 1-mm displacement has been measured by Yang et al. (1997). Figure 26.42 depicts the fabrication steps and the deflection achieved by Yang et al.'s microballoon actuator.

### 26.5.4 Mechanical Folding

A simple method to achieve out-of-plane bending of a microstructure is to use an external manipulator and fold a flexible or elastic joint/hinge, as shown in Figure 26.43. Unfortunately, this technique relies on the use of an external manipulator and is accordingly not batch compatible. However, to solve this problem various methods with integrated actuators have been presented by Fukuta et al. (1995; 1997) and Garcia (1998). The main drawback of these methods seems to be that they are quite complex and fragile. Elastic joints in polyimide were developed by Suzuki et al. (1992) as part of an attempt to fabricate a microrobot mimicking insects. Figure 26.44 shows their three-dimensional structure with the elastic polyimide joint and the surface micromachining steps involved in fabricating it. This structure is manually assembled into its final position just like paper folding, and bending angles up to  $70^\circ$  can be achieved.

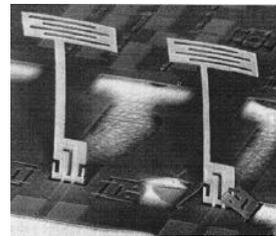

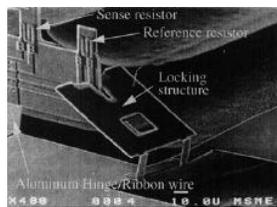

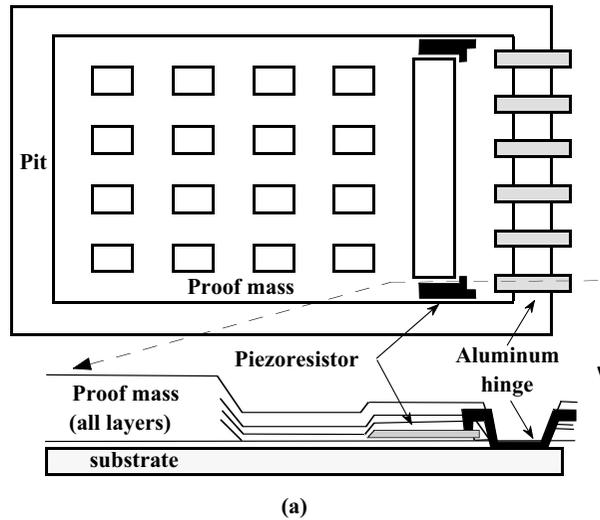

**FIGURE 26.43** A three-dimensional microstructure undergoing a mechanical folding caused by external manipulator. (From Ebefors, T. et al. (1997) *Euroensors XI*, September 21–24, Warsaw, Poland. © 1997 IEEE. With permission.)

**FIGURE 26.44** Steps involved in fabricating a three-dimensional structure that uses mechanical folding of an elastic polyimide joint (top figure), and isometric view of the resulting microactuator (bottom figure). (From Suzuki, K. et al. (1992) in *Proc. IEEE Fifth Int. Workshop MEMS (MEMS '92)*, February 4–7, Travemunde, Germany, pp. 190–195. © 1992 IEEE. With permission.)

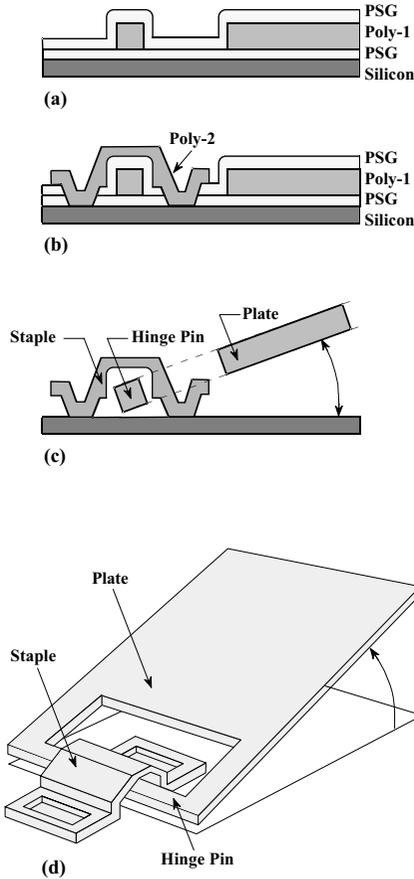

An approach similar to the elastic polyimide-joint was employed to fabricate three-dimensional piezoresistive sensors using post-process etching of standard CMOS wafers [Hoffman et al., 1995; Kruglick et al., 1998]. External manipulators were used to rotate the structures out of plane with a flexible aluminum hinge, as shown in [Figure 26.45](#). The advantage here is that three-dimensional actuators can readily be integrated on the same chip with the electronics. Moreover, the electrical interconnection to the folded structure is automatically obtained by the aluminum hinge; however, the main drawback is the non-self-assembling fabrication involved which requires interlocking braces. Furthermore, the resulting

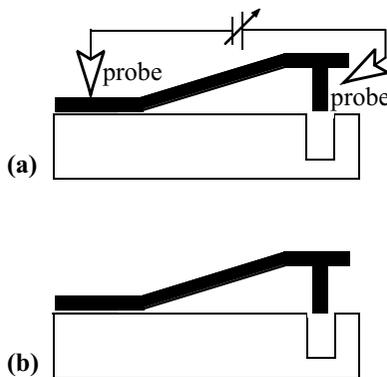

**FIGURE 26.45** (a) Overview of a three-dimensional accelerometer design based on aluminum hinges with piezoresistive detection. The aluminum hinges are formed by front-bulk silicon etching of standard CMOS-wafers. (b) Close-up of the aluminum hinge with an interlocking brace. (c) SEM-photo of raised test structures. (Parts (a) and (b) from Kruglick, E.J.J. et al. (1998) in *Proc. IEEE Eleventh Int. Workshop MEMS (MEMS '98)*, January 25–29, Heidelberg, Germany, pp. 631–636; part (c) from Hoffman, E. et al. (1995) in *Proc. IEEE Eighth Int. Workshop MEMS (MEMS '95)*, January 29–February 2, Amsterdam, The Netherlands, pp. 288–293. © 1995 IEEE. With permission.)

structure is usually extremely fragile. A micromachined polysilicon hinge has been presented by Pister et al. (1990). This hinge is fabricated using surface micromachining with two layers of polysilicon and phosphosilicate glass as the sacrificial layer, as shown in Figure 26.46. A variety of applications using the polysilicon hinge have been presented—for example, micro-optical devices such as mirrors and lenses [Lin et al., 1995; Wu et al., 1995; Gunawan et al., 1995; Solgaard et al., 1995; Tien et al., 1996a; Fan et al., 1997]. However, a drawback of these surface-made microstructures is that they cannot stand by themselves, so they require some kind of interlocking arrangement to stay bent out of the wafer which complicates the assembly process. The structure usually consists of many stacked layers resulting in rugged surfaces. To be useful for three-dimensional applications, the difficulties in achieving electrical interconnections to the assembled structure have to be resolved.

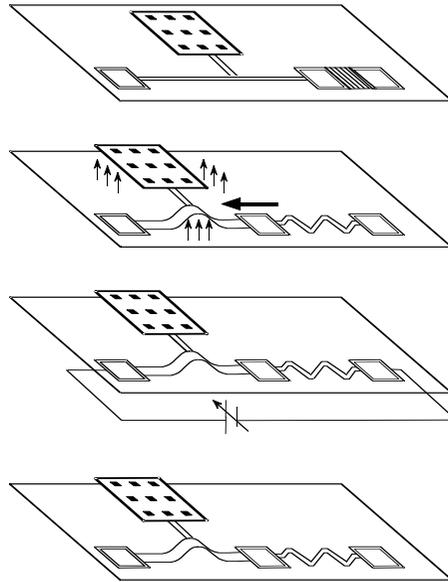

Fukuta et al. (1995) have presented a reshaping technique using Joule's heating to effect thermal plastic deformation for permanent three-dimensional polysilicon structures. Figure 26.47 illustrates the experimental procedure for the three-dimensional structure realization. To achieve self-assembling structures without the drawback of using an external micromanipulator, a technique using an integrated scratch-drive actuator for folding was presented by Akiyama et al. (1997). Figure 26.48 shows the principle of

**FIGURE 26.46** (a)–(c) Cross sections of the hinge during fabrication. (d) A perspective view of a hinged plate after release by external manipulator. (From Pister, K.S.J. et al. (1992) *Sensors and Actuators A*, **33**, 249–256. © 1992 IEEE. With permission.)

**FIGURE 26.47** An external manipulator is used to fold and supply the structure with a reshaping voltage. The Joule's heating raises the temperature of the arm to cause an annealing effect which results in stress release and plastic deformation. After removal of the voltage, the arm cools down and the structure retains its three-dimensional shape. (From Fukuta, Y. et al. (1995) in *Technical Digest, Int. Conf. on Solid-State Sensors and Actuators (Transducers '95)*, June 25–29, Stockholm, Sweden, pp. 174–177. With permission.)

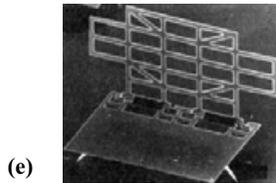

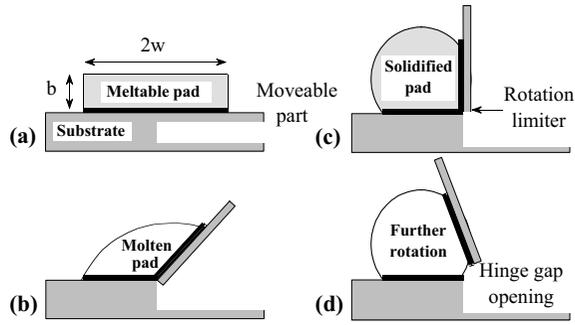

**FIGURE 26.48** Illustration of a three-dimensional self-assembled polysilicon structure based on scratch-drive actuators. (From Akiyama, T. et al. (1997) *J. MEMS*, 6, 10–17. © 1997 IEEE. With permission.)

the self-assembling process which produces permanent three-dimensional structure by using integrated scratch-drive actuator and reshaping technology. Fukuta et al. (1995) also discuss the self-assembling of three-dimensional structures with reshaping technology.

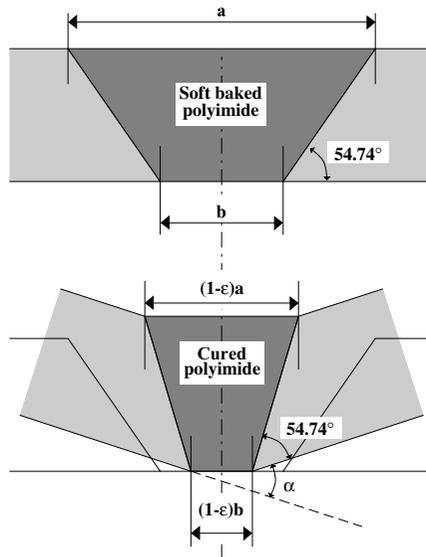

### 26.5.5 One-Layer Structures

All the techniques described in the previous subsection require external manipulators to raise the microstructures. To overcome this drawback, a self-assembling technique for fabrication of three-dimensional structures was presented by Green et al. (1996). The method is based on the surface tension force of a molten solder. The main drawback is that nonstandard IC material is used, meaning that very accurate process control is required. In addition, it seems difficult to achieve electrical connections to the out-of-plane rotated structures. To circumvent the lack of IC compatibility, Syms (1998) proposed using glass as the meltable material to achieve a more controlled assembly; however, the glass requires a high temperature to melt which makes it impossible to integrate metal interconnections and electronics together with the three-dimensional structure. Figure 26.49 shows the preparation of a three-dimensional structure based on surface tension forces. The structure after the out-of-plane rotation is shown in the bottom of this figure.

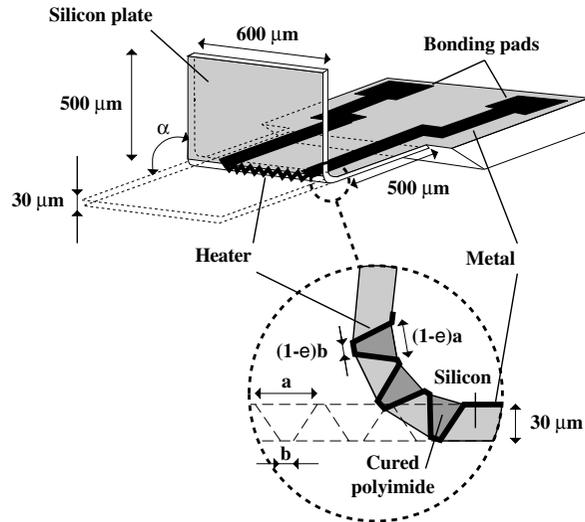

Another self-assembling microjoint technique was presented by Ebefors et al. (1998). In this technique, polyimide is used to create controlled out-of-plane rotations yielding small silicon structures with detailed features. The basic principle of the polyimide joint is shown in Figure 26.50. Polyimide in the V-grooves shrinks when cured in such a way that the absolute contraction length of the polyimide is larger at the top of the groove than at the bottom. This creates a rotation of the material which implies a bending of the freestanding structure out of the wafer plane. Larger bending angles can be achieved by connecting several V-grooves in a row. Figure 26.51 shows a schematic view of a polyimide joint with three V-grooves. The static, irreversible bending angle is obtained during the thermal curing process when cross-links between the molecules are effected and various solvents in the polyimide are out-gassed, yielding a reduction in the polyimide volume. The shrinkage depends on the curing temperature, which makes it possible to control the final bending angle rather well. A reversible bending angle can be obtained as a result of the thermal expansion of the cured polyimide. A metal conductor is used as a resistive heater to produce local power

**FIGURE 26.49** Production of a three-dimensional structure with Si mechanical parts based on surface tension forces (top figure), and SEM photo of the resulting three-dimensional structure (bottom figure). (From Syms, R.R.A. (1998) *Sensors and Actuators A*, 65, 238–243. © 1998 IEEE. With permission.)

**FIGURE 26.50** Principle of the polyimide V-groove joint. The polyimide in the V-groove shrinks when the polyimide is cured. The absolute lateral-contraction length of the polyimide is larger at the top of the V-groove than at the bottom, resulting in a rotation that bends the free-standing structure out of the wafer plane. (From Ebefor, T. et al. (1997) *Euroensors XI*, September 21–24, Warsaw, Poland. © 1997 IEEE. With permission.)

**FIGURE 26.51** Isometric view of a three-dimensional structure based on a polyimide joint with three V-grooves. The metal lead-wires through the V-grooves are used to realize electrical connections to the out-of-plane rotated structure. Exploiting the thermal expansion of the polyimide, the metal can also be used as a heater in the V-grooves to obtain reversible movements. (From Ebefors, T. et al. (1997) in *Transducers '97*, June 16–19, Chicago, IL. With permission.)

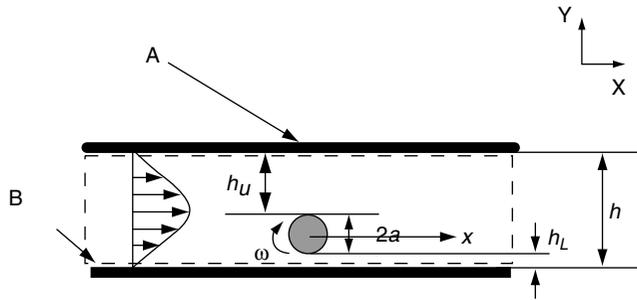

dissipation in the joint. A temperature increase results in an expansion of the polyimide and a dynamic change in the bending angle.

## 26.6 Microturbomachines

### 26.6.1 Micropumps

In the several studies of microfabricated pumps, some have used nonmechanical effects. The so-called Knudsen pump uses the thermal-creep effect to move rarefied gases from one chamber to another. Ion drag is used in electrohydrodynamic pumps [Bart et al., 1990; Richter et al., 1991; Fuhr et al., 1992]. These rely on the electrical properties of the fluid and are thus not suited for many applications. Valveless pumping by ultrasound has been proposed by Moroney et al. (1991), but it produces very little pressure difference. Mechanical pumps based on conventional centrifugal or axial turbomachinery will not work at micromachine scales where the Reynolds numbers are typically small, on the order of 1 or less. Centrifugal forces are negligible and, furthermore, the Kutta condition through which lift is normally generated is invalid when inertial forces are vanishingly small. In general there are three ways in which mechanical micropumps can work:

1. *Positive-displacement pumps*: These are mechanical pumps with a membrane or diaphragm actuated in a reciprocating mode and with unidirectional inlet and outlet valves. They work on the same physical principle as their larger cousins. Micropumps with piezoelectric actuators have been fabricated [Van Lintel et al., 1988; Esashi et al., 1989; Smits, 1990]. Other actuators such as thermopneumatic, electrostatic, electromagnetic or bimetallic can be used [Pister et al., 1990; Döring et al., 1992; Gabriel et al., 1992]. These exceedingly minute positive-displacement pumps require even smaller valves, seals and mechanisms, a not-too-trivial micromanufacturing challenge. In addition, there are long-term problems associated with wear or clogging and consequent leaking around valves. The pumping capacity of these pumps is also limited by the small displacement and frequency involved. Gear pumps are a different kind of positive-displacement device.

**FIGURE 26.52** Schematic of micropump developed by Sen et al. (1996). (From Sen, M., Wajerski, D., and Gad-el-Hak, M. (1996) *J. Fluids Eng.* **118**, pp. 624–627. With permission.)

2. *Continuous, parallel-axis rotary pumps:* A screw-type, three-dimensional device for low Reynolds numbers was proposed by Taylor (1972) for propulsion purposes and is shown in his seminal film. It has an axis of rotation parallel to the flow direction, implying that the powering motor must be submerged in the flow, the flow turned through an angle, or that complicated gearing would be needed.
3. *Continuous, transverse-axis rotary pumps:* This class of machines has been developed by Sen et al. (1996). They have shown that a rotating body, asymmetrically placed within a duct, will produce a net flow due to viscous action. The axis of rotation can be perpendicular to the flow direction, and the cylinder can thus be easily powered from outside a duct. A related viscous-flow pump was designed by Odell and Kovaszny (1971) for a water channel with density stratification; however, their design operates at a much higher Reynolds number and is too complicated for microfabrication.

As evidenced from the third item above, it is possible to generate axial fluid motion in open channels through the rotation of a cylinder in a viscous fluid medium. Odell and Kovaszny (1971) studied a pump based on this principle at high Reynolds numbers. Sen et al. (1996) carried out an experimental study of a different version of such a pump. The novel viscous pump, shown schematically in Figure 26.52, consists simply of a transverse-axis cylindrical rotor eccentrically placed in a channel, so that the differential viscous resistance between the small and large gaps causes a net flow along the duct. The Reynolds numbers involved in Sen et al.'s work were low ( $0.01 < Re \equiv 2\omega a^2/\nu < 10$ , where  $\omega$  is the radian velocity of the rotor, and  $a$  is its radius), typical of microscale devices, but were achieved using a macroscale rotor and a very viscous fluid. The bulk velocities obtained were as high as 10% of the surface speed of the rotating cylinder. Sen et al. (1996) have also tried cylinders with square and rectangular cross sections, but the circular cylinder delivered the best pumping performance.

A finite-element solution for low-Reynolds-number, uniform flow past a rotating cylinder near an impermeable plane boundary has already been obtained by Liang and Liou (1995). However, detailed two-dimensional Navier–Stokes simulations of the pump described above have been carried out by Sharatchandra et al. (1997), who extended the operating range of  $Re$  beyond 100. The effects of varying the channel height  $H$  and the rotor eccentricity  $\epsilon$  have been studied. It was demonstrated that an optimum plate spacing exists and that the induced flow increases monotonically with eccentricity, the maximum flow rate being achieved with the rotor in contact with a channel wall. Both the experimental results of Sen et al. (1996) and the two-dimensional numerical simulations of Sharatchandra et al. (1997) have verified that, at  $Re < 10$ , the pump characteristics are linear and therefore kinematically reversible. Sharatchandra et al. (1997; 1998a; 1998b) also investigated the effects of slip flow on the pump performance as well as the thermal aspects of the viscous device. Wall slip does reduce the traction at the rotor surface and thus lowers the performance of the pump somewhat. However, the slip effects appear to be significant only for Knudsen numbers greater than 0.1, which is encouraging from the point of view of microscale applications.

In an actual implementation of the micropump, several practical obstacles need to be considered. Among these are the larger stiction and seal design associated with rotational motion of microscale devices. Both the rotor and the channel have a finite (in fact, rather small) width. DeCourtye et al. (1998) numerically investigated the viscous micropump performance as the width of the channel  $W$  becomes exceedingly small. The bulk flow generated by the pump decreased as a result of the additional resistance to the flow caused by the side walls. However, effective pumping was still observed with extremely narrow channels. Finally, Shartchandra et al. (1998b) used a genetic algorithm to determine the optimum wall shape to maximize the micropump performance. Their genetic algorithm uncovered shapes that were nonintuitive but yielded vastly superior pump performance.

Though most of the micropump discussion above is of flow in the steady state, it should be possible to give the eccentric cylinder a finite number of turns or even a portion of a turn to displace a prescribed minute volume of fluid. Numerical computations will easily show the order of magnitude of the volume discharged and the errors induced by acceleration at the beginning of the rotation and deceleration at the end. Such system can be used for microdosage delivery in medical applications.

### 26.6.2 Microturbines

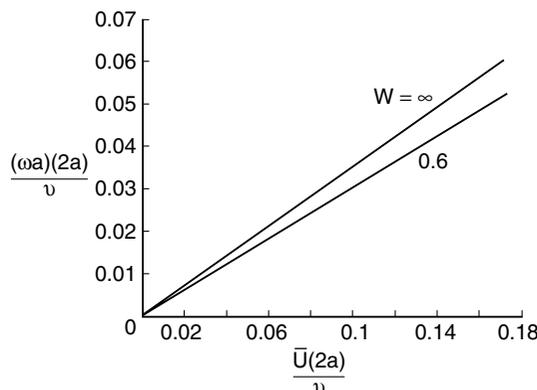

DeCourtye et al. (1998) have described the possible utilization of the inverse micropump device as a turbine. The most interesting application of such a microturbine would be as a microsensors for measuring exceedingly small flow rates on the order of nanoliters (i.e., microflow metering for medical and other applications).

The viscous pump described operates best at low Reynolds numbers and should therefore be kinematically reversible in the creeping-flow regime. A microturbine based on the same principle should, therefore, lead to a net torque in the presence of a prescribed bulk velocity. The results of three-dimensional numerical simulations of the envisioned microturbine are summarized in this section. The Reynolds number for the turbine problem is defined in terms of the bulk velocity, as the rotor surface speed is unknown in this case:

$$Re = \frac{\bar{U}(2a)}{\nu} \quad (26.69)$$

where  $\bar{U}$  is the prescribed bulk velocity in the channel,  $a$  is the rotor radius and  $\nu$  is the kinematic viscosity of the fluid.

Figure 26.53 shows the dimensionless rotor speed as a function of the bulk velocity for two dimensionless channel widths,  $W = \infty$  and  $W = 0.6$ . In these simulations, the dimensionless channel depth

**FIGURE 26.53** Turbine rotation as a function of the bulk velocity in the channel. (From DeCourtye, D. et al. (1998) *Int. J. Comp. Fluid Dyn.*, **10**, 13–25. With permission by Taylor & Francis Ltd.)

is  $H = 2.5$  and the rotor eccentricity is  $\epsilon/\epsilon_{\max} = 0.9$ . The relation is linear as was the case for the pump problem. The slope of the lines is 0.37 for the two-dimensional turbine and 0.33 for the narrow channel with  $W = 0.6$ . This means that the induced rotor speeds are, respectively, 0.37 and 0.33 of the bulk velocity in the channel. (The rotor speed can never, of course, exceed the fluid velocity even if there is no load on the turbine. Without load, the integral of the viscous shear stress over the entire surface area of the rotor is exactly zero, and the turbine achieves its highest albeit finite rpm.) For the pump, the corresponding numbers were 11.11 for the two-dimensional case and 100 for the three-dimensional case. Although it appears that the side walls have a greater influence on the pump performance, it should be noted that in the turbine case a vastly higher pressure drop is required in the three-dimensional duct to yield the same bulk velocity as that in the two-dimensional duct (dimensionless pressure drop of  $\Delta p^* \equiv \Delta p(2a)^2/\rho v^2 = -29$  vs.  $\Delta p^* = -1.5$ ).

The turbine characteristics are defined by the relation between the shaft speed and the applied load. A turbine load results in a moment on the shaft, which at steady state balances the torque due to viscous stresses. At a fixed bulk velocity, the rotor speed is determined for different loads on the turbine. Again, the turbine characteristics are linear in the Stokes (creeping) flow regime, but the side walls have a weaker, though still adverse, effect on the device performance as compared to the pump case. For a given bulk velocity, the rotor speed drops linearly as the external load on the turbine increases. At large enough loads, the rotor will not spin, and maximum rotation is achieved when the turbine is subjected to zero load.

At present, it is difficult to measure flow rates on the order of  $10^{-12}$  m<sup>3</sup>/s (1 nl/s). One possible way is to directly collect the effluent over time. This is useful for calibration but is not practical for online flow measurement. Another way is to use heat transfer from a wire or film to determine the local flow rate as in a thermal anemometer. Heat transfer from slowly moving fluids is mainly by conduction so that temperature gradients can be large. This is undesirable for biological and other fluids easily damaged by heat. The viscous mechanism that has been proposed and verified for pumping may be turned around and used for measuring. As demonstrated in this section, a freely rotating cylinder eccentrically placed in a duct will rotate at a rate proportional to the flow rate due to a turbine effect. In fact, other geometries such as a freely rotating sphere in a cylindrical tube should also behave similarly. The calibration constant, which depends on system parameters such as geometry and bearing friction, should be determined computationally to ascertain the practical viability of such a microflow meter. Geometries that are simplest to fabricate should be explored and studied in detail.

### 26.6.3 Microbearings

Many of the micromachines use rotating shafts and other moving parts that carry a load and need fluid bearings for support, most of them operating with air or water as the lubricating fluid. The fluid mechanics of these bearings is very different compared to that of their larger cousins. Their study falls in the area of microfluid mechanics, an emerging discipline which has been greatly stimulated by its applications to micromachines and which is the subject of this chapter.

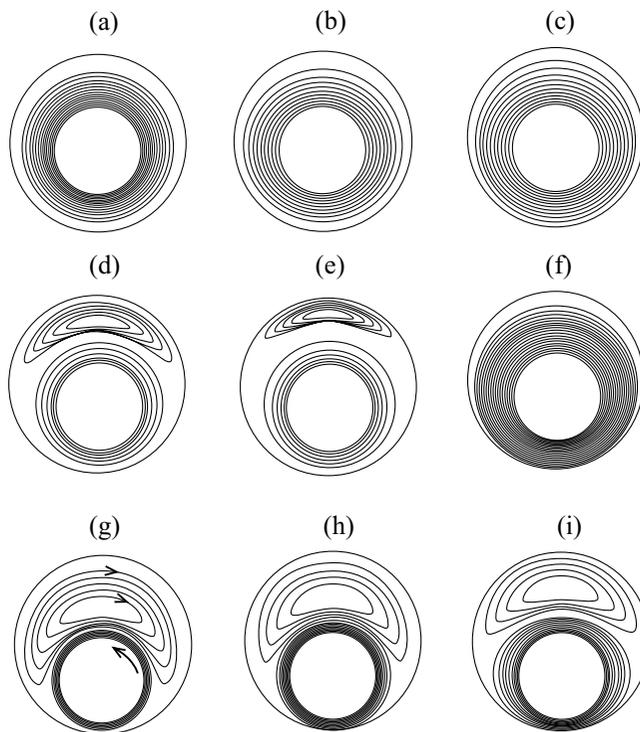

Macroscale journal bearings develop their load-bearing capacity from large pressure differences which are a consequence of the presence of a viscous fluid, an eccentricity between the shaft and its housing, a large surface speed of the shaft and a small clearance-to-diameter ratio. Several closed-form solutions of the no-slip flow in a macrobearing have been developed. Wannier (1950) used modified Cartesian coordinates to find an exact solution to the biharmonic equation governing two-dimensional journal bearings in the no-slip, creeping flow regime. Kamal (1966) and Ashino and Yoshida (1975) worked in bipolar coordinates; they assumed a general form for the stream function with several constants determined using the boundary conditions. Though all these methods work if there is no slip, they cannot be readily adapted to slip flow. The basic reason is that the flow pattern changes if there is slip at the walls and the assumed form of the solution is no longer valid.

Microbearings are different in the following aspects: (1) being so small, they are difficult to manufacture with a clearance much smaller than the diameter of the shaft; (2) because of the small shaft size, its

surface speed, at normal rotational speeds, is also small (the microturbomachines being developed currently at MIT operate at shaft rotational speeds on the order of 1 million rpm and are therefore operating at different flow regime from that considered here); and (3) air bearings in particular may be small enough for noncontinuum effects to become important. For these reasons the hydrodynamics of lubrication is very different at microscales. The lubrication approximation that is normally used is no longer directly applicable and other effects come into play. From an analytical point of view there are three consequences of the above: Fluid inertia is negligible, slip flow may be important for air and other gases, and relative shaft clearance need not be small.

In a recent study, Maureau et al. (1997) analyzed microbearings represented as an eccentric cylinder rotating in a stationary housing. The flow Reynolds number is assumed small, the clearance between shaft and housing is not small relative to the overall bearing dimensions, and there is slip at the walls due to nonequilibrium effects. The two-dimensional governing equations are written in terms of the streamfunction in bipolar coordinates. Following the method of Jeffery (1920), Maureau et al. (1997) succeeded in obtaining an exact infinite-series solution of the Navier–Stokes equations for the specified geometry and flow conditions. In contrast to macrobearings and due to the large clearance, flow in a microbearing is characterized by the possibility of a recirculation zone which strongly affects the velocity and pressure fields. For high values of the eccentricity and low slip factors the flow develops a recirculation region, as shown in the streamlines plot in Figure 26.54.

From the infinite-series solution the frictional torque and the load-bearing capacity can be determined. The results show that both are similarly affected by the eccentricity and the slip factor: They increase with the former and decrease with the latter. For a given load, there is a corresponding eccentricity which generates

**FIGURE 26.54** Effect of slip factor and eccentricity on the microbearing streamlines. From top to bottom, eccentricity changes as  $\epsilon = 0.2, 0.5, 0.8$ . From left to right, slip factor changes as  $S \equiv [(2 - \sigma_v)/\sigma]$ ,  $Kn = 0, 0.1, 0.5$ . (From Maureau, J. et al. (1997) *J. Micromech. Microeng.*, 7, 55–64. With permission.)

a force sufficient to separate the shaft from the housing (i.e., sufficient to prevent solid-to-solid contact). As the load changes, the rotational center of the shaft shifts a distance necessary for the forces to balance.

It is interesting to note that for a weight that is vertically downwards, the equilibrium displacement of the center of the shaft is in the horizontal direction. This can lead to complicated rotor dynamics governed by mechanical inertia, viscous damping and pressure forces. A study of this dynamics may of interest. Real microbearings have finite shaft lengths, and end walls, and other three-dimensional effects influence the bearing characteristics. Numerical simulations of the three-dimensional problem can readily be carried out and may also be of interest to the designers of microbearings. Other potential research includes determination of a criterion for onset of cavitation in liquid bearings. From the results of these studies, information related to load, rotational speed and geometry can be generated that would be useful for the designer.

Finally, Piekos et al. (1997) have used full Navier–Stokes computations to study the stability of ultra-high-speed gas microbearings. They conclude that it is possible, despite significant design constraints, to attain stability for specific bearings to be used with the MIT microturbomachines [Epstein and Senturia, 1997; Epstein et al., 1997], which incidentally operate at much higher Reynolds numbers (and rpm) than the micropumps/microturbines/microbearings considered thus far. According to Piekos et al. (1997), high-speed bearings are more robust than low-speed ones due to their reduced running eccentricities and the large loads required to maintain them.

## 26.7 Concluding Remarks

---

In a presentation to the 1959 annual meeting of the American Physical Society, Richard Feynman anticipated the extension of electronic miniaturization to mechanical devices. That vision is now a reality. Microelectromechanical systems, a fledgling field that took off just this decade, are already finding numerous applications in a variety of industrial and medical fields. This chapter focused on MEMS-based sensors and actuators especially as used for the diagnosis and control of turbulent flows. The miniaturization of sensors leads to improved spatial and temporal resolutions for measuring useful turbulence quantities at high Reynolds numbers. The availability of inexpensive, low-energy-usage microsensors/microactuators that can be packed densely on a single chip promises a quantum leap in the performance of reactive flow control systems. Such control is now in the realm of the possible for future vehicles and other industrial devices. In a turbulent flow, an increase in Reynolds number will automatically generate smaller length scales and shorter time scales, which both in turn require small and fast sensors for correct resolution of the flow field. MEMS offer a solution to this problem, as sensors with length and time scales of the order of the relevant Kolmogorov microscales can now be fabricated. Additionally, these sensors are produced with high accuracy at a relatively low cost per unit. For instance, a MEMS pressure sensor can be used to determine fluctuating pressures beneath a turbulent boundary layer with a spatial resolution that is about one order-of-magnitude finer than what can be achieved with conventional microphones.

In this chapter, we have reviewed the state-of-the-art of microsensors used to measure the instantaneous velocity, wall-shear stress and pressure, which we deem as quantities of primary importance in turbulence diagnosis. For each group, we gave a general background, design criteria and calibration procedure; provided examples of measurements conducted with MEMS-based sensors; and, when possible, compared the results to conventional measurements. Microsensors can be fabricated at low unit costs and can be spaced close together in dense arrays. These traits are particularly useful for studies of coherent structures in wall-bounded turbulent flows.

Reactive flow control is another application for which microdevices may play a crucial future role. MEMS sensors and actuators provide opportunities for targeting the small-scale coherent structures in macroscopic turbulent shear flows. Detecting and modulating these structures may be essential for successful control of wall-bounded turbulent flows to achieve drag reduction, separation delay and lift enhancement. To cover areas of significant spatial extension, many devices are needed that utilize small-scale, low-cost and low-energy-use components. In this context, the miniaturization, low-cost fabrication and low-energy consumption of microsensors and microactuators are of utmost interest and promise a

quantum leap in control system performance. Combined with modern computer technologies, MEMS yield the essential matching of the length and time scales of the phenomena to be controlled.

Numerous actuators have been developed during the past few years. In this chapter, we reviewed the state-of-the-art of microactuators based on the bilayer effect, electrostatic or electromagnetic forces, mechanical folding and one-layer structures. We have also briefly described recently advanced ideas for viscous micropumps and microturbines. Future challenges include achieving significant actuation perpendicular to the plane of what is basically a two-dimensional chip, further reducing unit cost and energy expenditure of microactuators, and designing microdevices that are capable of withstanding the harsh field environment of, for example, an aircraft. These are not easy tasks, but the payoff if, for example, the drag of air, water, or land vehicles could be reduced by a few percentage points, would come as fuel savings in the billions of dollars as well as tremendous benefits to the environment.

Microelectromechanical systems have witnessed phenomenal advances in a mere 10-year period. The 1960s and 1970s were arguably the decades of the transistor, 10 years after its discovery, and it is likely that the first years of the third millennium will be the MEMS decades. Medical and industrial breakthroughs are inevitable with every advance in MEMS technology, and the future worldwide market for micromachines is bound to be in the tens of billions of dollars.

## Acknowledgments

---

The authors would like to acknowledge the valuable help of Dr. Andrey Bakchinov and Mr. Peter Johansson for preparing the figures. Our thanks are extended to Professors Haim Bau, Ali Beskok, Kenneth Breuer, Chih-Ming Ho, Stuart Jacobson and George Karniadakis, who all shared with us several of their reports and papers. Our sincere appreciation to Professor Mihir Sen for sharing his ideas regarding shear-sensor calibration and microturbomachines.

### 27.1 Introduction

---

Surface-micromachining technologies have offered the following advantages to mechanism users and designers: smaller machines, different physical effects that dominate at the microscale, and reduced assembly costs. The advantages of smaller machines are sometimes very important. For example, small machines are important in aviation and space applications where a decrease in size and weight corresponds to an increased range or a reduction in the amount of fuel required for a given mission. The advantages of the different physical effects that dominate at the microscale are less obvious. Mechanisms that operate at high frequencies can greatly benefit (or suffer) from the reduced influence of inertia (typical of surface-micromachined devices) if the aim is to start and stop quickly. Smaller scales also mean surface-micromachined mechanisms are more resistant to shock and vibration than macrosized mechanisms because the component strength decreases as the square of the dimensions while the mass and inertia decrease as the cube of the dimensions. Another difference is that forces, such as van der Waals forces and electrostatic attraction, are much more important at the microscale than at the macroscale. Reduced assembly costs are another advantage of surface-micromachined mechanisms. Surface micromachining in most cases allows the creation of machines that are assembled at the same time as their constituent components. Instead of using skilled workers to assemble intricate mechanisms by hand or investing in complicated machinery, the assembly is done as a batch process during the integrated-circuit-derived fabrication process. Preassembly does impose certain limitations on the designer, such as the inability to build devices with as-fabricated stored mechanical energy. Instead, structures such as

springs must have energy mechanically added to them. Preassembly also requires structures that operate out of the plane of the substrate be erected prior to use.

Perhaps the greatest disadvantage of surface-micromachined mechanisms is the limit on the number and type of layers available to a designer. Usually only one structural material with a restricted number of layers (usually two or three) is available to the designer. The thickness of the layers is restricted by the limited deposition rate of equipment and stress in the thin films. The uninterrupted span of a structure in the plane of the substrate is limited by the speed of the release etch. Having only one structural material also leads to tribology issues. The friction and wear created by like materials rubbing on each other are one of the greatest problems in surface-micromachined mechanisms.

The intent of this chapter is to provide theoretical and practical information to designers of surface-micromachined mechanisms. The design of surface-micromachined mechanisms has much in common with the design of macrosized mechanisms but there are also many differences. For example, the function of four bar linkages is similar for both macro- and macrosized but the joints and connections between the linkages differ at the microscale. Rotating joints are commonly used in macrosized mechanisms, and flexible joints are more common in surface-micromachined mechanisms. The design of surface-micromachined mechanisms requires a good understanding of the fabrication process as well as an appreciation of the unique advantages of designing in the microdomain.

This chapter covers some of the limitations inherent in the design and performance of surface-micromachined mechanisms. It also covers several advantages. Some of the basics of the mechanics of materials, with an emphasis on those concepts important in the design of simple surface-micromachines, are also described. The chapter concludes by describing some failure modes in microelectromechanical systems (MEMS) mechanisms.

## 27.2 Material Properties and Geometric Considerations

---

Loads and forces acting on a body or structure will cause it to undergo a change in shape. Most engineering materials will return to their original shape after the load is removed, providing that the load is not too large. If the body returns to its original shape after the load is removed, it has experienced elastic deformation. If the load exceeds the elastic limit, the body will not completely return to its original shape after the load is removed. If the body retains some permanent change in shape, it has experienced plastic or nonelastic deformation.

Most mechanisms are designed so that the expected loads cause only elastic deformation. In fact, plastic deformation is usually deemed to be mechanism failure. The designer must be able to quantify the threshold between elastic and plastic deformation. The equations typically used in design are based on certain assumptions about the material and its geometric configuration. The theory of elasticity contains expressions for relating deformation and load that do not require simplifying assumptions, but those are usually too mathematically complex for designers to use.

One assumption made in the derivation of simple design equations is that the material is isotropic. An isotropic material is one whose elastic properties are the same in all directions. The designer is cautioned about blindly accepting the assumption of isotropy. Single-crystal silicon [Worthman and Evans, 1965], individual crystals of polysilicon [Madou, 1997] and electroformed materials in the LIGA process [Sharpe et al., 1997] are known to show nonisotropic behavior.

A second common assumption is homogeneity. A homogeneous body is one that has the same properties throughout its entire extent. Actually, no material is homogeneous. Materials consist of an aggregate of very small crystals spread out through the body. When a cross section of the body contains a large number of crystals, the effects of forces and loads are spread out and shared. In this case, the assumption of homogeneity is fulfilled. Again, the designer is cautioned about accepting this assumption. With microfabrication techniques, mechanism dimensions can approach the size scale of the crystals. In those cases, the critical cross section may contain only a few crystals. The effect of the load cannot be averaged and nonhomogeneity occurs. With the cautions described above, the equations to be presented are the best starting point for mechanism designers.

### 27.2.1 Stress and Strain

When a body supports a load, the material is under stress. Stress is a measure of the intensity of the body's reaction to the load. Stress is a field quantity. Like most fields, the solution for stress can be obtained by the use of cutting planes and exposed area. Stress is measured as the force per unit of exposed cross-sectional area. In SI units, stress is measured in Pascals (Newtons per square meter).

In many instances, the distribution of stress across the area is ignored so that only the average stress is considered. This is especially true in the cases of axial loads along slender bodies that cause only lengthening or shortening. The average stress,  $\sigma$ , is equal to the load divided by the cross-sectional area:

$$\sigma = \frac{F}{A} \quad (27.1)$$

Stress that tends to lengthen a body is called *tension*; stress that tends to shorten a body is called *compression*.

The deformation,  $\delta$ , of a body under load is dependent on the size and shape of the body. The amount of deformation normalized by the dimensions of the body is called *strain*,  $\varepsilon$ . Strain is represented mathematically as:

$$\varepsilon = \frac{\delta}{L} \quad (27.2)$$

### 27.2.2 Young's Modulus

In a body undergoing elastic deformation in the normal direction, the ratio of stress to strain is known as the Young's modulus,  $E$ , which is also called the modulus of elasticity:

$$E = \frac{\sigma}{\varepsilon} \quad (27.3)$$

If the body is undergoing shear, the corresponding proportionality constant is  $G$ , the modulus of rigidity or the shear modulus of elasticity. Both of these proportionality constants have units of Pascals (Pa). These material properties describe the stiffness of the material. A compliant material, such as rubber, has a small Young's modulus, 0.5 GPa; a hard material, such as stainless steel (18–8), has a large Young's modulus, 190 GPa; and a single-crystal diamond has a Young's modulus of 1035 GPa.

### 27.2.3 Poisson's Ratio

Poisson's ratio,  $\nu$ , describes the ratio of the transverse strain to the axial strain when a body is subjected to an axial load:

$$\nu = -\frac{\varepsilon_{\text{transverse}}}{\varepsilon_{\text{axial}}} \quad (27.4)$$

This can be visualized by thinking about pieces of rubber. If a rubber band is stretched (a positive axial strain), then the rubber band becomes narrower, which is a negative transverse strain. Conversely, if a pencil eraser is compressed, then it becomes wider. In most cases,  $\nu$  has a value between 0.2 and 0.5. A value of 0.5 corresponds to a conservation of volume.

In situations where the shear modulus is not known, it can be estimated using  $E$  and  $\nu$  in the following relationship:

$$E = 2G(1 + \nu) \quad (27.5)$$

if the materials are assumed to be isotropic.

## 27.2.4 Contact Stresses

When two bodies are pressed together, the point or line of contact expands to area contact. As the surfaces move together, their progress is interrupted when an asperity from one body contacts an asperity from the other body. These asperities attempt to carry the entire contact force, but quickly yield and plastically deform. This allows the bodies to move closer together until more asperities touch. This process of contact and yield continues until there is enough total contact area to support the force at the yield strength of the material. These regions of contact, called *a-spots*, typically form a circular pattern known as the Hertzian stress circle.

If the contacting surfaces have a radius of curvature, the radius of the resulting Hertzian stress circle can be calculated using the equation originally developed by Hertz:

$$a = \sqrt[3]{\frac{3F}{4} \times \frac{(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2}{(1/r_1 + 1/r_2)}} \quad (27.6)$$

where  $F$  is the force of contact,  $\nu$  is Poisson's ratio,  $E$  is Young's modulus and  $r$  is the radii of curvature for the two contacting surfaces [Johnson, 1985]. For the case of a curved surface contacting a plane, the radius of curvature of the plane is equal to infinity. It is a good design practice to ensure that the apparent contact area (determined by the nominal dimensions) is larger than the Hertzian contact area. A more detailed description can be found in Roark and Young (1989).

## 27.2.5 Stress in Films and Stress Gradients

One of the important nonidealities in designing surface-micromachined mechanisms is stress in the thin films. Stress has different sources and different effects depending on the application and the geometries involved. One of the sources of stress in thin films is the difference in the thermal expansion coefficients between the film and the substrate, especially if the film was deposited at an elevated temperature. Other sources include the doping of semiconductor films if the dopant atoms are a different size than the host atoms and the method of film deposition. An example of stress in thin films is thermally grown silicon dioxide ( $\text{SiO}_2$ ) that is in compression because the silicon dioxide molecules are larger than the lattice spacing of the host silicon atoms.

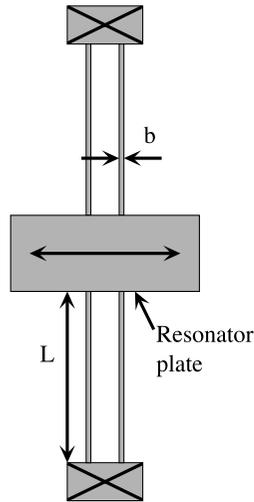

There are also many effects of stresses in thin films. Excessive stress can result in cracking or delamination of thin films. Stress in films can also be relieved as strain or deformed microstructures. For example, a compressive stress will buckle a clamped-clamped beam if the stress is above a certain level. This will be discussed later in the section on buckling. Another effect of stress is that it will change the frequency of resonant devices. For a lateral resonator with four cantilever beam springs, Madou (1997) discusses the effect of residual stress on resonant frequency. A drawing of the device is shown in [Figure 27.1](#) and its resonant frequency is given by:

$$f_0 \approx \frac{1}{2\pi} \sqrt{\frac{4Et b^3}{mL^3} + \frac{24\sigma_r t b}{5mL}} \quad (27.7)$$

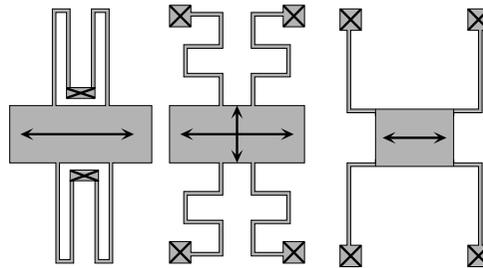

where  $m$  is the mass of the resonator plate,  $E$  is the Young's modulus,  $t$  is the flexure thickness,  $L$  is the flexure length,  $b$  is the width and  $\sigma_r$  is the residual stress in the flexures. The assumption in this equation is that the mass of the springs is negligible compared to the mass of the resonator plate.

### Example

Find the resonant frequency of the device in [Figure 27.1](#). Then recalculate the resonant frequency assuming that the residual stress increases by 30%. Assume the device is constructed of polycrystalline silicon with a Young's modulus of 155 GPa and a density of  $2.33 \times 10^3 \text{ kg/m}^3$ . The support beams are

**FIGURE 27.1** Lateral resonator. The “X” at each end of the device depicts an anchor and the mass is at the center with an arrow depicting the direction of motion.

**FIGURE 27.2** Three flexure designs. From left to right they are folded flexures, meandering flexures and crab-leg flexures.

2.25  $\mu\text{m}$  thick, 2  $\mu\text{m}$  wide and 200  $\mu\text{m}$  long. The shuttle is 2.25  $\mu\text{m}$  thick, 120  $\mu\text{m}$  wide and 250  $\mu\text{m}$  long. The residual stress is 50 MPa.

The first step is to calculate the mass of the shuttle:

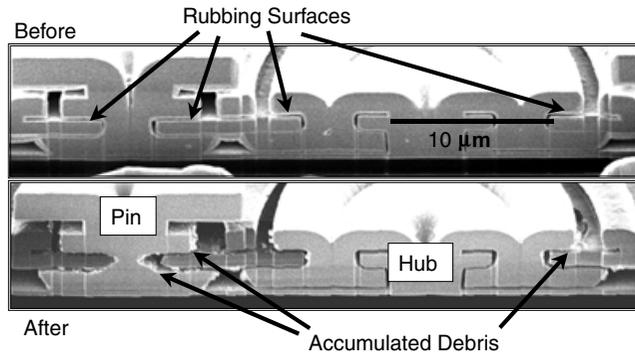

$$\text{mass} = (2.25 \times 10^{-6} \text{m})(1.2 \times 10^{-4} \text{m})(2.5 \times 10^{-4} \text{m}) \times 2.33 \times 10^3 \text{ kg/m}^3 = 160 \times 10^{-12} \text{ kg}$$

The resonant frequency is equal to:

$$f_0 = \frac{1}{2\pi\sqrt{\frac{4 \times 155 \text{ GPa} \times 2.25 \mu\text{m} \times (2 \mu\text{m})^3}{160 \times 10^{-12} \text{ kg} \times (200 \mu\text{m})^3} + \frac{24 \times 50 \text{ MPa} \times 2.25 \mu\text{m} \times 2 \mu\text{m}}{5 \times 160 \times 10^{-12} \text{ kg} \times 200 \mu\text{m}}}} = 33 \text{ KHz}$$

If the residual stress increases by 30% (not a huge change even for a production facility), then the resonant frequency shifts to 37 kHz. Notice that designers need to design their machines to be resistant to changes in the fabrication process.

One method of relieving stresses in thin-film mechanical elements is the use of folded flexures. Folded flexures relieve axial stress because each flexure is free to expand or contract in the axial direction. This eliminates most of the stress caused by the fabrication process and by thermal expansion mismatches between the flexures and the substrate. Crab-leg flexures and meandering flexures also relieve some of the residual stress. All three flexure types are shown in [Figure 27.2](#).

**FIGURE 27.3** A pin joint and hub joint before and after accelerated wear. (Courtesy of D. Tanner, Sandia National Laboratories.)

Another nonideality of MEMS is stress gradients in the films. Stress gradients are variations in the stress of the film through the thickness of the film and cause cantilevers to either curl away from or toward the substrate. This can be partially compensated for by folding the flexures. Stress gradients will also warp thin plates or gears into dome shapes and cause spiral-shaped cantilever beams to deform [Fan et al., 1990].

### 27.2.6 Wear

One of the limitations of many types of mechanisms, including surface-micromachined mechanisms, is wear. This is not surprising as surface-micromachined mechanisms can have touching, rubbing or impacting surfaces and both surfaces are typically constructed of the same material. This is different than conventional machines, which commonly use dissimilar materials to reduce wear. Also, surface-micromachines typically run without liquid lubrication. A great deal of research into the wear of polysilicon surface micromachines has been done by Tanner (2000) and Dugger et al. (1999). They report that the wear of polysilicon surface micromachines has similarities to the wear of macroscopic mechanisms. Friction and wear have been correlated with the normal forces on a surface akin to the coefficient of friction concept. The greater the force, the higher the wear rate. Also, the wear rate was found to increase at operating frequencies above the resonant frequency. It has been theorized that wear is caused by adhesion and stick-slip behavior between two moving surfaces. The accumulation of wear debris that results in three-body wear (the two surfaces and the wear debris) has also been observed in surface-micromachined mechanisms. [Figure 27.3](#) shows the effects of extreme, accelerated wear on a surface-micromachined pin joint and a hub. Another source of information on the tribology of surface-micromachined devices is Chapter 16 of the *Handbook of Micro/Nano Tribology*, 2nd ed., by Bhushan (1999).

### 27.2.7 Stiction

Potentially, one of the most destructive influences on the performance of MEMS mechanisms is stiction, which is the unintended adhesion of surface-micromachined parts to each other or to the substrate. It is a combination of various effects (including capillary forces, van der Waals forces, electrostatic attraction and hydrogen bonding) that conspire to pull flat, compliant MEMS structures together and to keep them stuck together. Contributing factors to stiction include very flat (nanometer-scale roughness) surfaces, large surface areas, compliant structures, electrostatic attraction, humidity and hydrophilic surfaces. There are two major categories of stiction: stiction due to the release process and in-use stiction. The main cause of stiction in the release process is capillary forces of the liquids in the release process that attempt to pull the parts together. Release-stiction can be countered with various hydrophobic coatings or sublimation drying processes. The mechanism designer can combat release-stiction by designing

structures that are stiff in the out-of-plane direction. This is very important because it increases the amount of force that must be expended to pull the structure down to the substrate. Another way the mechanism designer can help the release process is by reducing the surface area of the parts—for example, by using a spoked gear instead of a solid gear. Another way of reducing the surface area is to use dimples, which are minimum feature-sized protrusions on the bottom of a surface-micromachined part. Dimples greatly reduce the surface area in contact with the substrate and also increase the out-of-plane stiffness.

The prevalence of in-use stiction can be reduced by many of the same ways as release stiction. Hydrophobic coatings, reduced surface area, dimples and increasing the stiffness of the parts all help to reduce stiction. These are very important tools to reduce stiction and should be utilized even if the release process is relatively robust. A cause of stiction not found in the release process is electrostatic attraction. This usually involves insulating materials, such as silicon nitride, that can trap a charge. The trapped charge causes an electrostatic force whose magnitude can shift in an unpredictable manner. The best method of avoiding this problem is to use a conductive ground plane to cover any exposed insulating layers and to connect every object to the ground. If this is not possible (for instance, with a rotating gear), the hub at a minimum should be tied to the ground. Packaging is another area where the mechanism designer can combat stiction. A high-humidity environment increases the adhesive energy between parts. If water vapor in the package condenses on the surface micromachine, the water will cause capillary adhesive forces similar to those found in the release process. Therefore, a package with a dewpoint well below the minimum storage or operating temperature of the mechanism is essential.

## 27.3 Machine Design

---

The fundamental difference between structures and machines is that machines have intended degrees of freedom—usually one. Micromachines can be further divided into two classes by the element used to provide the motion. Elastic-mode machines use compliance elements, such as springs and flexures, to allow motion. Rigid-body-mode (or gross-motion) machines permit motion through joints and bearings. Gross-motion machines allow parts to accumulate motion. As an example of gross motion, a gear spinning on a hub accumulates angular displacement. Elastic-mode machines force the machine parts to oscillate about a fixed point or axis.

### 27.3.1 Compliance Elements—Columns, Beams and Flexures

Compliance elements or springs allow machine parts to move. Springs come in many forms, but they are primarily realized in microsystems as beams or flexures. Elastic-mode machines are usually focused on resonating devices. In some cases, the spring element also serves as the resonating mass. In those cases, the spring must be evaluated using the beam equations from continuum mechanics. If the spring supports another element whose mass is significantly larger, then the spring can be treated as a lumped element described by a parameter called the *spring constant* or *spring rate*. The spring rate is the ratio of applied force to deflection:

$$k = \frac{F}{\delta} \quad (27.8)$$

where  $k$  is the spring constant,  $F$  is the applied force and  $\delta$  is the resulting deflection.

### 27.3.2 Columns

A column is a structural member that supports pure tension or compression. Columns are loaded along their longitudinal axis and are generally stiff in comparison to beams and flexures. Columns are not frequently used by themselves but more often as part of more complex structures and, consequently, are important to understand. If loaded in compression beyond a critical value, columns fail by buckling.

**FIGURE 27.4** Illustration showing the elongation of a column.  $L$  is the original length of the column, and  $\delta$  is the change in the length of the column.

Buckling is a large lateral deformation caused by an axial load. Columns that buckle but do not yield can provide a mechanism for out-of-plane movement [Garcia, 1998]. The force  $P$  on a column creates an elongation  $\delta$ , shown in Figure 27.4, and whose relationship is derived from Eqs. (27.1) to (27.3):

$$\frac{P}{A} = E \frac{\delta}{L} \quad (27.9)$$

where  $E$  is Young’s modulus,  $A$  is the cross-sectional area and  $L$  is the length of the column. The resulting spring rate for columns is

$$k = \frac{EA}{L} \quad (27.10)$$

### 27.3.3 Beams

Beams are structural members characterized by their ability to support bending and they can provide structures with a linear degree of freedom. Moments and transverse loads applied to beams deform them into curves, as opposed to axial loads that only make them longer or shorter. As the loaded beam takes on a curved shape, one side of the beam must grow longer while the opposite side grows shorter. The outside surface of the beam is in tension and the inside surface of the beam is in compression. A plane through the geometric center of the beam, called the *neutral axis*, does not change in length at all and is unstressed as a result of bending.

For simple cases, the maximum stress in a beam occurs at the surface and is independent of the material composing the beam. The magnitude of the stress of a beam bent into a curved shape by either a moment or a transverse load is

$$\sigma = \frac{Mc}{I} \quad (27.11)$$

where  $M$  is the moment causing the curvature,  $c$  is the distance from the neutral axis to the surface of the beam (usually half the thickness) and  $I$  is the area moment of inertia of the beam’s cross section.

Moment of inertia is a measure of the dispersion of area about the centroid. For those familiar with statistics, the centroid is directly analogous to the mean, and the moment of inertia is directly analogous to the standard deviation. In fact, moment of inertia is calculated similarly to standard deviation for a continuous distribution. There are different types of moment of inertia. What is commonly called “moment of inertia” is calculated when the axis of rotation is in the same plane as the cross section. The “polar moment of inertia” is calculated for cases when the axis of rotation is normal to the cross section. Expressions for moment of inertia for common geometric shapes can be found in most mathematics and mechanical engineering handbooks, as well as mechanics of materials textbooks. The moments of inertia for the two common shapes encountered in surface-micromachined mechanisms are illustrated in Figure 27.5. The lines through the cross sections in Figure 27.5 show the axis of rotation for the curving beam. The moment of inertia for a rectangular beam with a rotation about the  $y$ -axis

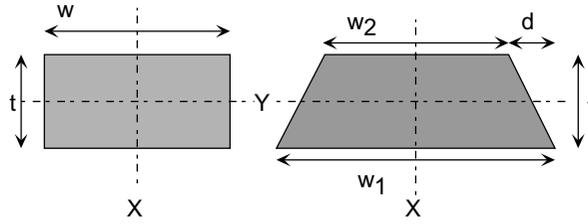

FIGURE 27.5 Moments of inertia for two common beam shapes.

of rotation is

$$I = \frac{wt^3}{12} \quad (27.12)$$

and for rotation about the  $x$ -axis:

$$I = \frac{tw^3}{12} \quad (27.13)$$

where  $w$  and  $t$  are the two dimension shown in Figure 27.5. For a trapezoidal beam about the  $y$ -axis the moment of inertia is

$$I = \frac{t^3(w_1^2 + 4w_1w_2 + w_2^2)}{36(w_1 + w_2)} \quad (27.14)$$

and the moment of inertia about the  $x$ -axis is

$$I = \frac{t}{36(w_1 + w_2)} [w_1^4 + w_2^4 + 2w_1w_2(w_2^2 + w_1^2) - d(w_1^3 + 3w_1^2w_2 - 3w_1w_2^2 - w_2^3) + d^2(w_1^2 + 4w_1w_2 + w_2^2)] \quad (27.15)$$

where the dimensions  $w_1$ ,  $w_2$ ,  $d$  and  $t$  are shown in Figure 27.5.

### Example

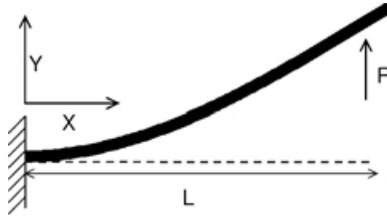

At a given cross section in a beam, the moment acting on it is 2 nN-m. The beam is rectangular with a thickness of 2  $\mu\text{m}$  and a width of 30  $\mu\text{m}$ . What is the maximum stress in the beam?

The stress caused by bending in the beam is  $\sigma = Mc/I$ , where  $c$  is the distance from the neutral axis to the surface of interest. Because we want the maximum stress,  $c$  is half the thickness. The moment of inertia must be calculated from the expression for rectangular cross sections:

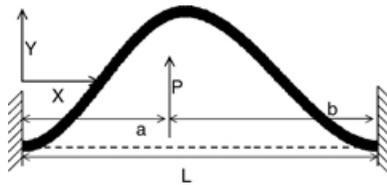

$$I = \frac{30 \mu\text{m} \times (2 \mu\text{m})^3}{12} = 2 \times 10^{-23} \text{m}^4$$

The resulting maximum stress at the cross section is

$$\sigma = \frac{2 \text{ nN-m} \times 1 \mu\text{m}}{2 \times 10^{-23} \text{m}^4} = 10^8 \text{N/m}^2 = 100 \text{ MPa}$$

**FIGURE 27.6** Cantilever beam spring. The deformation of the beam is due to the load  $P$  and can be calculated using Eqs. (27.19) and (27.20).

**FIGURE 27.7** Deflection of a fixed-beam spring due to a point load. The applied load is  $P$ , the load's location is shown by  $a$  and  $b$  on the  $x$ -axis, and the spring deflects in the direction of the  $y$ -axis.

Note that in this example it was not necessary to know the length of the beam or the location of the applied loads.

Beams can be categorized by their supports. A beam held rigid on one end and free to move on the other is called a *cantilever beam*. A beam held rigid at both ends is called a *fixed beam*. In general, cantilever beams have more flexibility than fixed beams, so cantilevers will have lower natural frequencies and larger deflections. A diving board at a swimming pool is a classic cantilever beam. A shelf on a bookcase (if only the ends of the shelf are attached to the bookcase) is an example of a fixed beam. Drawings of a cantilever beam spring and a fixed beam spring are shown in Figures 27.6 and 27.7, respectively.

The equations for deflection of cantilever beams and fixed beams are relatively straightforward and can be applied accurately in most cases. In situations of complex geometry or intricate loading or if more precision is required, alternate methods, such as finite element analysis, should be employed.

### 27.3.4 Stress Concentration

Stress equations are developed for homogeneous bodies with mathematically simple geometries. In real devices, the geometry is usually complex and this can lead to regions of highly localized stresses not predicted by the simple equations. Stress concentrations are significant for ductile materials only when the loads are repeated. For the case of static loading, stress concentration is important only for materials that are both brittle and relatively homogeneous. These amplifications of stress must be accounted for in design.

Stress concentration is an empirical contrivance for design engineers. Stress concentration factors better predict the stress than the nominal stress equations. More importantly, information about stress concentration can be used as design guidance to avoid performance complications or failures. Because changes in geometry can occur in an infinite variety of ways, it is not possible to find an empirical stress concentration that applies for every case. Thus, engineering judgement with considerable estimation is essential.

As a general rule, practical approaches to accommodate micromachine fabrication are adverse for managing stress. Etch release holes serve as stress concentrations in plates. Sharp corners in Manhattan (right-angle) geometries also create stress concentrations. The stress concentration factor is used to adjust the stress calculated from the standard equations, such as Eqs. (27.1) and (27.11), which were discussed

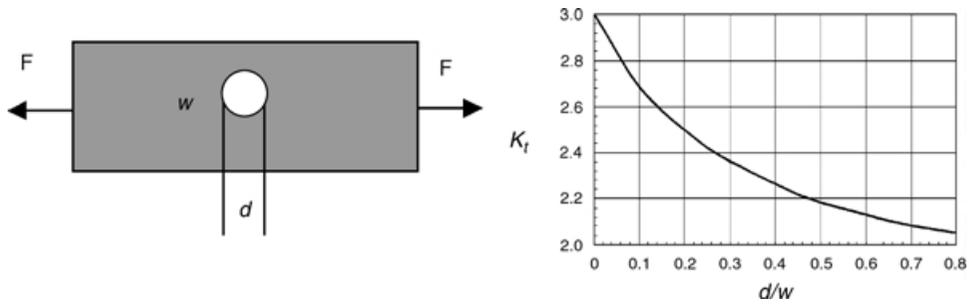

FIGURE 27.8 Stress concentrations for a flat plate loaded axially with a circular hole.

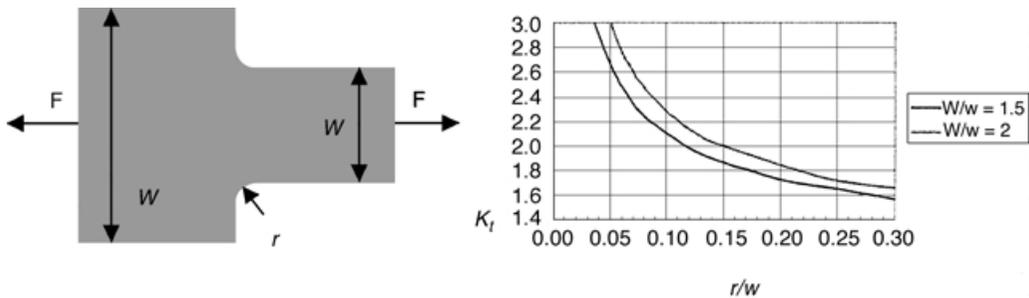

FIGURE 27.9 Stress concentrations for a flat plate loaded axially with two different widths and fillet radius  $r$ .

earlier, where  $K_t$  is the stress concentration factor:

$$\sigma_{CONCENTRATION} = K_t \sigma_{NOMINAL} \quad (27.16)$$

For flat plates loaded axially with a circular hole in them, the nominal stress is given by:

$$\sigma_{NOM} = \frac{F}{t(w-d)} \quad (27.17)$$

where  $w$  is the width of the plate and  $d$  is the diameter of the hole. The stress concentration  $K_t$  is shown in Figure 27.8 along with a drawing of the geometry. For square etch release holes, refer to Figure 27.8 and Eq. (27.17), with the length of the sides of the square opening being equal to the diameter of the circle.

For flat plates with two different widths the nominal stress is given by Eq. (27.18). A drawing of the geometry and a graph of the stress concentration factor are shown in Figure 27.9. Note that the stress concentration factor depends on the radius of the fillet that is denoted as  $r$ . For surface-micromachines designed with a Manhattan geometry,  $r$  is nominally zero but the fabrication process will create small non-zero radii in the corners. The process engineer should be able to provide a reasonable estimate for  $r$ .

$$\sigma_{NOM} = \frac{F}{wt} \quad (27.18)$$

### 27.3.5 Cantilever Beam Springs

The deformation  $y$  at any arbitrary point  $x$  along a cantilever beam, illustrated in Figure 27.6, can be calculated by:

$$y = \frac{P}{6EI}(3Lx^2 - x^3) \quad (27.19)$$

where  $L$  is the length of the beam,  $E$  is Young's modulus of the beam material and  $P$  is the applied load. The maximum deflection occurs at the end of the beam and can be calculated by:

$$y_{MAX} = \frac{PL^3}{3EI} \quad (27.20)$$

The maximum bending stress in a cantilever beam occurs at the attachment or fixed end where the internal moment is  $PL$ . For a rectangular cross section of thickness  $t$  and width  $w$ , the maximum stress can be calculated with Eq. (27.11) to be

$$\sigma_{MAX} = \frac{6PL}{bh^2} \quad (27.21)$$

The fundamental resonant frequency in Hertz of a simple cantilever beam is

$$f_1 = \frac{3.52}{2\pi} \sqrt{\frac{EI}{\rho AL^4}} \quad (27.22)$$

where  $E$  is Young's modulus,  $A$  is the cross-sectional area and  $\rho$  is the density (mass per unit volume).

### Example

A cantilever beam fabricated in polycrystalline silicon with a rectangular cross section is pulled down to an electrode on a substrate by electrostatic attraction. The beam is  $50 \mu\text{m}$  wide,  $6 \mu\text{m}$  thick and  $200 \mu\text{m}$  long. The gap between the bottom of the beam and the electrode is  $2 \mu\text{m}$ . What is the required electrostatic force? If the beam were suddenly released, at what frequency would it vibrate?

The equation for cantilever beam deflection can be solved for force:

$$P = \frac{3EIy}{L^3} \quad (27.23)$$

A reasonable value for the Young's modulus for polycrystalline silicon is  $155 \text{ GPa}$  or  $0.155 \text{ N}/\mu\text{m}^2$ . The area moment of inertia for a rectangular cross section is  $I = wt^3/12 = (50 \mu\text{m})(6 \mu\text{m})^3/12 = 900 \mu\text{m}^4$ . So,

$$P = \frac{3(0.155 \text{ N}/\mu\text{m}^2)(900 \mu\text{m}^4)(2 \mu\text{m})}{(200 \mu\text{m})^3} = 105 \mu\text{N}$$

A reasonable value for the density of solid polycrystalline silicon is  $2.33 \times 10^{-15} \text{ kg}/\mu\text{m}^3$ . The cross-sectional area of the beam is  $A = wt = (50 \mu\text{m})(6 \mu\text{m}) = 300 \mu\text{m}^2$ :

$$f = \frac{3.52}{2\pi} \sqrt{\frac{(0.155 \text{ N}/\mu\text{m}^2)(900 \mu\text{m}^4)(10^6 \mu\text{m}/\text{m})}{[2.33(10^{-15}) \text{ kg}/\mu\text{m}^3](50 \mu\text{m} \times 6 \mu\text{m})(200 \mu\text{m})^4}} = 198 \text{ kHz}$$

## 27.3.6 Fixed Beam Springs

The deflection at any point  $0 < x < a$  along a fixed beam, shown in [Figure 27.7](#), can be calculated using the following equation:

$$y = \frac{Pb^2x^2[3aL - (3a + b)x]}{6L^3EI} \quad (27.24)$$

The equation above is based on a point-applied load somewhere along the length of the beam. The deflection caused by a distributed load is somewhat different. Deflection can be estimated by assuming the entire load is applied at the center with some error. An exact solution can be found in texts on mechanics of materials such as Timoshenko (1958).

The fundamental frequency for a fixed beam is

$$f_1 = \frac{22.4}{2\pi} \sqrt{\frac{EI}{\rho AL^4}} \quad (27.25)$$

The form of this equation is similar Eq. (27.22) for cantilever beams. Note that fixing the other end of the beam increases the fundamental frequency by more than a factor of six.

### Example

Assuming the same parameters as the cantilever beam example, except that it is fixed on both ends, calculate the force applied at the center necessary to pull it down to the substrate and the resulting frequency of vibration when released.

For this case,  $x = a = b = L/2$ , so the equation for deflection reduces to:

$$y_{MAX} = \frac{PL^3}{192EI} \quad (27.26)$$

and solving for load:

$$P = \frac{192EIy}{L^3} = \frac{192(0.155 \text{ N}/\mu\text{m}^2)(900 \mu\text{m}^4)(2 \mu\text{m})}{(200 \mu\text{m})^3} = 6700 \mu\text{N}$$

$$f = \frac{22.4}{2\pi} \sqrt{\frac{(0.155 \text{ N}/\mu\text{m}^2)(900 \mu\text{m}^4)(10^6 \mu\text{m}/\text{m})}{[2.33(10^{-15}) \text{ kg}/\mu\text{m}^3](6 \mu\text{m} \times 50 \mu\text{m})(200 \mu\text{m})^4}} = 1.26 \text{ MHz}$$

### 27.3.7 Flexures

Flexures are typically used when a rotational degree of freedom is desired. As opposed to beams where the applied moments cause curvature, torque applied to flexures causes twisting. The ends of the flexure will rotate relative to one another through some angle  $\theta$ . The resultant twisting creates shear stress in the element. Strictly speaking, the only cross section for which the simple torsion equation applies is circular. Circular cross sections do not appear frequently in micromachine design; rather, rectangular cross sections are the norm. The simple equation can be adapted for use with little problem.

The shear stress in a circular bar arising from an applied torque is

$$\tau = \frac{Tc}{J} \quad (27.27)$$

where  $\tau$  is the shear stress,  $T$  is the applied torque,  $c$  is the distance from the central axis to the point where the stress is desired and  $J$  is the polar area moment of inertia.

The equation above must be modified to account for rectangular cross sections violating a basic assumption used in deriving the equation above. More precise analysis suggests the following equation:

$$\tau = \frac{9T}{2wt^2} \quad (27.28)$$

where  $w$  is the width (larger dimension) of the flexure and  $t$  is the thickness (smaller dimension). The deflection created by the applied torque is

$$\theta = \frac{TL}{JG} \quad (27.29)$$

where  $L$  is the length of the flexure,  $G$  is the shear modulus and  $J$  is the polar moment of inertia. The polar moment of inertia is defined as:

$$J = I_x + I_y \quad (27.30)$$

### Example

A 150- $\mu\text{m}$  square plate made of polysilicon is supported by 6- $\mu\text{m}$ -wide torsional flexures forming an axis of rotation through the plate's midpoint. The plate is 4  $\mu\text{m}$  thick and the flexures are 20  $\mu\text{m}$  long. If one edge is pulled down to the substrate 3  $\mu\text{m}$  from the bottom of the plate, what is the resulting shear stress in the flexure? When the force is released, at what frequency will the system vibrate?

Assuming that the plate does not significantly deform, the flexures are required to rotate through an angle of  $2.3^\circ$  for the plate to touch the substrate. This angle can be estimated by:

$$\theta = \tan^{-1}\left(\frac{3\mu\text{m}}{(150\mu\text{m}/2)}\right) = 2.3^\circ = 0.040 \text{ rad} \quad (27.31)$$

*The reader is challenged to understand why the arctan approach is an approximation instead of an exact expression.*

A reasonable value for the modulus of rigidity is  $0.0772 \text{ N}/\mu\text{m}^2$ . The polar area moment of inertia for a rectangular section is

$$J = \frac{wt}{12}(w^2 + t^2) = \frac{(6\mu\text{m})(4\mu\text{m})}{12}[(6\mu\text{m})^2 + (4\mu\text{m})^2] = 104\mu\text{m}^4 \quad (27.32)$$

The torque required to rotate one flexure through the angle  $\theta$  is

$$T = \frac{JG\theta}{L} = \frac{(104\mu\text{m}^4)(0.0772 \text{ N}/\mu\text{m}^2)(0.04 \text{ rad})}{20\mu\text{m}} = 1.6 \times 10^{-2} \mu\text{Nm} \quad (27.33)$$

This is the torque per flexure. The total torque on the plate is twice that value because there are two flexures. If it could be applied at the edge, the value of the force needed to create this much rotation is

$$F = 2\frac{T}{r} = 2 \times \frac{1.6 \times 10^{-2} \mu\text{N}\cdot\text{m}}{(150\mu\text{m}/2)} = 4.3 \times 10^{-4} \text{ N} \quad (27.34)$$

The resulting shear stress in each flexure is

$$\tau = \frac{9T}{2wt^2} = \frac{9 \times 1.6 \times 10^{-2} \text{ N} \cdot \mu\text{m}}{2(6\mu\text{m})(4\mu\text{m})^2} = 7.5 \times 10^{-4} \text{ N}/\mu\text{m}^2 = 0.75 \text{ GPa} \quad (27.35)$$

In a dynamics context, the system can be modeled as a rigid body vibrating about a spring. The differential equation of motion for a simple mass–spring system and the associated natural frequency are

$$i\ddot{\phi} + K\phi = 0 \quad (27.36)$$

$$f_n = \frac{1}{2\pi} \sqrt{\frac{K}{i}} \quad (27.37)$$

where  $i$  is the mass moment of inertia (different than area moment of inertia used to calculate stress) and  $K$  is the torsional spring rate. The spring rate of the flexures is

$$K = \frac{T}{\theta} = \frac{JG}{L} = \frac{(104 \mu\text{m}^4)(0.0772 \text{ N}/\mu\text{m}^2)}{20 \mu\text{m}} = 0.40 \mu\text{Nm}/\text{rad}$$

The mass of the plate is

$$m = \rho wlt = [2.33 \times 10^{-18} \text{ kg}/\mu\text{m}^3](150 \mu\text{m})^2(4 \mu\text{m}) = 2.1 \times 10^{-13} \text{ kg}$$

The mass moment of inertia for a thin rectangular plate vibrating about its center is

$$i = \frac{1}{12}mw^2 = \frac{[2.1 \times 10^{-13} \text{ kg}](150 \mu\text{m})^2}{12} = 3.93 \times 10^{-10} \text{ kg} \cdot \mu\text{m}^2 \quad (27.38)$$

The natural frequency is

$$f_n = \frac{1}{2\pi} \sqrt{\frac{(0.40 \text{ N} \cdot \mu\text{m})(10^6) \mu\text{m}/\text{m}}{3.93 \times 10^{-10} \text{ kg} \cdot \mu\text{m}^2}} = 5.1 \text{ MHz}$$

### 27.3.8 Springs in Combinations

Springs are energy storage elements analogous to electrical capacitors, and the laws for calculating equivalent spring rates are the same as the laws for calculating equivalent capacitance. Springs are in parallel if they undergo the same deflection; springs are in series if they support the same loading. The equivalent spring rate for springs in parallel is

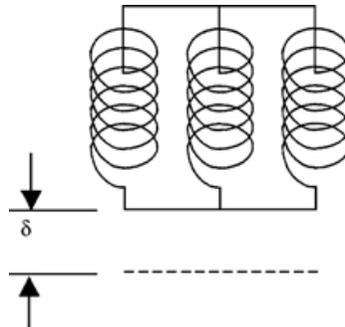

$$k_{eq} = k_1 + k_2 + k_3 + \dots \quad (27.39)$$

where springs in parallel experience the same deflection  $\delta$ .

The equivalent spring rate for spring in series is

$$\frac{1}{k_{eq}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \dots \quad (27.40)$$

where springs in series can be identified because each spring experiences the same force. Springs in parallel and series are shown in [Figures 27.10](#) and [27.11](#), respectively.

**FIGURE 27.10** Springs in parallel.

FIGURE 27.11 Springs in series.

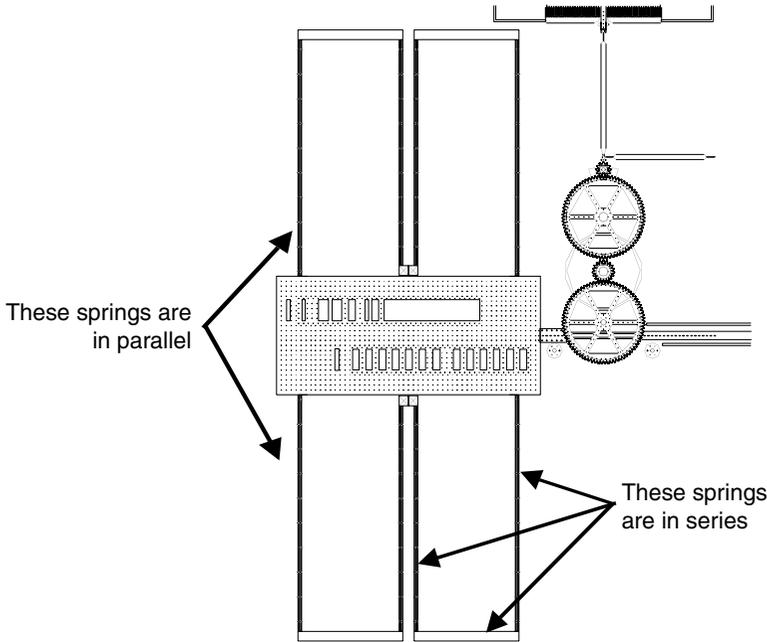

FIGURE 27.12 Surface-micromachined oscillating mechanism supported by springs in series and parallel. (The original drawing was courtesy of G. Vernon and M. Polosky at Sandia National Laboratories.)

To tailor the performance or to conserve real estate, it is sometimes desirable to use springs in combinations. Figure 27.12 shows an oscillating structure supported by a complex suspension system. The suspension is comprised of a parallel combination of four spring systems and each spring system is a series combination of three individual beam and column elements. In the case shown in Figure 27.12, the U-shaped springs are all attached to the substrate and to the resonator shuttle. When the shuttle moves, each of the four U-shaped springs deflects the same amount—the motion of the shuttle. There are four different paths from the shuttle to the ground, which is another indication that the springs are in parallel.

Closer inspection of a single U-shaped spring reveals three beams in series. Because the beams form a single path between the shuttle and ground, they must carry the same load. A free-body diagram shows that the load from one beam is transmitted fully to the next until the load is transmitted to ground.

**Example**

Calculate the equivalent spring of the U-shaped spring shown in Figure 27.13.

The spring system consists of three springs in series: two cantilever beam springs connected by one column. It is reasonable to treat spring 2 simply as a column even though it supports reaction moments from springs 1 and 3 because none of the resulting bend in spring 2 contributes to the motion of the shuttle. The springs are clearly in series, as the load from one spring is transmitted fully to the next and each spring is allowed to deflect whatever amount is required to support the load.

For springs in series, the equivalent spring rate is given by:

$$\frac{1}{k_{eq}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} \tag{27.40}$$

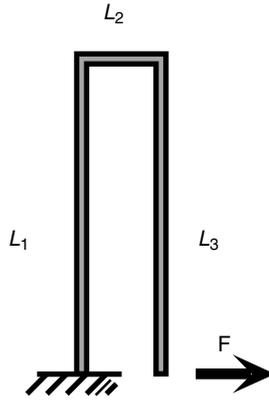

FIGURE 27.13 U-shaped spring comprised of three beam springs connected in series and parallel.

For MEMS, it is reasonable to assume that all the springs are fabricated of the same material. Springs 1 and 3 are cantilever beams and their rates, respectively, are  $k_1 = \frac{3EI_1}{L_1^3}$  and  $k_3 = \frac{3EI_3}{L_3^3}$ . The rate for the column, spring 2, is

$$k_2 = \frac{EA_2}{L_2} \tag{27.41}$$

The equivalent rate for the three-spring combination is

$$\frac{1}{k_{eq}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} = \frac{L_1^3}{3EI_1} + \frac{L_2}{EA_2} + \frac{L_3^3}{3EI_3} \tag{27.42}$$

### 27.3.9 Buckling

When a short column is loaded in compression, the average compressive stress is calculated by simply dividing the load by the cross-sectional area as in Eq. (27.1). However, when the column is long and slender, the situation is complicated by the possibility of static instability, also known as *lateral buckling*.

Buckling occurs in columns loaded in compression beyond their critical value. When loaded below the buckling threshold, a column under a compressive load will get shorter while remaining essentially straight. After the buckling threshold is exceeded, the column deflects normally to the axis of the column, and the stress increases rapidly. In addition to the direct compression, the beam experiences bending stress created by the couple between the offset beam and the line of action of the force. Recall that bending creates compressive stress on the inside surface of the beam. The direct and bending compressive stresses add to and cause failure by rupture.

The phenomenon of buckling is much different from the phenomenon of bending. A beam will begin to bend as soon as any moment (bending load) is present. A column will not exhibit any lateral deflection until the critical or buckling load is reached. Additional loading above the critical load causes large increases in lateral deflection. Because of the tensile properties of polysilicon, it is possible to design a column to buckle without exceeding the yield strength. If yield does not occur, the column will return to its original straight position after the load is removed. If designed appropriately, a buckling column can be used as an out-of-plane flexure.

Buckling is a complex nonlinear problem and predicting the resulting shape is beyond the scope of this text. It is, however, covered in several references including Timoshenko and Gere (1961), Brush and Almroth (1975), Hutchinson and Koiter (1970) and Fang and Wickert (1994). But, the equation for predicting the onset of buckling is relatively straightforward. For a column with one end fixed and the

other free to move in any direction (i.e., a cantilever), the critical load to cause buckling is

$$F_{CR} = \frac{\pi^2 EI}{4L^2} \quad (27.43)$$

It is important to remember that the critical load for buckling cannot exceed the maximum force supported by the material. In other words, if the load needed to cause buckling is larger than the load needed to exceed the compressive strength, the column will fail by rupture before buckling.

## 27.4 Applications

The applications section of this chapter uses the material that has been covered thus far. It describes some surface-micromachined mechanisms and discusses them with regard to concepts such as spring constant and critical buckling load. The chapter concludes with a discussion of some design rules and lessons learned in the design of surface-micromachined mechanisms.

### 27.4.1 Microengine

One important element of many polysilicon mechanism designs is the “microengine.” This device, described by Garcia and Sniegowski (1995) and shown in Figures 27.14 to 27.16, uses a comb drive connected to a pinion gear by a slider-crank mechanism with a second comb drive to move the pinion past the top and bottom dead center. Comb drives are electrostatic devices that use fringe fields to produce a uniform force over a large displacement. Two comb drives are necessary because the torque on a pinion produced by a single actuator has a dependence on angle and is given by the following equation:

$$\text{Torque} = F_0 r |\sin(\theta)| \quad (27.44)$$

where  $F_0$  is the force of the comb drive,  $\theta$  describes the angle between hub of the output gear and the linkage, and  $r$  is the distance between the hub and the linkage. The torque produced by the “Y” actuator has a similar dependence on angle. A second reason for two comb drives is that the inertia of the pinion gear is not great enough to rotate the gear past the top and bottom dead center. A drawing of a microengine is shown in Figure 27.15. One important feature of this device is that the conversion from linear motion to rotary motion requires the beams between the actuator and the driven gear to bend. The bending is permitted by a polysilicon linkage that is 40  $\mu\text{m}$  in length and 1.5  $\mu\text{m}$  in width with a thickness of 2.5  $\mu\text{m}$ .

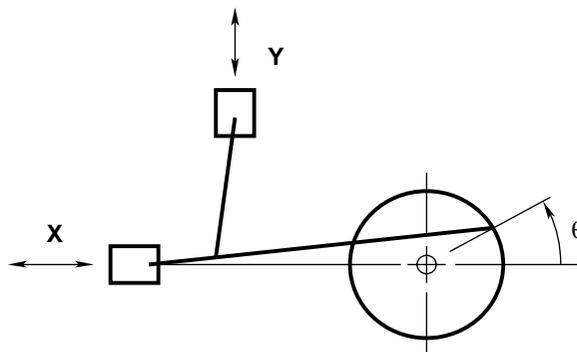

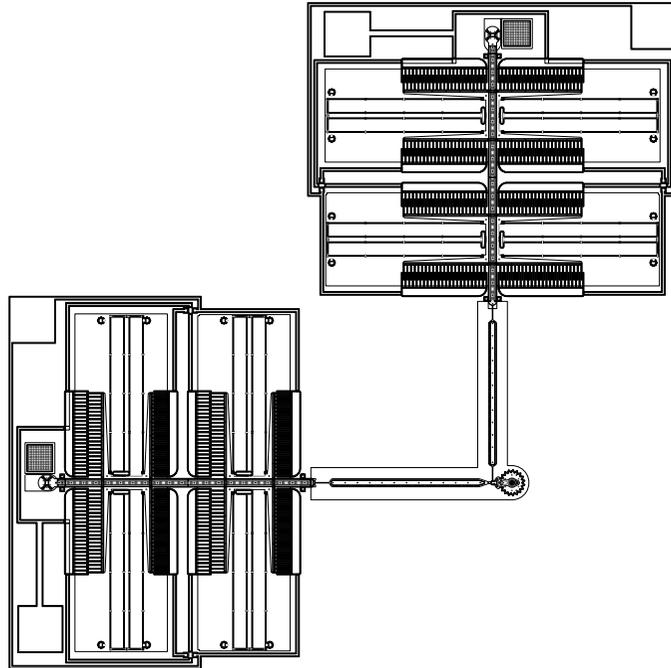

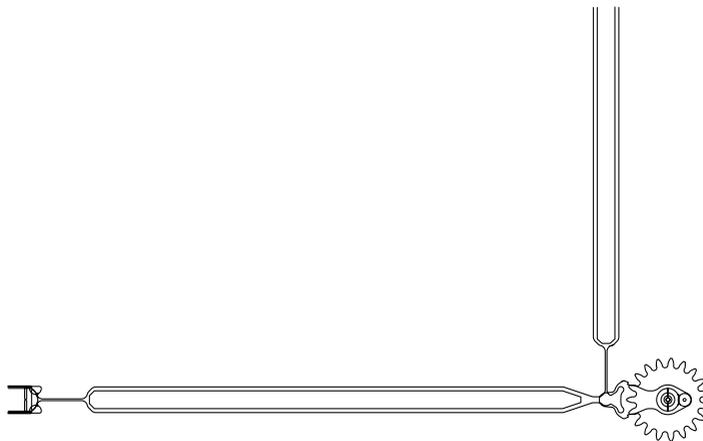

FIGURE 27.14 Mechanical representation of a microengine.

**FIGURE 27.15** Drawing of a microengine. The actuator measures  $2.2 \text{ mm} \times 2.2 \text{ mm}$  and produces approximately  $55 \text{ pN}\cdot\text{m}$  of torque.

**FIGURE 27.16** Detail of [Figure 27.15](#) showing the thin linkages that connect the comb drives to the gear.

### Example

The comb drive labeled “X” in [Figure 27.14](#) has an actuator arm that must bend  $17 \text{ }\mu\text{m}$  in the lateral direction as the gear rotates from  $0$  to  $90^\circ$ . The gear is connected to the comb drive via a  $50\text{-}\mu\text{m}$ -wide beam that is  $50 \text{ }\mu\text{m}$  long in series with a thin flexible link that is  $1.5 \text{ }\mu\text{m}$  wide and  $45 \text{ }\mu\text{m}$  long. The thin link is connected to the comb drive actuator and both beams have a Young’s modulus of  $155 \text{ GPa}$ . Given that both beams are  $2.5 \text{ }\mu\text{m}$  thick, approximately how much force does it take to rotate the gear from  $\theta = 0$  to  $\theta = 90^\circ$  if friction and surface forces are neglected? A drawing of this linkage is shown in [Figure 27.16](#).

Assume that each segment is a cantilever beam spring that has one end fixed while the other end is undergoing a small deflection. For each beam:

$$y_{\max} = \frac{PL^3}{3EI} \quad (27.45)$$

and

$$k = \frac{P}{y_{\max}} = \frac{3EI}{L^3} \quad (27.46)$$

Recall that for rectangular cross sections,

$$I = \frac{tw^3}{12} \quad (27.13)$$

Using substitution, the equivalent spring constant for the long beam is

$$k = \frac{Et w^3}{4L^3} = \frac{155 \text{ GPa} \times (2.5 \text{ } \mu\text{m})(50 \text{ } \mu\text{m})^3}{4 \times (500 \text{ } \mu\text{m})^3} = 97 \text{ N/m}$$

and for the short beam,

$$k = \frac{Et w^3}{4L^3} = \frac{155 \text{ GPa} \times (2.5 \text{ } \mu\text{m})(1.5 \text{ } \mu\text{m})^3}{4 \times (45 \text{ } \mu\text{m})^3} = 3.6 \text{ N/m}$$

By Eq. (27.40), the equivalent spring rate is

$$\frac{1}{k_{eq}} = \frac{1}{k_1} + \frac{1}{k_2} = \frac{1}{97 \text{ N/m}} + \frac{1}{3.6 \text{ N/m}} = 3.5 \text{ N/m}$$

We can employ some simple trigonometry and calculus to determine the needed deflection of the flexure. From the section on cantilever beam springs,

$$y = \frac{P}{6EI}(3Lx^2 - x^3) \quad (27.19)$$

Because the majority of the bending occurs in the thin flexible link the desired slope of the flexible link at its end is

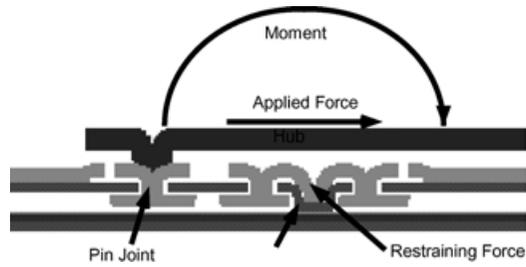

$$\frac{dy}{dx} = \frac{17 \text{ } \mu\text{m}}{545 \text{ } \mu\text{m}} = \frac{P}{6EI}(6Lx - 3x^2) \quad (27.47)$$

For the case of the small flexible link,  $I$  is equal to:

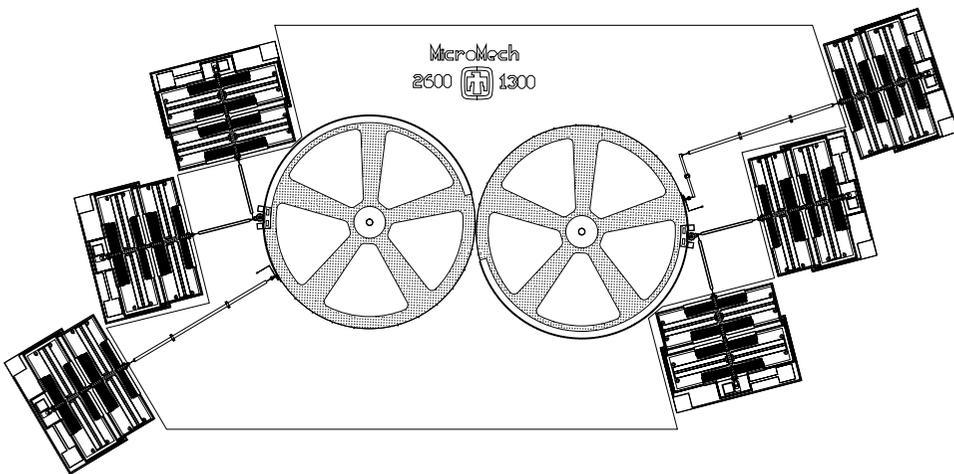

$$I = \frac{tw^3}{12} = \frac{2.5 \text{ } \mu\text{m} \times (1.5 \text{ } \mu\text{m})^3}{12} = 7 \times 10^{-25} \text{ m}^4$$

Because  $x = L = 45 \text{ } \mu\text{m}$ ,  $P$  can be calculated as:

$$P = \frac{17 \text{ } \mu\text{m}}{545 \text{ } \mu\text{m}} \times 6 \times 155 \text{ GPa} \times 7.0 \times 10^{-25} \text{ m}^4 \times \frac{1}{(6 \times (45 \text{ } \mu\text{m})^2 - 3 \times (45 \text{ } \mu\text{m})^2)} = 3.4 \text{ } \mu\text{N}$$

**FIGURE 27.17** Cross section of the hub and pin joint. This joint connects the comb drive actuators to the gear and the gear to the substrate. The arrows show the applied forces and the moment that results from them. The hub is on the center of the drawing; the pin joint is to the left of it and is attached to the top layer of polysilicon.

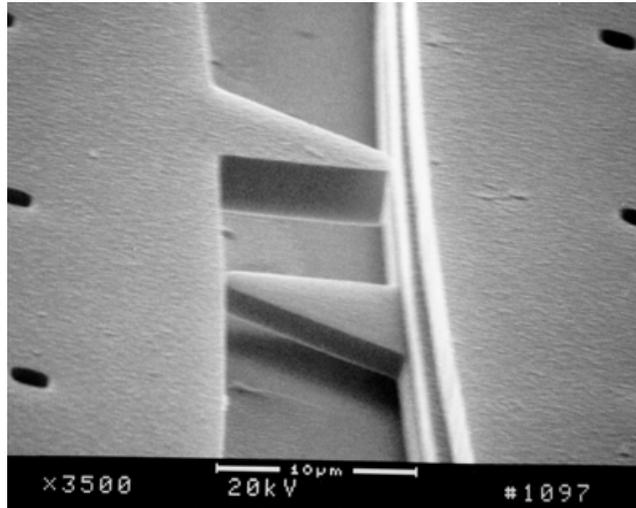

**FIGURE 27.18** The counter-meshing gear discriminator. The two code wheels are the large gears with five spokes in the center of the drawing; the counter-rotation pawls are connected to the comb drives and the long beams in the upper right and lower left portion of the photograph. (Drawing courtesy of M. Polosky, Sandia National Laboratories.)

A second important aspect of this device is the pin joint that connects the actuators to the gear. This joint rotates with respect to the gear and allows the actuators to apply force to the gear at any angle. The linkage does not mechanically interfere with the hub because it is constructed of a different layer of polysilicon and passes over the hub. Flanges on the hub restrict the amount of vertical play. However, because the linkage is above the plane of the gear, there may be rotational moments that will attempt to push or pull the gear out of plane. A cross section of a pin joint and a rotating hub are shown in [Figure 27.17](#).

## 27.4.2 Counter-meshing Gear Discriminator

One example of a surface-micromachined mechanism that incorporates comb drives and many other components is the counter-meshing gear discriminator that was invented by Polosky et al. (1998). This device has two large wheels with coded gear teeth that are driven by microengines. Counter-rotation pawls restrain each wheel so that it can rotate counterclockwise and is prevented from rotating clockwise. The wheels have three levels of teeth that are designed so that the teeth will interfere if the wheels are rotated in the incorrect sequence. Only the correct sequence of drive signals will allow the wheels to rotate and open an optical shutter. If mechanical interference occurs, the mechanism is immobilized in the counterclockwise direction by the interfering gear teeth and by the counter-rotation pawls in the clockwise direction. A drawing of the device and a closeup of the teeth are shown in [Figures 27.18](#) and [27.19](#), respectively. The wheels have three levels of intermeshing gear teeth that will allow only one

**FIGURE 27.19** Photograph of teeth in the countermeshing gear discriminator. The gear tooth on the left is on the top level of polysilicon and the gear tooth on the right is on the bottom layer of teeth. If the gears do not tilt or warp, the teeth should pass without interfering with each other. (Photograph courtesy of M. Polosky, Sandia National Laboratories.)

sequence of rotations out of the more than the 16 million that are possible. Because the gear teeth on one level are not intended to interfere with gear teeth on another level and because the actuators must remain meshed with the code wheels, the vertical displacement of the code wheels must be restricted. This was accomplished with dimples on the underside of the coded wheels that limited the vertical displacement to  $0.5\ \mu\text{m}$ . Warpage of the large 1.9-mm-diameter coded wheels is reduced by adding ribs with an additional layer of polysilicon.

The large coded wheels are prevented from rotating backward by the counter-rotation pawls. These devices must be compliant in one direction and capable of preventing rotation in the other direction. The next example discusses counter-rotation pawls.

### Example

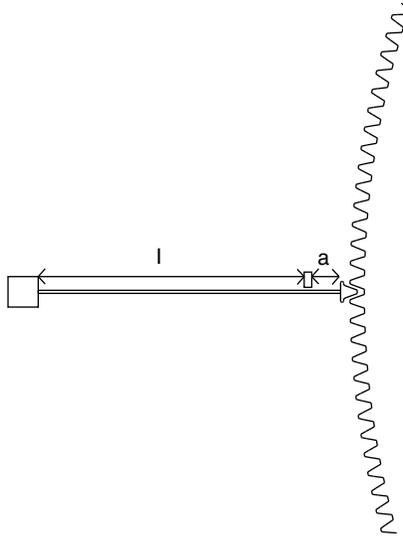

Figure 27.20 shows a counter-rotation pawl. The spring is  $180\ \mu\text{m}$  long from the anchor to a stop (labeled as  $l$ ) and  $20\ \mu\text{m}$  long from the stop to the end of the flexible portion (denoted as  $a$ ), with a width of  $2\ \mu\text{m}$  and a thickness of  $3\ \mu\text{m}$ . The Young's modulus is 155 GPa. Assume that the tooth on the free end of the beam does not affect the stiffness and that the width of the stop is negligible. Find the spring constant of the pawl if the gear is rotated in the counterclockwise direction. Comment on the spring constant if the gear is rotated in the clockwise direction.

In the counterclockwise direction, the spring constant  $k$  is

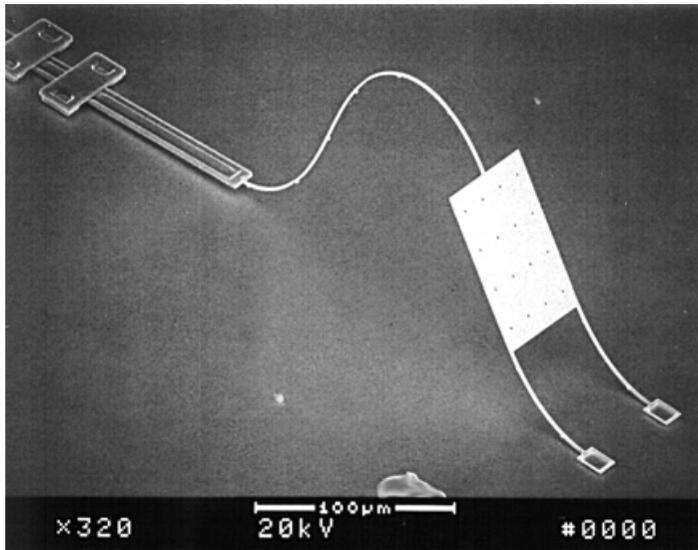

$$k = \frac{Ew^3t}{4L^3} = 0.12\ \text{N/m}$$

using a length  $l + a$  of  $200\ \mu\text{m}$ . In the clockwise direction, it is tempting to redefine the spring length as  $20\ \mu\text{m}$ . If you do so, you will obtain a result of 116 N/m. Unfortunately, this is an oversimplification because the beam will deform around the stop. The exact equation is in Timoshenko's *Strength of Materials* [Timoshenko, 1958] and in Eq. (27.48):

$$k = \frac{1}{\left(\frac{a^3}{3EI} + \frac{a^2l}{4EI}\right)} \quad (27.48)$$

**FIGURE 27.20** Example of a simple counter-rotation pawl. The stop is assumed to be a point load with a width of 0.

**FIGURE 27.21** A flexible pop-up mirror that operates via buckling. (Photograph courtesy of E. Garcia, Sandia National Laboratories, a further description of this device can be found in Garcia, 1998.)

This equation results in a spring constant of 15 N/m, which is still very stiff but not as stiff as the results of the oversimplified calculation.

### 27.4.3 Micro-Flex Mirror

The next example is a device that deforms out of plane [Garcia, 1998]. It can be built in any surface micromachining process that has at least one level of released structural material. This device can be configured as a mirror, an optical shutter, a valve or any structure that requires a plate or beam to move out of the plane of fabrication. A scanning electron microscope (SEM) photograph of the device is shown in [Figure 27.21](#). The mirror consists of a long flexible beam connected to a plate that in turn is connected

to two anchors via two additional flexible beams. The device operates by buckling. When a force is placed on the long flexible beam in the direction of the anchors, the structure is placed under a compressive force. When the force exceeds the critical value described by Eq. (27.43), the structure buckles. Because the long flexible beam is larger in the direction parallel to the plane of the substrate than it is in the direction away from the substrate, it preferentially buckles out of the plane of the substrate. Also, because the plate and the two anchor beams are wider than the long flexible beam, the majority of the bending occurs in the long flexible beam and not in the plate or the anchor beams. The next example discusses the buckling criteria.

### Example

Determine how much axial force is needed for a micromachined polysilicon mirror to buckle given the following dimensions. The main beam is 300  $\mu\text{m}$  long, 4  $\mu\text{m}$  wide and 1  $\mu\text{m}$  thick with a Young's modulus of 155 GPa. Assume that the beam can be simplified to be a cantilever. Neglect the buckling of the anchors and the mirror.

From the mechanics of materials section we know that the minimum force to buckle the beam is

$$F_{cr} = \frac{\pi^2 EI}{4L^2} \quad (27.49)$$

The moment of inertia for this situation is

$$I = \frac{wt^3}{12} = 3.3 \times 10^{-25} \text{ m}^4$$

Substituting this into the equation for force and using 155 GPa as the value of Young's modulus we have the following:

$$F_{cr} = \frac{\pi^2 \times 155 \times 10^9 \text{ N/m}^2 \times 3.3 \times 10^{-25} \text{ m}^4}{4 \times (300 \times 10^{-6} \text{ m})^2} = 1.4 \text{ } \mu\text{N}$$

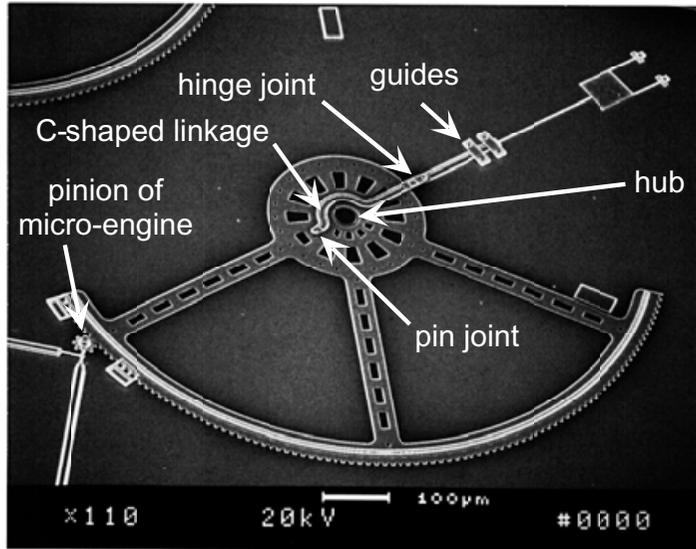

As the example shows it is necessary to have a great deal of force in order to buckle the flexible mirror. In the original paper by Garcia (1998), a transmission, shown in [Figure 27.22](#), was used to increase the force on the mirror. The transmission traded displacement for force to ensure that the mirror buckled. The amount of deflection after buckling is, unfortunately, a nonlinear dynamics problem and beyond the scope of this book. For those readers interested in the subject, good references include the work of Timoshenko and Gere (1961), Brush and Almroth (1975) and Hutchinson and Koiter (1970). Fang and Wickert (1994) have examined the subject for micromachined beams. One interesting point about buckling is that it is impossible to determine if the beam will initially buckle toward or away from the substrate. If the beam buckles away from the substrate, it will continue to deflect away from the substrate. If it initially buckles toward the substrate, it will contact the substrate and further compression of the beam will result in the structure buckling away from the substrate.

### Example

For the mechanism shown in [Figure 27.22](#), how much mechanical force is made available by the transmission if the microengine output gear has a diameter of 50  $\mu\text{m}$  and a torque of 50 pN-m, the large spoked wheel has a diameter of 1600  $\mu\text{m}$ , and the pin joint that links the spoked wheel to the mirror is 100  $\mu\text{m}$  from the hub? Find the radial force at the pin joint and determine the force on the mirror when the pin joint, hub and mirror are perfectly aligned.

The torque available at the pin joint is

$$\text{torque} = 50 \text{ pNm} \times \frac{1600 \text{ } \mu\text{m}}{50 \text{ } \mu\text{m}} = 1600 \text{ pNm}$$

**FIGURE 27.22** Photograph showing a flexible mirror in its initial state and a large gear with spokes. The spoked wheel acts as a transmission and is used to gain enough mechanical advantage to buckle the beam. Two important features are the hinge joint and guides which convert the off-axis motion of the “c”-shaped linkage to motion that is aligned with the mirror. (Photograph courtesy of E. Garcia, Sandia National Laboratories.)

and the radial force at the pin joint is

$$F_{radial} = \frac{1600 \text{ pNm}}{100 \text{ }\mu\text{m}} = 16 \text{ }\mu\text{N}$$

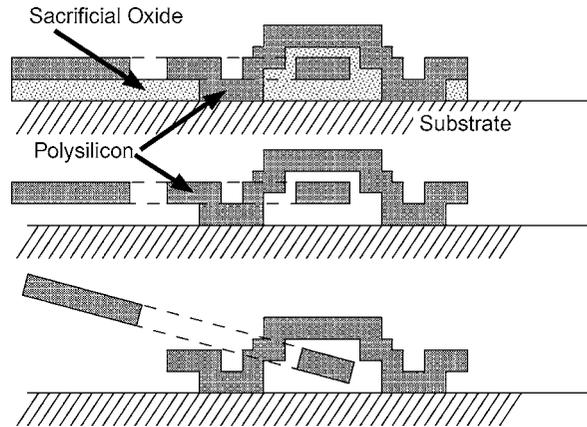

At the mirror, the force is given by:

$$F_{mirror} = \frac{F_{radial}}{\sin(\theta)} \tag{27.50}$$

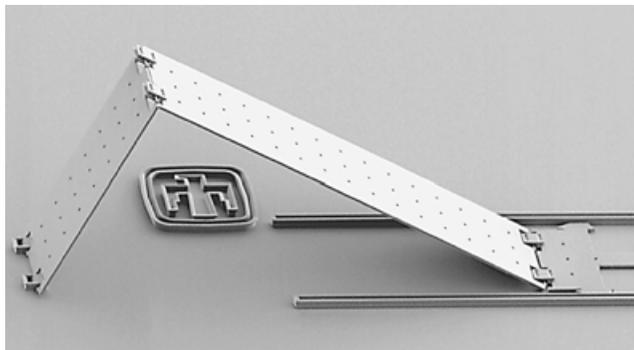

where  $\theta$  is the angle between a line connecting the pin joint and the mirror and a line connecting the pin joint and the hub. Because  $\theta = 0$  when all the points are collinear, the force applied on the mirror approaches infinity for angles approaching zero degrees. This example is taken after Garcia (1998), who included a more detailed derivation that accounts for the rotation of a “c”-shaped linkage.

A different type of rigid-body-mode machine is a vertical axis hinge. These hinges are used in surface micromachining to create three-dimensional structures out of a two-dimensional surface micromachining process. In the surface micromachining process, hinges are constructed by stapling one layer of polysilicon over another layer of polysilicon with a sacrificial layer between them. A cross section of a simple hinge is illustrated in Figure 27.23. Photographs of more complex hinges are shown in Figures 27.24 and 27.25. Hinges have some advantages over flexible joints. One advantage is that no stress is transmitted to the hinged part so greater angles of rotation are possible. Also, the performance of hinged structures is not influenced by the thickness of the material, and deformation of the machine is not required. The limitations of hinged structures are that the sacrificial layers must be thick enough for the hinge pin to rotate and at least two released layers of material are required.

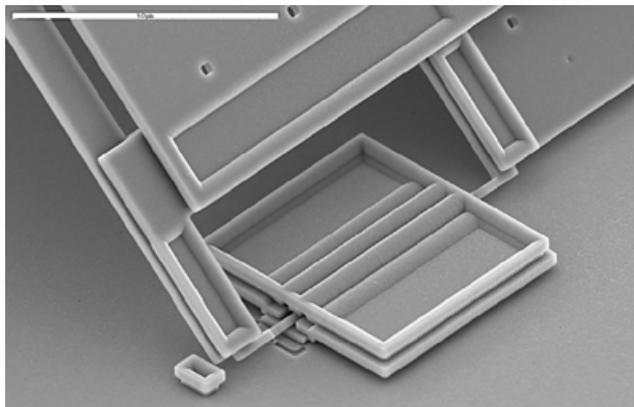

Hinges in the surface micromachining process are not always trouble free. There is a problem with friction in hinges because the sliding surfaces are neither round nor lubricated. There is also a substantial

**FIGURE 27.23** Cross section of polysilicon mirror hinge. The top figure shows the device before release, the middle drawing is after release, and the bottom depicts the mirror actuated.

**FIGURE 27.24** Hinged polysilicon micromirror fabricated in the Sandia National Laboratories SUMMiT™ process. (Photograph courtesy of Sandia National Laboratories.)

**FIGURE 27.25** Detail of polysilicon hinge. (Photograph courtesy of M. Polosky and A. Jojola, Sandia National Laboratories.)

amount of backlash built into the system. A third problem relates to the ability of the hinge to pivot. Often there is not a large rotational moment to rotate the mirror out of plane when planar hinged structures are connected to planar-surface-micromachined actuators. This means that the designer must take great care to ensure that the hinge always rotates in the correct direction.

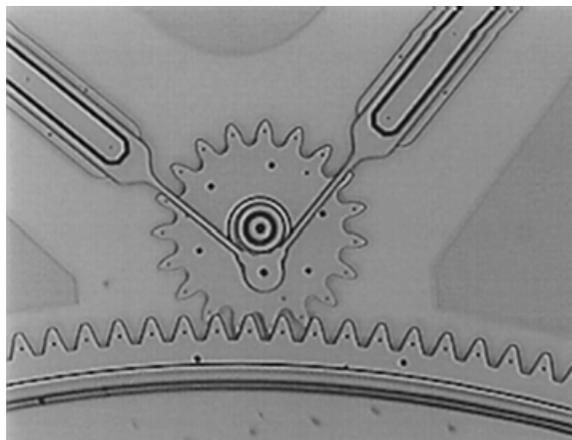

## 27.5 Failure Mechanisms in MEMS

One of the most effective ways we can learn is to learn from our own mistakes. This can be a memorable experience but in the field of MEMS it can be a very expensive and inefficient one. One reason is that the time between design completion and testing is usually measured in months and the price per fabrication run is many thousands of dollars. As of the year 2000, there were only rudimentary modeling and simulation tools available for surface-micromachined mechanisms. This section seeks to share learning obtained at the expense of others by describing some mechanical failures in surface-micromachined mechanisms. The hope is that the reader will gain a deeper appreciation for the complexities of surface-micromachined mechanism design and learn about some of the pitfalls.

### 27.5.1 Vertical Play and Mechanical Interference in Out-of-Plane Structures

Surface-micromachined parts typically have a thickness that is very small in relationship to their width or breadth. In the out-of-plane direction, the thickness is limited to a few micrometers due to the limited deposition rates of low-pressure chemical vapor deposition (LPCVD) systems and the stresses in the deposited films. In the plane of the substrate, structures can be millimeters across. These factors typically lead to surface-micromachined structures that have a very small aspect ratio as well as stiffness issues in the out-of-plane direction due to the limited thickness of the parts. The result is that designers of surface-micromachines need to design structures in three dimensions and account for potential movements out of the plane of the substrate. One instance of a potential problem is when gears fabricated in the same structural layer of polysilicon fail to mesh because one or both of the gears are tilted. Another is when structures moving above or below another structure mechanically interfere with each other when it was the intended for them to clear each other without touching. Both of these instances will be examined separately.

An example of the out-of-plane movement of gears is illustrated in [Figure 27.26](#). In this instance, the driven gear in the top of the figure has been wedged underneath the large load gear at the bottom of the photograph. The way to prevent this situation is to understand the forces that create the out-of-plane motion

**FIGURE 27.26** The gear teeth of the small gear are wedged underneath the teeth of the large diameter gear. In this case, gear misalignment is about  $2.5\ \mu\text{m}$  in the vertical direction.

and to reduce or restrain them. One way of reducing the relative vertical motion of meshed gears is to increase the ratio of the radius of the hub to the radius of the gear. Mathematically, the maximum displacement of the outside edge of a gear from its position parallel to the plane of the substrate is

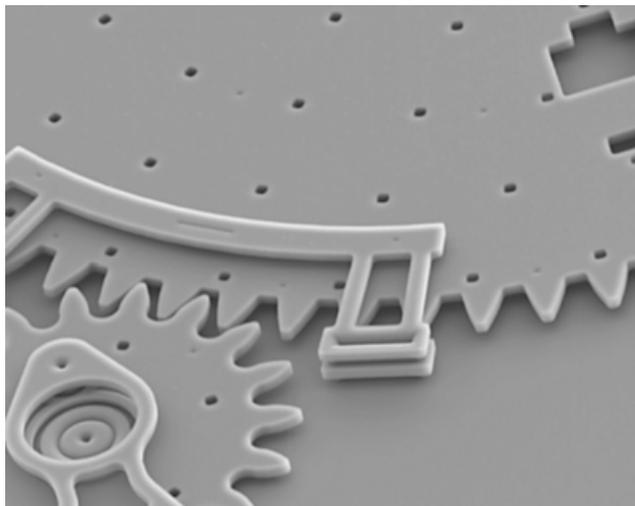

$$Y_{\max} = R \times Y/X \quad (27.51)$$

where the radius of the hub is  $X$ , the vertical play in the hub is  $Y$ , the radius of the gear is  $R$  and the maximum vertical displacement is  $Y_{\max}$ . The increase in hub diameter, while it can increase the amount of adhesive forces in the hub, does not increase the amount of frictional forces in the rotating or sliding structure.

The vertical displacement of a gear can also be limited by contact with the substrate, and one way of limiting the vertical displacement of the gear is to place dimples on the underside of the gear. Dimples are available in several commercially available surface micromachining processes including the MUMPS process offered by Cronos Integrated Microsystems and the SUMMIT<sup>TM</sup> process from Sandia National Laboratories. The dimples are generally spaced well apart from each other, depending on the stiffness of the gear and the prevalence of stiction. They typically occupy less than 1% of the surface area.

Another method of restraining the vertical motion of surface-micromachined parts involves the use of clips above or below the gear or other moving structure as shown in [Figure 27.27](#). Generally, a maximum of three or four clips are used, which is enough to restrain the moving structure while limiting the increase in the amount of frictional forces on the gear. Dimples on the bottom of the clips can further reduce the amount of play. Of course, all of these techniques can be combined to reduce vertical play.

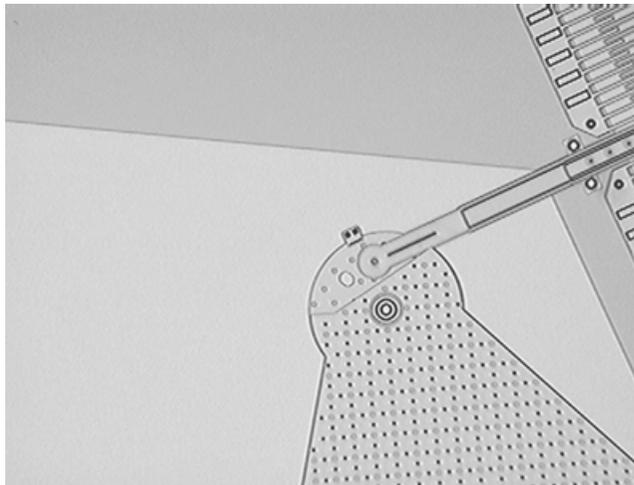

Murphy's law for surface-micromachined mechanisms causes a completely different type of reliability problem. It can be stated as, "Whatever can be disconnected will become disconnected." The following example illustrates the point: A pin and socket joint was the connection between an actuator and an optical shutter. A cross section of the joint is shown in [Figure 27.28](#). Unfortunately, the side walls of the socket are slightly sloped and the arm is not restrained in the vertical direction. In [Figure 27.29](#), the force between a pin and the optical shutter was relieved not by the horizontal movement of the shutter but by the vertical movement of the pin, which slid up the sloped side walls of the shutter and out of the socket. The proper way to design this joint would be to use an additional layer of polysilicon below the

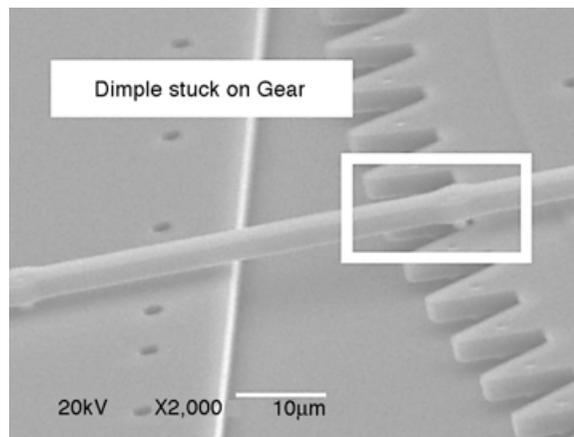

**FIGURE 27.27** SEM photograph of clip-over gear. The purpose of the clip is to limit the vertical displacement of the gear and to help ensure that the gear remains meshed. The line in the center of the clip is a dimple that further reduces the amount of vertical play in the gear. (Photograph courtesy of the Intelligent Micromachine Department at Sandia National Laboratories.)

**FIGURE 27.28** A cross section of a pin and socket joint.

**FIGURE 27.29** The pin and socket joint that connects the actuator to the shutter has failed. The pin, which should have been restrained in the vertical direction, was originally located near the center of the shutter.

**FIGURE 27.30** SEM image of polysilicon beam with dimples that is caught on surface-micromachined gear. The main problem with the beam is that it was designed to be compliant in the vertical direction. A secondary problem was that the dimple was small enough to be caught in the gear teeth.

shutter to restrain the linkage in the vertical direction. An example of this type of connection is shown in [Figure 27.17](#). An alternative approach would be to attach the linkage to the shutter and make the linkage compliant to compensate for the rotation of the shutter.

Unintended vertical motion of surface-micromachined parts can be exacerbated by structures that are soft in the vertical direction. [Figure 27.30](#) shows a beam with a dimple that is caught on a gear. Note that

there should be no interaction between the two elements, as the dimple should clear the gear by 0.5  $\mu\text{m}$ . Unfortunately, in this case neither the gear nor the spring is adequately grounded, which may have caused some attractive force between the two. Stiction may also have contributed to the proximity of the two parts. The spring constant of this beam in the vertical direction is much too soft at  $1.5 \times 10^{-3}$  N/m. The solution to the problem is to make the surface-micromachined part stiff in the vertical direction. As noted earlier in Eq. (27.46):

$$k = \frac{Ew^3t}{4L^3} \quad (27.46)$$

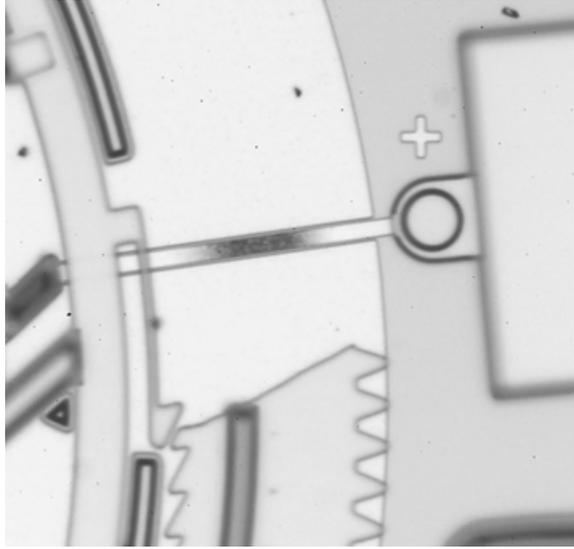

for a rectangular cantilever beam. Therefore, to increase the stiffness in the vertical direction the thickness of the structure should be increased and the length should be decreased. If the spring constant is increased, it takes more energy to pull the structure down to the substrate. Another, but less effective, option is to increase the width. A completely different but complementary approach would be to change the size of the dimple so that it is larger than the space between the gear teeth.

Another source of vertical motion in surface-micromachined parts is electrostatic forces. Unintended electrostatic forces in surface micromachines have two basic causes. One is fixed charge buildup in dielectric layers. Charges in silicon nitride and silicon dioxide, especially silicon nitride, are not mobile and tend to attract other structures. This can be a great problem in accelerometers or gyroscopes because they are designed to be sensitive to the vertical displacement of the proof mass. Unfortunately, techniques from the integrated circuit industry that seek to avoid trapped charges are not typically applicable to MEMS, aside from careful processing, which seeks to avoid the incorporation of sodium in the dielectrics. Currently, the best way to avoid the influences of trapped charge is to avoid them by minimizing exposure of the dielectrics to radiation and energetic electrons. The other method is to shield the moveable mechanism parts from the charge buildup in the dielectric by using a conductive ground plane between the movable structure and the dielectrics.

Another instance when unintended electrostatic forces are important is when features and structures in a design are left electrically floating. In this situation, as in the dielectric charging case, the floating potential can eventually cause mobile structures to be attracted. The cure for this situation is to fix all potentials to a known level. For dielectrics, a grounded conductor should shield them from other structures and layers. For rotating gears or other structures that are not electrically connected to the substrate, the hubs or mechanical restraints should be connected to the ground. If the restraints and the moving component momentarily touch, the moving part can discharge through the support to the substrate. Electrostatic attraction of floating components can be a maddening problem, as the potentials on the various conductors and dielectrics can seemingly shift randomly and cause structures to be unexpectedly attracted to each other.

## 27.5.2 Electrical Shorts

One problem that is unique to surface-micromachines made of conductive materials is the problem of shorting between different parts of the machine. One common situation is when the fingers of a comb drive touch. Another situation is when the dimple of a moving structure such as a gear or a shutter comes in contact with an underlying conductive trace. An example is shown in [Figure 27.31](#). The problem is that bare polysilicon structures (and silicon-germanium) are neither good conductors nor good insulators even when coated by a thin anti-stiction coating or native oxides. The native oxide coatings and anti-stiction coatings are prone to breakdown under the high voltages commonly used to power electrostatic actuators. Because insulating dielectrics are not normally used between layers, the designer must resort to minimizing the chances for contact between conductors at different potentials. One method of doing this is to make structures, especially comb drives, stiff in all directions but the direction of intended motion. Another is to use stops or other mechanical restraints to prevent contact between conductors at different potentials.

**FIGURE 27.31** (Color figure follows p. 12.26.) The blackened trace near the “+” sign was caused by a dimple on a grounded gear touching a high potential signal line. (Photograph courtesy of S. Barnes, Sandia National Laboratories.)

### 27.5.3 Lithographic Variations

One problem common to all types of mechanism design is tolerances in the manufacturing process. This is an especially grave problem in surface-micromachined mechanisms because the manufacturing tolerances approach the size of the parts. For example, assume a cantilever beam spring with a width of  $2\ \mu\text{m}$  and a variation in the width of  $0.2\ \mu\text{m}$ . Cantilever beam springs have a spring constant that has been given in Eq. (27.46):

$$k = \frac{Ew^3t}{4L^3} \quad (27.46)$$

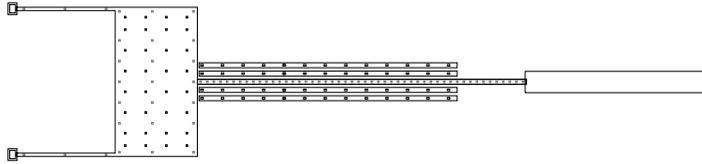

Due to the cubic relation between  $w$  and  $k$ , a small change in  $w$  will result in a large change in  $k$ . For example, if the linewidth changes by 1%, the resulting spring constant changes by about 3%:

$$\Delta k = \left(\frac{\partial k}{\partial w}\right)\Delta w = \frac{3Ew^2}{4L^3}\Delta w \quad (27.52)$$

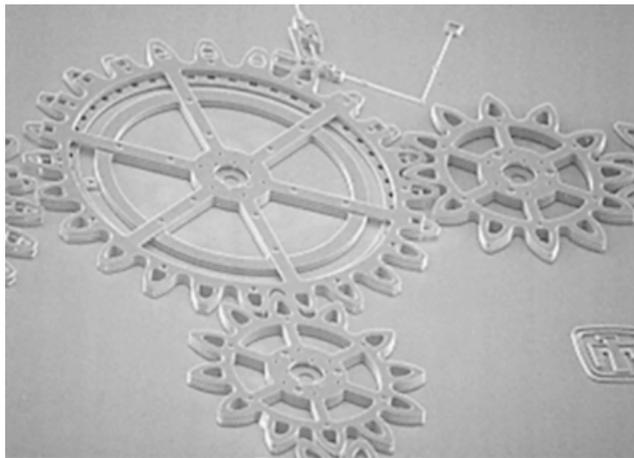

$$\frac{\Delta k}{k} = 3\frac{\Delta w}{w} \quad (27.53)$$

There are a few ways of minimizing the effects of features that vary in size. The first is not to design minimum-sized features. The linewidth is not reduced as a fixed percentage of the feature size but instead all features are reduced by the same amount. For example, a  $0.2\text{-}\mu\text{m}$  reduction in the size of a  $5\text{-}\mu\text{m}$ -wide beam spring is only a 4% reduction in the width of the spring and results in approximately a 12% change in the spring constant, while a  $1\text{-}\mu\text{m}$ -wide spring reduced by the same amount changes the linewidth by 20% and the spring constant by 49%.

The second method of minimizing the variation of mechanism performance due to linewidth is to borrow techniques from integrated analog circuit layout techniques. A good introduction to this topic can be found in the text by Johns and Martin (1997). Probably the most applicable technique they discuss

**FIGURE 27.32** Dummy columns next to a column on a micro-flex mirror. The structures ensure that the micro-flex mirror is matched to other micro-flex mirrors on the same substrate and is exposed to similar processing conditions. Note that the dummy columns do not extend the length of the center column to avoid mechanically interfering with the structure attached to the center column as it moves from right to left.

**FIGURE 27.33** Gears with spokes that were designed to reduce stiction. (Photograph courtesy of M. Polosky, Sandia National Laboratories.)

is to build dummy features adjacent to the intended mechanical features. Dummy features make processing boundary conditions (for example, in reactive ion etching or chemical mechanical polishing) similar for all parts of the mechanism and reduce the variation in feature size between mechanism parts. An example of this technique is shown in [Figure 27.32](#) where dummy columns are placed adjacent to the column on the micro-flex mirror. This will help ensure that the column on the micro-flex mirror is etched to a reproducible width and will be matched to other columns elsewhere on the chip. Care must be taken, however, so that the dummy parts do not interfere with the mechanism parts.

### 27.5.4 Methods of Increasing the Reliability of Mechanisms

There are several ways to increase the reliability of surface-micromachined mechanisms. One common problem is adhesion of the surface-micromachined mechanism to the substrate or stiction. Stiction can occur during the release process or afterward. One method of avoiding stiction is to make mechanisms stiff in the vertical direction. A second method of stiction avoidance is to minimize the overlapping surface area between flat parts, such as using dimples. Dimples reduce the contact area by more than a factor of a 1000 if a  $2\text{-}\mu\text{m} \times 2\text{-}\mu\text{m}$  dimple is used every  $75\ \mu\text{m}$ . A second method of reducing stiction is to use large cutouts in gears and other structures. In most cases, a surface-micromachined gear does not need the stiffness provided by the material between the teeth and the hub. A gear with spokes, shown in [Figure 27.33](#), performs as well as one without spokes and has a reduced probability of stiction.

Another way of increasing the reliability of surface-micromachined mechanisms is to know the limitation of the technology. This is important as few practitioners in the field of MEMS can change a fabrication process without a compelling reason. Therefore, it is imperative that designers operate within

the available fabrication and packaging processes and know the limitations of the fabrication process. Designers must be able to predict problems that might occur during the fabrication process and ensure that their designs will still work in spite of the problems. For example, a release process with an abundance of conductive particles is not compatible with designs that employ electrostatic comb drives because the particles may become lodged between the comb fingers and short them together. Thermal actuators over a nonconductive substrate would be a better alternative. Also, a nonhermetic packaging process would not be compatible with devices that are susceptible to humidity-induced stiction. A third example is that a release process that is prone to stiction is more compatible with designs that have limited surface area and are stiff in the vertical direction.

A final method of improving the reliability of surface-micromachined mechanisms is to design with regard to the packaging of the MEMS. While the package protects the surface-micromachined mechanism from particles, humidity and handling, it can also generate problems such as the outgassing of water vapor from the die-attach adhesive. Many types of electronic packages are not designed for surface-micromachined mechanisms both in terms of hermeticity and in interfacing the mechanism with the next assembly. Many times a MEMS device is designed without regard to the final package or the packaging process; however, better systems typically result if the packaging is contemplated at the beginning of the design process instead of at the end.

## Acknowledgments

---

The authors would like to thank their colleagues in the Electromechanical Engineering and Intelligent Micromachines Departments at Sandia National Laboratories for their efforts. Many of the devices and concepts reported here are due to their efforts. Special thanks are due to Jim Allen, Steve Barnes, Jennifer Brecheisen, Chris Dyck, Ernie Garcia, Adam Harris, Larry Hostetler, Andy Jojola, Alice Kilgo, Bob Kipp, Sita Mani, Bill Miller, Marc Polosky, Rosemarie Renn, Danelle Tanner and Ed Vernon for their contributions to this effort. The authors are with Sandia National Laboratories. Sandia National Laboratories is a multiprogram laboratory operated by the Sandia Corporation, a Lockheed Martin Company, for the U.S. Department of Energy under contract DE-AC04-94AL8500.

## Defining Terms

**Beam:** A structural member that can bend.

**Buckling:** Lateral deformations of a column caused by an axial load.

**Column:** A structural member that supports pure tension or compression.

**Dimple:** Small protusion on the bottom of a structure that acts to reduce the area in contact with the structure below.

**Isotropic:** The same in all directions.

**Microengine:** A surface-micromachined electric motor invented by Garcia and Sniegowski at Sandia National Laboratories [Garcia and Sniegowski, 1995].

**Moment of inertia:** A measure of the dispersion of area about the centroid. It is calculated when the axis of rotation is in the same plane as the cross section. In rectangular coordinates for simple situations it is given by:

$$I_x = \int_A y^2 dA \quad (27.54)$$

$$I_y = \int_A x^2 dA \quad (27.55)$$

**Poisson's ratio:** The ratio of transverse to axial strain when a body is subjected to an axial load. Its symbol is  $\nu$ .

**Polar moment of inertia:** The moment of inertia for objects whose axis of rotation is normal to the cross section.

**Stiction:** Adhesion or sticking of smooth surfaces together by one or more of the following: capillary forces, van der Waals forces, electrostatic forces and hydrogen bonding.

**Stress:** The intensity of a body's reaction to a load.

**Stress gradients:** Variations in the stress of the film through the thickness of the film. They cause released cantilevers to either curl away from or toward the substrate and can warp other released structures.

**Strain:** The deformation per unit length.

**Tribology:** The study of friction, lubrication and wear.

**Young's modulus:** Also known as the modulus of elasticity, it is the ratio of stress to strain in a body undergoing elastic deformation in the normal direction. It is normally denoted by  $E$ .

## For Further Reading

Among the several excellent sources of information on surface-micromachining and surface-micromachined devices are the recommended books by Madou (1997) and Kovacs (1998). Many conferences—for example, IEEE Micro Electro Mechanical Systems Conferences, biannual conferences on Solid State Sensors and Actuators (Transducers)—are mainly focused on device fabrication are also good sources for some

good device and mechanism papers. SPIE and ASME also sponsor MEMS conferences or workshops. Some of the heavily read journals in the field of MEMS include *Sensors and Actuators* and the *Journal of Microelectromechanical Systems (J. MEMS)*. Of the two, *J. MEMS* is the better source for surface-machined mechanism papers. For information on designing and building surface micromachines, both Cronos and Sandia provide information about their processes. The internet address for Cronos is <http://www.memsrus.com/>; for Sandia, the address is <http://www.mdl.sandia.gov/Micromachine/>. Good references on mechanical engineering and mechanism design include *Mechanical Engineering Design* [Shigley and Mischke, 1989] and the *Mechanisms and Mechanical Devices Sourcebook* [Chironis and Sclater, 1996].

## 28.1 Introduction

---

### 28.1.1 MEMS as the Motivation for Robot Miniaturization

The microelectromechanical systems (MEMS) field has traditionally been dominated by silicon micro-machining. In the early days, efforts were concentrated on fabricating various silicon structures and relatively simple components and devices were then developed. For describing this kind of microelectromechanical *structures* the acronym MEMs is used. A growing interest in manufacturing technologies other than the integrated circuit (IC)-inspired silicon wafer and batch MEMs fabrication is evident in the microsystem field today. This interest in alternative technologies has surfaced with the desire to use new MEMs materials, that enable a greater degree of geometrical freedom than materials that rely on planar photolithography as a means to define the structure. One such new MEMs material is plastic, which can be used to produce low-cost, disposable microdevices through microreplication. The micro-machining field has also matured and grown from a technology used to produce simple devices to a technology used for manufacturing complex miniaturized systems which has shifted the acronym from representing *structures* to microelectromechanical *systems*. Microsystems encompass microoptical systems (microoptoelectromechanical systems, MOEMS), microfluidics (micro-total analysis systems,  $\mu$ -TAS) etc. These systems contain micromechanical components including moveable mirrors and lenses, sensors, light sources, pumps and valves and passive components such as optical and fluidic waveguides, as well as electrical components and power sources of various types.

With the growing focus on systems perspective—for example, the integration of various functions such as sensors, actuators and processing capabilities into miniaturized systems (which may also be fabricated by different fabrication technologies in the MEMS field)—new problems arise. For example, how does one assemble these very small devices to form larger systems? As early as 1959 Professor Feynman addressed “the problem of manipulating and controlling things on small scale” in his famous APS talk [Feynman, 1960]. Feynman’s solution to microassembling problems was the use of micromachines (or microrobotic devices as they will be named in this chapter) which would be used to build or assemble other micromachines (microsystems) consisting of different microdevices. This approach can be regarded as a hybrid technology or *serial* (one-at-a-time) fabrication/assembly, as opposed to the monolithic approach, where all integration is done on one single silicon chip, preferably using wafer-level assembly. Wafer-level assembly performed on several wafers at the same time (so-called batch fabrication) is a *parallel* (several-at-a-time) manufacturing process originally developed for the IC industry but now also commonly used for MEMS fabrication. General and good reviews of the different assembly approaches for MEMS have been presented [Cohn et al., 1998; MSTnews, 2000]. The different aspects of MEMS assembly will be further discussed in Section 28.3.2.

All systems, no matter what kind of components they consist of, must be assembled in some way. The assembly of complete microsystems can be done either *monolithically* (i.e., several systems simultaneously assembled at wafer level) or in a *hybrid* fashion (i.e., by serial assembly of several individual microcomponents fabricated by different technologies and on different wafers). In both cases *microrobotic* devices could simplify the assembly process (i.e., microrobots for making MEMS); however, these microrobots must be highly miniaturized. A common way to obtain miniaturization is by using MEMS technologies (i.e., MEMS for making microrobots). The benefits of scaling down all the subsystems of a robot to the same scale as the control systems by integrating motors, sensors, logic and power supplies onto a single piece of silicon have been discussed by Flynn et al. (1989). Enormous advantages can be obtained in the form of mass producibility, lower costs and fewer connector problems encountered when interconnecting these discrete subsystems in comparison to the macro- (or miniature) robot concepts.

The hybrid microassembling approach, allowing microdevices to be fabricated by various techniques and in various materials to be assembled into more complex systems, is one of the driving motives for robotic miniaturization, in general, and MEMS-based microrobotics, in particular. Of course, miniaturized robots are also very attractive for assembling all kinds of miniaturized components (e.g., watch components). Besides the use of microrobotic devices for assembling purposes, other application fields such as medical technology may benefit greatly from the use of miniaturized robot devices. One such example is the steerable catheters used for minimal invasive surgery (MIS) shown in Figure 28.1. Such microrobotic catheters have been fabricated using MEMS technologies [Haga et al., 1998; Park and Esashi, 1999].

## 28.2 What is Microrobotics?

---

Today we can see a growing worldwide interest in microrobotic devices and their potential, including micro-manipulation tools and microconveyers and/or microrobots as locomotive mechanisms [Ebefors, 2000]. The term *microrobotics* covers several different types of small robot devices and systems. The term mainly refers to the complete robot system—that is, what type of work the microrobot(s) perform, how to accomplish those tasks and other system-oriented aspects. Often, the term *microrobotics* also includes more fundamental building blocks, such as steerable links, microgrippers, conveyer systems and locomotive robots, as well as the technologies used to fabricate these devices and the control algorithms used to carry out the robot’s task. The term *microrobotic* can be compared with the MEMS (or MEMs) term in that the former often encompasses not only the system itself, but also fabrication and material issues, as well as simple devices used as building blocks for the system. Although the microrobotics field currently is an area of intensive research, no clear definition of the term *microrobot* exists. As stated by other authors reviewing the microrobotics field [Dario et al., 1992; Fatikow and Rembold, 1997], many “micro” terms such as *micromechatronics*, *micromechanism*, *micromachines* and *microrobots* are used synonymously to

**FIGURE 28.1** Example of a microrobotic application. In minimal invasive surgery (MIS), MEMS-based microrobotic devices such as steerable catheters, microgrippers and other microtools are expected to have a deep impact on endoscopic applications in the near future. (Illustration published with permission from Surgical Vision, Ltd., U.K. Courtesy of Graham Street.)

indicate a wide range of devices whose function is related to the “fuzzy” concept of operating at a “small” scale; however, “small” scale is a relative term so a more clear definition is needed.

### 28.2.1 Task-Specific Definition of Microrobots

The basic definition of a microrobot parallels the features attributed to a robot in the macroworld; i.e., a microrobot should be able to move, apply forces, manipulate objects, etc. in the same way as a “macrorobot.” The obvious difference between a macrorobot and a microrobot is the size of the robot. Thus, one definition of a microrobot is “a device having dimensions smaller than classical watch-making parts (i.e.,  $\mu\text{m}$  to  $\text{mm}$ ) and having the ability to move, apply forces and manipulate objects in a workspace with dimensions in the micrometer or submicrometer range” [Johansson, 1995]. However, in many cases it is important that the robot can move over much larger distances. The above-stated task-specific definition is quite wide and includes several types of very small robots as well as stationary micromanipulation systems, which are a few decimeters in size but can carry out very precise manipulation (in the micron or even nanometer range) [Fatikow and Rembold, 1997]. Because the fabrication technologies used to fabricate these devices play an important role, another more precise subdivision is desirable in order to help identify the practical capabilities of the different technologies.

### 28.2.2 Size- and Fabrication-Technology-Based Definitions of Microrobots

Following the classification scheme of microrobots used by Dario et al. (1992) and Fatikow and Rembold (1997), one can categorize the microrobot into many different groups. In the definition made by Dario et al., the microrobots were separated into three different subcategories, each characterized by the fabrication technology used to obtain the robot and the size of the device, as illustrated in [Table 28.1](#).

Some good examples of “miniature robots” are those that competed in the annual “Micro Robot Maze Contest 1992–99” at the International Symposium on Micromachine and Human Science (MHS) in Nagoya, Japan [Dario et al., 1998; Ishihara, 1998]. MEMS-based microrobots will be further described in the rest of this chapter.

While MEMS-based microrobots consist of billions of atoms and are fabricated using photolithography techniques and various etching methods, nanorobots will most likely be built by assembling individual

**Table 28.1** Classification of Microrobots According to Size and Fabrication Technology

Robot Class	Size and Fabrication Technology
Miniature robots or minirobots:	Having a size on the order of a few cubic centimeters and fabricated by assembling conventional miniature components as well as some micromachines (such as MEMS-based microsensors)
MEMS-based microrobots (or microrobots <sup>a</sup> )	Defined as a sort of “modified chip” fabricated by silicon MEMS-based technologies (such as batch-compatible bulk or surface micromachining or by micromolding and/or replication method) having features in the micrometer range
Nanorobots	Operating at a scale similar to the biological cell (on the order of a few hundred nanometers) and fabricated by nonstandard mechanical methods such as protein engineering

<sup>a</sup> To distinguish a MEMS-based microrobot with *micrometer*-sized components from the whole class of microrobots (including mini-, micro- and nanorobots), several more or less confusing notations have been proposed. In this publication, the term “MEMS-based microrobot” is introduced and used. The term “MEMS-based microrobot” differs from the notation originally used by Dario et al., but the content is the same.

Source: Adapted from Dario et al., 1992.

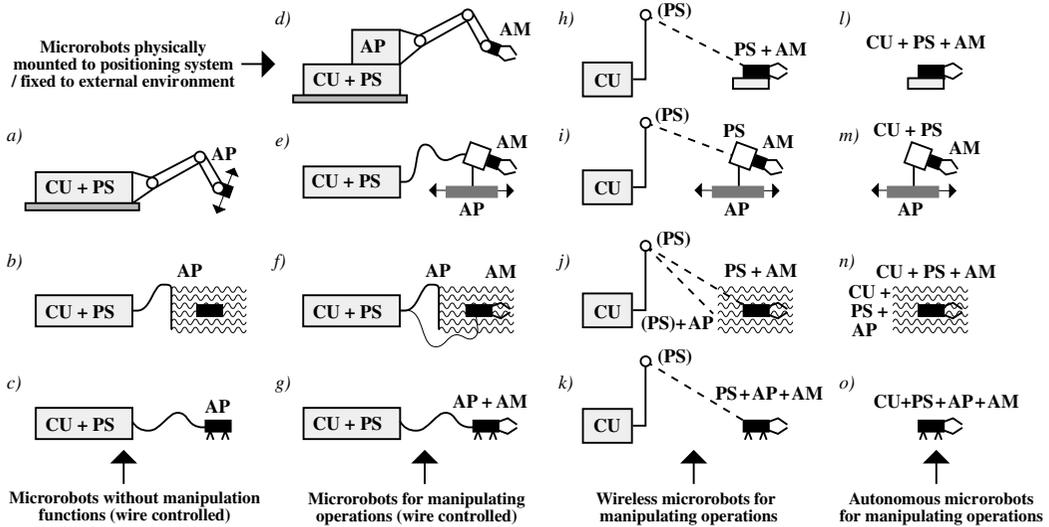

atoms or molecules one at a time. Instead of using conventional mechanical principles, an approach based on chemical self-assembly will most likely be the technology used to fabricate nanorobots. Examples of these nanorobots (nanomachines or molecular machines) and some proposed fabrication methods used to achieve the different components, such as gears, bearings and harmonic drives, needed for the realization of a nanorobot are found in the textbook of Drexler (1992). In 1999, the first reports of a successful molecular motor were presented [Kelly et al., 1999]. That nanomotor, consisting of a 78-atom molecular paddle wheel, was able to rotate one third of a complete revolution in approximately 3 to 4 hours. Researchers in the field of theoretical physics pushing for further miniaturization have introduced the concept of quantum machines and quantum computers, which will consist of stretched parts of a single atom [Wilson, 1997]. If we stretch the term *microrobotic* a bit, devices such as the atomic force microscope (AFM) or scanning tunneling microscope (STM) could also be categorized as microrobotic tools. The sharp probe tip of these microscope devices, which most often are fabricated using MEMS technologies, have been used to manipulate single atoms [Eigler and Schweizer, 1990]. To extend this further, nanorobots and other nanoelectromechanical systems (NEMS) may be fabricated using sharp silicon tips and other microrobotic tools (i.e., MEMS for nanorobots and NEMS).

### 28.2.3 Mobility- and Functional-Based Definition of Microrobots

Besides classification by task or size, microrobots can also be classified by their mobility and functionality [Hayashi, 1991; Dario et al., 1992]. Many robots, including the three different classes of microrobots mentioned in Table 28.1, usually consist of sensors and actuators, a control unit and an energy source. Depending on the arrangement of these components, one can classify microrobots according to the following criteria:

- Locomotive and positioning possibility (yes or no)
- Manipulation possibility (yes or no)
- Control type (wireless or wires)
- Autonomy (energy source onboard or not onboard)

Figure 28.2 illustrates 15 different possible microrobot configurations by combining the four criteria. As depicted in Figure 28.2, the classification is dependent on the following microrobot components: the control (CU), the power source (PS), the actuators necessary for moving the robot platform (i.e., robot drive for locomotion and positioning; AP), and the actuators necessary for operation (i.e., manipulation

**FIGURE 28.2** Classification of microrobots by functionality (modification of earlier presented classification schemes [Hayashi, 1991; Dario et al., 1992; Fatikow and Rembold, 1997]). CU indicates the control unit; PS, the power source or power supply; AP, the actuators for positioning; AM, the actuators for manipulation.

using robot arms and hands; AM). Besides the different actuation functions, sensory functions are also needed—for example, tactile sensors for microgrippers or charge-coupled device (CCD) cameras for endoscope applications (compare Figures 28.2d and a).

The ultimate goal is to create a fully autonomous, wireless mobile microrobot equipped with suitable microtools according to Figure 28.2o. Because this is a very difficult task, a good start is to investigate the possibility of making silicon microrobot platforms that are steered and powered through wires, like the one in Figure 28.2c, and to study their locomotion capability.

The majority of MEMS-based microrobotic devices developed so far could be categorized as moveable links—microcatheters [Haga et al., 1998; Park and Esashi, 1999], according to Figure 28.2a, or microgrippers [Kim et al., 1992; Keller and Howe, 1995; 1997; Greitmann, 1996; Keller, 1998a; 1998b; Ok et al., 1999], as those in Figure 28.2d, or the microgrippers [Jager, 2000a, 2000b] shown in Figure 28.2e. Among the research publications covering locomotive microrobots, most publications have addressed microconveyance systems (Figure 28.2b) [Kim et al., 1990; Pister et al., 1990; Ataka et al., 1993a; 1993b; Konishi and Fujita, 1993; 1994; Goosen and Wolffenbuttel, 1995; Liu et al., 1995; Böhringer et al., 1996; 1997; Nakazawa et al., 1997; Suh et al., 1997; 1999; Hirata et al., 1998; Kladitis et al., 1999; Nakazawa et al., 1999; Ruffieux and Rooij, 1999; Smela et al., 1999]; see Table 28.3 for more details. Robots using external sources for locomotion could be used (compare Figures 28.2b, f, j, n). According to Fatiokow and Rembold (1997), several researchers are working on methods to navigate micromechanisms through human blood vessels; however, these microrobots are difficult to control. Examples of partially autonomous systems (compare Figure 28.2j) are the concept for so-called “smart pills.” Centimeter-sized pills for sensing temperature and/or pH inside the body have been presented [Zhou, 1989; Uchiyama, 1995] as well as pills equipped with video cameras [Carts-Powell, 2000]. The pill is swallowed and transported to the part of the body where one wants to measure or record a video sequence. The information of the measured parameter or the signals from the camera are then transmitted (telemetrically) out of the body. More sophisticated approaches involving actuators (AM) for drug delivery of various kinds have also been proposed [Uchiyama, 1995; Fatikow and Rembold, 1997]. The position of the pill inside the body is located by an X-ray monitor or ultrasound. As soon as the pill reaches an infected area, a drug encapsulated in the pill can be released by the actuators onboard. External communication could be realized through radio signals.

Several important results have been presented regarding walking microrobots (see [Figures 28.2c,g,k](#)) fabricated by MEMS technologies and batch manufacturing. Different approaches for surface-micromachined robots [Yeh et al., 1996; 2000; Kladitis, 1999] and for a piezoelectric dry-reactive-ion-etched microrobot should be mentioned. A suitable low-power Application Specific Integrated Circuit (ASIC) for robot control has been successfully tested and is planned to be integrated on a walking microrobot [Ruffieux and Rooij, 1999]. The large European Esprit project *MINIMAN* (1997) has the goal of developing moveable microrobotic platforms with integrated tools with six degrees of freedom for applications such as microassembly within a scanning electron microscope (SEM) and involves different MEMS research groups from several universities and companies across Europe. One of the *MINIMAN* robots, as well as other MEMS-based microrobots, will be further described in Section 28.5.3. Further, miniature robot systems with MEMS/MST (MicroSystem Technology) components have been developed [Breguet, 1996; Breguet and Renaud, 1996]. Several research publications on “gnat” minirobots and actuator technologies for MEMS microrobots [Flynn et al., 1989; 1992] were reported by U.S. researchers in the early 1990s, and also several groups in Japan are currently developing miniaturized robots based on MEMS devices [Takeda, 2001]. In Japan, an extensive 10-year program on “micromachine technology,” supported by the Ministry of International Trade and Industry (MITI), started in 1991. One of the goals of this project is to create micro- and miniature robots for microfactory, medical technology and maintenance applications. Several microrobotic devices including locomotive robots, and microconveyers have been produced within this program. Miniature robot devices or vehicles [Teshigahara et al., 1995] for locomotive tasks, containing several MEMS components, have been presented. Even though great efforts have been made on robot miniaturization using MEMS technologies, no experimental results on MEMS batch-fabricated microrobots suitable for autonomous walking (i.e., robust enough to be able to carry its own power source or to be powered by telemetric means) have been presented yet (as of year 2000). The first batch-fabricated MEMS-based microrobot platform able to walk was presented in 1999 [Ebefors et al., 1999] (see [Figures 28.17](#) and [28.23](#)). However, this robot was powered through wires and not equipped with manipulation actuators. Besides the walking microrobotic devices, several reports on flying [Arai et al., 1995; Mainz, 1999; Miki and Shimoyama, 1999; 2000] and swimming [Fukuda et al., 1994; 1995] robots have been published. Micromotors and gear boxes made using LIGA technology (a high-precision, lithographically defined plating technology) are used to build small flying microhelicopters, which are commercially available from Institute of Microtechnology in Mainz, Germany, as rather expensive demonstration objects [Mainz, 1999]. Besides the pure mechanical microrobots, hybrid systems consisting of electromechanical components and living organisms such as cockroaches have also been reported [Shimoyama, 1995a].

## 28.3 Where To Use Microrobots?

---

### 28.3.1 Applications for MEMS-Based Microrobots

Already in the late 1950s, Feynman (1961) foresaw the utility and possibility for miniaturization of machines and robots. According to Feynman, the concepts of *microfactory* and *microsurgery* (based on tiny microdevices inserted in a patient’s blood vessels) were very interesting possibilities for small machines.

Microrobotic research has gone from being only theoretical ideas in the 1960s and 1970s to actual building blocks when complex systems and “micromachines” on a chip started to emerge in the late 1980s. These building blocks took the form of surface-micromachined micromotors made of polysilicon fabricated on a silicon chip [Muller, 1990]. In the late 1980s and early 1990s, more concrete suggestions on how one should realize MEMS-based microrobotic devices using such micromotors and potential applications were published [Flynn et al., 1989; Trimmer and Jebens, 1989]. Now, 10 years later one finds research publications on microrobotic devices for practical use in various fields. One of these application fields is medical technology [Dario et al., 1997; Haga et al., 1998; Tendick et al., 1998; Park and Esashi, 1999]. In surgery, the use of steerable catheters and endoscopes, as illustrated in [Figure 28.1](#), is very attractive and they may be further miniaturized by MEMS-based microrobotic devices, allowing advanced

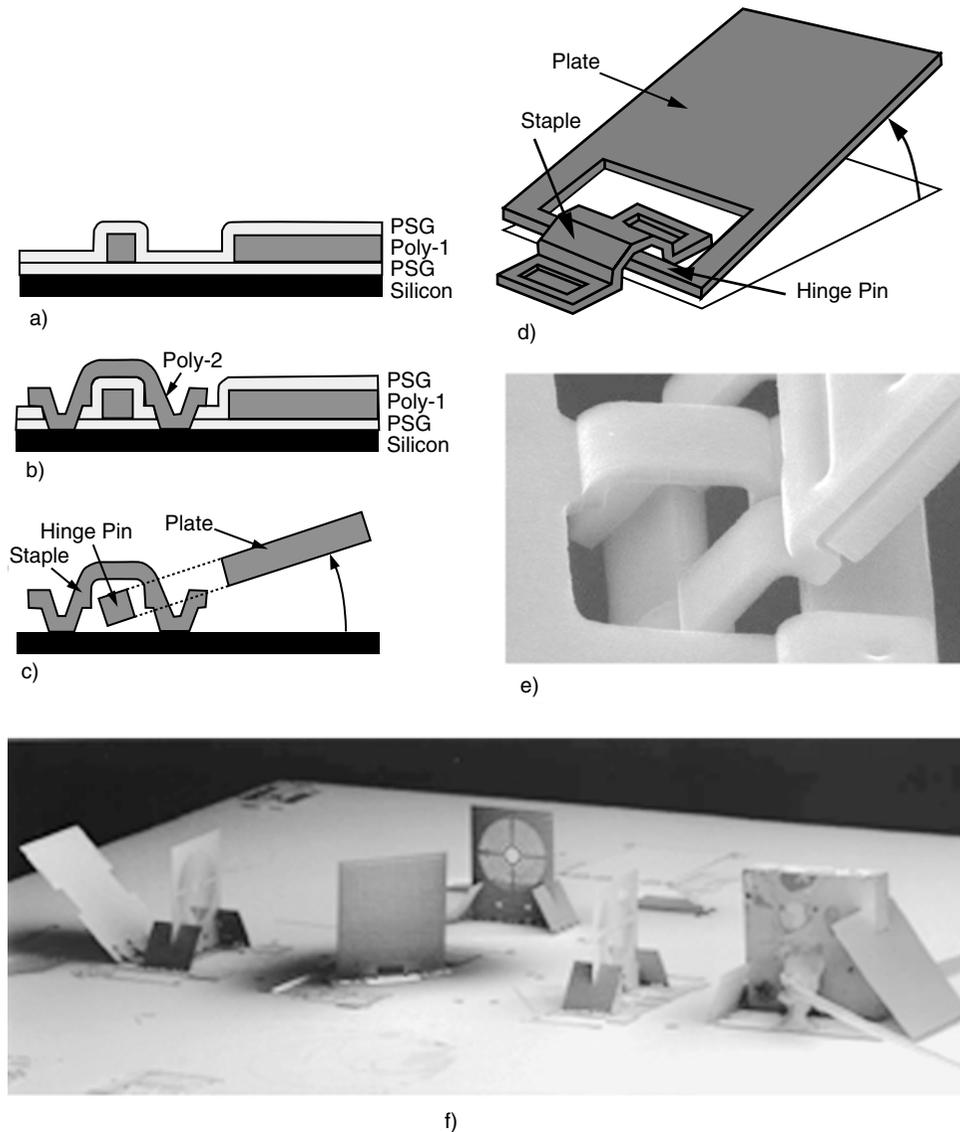

computer-assisted surgery (CAS) and even surgery over the Internet. For such applications, smaller and more flexible active endoscopes that can react to instructions in real time are needed in order to assist the surgeon. They may enter into the blood vessels and enter various cavities (angioplasty) by remote control, where they carry out complex measurements and manipulations (gripping, cutting, applying tourniquets, making incisions, suction and rinsing operations etc.) To meet these demands, an intelligent endoscope must have a microprocessor, several sensors and actuators, a light source and possibly an integrated image processing unit. These microrobotic devices will revolutionize classical surgery, but their realization is still a problem because of friction, poor navigability, biocompatibility issues, etc.; they are also not small enough yet [Fatikow and Rembold, 1997].

Other interesting areas for microrobotic devices are production (microassembly [Fatikow and Rembold, 1996; Cohn et al., 1998] and microfactory [Ishikawa, 1997; Kawahara et al., 1997]), metrology (automated testing of microelectronic chips, surface characterization, etc.) [Li et al., 2000], inspection and maintenance [Suzumori et al., 1999; Takeda, 2001], biology (capturing, sorting and combining cells [Ok, 1999]), bio-engineering [Takeuchi and Shimoyama, 1999] and microoptics (positioning of microoptical chips, microlenses and prisms) [Frank, 1998]. Many of these applications require automated handling and assembly of small parts with accuracy in the submicron range. Different approaches for microassembly, among them microrobotic-assisted assembly, are described in the following section.

### 28.3.2 Microassembly

Two different aspects of MEMS microrobotics and microassembly should be addressed. The first aspect is the use of MEMs for making microrobots using the silicon monolithic chip fabrication technology (several robots at a time; see [Table 28.1](#)). Because many microrobotic devices need three-dimensional (i.e., out-of-plane) arms and legs, the folding of these component is an essential assembly issue and constitutes one side of the assembling technology (i.e., MEMs for making microrobots). The second aspect is the use of microrobots for assembling more complex microsystems (i.e., microrobots for making MEMS). The use of microrobots for assembly of microcomponents and devices (i.e., fundamental building blocks) into complete microsystems is classified as hybrid manufacturing (one system at a time). Following is an introduction to and background of the two different assembling approaches.

The MEMS fabrication technology, especially surface-micromachining, allows batch-fabricated mechanisms to be preassembled *in situ*, and all structures on the entire wafer are released simultaneously (parallel assembly) by etching of sacrificial layers. This, together with the ability to integrate electronics on the chip, is a very attractive feature. Micromechanical systems of impressive complexity such as linear motors, rotating gears and linkages between these components have been made with alignment tolerances in the micrometer range by the use of parallel fabrication methods [Rodgers et al., 1999]. In the MOEMS and microrobotic fields, several devices make use of both parallel and serial assembling. To fold micro-mirrors out of the wafer plane to achieve, for example, microoptical benches, several serially addressed motors fabricated by standard parallel processing (i.e., lithography, thin-film depositions and etching) can be used to achieve the assembling of each individual micromirror. These mirrors are controlled externally by electrical signals connected to the integrated micromotors [Rodgers et al., 1999]. [Figure 28.3f](#) shows a complex free-space microoptical bench (FSMOB) that integrates several different optical elements [Lin et al., 1996]. To implement free-space optics monolithically, tall out-of-plane optical elements (moveable mirrors lenses etc.) with optical axes parallel to the substrate are needed. A common way to realize this kind of system is by using the surface-micromachined microhinge technology [Pister et al., 1992], which enables out-of-plane rotated optical elements to be fabricated using planar processes as shown in [Figures 28.3a to e](#). The planar elements are then assembled into three-dimensional structures after fabrication either by built in-motors for self-assembly or by the use of microrobotic devices and external manipulation. Also integrated in the FSMOB system, shown in [Figure 28.3](#), is a self-alignment technique that incorporates hybridly mounted active optoelectronic devices such as semiconductor lasers and vertical cavity surface-emitting lasers [Lin et al., 1996]. One key advantage of FSMOB is that the optics can be “prealigned” during the design stage by CAD.

**FIGURE 28.3** (a)–(c) Cross sections of a microhinge during fabrication. (d) A perspective view of a hinged plate after release by external manipulators. (e) SEM photograph of a polysilicon hinge. (f) Example of a complex microoptical system based on out-of-plane rotated optical elements using the surface-micromachined microhinge and hybrid mounting of a laser [Lin et al., 1996]. (Photograph of the optical bench taken by David Scharf and published with permission. Courtesy of M. C. Wu, UCLA and K. Pister, BSAC-Berkeley.)

For some applications with very complex out-of-plane folding, the serial self-assembly technology using integrated micromotors is not feasible; therefore, quasi-manual or semi-automated assembly using external manipulators is required. To assemble several folded microstructures into more complex out-of-plane devices, MEMS-based microrobotic tools are used mainly because of their precise and small dimensions. Different MEMS technologies can be used to achieve out-of-plane rotated structures [Ebefors, 2000]. Besides MOEMS applications, out-of-plane rotated microstructures are also essential for the realization of most MEMS-based microrobotic devices. However, for most microrobot application the robustness of surface-micromachined legs and arms that are folded out of the wafer are limited.

Therefore, bulk micromachining is an attractive technology to fabricate more robust legs and arms for various microrobots.

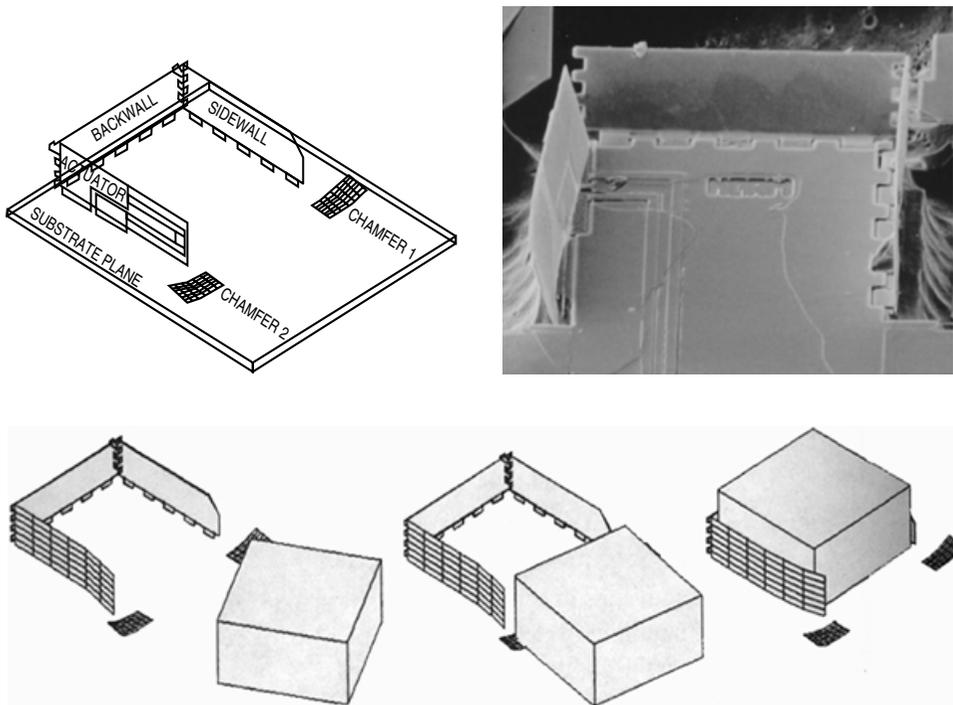

Besides by use of surface-micromachining, impressive and complex microsystems can also be achieved using bulk micromachining where different kinds of wafers can be stacked on top of each other by bonding [Tong and Gössle, 1999]. However, by using bulk micromachining the size is generally one order of magnitude larger than for surface-micromachined devices. Several packaging schemes have been used to assemble complete microsystems on the wafer level (i.e., parallel batch fabrication) [Corman, 1999]. However, for many applications the use of lithography, etching and bonding alone cannot fulfill the requirements on the system level. Monolithic integration of electronic and micromechanical functions is not always the most suitable. By combining microelectronics, micromechanics, microfluidics and/or microoptics into a single fabrication process one faces the risk that one may have to compromise the performance of all subsystems.

A disadvantage for all integration of electronic and mechanical components is that the electronics (complementary metal oxide semiconductor [CMOS], bipolar CMOS [BiCMOS], etc.) and MEMS fabrication processes often are not compatible, due to thermal budgets, wafer size, etc. Wafer bonding (flip chip, fusion bonding, etc.) and the monolithic integration approaches of electronics and MEMS on the same chip are then not realistic assembling alternatives. In those cases, the serial assembly (i.e., “pick-and-place”) can be the only assembly approach that allows integration of electrical and mechanical components. Such micro “pick-and-place” systems can be achieved by microrobotic devices in the form of microtweezers and microgrippers [Kim et al., 1992; Keller and Howe, 1995; 1997; Greitmann, 1996; Keller, 1998a; 1998b; Ok et al., 1999] and will be further described in Section 28.5.1. To extend this serial assembling approach further, other microrobotic components such as conveyers and miniaturized robots (preferably fabricated using MEMS technologies) are also required; see Section 28.6 regarding the concepts on microfactories and desktop micromanipulation stations.

Besides the monolithic assembling on the wafer level and the serial “pick-and-place” assembly, parallel approaches for hybrid assembling are also possible. Pister et al. [see Tahhan et al., 1999] presented a concept where folded boxes using three-dimensional microstructures based on aluminum hinges were used to obtain wafer-sized pallets for automated microparts assembly and inspection, as illustrated in [Figure 28.4](#). The microparts (e.g., small diced MEMS or electronic chips) are supposed to be randomly transported on the pallet, by an external vibration field or by integrated microconveyers (see Section 28.5.2). The boxes with three walls, connected with microlocks, have one opening to capture the conveyed microparts. The microparts are sorted by their size or geometrical dimensions and kept in place by the walls of the boxes for handling, testing or assembling tasks. In the proposed concept, the fixtures should have integrated sensors and actuators by which the clamps actively close the box when the parts enter the fixture. For this concept, large fixture arrays and electrostatic or optical sensors integrated into the fixture cell should trigger the clamping function. Each cell operates autonomously and no global control should then be necessary.

Parallel sorting and assembling can also be obtained by other MEMS-based microconveyor strategies. Autonomous distributed micromachines (ADMs) are composed of several microcells and are smart enough to decide their behavior by themselves (i.e., by the use of integrated sensors) [Konishi and Fujita, 1995]. This concept has been validated for conveyance systems using a computer simulation model. Theories on programmable vector fields for advanced control of microconveyance systems have been presented [Böhringer et al., 1997]. Recently, these algorithms, which do not require sensing or feedback, were experimentally tested using polyimide thermal bimorph ciliary microactuator arrays with integrated CMOS electronics [Suh et al., 1999].

Besides the assembling of complete microsystems, other types of assembling are also required in MEMS. One such example, which already has been mentioned, is the need for three-dimensional MEMS structures for which one wants to create structures or sensor elements with feature sizes so small (micron or submicron) that they require photolithography in all three dimensions. Because normal IC-inspired lithography is planar, one commonly used method is to fabricate all structures requiring high-resolution patterns in the plane and then in a final process step-fold these structures out-of-plane using various

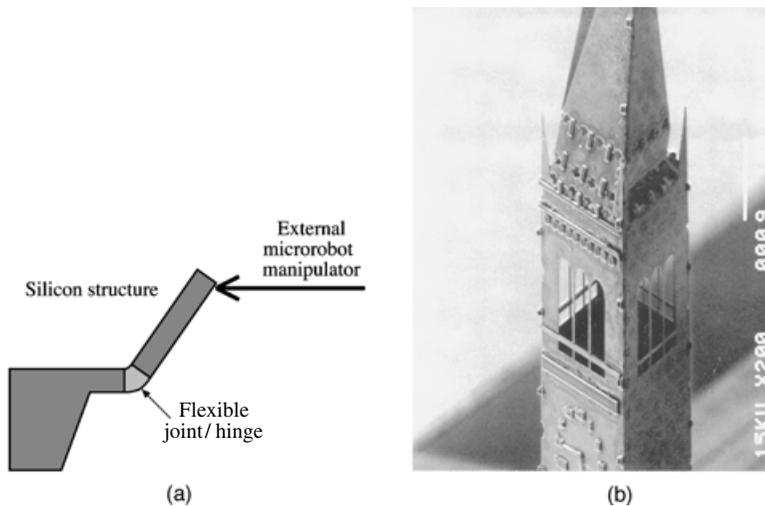

**FIGURE 28.4** Illustrations and SEM micrograph of a folded fixture cell for automated microparts assembly and inspection. From: <http://www.ee.washington.edu/research/mems/>. Illustration published with permission and courtesy of K. Böhringer, University of Washington.)

types of microhinges or microjoints [Ebefors et al., 1998b]. The out-of-plane microstructure assembling can be obtained in the same way as the system level assembling by: (1) serial self-assembling (built-in actuation by micromotors); (2) parallel batch self-assembly (using built-in mechanisms such as surface tension forces [Green et al., 1995; Syms, 1998; 1999] or volume shrinkage effects in polymers [Ebefors, 1998a]) for the assembling; or (3) the use of external manipulators (not self-assembly). Self-assembling of three-dimensional microstructures have been obtained using a variety of techniques [Ebefors, 2000]. All of these techniques are of great interest, as manual assembly is very time, labor and cost intensive. However, since self-assembly is not feasible in all applications, quasi-manual or semi-automatic assembling using microrobotic tools is one way of reducing costs and time. Complex three-dimensional structures, such as the clock tower model shown in Figure 28.5, have been assembled using MEMS-based microrobotic tools connected to motorized micromanipulators, as illustrated in Figure 28.9 [Hui et al., 2000]. For most MEMS-based microrobotic devices robust out-of-plane working structures are essential (e.g., arms and legs fabricated by bulk micromachining). To be useful as microrobots, these structures also need to produce large strokes and forces when actuated. The next section describes how this can be realized.

## 28.4 How To Make Microrobots

During the design of a MEMS-based microrobotic device, trade-offs among several parameters such as range of motion, strength, speed (actuation frequency), power consumption, control accuracy, system reliability, robustness, force generation and load capacity must be taken into consideration. These parameters strongly depend on the actuation principle. In the following section, the physical parameters influencing the performance, as well as different aspects, of actuators are described.

**FIGURE 28.5** (a) Illustration of an out-of-plane folded silicon microstructure using an external microrobot tool for the assembly manipulation. The three-dimensional silicon structure which is structured in-plane could be fabricated both with surface- and bulk-micromachining techniques. (b) Example of a complex three-dimensional structure assembled by a MEMS-robotic tool. The three-dimensional model shows the University of California, Berkeley, Campanile clock tower having a total height of 1.8 mm above the wafer surface. The microassembly was made manually by the use of the microtool shown in Figure 28.9. (Published with permission and courtesy of Hui Elliot, BSAC-Berkeley, CA.)

### 28.4.1 Arrayed Actuator Principles for Microrobotic Applications

For most microactuators, the force that can be generated and the load the actuator withstands are limited. This constitutes a fundamental drawback for all miniaturization in the robotic field. However, by using MEMS microfabrication it is easy to fabricate large arrays of actuators where the actuators are working together and thereby increasing the total force and load capability. This approach, which takes advantage of lithographic fabrication, also has the potential for integrating electronics on the robot chip to carry out more sophisticated tasks (e.g., autonomous microrobots). The concept of array configuration of microactuators, where the cooperative work of many coordinated simple actuators generates interaction with the macro world, was introduced by Fujita and Gabriel in 1991 [Fujita and Gabriel, 1991]. They called their technique *distributed micromotion systems* (DMMS). The driving schemes for the actuators in the array can be in either a synchronous mode (all actuators are switched on and off at the same time) or an asynchronous mode (different actuators are switched on and off at different times). Most often, the asynchronous mode is favorable as it is more effective and smoother movements can be achieved. Intelligent control of the actuation schemes for the actuators can be achieved by integration of sensors in the system [Suh et al., 1997]. Based on information from these sensors (i.e., object weighing and/or positioning), advanced control of each actuator can be obtained for improved functionality of the micromotion system.

### 28.4.2 Microrobotic Actuators and Scaling Phenomena

Several theoretical reports on the scale effects and the applicability of various actuation principles for microrobotic devices have been published [Trimmer and Jebens, 1989; Dario et al., 1992; Shimoyama, 1995b; Fearing, 1998; Thornell, 1998]. As stated in the previous section, most microactuators generate relatively small forces and strokes, but these could somewhat be increased by array configurations. However, there are large variations between how different actuation principles scale to microscale; some principles scale more favorably than others. Some actuators (for example, piezoelectric- and electrostatic-based actuators) have the advantage of low power consumption and can be driven at high speeds (kHz regime and above).

**TABLE 28.2** Comparison of a Selection of Microactuators for Microrobotic Applications

Actuator Type	Volume ( $10^{-9}$ m <sup>3</sup> )	Speed (s <sup>-1</sup> or rad/s <sup>*</sup> )	Force (N)	Stroke (m)	Power Density (W/m <sup>3</sup> )	Power Consumption (W)	Ref.
			Torque (Nm) <sup>**</sup>				
Linear electrostatic	400	5000	$10^{-7}$	$6 \times 10^{-6}$	200	NA	[Kim et al., 1992]
Rotational electrostatic	$\pi/4 \times 0.5^2 \times 3$	40 <sup>*</sup>	$2 \times 10^{-7**}$		900	NA	[Nakamura et al., 1995]
Rotational piezoelectric	$\pi/4 \times 1.5^2 \times 0.5$	30 <sup>*</sup>	$2 \times 10^{-11**}$		0.7	NA	[Udayakumar et al., 1991]
Rotational piezoelectric	$\pi/4 \times 4.5^2 \times 4.5$	1.1 <sup>*</sup>	$3.75 \times 10^{-3**}$		$90 \times 10^3$	2.5% efficiency	[Bexell and Johansson, 1999; Johansson, 2000]
Linear magnetic	$0.4 \times 0.4 \times 0.5$	1000	$2.9 \times 10^{-6}$	$10^{-4}$	3000	NA	[Liu et al., 1994]
Scratch drive actuator (SDA)	$0.07 \times 0.05 \times 0.5$	50	$6 \times 10^{-5}$	$160 \times 10^{-9}$	300	NA	[Akiyama and Fujita, 1995]
Rotational magnetic	$2 \times 3.7 \times 0.5$	150 <sup>*</sup>	$10^{-6**}$		$3 \times 10^3$	0.002% efficiency	[Teshigahara et al., 1995]
Rotational magnetic	$10 \times 2.5 \times ??$	20 <sup>*</sup>	$350 \times 10^{-**}$		$3 \times 10^4$	8% efficiency	[Stefanni et al., 1996]
EAP (Ppy–Au bimorph)	$1.91 \times 0.04 \times 0.00008$	0.2	$1.25 \times 10^{-3}$		$1.4 \times 10^4$	0.2% efficiency	[Smela et al., 1999]
Thermal polysilicon heatuator	Approx. $0.27 \times 0.02 \times 0.002$	2	$1/96 \times 30 \times 10^{-3}$	$3.75 \times 10^{-6}$	$2 \times 10^4$	NA	[Kladitis et al., 1999]
Thermal bimorph polyimide	Approx. $0.4 \times 0.4 \times 0.01$	1–60	$69 \times 10^{-6}$ N/mm <sup>2</sup>	$2.6–9 \times 10^{-6}$	$<10^4$	$\approx 16.7 \times 10^{-3}$	[Suh et al., 1997]
PGV-joint actuator	$0.75 \times 0.6 \times 0.03$	3–300	$10^{-3}$	$10–150 \times 10^{-6}$	$10^5$	200 mW; 0.001% efficiency	[Ebefors, 2000]

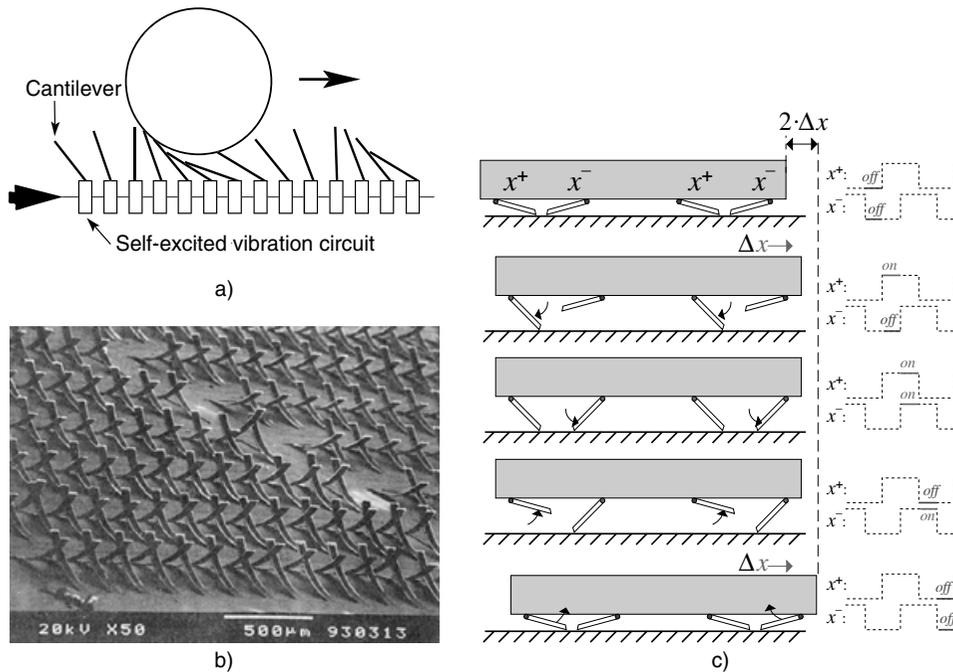

\* A rotational actuator that has speed measured in rad/s compared to a linear actuator (s<sup>-1</sup>).

\*\* It is impossible to separate the torque = force  $\times$  stroke into force and stroke for a rotational actuator; therefore, only the torque is given.

However, they generally show relatively low force capacity and small strokes, while others such as magnetic and thermal actuation principles have the potential to exert large forces and displacements when the driving speed is the limiting factor. The thermal and magnetic actuator principles rely on significant currents and power levels which may require forced cooling. During the design of a microrobotic device, the trade-offs among range of motion, strength, speed (actuation frequency), power consumption, control accuracy, system reliability, robustness, load capacity, etc. must be taken into consideration. In an extensive actuator review focusing on microrobotics [Fearing, 1998], the general conclusion was that actuators generating large strokes and high forces are best suited for microrobotics applications. The speed criteria are of less importance as long as the actuation speed is in the range of a couple of hertz and above. Table 28.2 provides some data on stroke and force generation capability as well as power densities and efficiencies for a small selection of actuators suitable for microrobotic applications.

### 28.4.3 Design of Locomotive Microrobot Devices Based on Arrayed Actuators

Living organisms very often offer good models for designing microrobotic systems [Ataka et al., 1993; Zill and Seyfarth, 1996]. Mimicry of a six-legged insect's gait [Zill, 1996] has been proposed for the design of multilegged robots implemented using microfabrication techniques [Kladitis, 1999]. The first

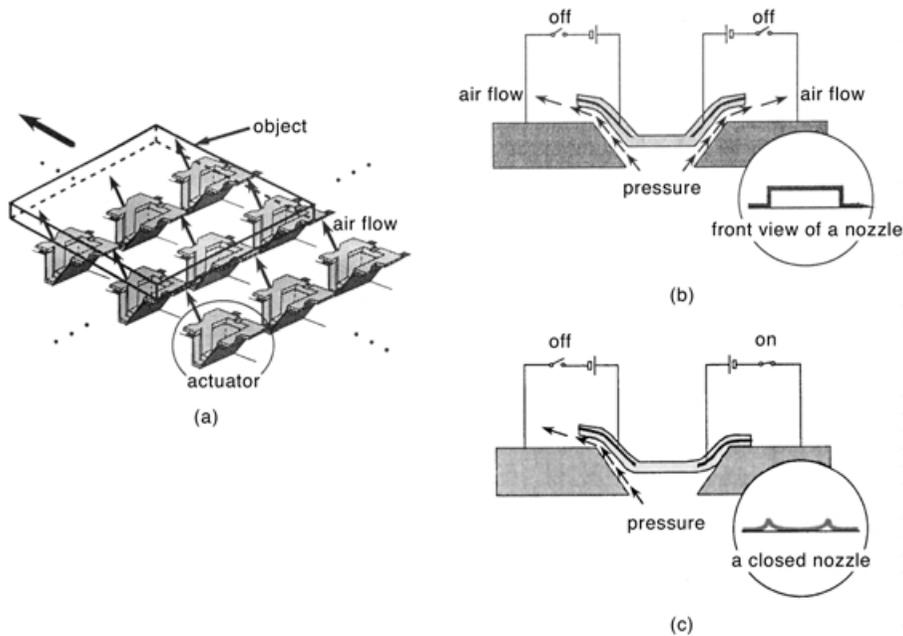

**FIGURE 28.6** The ciliary motion principle used in most contact-based microrobotic systems. (a) Conveyance system used in nature to convey object. The cantilevers (ciliary hair) are actuated by a certain phase shift. (b) SEM photograph of the first microconveyer system based on the ciliary motion principle using bimorph polyimide legs. (Illustrations published with permission and courtesy of H. Fujita, University of Tokyo, Japan.) (Note: A video of the CMS microconveyance systems is available at <http://www.s3.kth.se/mst/research/dissertations/thorbjornedoc/multimedia.html>.) (c) A two-phase CMS for a walking microrobot platform when implemented using MEMS technology for out-of-plane working three-dimensional actuators. By using two rows of legs it is possible to steer in the forward-backward, left-right and up-down directions. More details of the robot are given in Section 28.5.3.1. (Note: A video animation on the dynamic, asynchronous operation of arrayed out-of-plane erected legs for micro robotics is available at <http://www.s3.kth.se/mst/research/dissertations/thorbjornedoc/multimedia.html>, Figure 47.)

proposed [Benecke, 1988] and realized [Ataka et al., 1993] MEMS contact conveyance transportation system was based on the ciliary motion principle adopted from nature. The principle for a *ciliary motion system* (CMS) is illustrated in Figure 28.6. The CMS principle relies on an asynchronous driving technique which requires at least two spatially separated groups of actuators turned on and off at different times, alternately holding and driving the device. Higher speeds and smoother motions can be achieved with such asynchronous driving than with synchronous driving.

For locomotive microrobotic applications such as conveyance systems and walking robots it is essential to have actuators that can both generate forces to lift an object or the robot itself out from the plane (i.e., to avoid surface sticking) and also generate forces that cause in-plane movements. Two fundamental principles exist, the first being contact-free (CF) systems. Here, different force fields, such as electrostatic, magnetic or pneumatic forces, are used to create a cushion to separate the object from the surface, as illustrated in Figure 28.7. To drive the device in the in-plane direction, these force fields need to have a direction dependence to force the device forward (i.e., directed air streams for a pneumatic system [Hirata et al., 1998] or the Meissner effect for levitation and orthogonal Lorentz force for driving a magnetic actuator system [Kim et al., 1990]).

The second fundamental principle is contact (C) systems, where a structure is in contact with the moving object (e.g., legs for walking), as illustrated in Figure 28.6c). To avoid surface stiction, these structures must create out-of-plane movements. A review of different techniques available to create such

**FIGURE 28.7** Electrostatic-controlled pneumatic actuators for a one-dimensional contact-free conveyance system. (a) Concept for the arrayed pneumatic conveyer (i.e., contact-free operation). (b) and (c) Mechanism for flow control by electrostatic actuation of nozzle when (b) the electrostatic nozzle is in the normal situation (off) and (c) when voltage is applied to one electrode (on). (Illustration published with permission and courtesy of H. Fujita, University of Tokyo.)

three-dimensional actuators have been presented [Ebefors, 2000]. Most of these techniques could be arranged in array configurations for distributed micromotion systems (DMMS).

For out-of-plane actuators using an external force field it is difficult to control each individual actuator in a large array of folded structures. Therefore, a synchronous jumping mode is used to convey the objects or move the device itself. This jumping mode involves quick actuation of all the actuators simultaneously, which forces the object to jump. When the object lands on the actuators (located in their off position), the object has moved a small distance and the actuators can be actuated again to move (walk or convey) further [Liu et al., 1995].

A critical aspect of large distributed micromotion systems based on arrayed actuators and distributed (or collective) actuation is the problem associated with the need for the very high yield of the actuators [Ruffieux and Rooij, 1999]. Just one nonworking actuator could destroy the entire locomotion principle. Therefore, special attention must be paid to achieve high redundancy by parallel designs wherever possible. These aspects will be further addressed in Section 28.5.3.

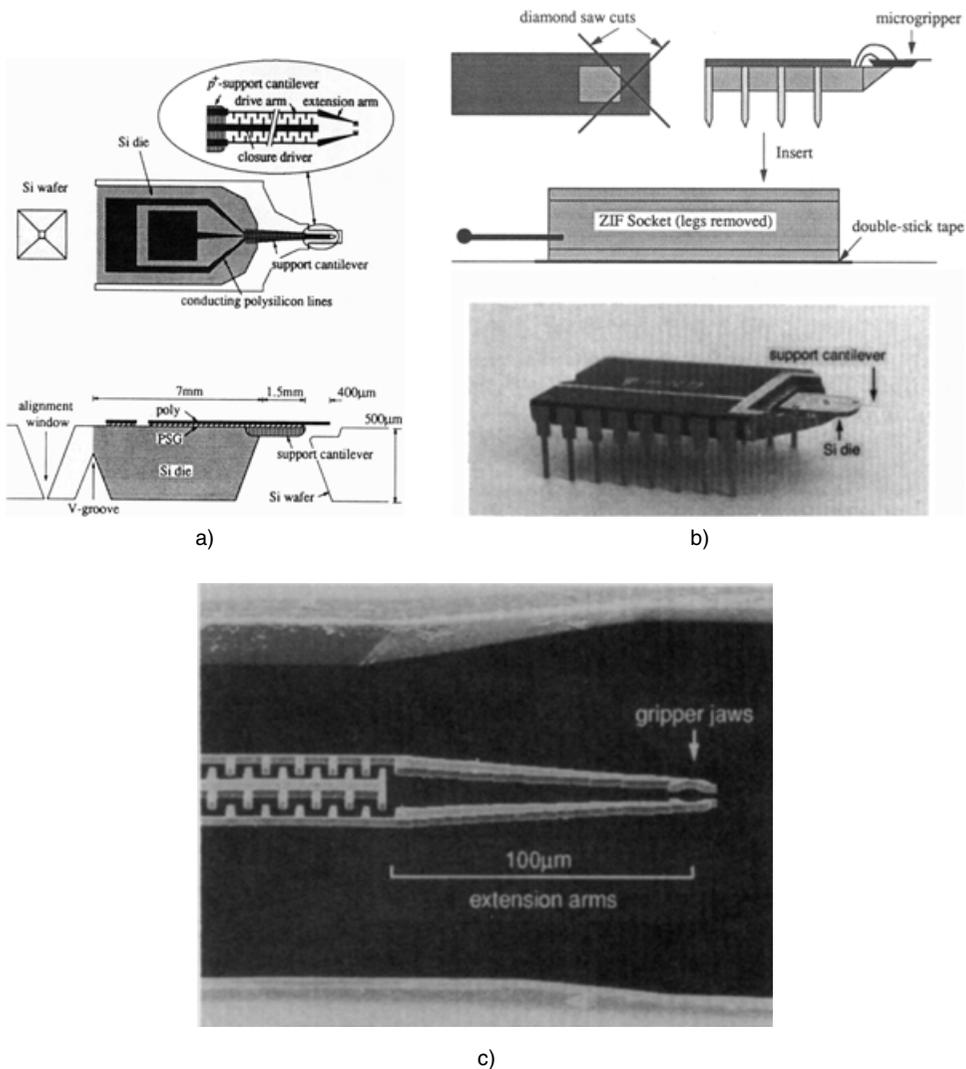

## 28.5 Microbotic Devices

As pointed out in Section 28.2, a microbotic device can be either a simple catheter with a steerable joint (see Figure 28.2a), or a complex autonomous walking robot equipped with various microtools as in Figure 28.2o). Between these two extremes one finds microgrippers and microtools of various kinds, as well as microconveyers and walking microbot platforms. Each of these three microbotic devices will be presented more in detail in the following discussion. Section 28.6 describes more complex microbotic systems where both microtools and actuators for locomotion are integrated to form so-called microfactories or desk-to-manipulation stations. Also, multirobot systems and communication between microbots in such multirobot systems will be discussed.

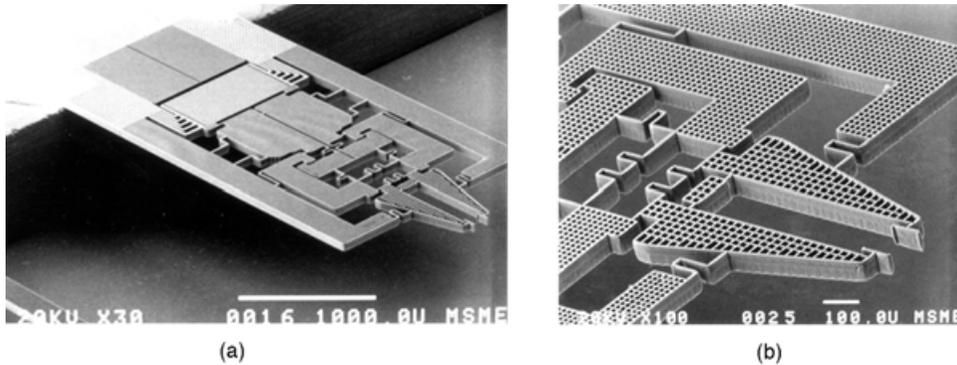

## 28.5.1 Microgrippers and Other Microtools

The first presented microrobotic device was based on in-plane electrostatic actuation [Kim et al., 1992]. This microgripper had two relatively thin gripping arms (i.e., thin-film deposited polysilicon) as shown in Figure 28.8. Other microgrippers based on quasi-three-dimensional structures with high-aspect-ratios fabrication techniques (i.e., beams perpendicular rather than parallel to the surface) have also been presented [Keller and Howe, 1995; 1997] (see Figure 28.9). These kinds of grippers, so-called over-hanging tools, are formed by etching away the substrate under the gripper.

One critical parameter for the in-plane technique is how to achieve actuators with large displacement and force generation capabilities. Thermal actuators are known for their ability to generate high forces. A thermal actuator made from a single material would be easy to fabricate, but the displacement due to thermal expansion of a simple beam, for example, is quite small. This is a general drawback for in-plane

**FIGURE 28.8** (a) Schematics of the microgripper unit (top and cross-sectional view). (b) Schematic showing gripper packaging and electrical access and a photograph of the packaged gripper. (c) SEM photograph showing a close-up of the gripper jaws and the comb-drive structures and extension arms. (Illustration published with permission and courtesy of C.-J. Kim, UCLA.)

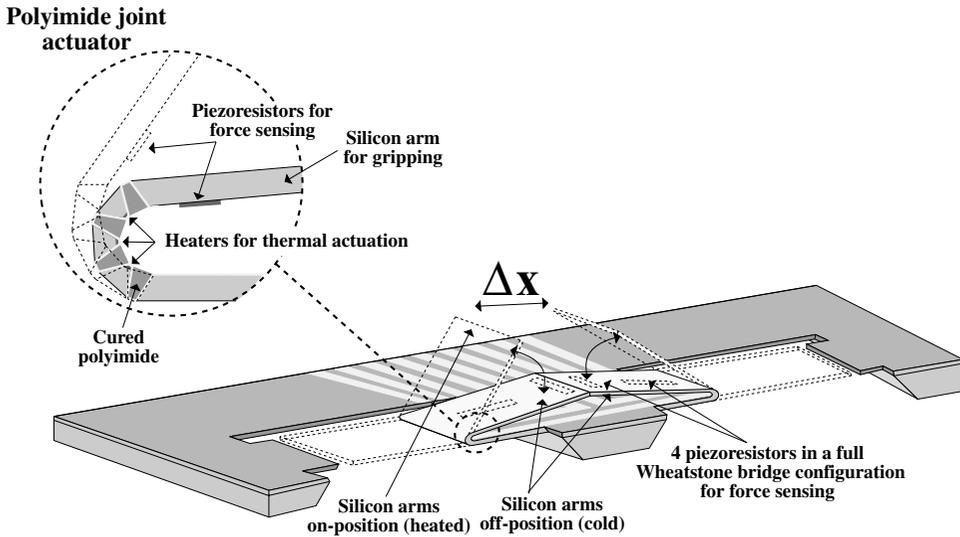

**FIGURE 28.9** Photograph of fabricated HEXSIL tweezers. (a) Overview of the overhanging microtweezers with a compliant linkage system. (b) Close-up of the 80- $\mu\text{m}$ -tall HEXSIL tweezers. The tip displacement between the closed and open position is typically 40  $\mu\text{m}$  with a time constant  $<0.5$  s for a typical actuation power of 0.5 A at 6 V. (Published with permission from MEMS Precision Instruments, Berkeley, CA; courtesy of C. Keller.)

actuators that occurs independently of the fabrication technique used. However, by using mechanical leverage, large displacements can be obtained, as was demonstrated by Keller and Howe (1995). They used a replication and micromolding technique, named HEXSIL, to fabricate thermally actuated microtweezers made from nickel and later in polysilicon [Keller and Howe, 1997]. In the HEXSIL process [Keller, 1998a] the mold is formed by deep trench etching in the silicon substrate. A sacrificial layer of oxide is deposited in the silicon mold which is then filled with deposited polysilicon. Then the polysilicon structure is released from the mold by sacrificial etching of the oxide. Afterwards, the mold can be reused by a new oxide and polysilicon deposition process. One advantage of this process is the ability to make thick (100  $\mu\text{m}$  or greater) polysilicon structures (i.e., quasi-three-dimensional structures) on which electronics can be integrated. Figure 28.9b shows a close-up of the leverage design for the HEXSIL microtweezer; a large beam is resistively heated by the application of current, and subsequently expansion causes other beams in the link system to rotate and open the tweezer tips. When cooled, the contraction of the thermal element closes the tweezers.

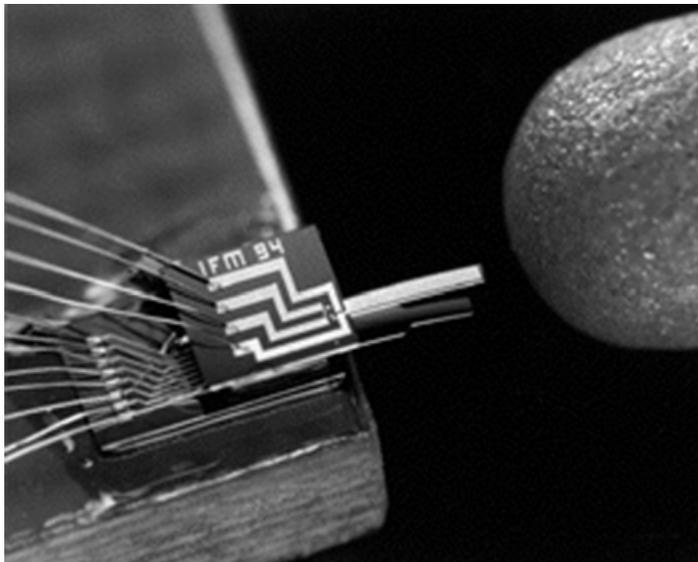

Leverage and linkage systems (sometimes combined with gears for force transfer) are useful techniques for obtaining large displacements or forces that can be used for thermal actuation as well as electrostatic comb-drive actuators [Rodgers et al., 1999]. Several publications on design optimization schemes for various leverage techniques applied to thermal actuators (so-called compliant microstructures) have been presented [Jonsmann et al., 1999]. Another way to achieve a leverage effect is to use clever geometrical designs for single material expansion. One such method is the polyimide-filled V-groove (PVG) joint technology shown in Figure 28.10. The PVG joint technique has also been used for microconveyers and walking microrobots, as will be described in Sections 28.5.2 and 28.5.3. The purpose of the PVG joint microgripper in Figure 28.10 is easy integration with a walking microrobot platform.

Several publications on LIGA-based microgrippers have been presented. The reason for using LIGA is to get quasi-three-dimensional structures (i.e., thick structures) similar to the HEXSIL tweezers in Figure 28.9. The LIGA process has also been used to produce single material (unimorph) in-plane thermal actuators for micropositioning applications. Guckel et al. (1992) presented an asymmetric LIGA structure with one “cold” and one “hot” side to generate large displacements (tenths of a millimeter) with relatively low power consumption, as illustrated in Figure 28.20a). More recently, this approach was used by Bright et al. [Comotis and Bright, 1996] for surface micromachined polysilicon thermal actuators. With this in-plane actuator they have successfully fabricated over-hanging microgrippers.

As an alternative to single-material expansion actuators, bimorph structures could also be used for out-of-plane acting gripping arms [Greitmann and Buser, 1996]. A bimorph microgripper for automated handling of microparts is shown in Figure 28.11. This device consists of two gripping arm chips assembled

**FIGURE 28.10** Concept of a microgripper fabricated by polyimide V-groove joints [Ebefors, 2000]. The polyimide in the V-grooves expands due to heating and the gripping arms are opened. Self-assembling out-of-plane rotation of the arms as well as the leverage effect for single material expansion are accomplished by the well-controlled geometrical shape of the V-groove. Polysilicon resistors are used both as resistive heaters and as strain gauges for force sensing.

**FIGURE 28.11** Photograph of a microgripper based on bimorph thermal actuation and piezoresistive tactile sensing. (From Greitmann, G., and Buser, R. (1996) *Sensors and Actuators A*, 53(1–4), 410–415. With permission.)

together. Each gripper arm has integrated heating resistors for actuation of the bimorph and tactile piezoresistors for force sensing.

Several different approaches to obtain three-dimensional microgrippers working out-of-plane like the ones in Figures 28.10 and 28.11 exist. One commonly used approach is use of the surface-micromachined polysilicon microhinge technology shown in Figure 28.3a–e. Such microhinges have been used both for microgrippers and for articulated microrobot components [Pister et al., 1992; Yeh et al., 1996].

One major drawback of these microgrippers (mainly based on thermal or electrostatic actuation) is found in biological applications. Microgrippers based on thermal, magnetic or high-voltage electric actuation could easily kill or destroy biological and living samples. The pneumatic microgripper presented by Kim et al. [Ok et al., 1999] avoids such problems. An alternative to heating grippers (such as the ones shown in [Figures 28.10](#) and [28.11](#), which require relatively high heating temperatures) is the use of shape memory alloy (SMA) actuators. Microgrippers based on SMA often require lower temperatures than thermally actuated bimorph or unimorph grippers. SMA-based three-dimensional microgrippers have been used to grip (clip) an insect nerve for recording the nerve activity of various insects [Takeuchi and Shimoyama, 1999].

In the biotechnology field—for example, the growing area of genomics and proteomics—microtools for manipulation of single cells are of major importance. In particular, massive parallel single-cell manipulation and characterization by the use of microrobotic tools are very attractive. In this type of application, the microgrippers usually must operate in aqueous media. Most of the microgrippers presented so far in this review cannot operate in water because of electrical short-circuiting, etc. One possible solution is to use conductive polymers. Such conductive polymers, which undergo volume changes during oxidation and reduction, are often referred to as electroactive polymers (EAPs) or micromuscles. These kinds of micromuscles have been used as joint material for microrobotic arms for single-cell manipulation devices [Smela et al., 1995; Jager, 2000a,b]. [Figure 28.12](#) describes the fabrication of a microrobot arm based on a polypyrrole (PPy) conductive polymer. During electrochemical doping of PPy, volume changes take place which can be used to achieve movement of micrometer-size actuators. The actuator joints consist of a PPy and gold bimorph structure, and the rigid parts between the joints consist of benzocyclobutene (BCB). The conjugated polymer is grown electrochemically on the gold electrode, and the electrochemical doping reactions take place in a water solution of a suitable salt. The voltages required to drive the motion are in the range of a few volts.

One of the many experiments conducted with the various robot arms fabricated with the PPy micromuscles is shown in [Figure 28.13](#). The drawback of microrobotic devices based on the conductive polymer hinge (or “micromuscles”) is that they cannot operate in dry media.

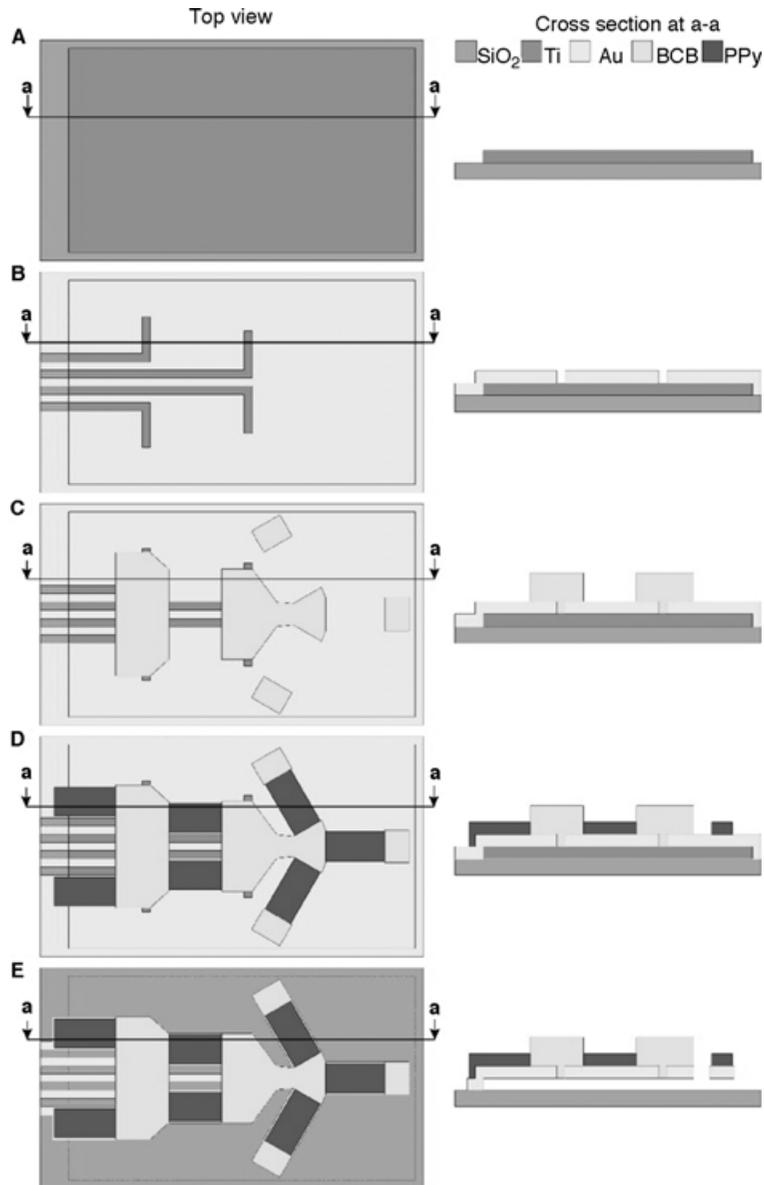

## 28.5.2 Microconveyers

Recently, a variety of MEMS concepts for realization of locomotive microrobotic systems in the form of microconveyers have been presented [Riethmüller and Benecke, 1989; Kim et al., 1990; Pister et al., 1990; Ataka et al., 1993a,b; Konishi and Fujita, 1993; 1994; Goosen and Wolffenbuttel, 1995; Liu et al., 1995; Böhringer et al., 1996; 1997; Nakazawa et al., 1997; 1999; Suh et al., 1997; 1999; Hirata et al., 1998; Kladitis et al., 1999; Ruffieux and Rooij, 1999; 2000; Smela et al., 1999; Ebefors et al., 2000]. The characteristics for some of these devices are summarized in [Table 28.3](#), where the microconveyers are classified in two groups: contact-free or contact systems, depending on whether the conveyer is in contact with the moving object or not, and synchronous or asynchronous, depending on how the actuators are driven. Examples of both contact and contact-free microconveyance systems were shown in [Figures 28.6](#) and [28.7](#), respectively.

Contact-free systems have been realized using pneumatic, electrostatic or electromagnetic forces to create a cushion on which the mover levitates. Magnetic levitation can be achieved by using permanent magnets, electromagnets or diamagnetic bodies (i.e., a superconductor). The main advantage of the contact-free systems is low friction. The drawback of these systems is their high sensitivity to the cushion thickness (i.e., load dependent), while the cushion thickness can also be quite difficult to control. Also, this kind of conveyance system often has low load capacity.

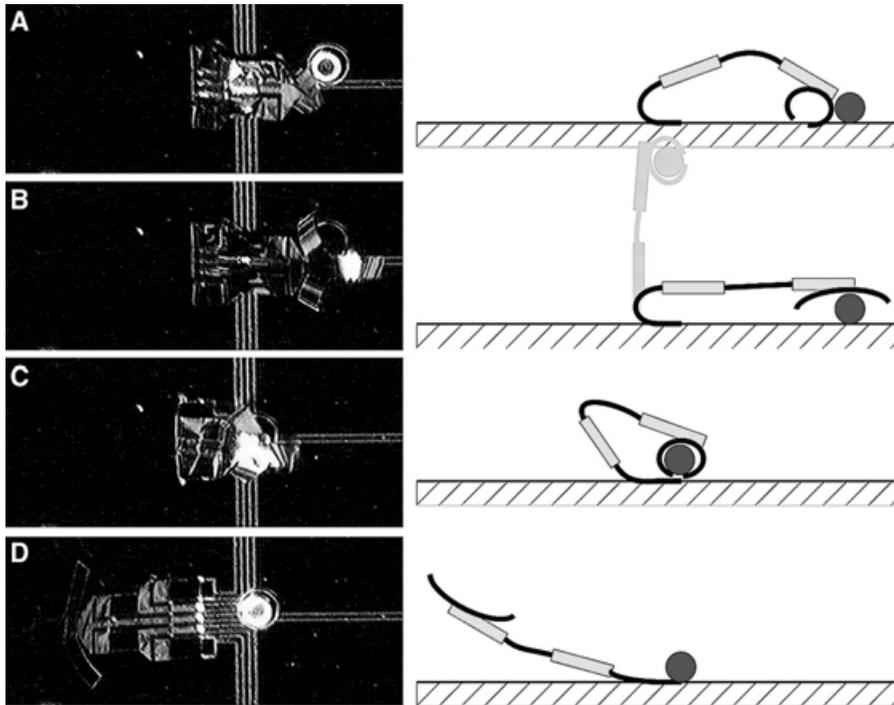

Systems where the actuators are in contact with the moving object have been realized based on arrays of moveable legs erected from the silicon wafer surface. The legs have been actuated by using different principles such as thermal, electrostatic and magnetic actuation. Both synchronous driving [Liu et al., 1995] and the more complex, but also more effective, asynchronous driving modes have been used.

The magnetic [Nakazawa et al., 1997; 1999] and pneumatic [Hirata et al., 1998] actuation principles for contact-free conveyer systems have the disadvantage that they require a specially designed magnet

**FIGURE 28.12** Schematic drawing of the process steps for fabricating microrobotic arms (in this case, an arm with three fingers arranged in a  $120^\circ$  configuration) based on hinges (micromuscle joints) consisting of PPy(DBS)/Au bimorph structures. (a) Deposition and patterning of a sacrificial Ti layer. (b) Deposition of a structural Au layer and etching of the isolating slits. (c) Patterning of BCB rigid elements. (d) Electrodeposition of PPy (conductive polymer). (e) Etching of the final robot and electrode structure and removal of the sacrificial layer. Each microactuator is  $100\ \mu\text{m} \times 50\ \mu\text{m}$ . The total length of the robot is  $670\ \mu\text{m}$ , and the width at the base is either  $170$  or  $240\ \mu\text{m}$  (depending on the wire width). (Published with permission and courtesy of E. Jager, LiTH-IFM, Sweden.)

mover or slider which limits its usefulness. With a contact system based on thermal actuators it is possible to move objects of various kinds (nonmagnetic, nonconducting, unpatterned, unstructured, etc.); however, the increased temperature of the leg in contact with the conveyed object may be a limitation in some applications. The contact-free techniques have been developed mainly to meet the necessary criteria for a cleanroom environment, where a contact between the conveyer and the object may generate particles that would then serve to restrict its applicability for conveyance in clean rooms.

**FIGURE 28.13** (a)–(d) Sequence of pictures (left) showing the grabbing and lifting of a 100- $\mu\text{m}$  glass bead and schematic drawings (right) of the motion. In this case, the arm has three fingers, placed 120° from each other (see Figure 28.12). The pictures do not illustrate the fact that the bead is actually lifted from the surface before it is placed at the base of the robot arm. This is illustrated in the second sketch on the right where the lifting stage is shown in gray. (Published with permission and courtesy of E. Jager, LiTH-IFM, Sweden.) (Note: Video sequences showing the full movement of various robot arms for the different experiments are available at <http://www.sciencemag.org/feature/data/1050465.shl> and [http://www.ifm.liu.se/Applphys/ConjPolym/research/micromuscles/CPG\\_micromuscles.html](http://www.ifm.liu.se/Applphys/ConjPolym/research/micromuscles/CPG_micromuscles.html).)

A microconveyor structure based on very robust polyimide V-groove actuators has been realized [Ebefors et al., 2000]. This conveyor is shown in Figure 28.14. In contrast to most of the previously presented microconveyance systems, the PVG joint approach has the advantage of producing robust actuators with high load capacity. Another attractive feature of this approach is the built-in self-assembly by which one avoids time-consuming manual erection of the conveyor legs out of plane. Some of the conveyers listed in Table 28.3 require special movers (e.g., magnets or sliders with accurate dimensions). The PVG joint conveyor solution is more flexible because one can move flat objects of almost any material and shape. The large actuator displacement results in a fast system which is less sensitive to the surface roughness of the moving object. By using individually controlled heaters in each actuator, an efficient asynchronous driving mode has been realized, which also allows a parallel design giving relatively high redundancy for actuator failure. The first experiments with the conveyor showed good performance, and one of the highest reported load capacities for MEMS-based microconveyers was obtained. The maximum load successfully conveyed on the structure had a weight of 3500 mg and was placed on a 115-mg silicon mover, as shown in Figure 28.14d. Conveyance velocities up to 12 mm/s have been measured. Both forward–backward and simple rotational conveyance movements have been demonstrated. The principle for rotating an object by a two-row conveyor is shown in Figure 28.14a. The lifetime of the PVG joints actuator exceeds  $2 \times 10^8$  load cycles and so far no device has broken due to fatigue.

**TABLE 28.3** Overview of Some Microconveyance Systems

Principle <sup>a</sup>	Maximum Velocity	Moved Object/Load Capacity	Length per Stroke/Frequency	No. of Actuators/Size	Ref.
CF: pneumatic air bearing (for low-friction levitation)+ electrostatic force for driving	Slow	Flat Si pieces/ <1.8 mg	100–500 μm/ max at 1–2 Hz	Not specified	[Pister et al., 1990]

FIGURE 28.14 Continued.

The most sophisticated microrobotic device fabricated to date is the two-dimensional microconveyer system with integrated CMOS electronics for control which have been fabricated by Suh et al. (1999). The theories on programmable vector fields for advanced control of microconveyance systems presented by Böhringer et al. (1997) were tested on this conveyer. Several different versions of these conveyers have been fabricated throughout the years [Suh et al., 1997; 1999]. All versions are based on polyimide thermal bimorph ciliary microactuator arrays, as shown in [Figure 28.15](#).

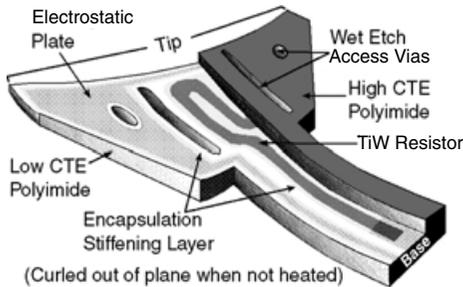

### 28.5.3 Walking MEMS Microrobots

In principle, most of the microconveyer structures described in the previous section could be turned upside down to realize locomotive microrobot platforms. For contact systems, that means that the device will have legs for walking or jumping. The contact-free systems relying on levitation forces will “float” over the surface rather than walk. Such systems seem more difficult to realize than the contact-operating robots. The focus for the rest of this section is, therefore, on contact microrobot systems for walking.

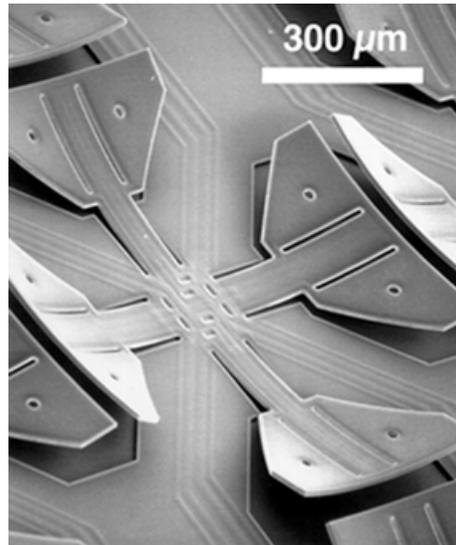

Although it seems straightforward to turn a microconveyer upside down, most of the existing conveyers do not have enough load capacity to carry their own weight. Further, there are problems on how to supply the robot with the required power. As illustrated in [Figure 28.16](#), power supply through wires may influence the robot operation range, and the stiffness of the wires may degrade the controllability too much. On the other hand, telemetric or other means of wireless power transmission require complex electronics on the robot. Because many actuators proposed for microrobotics require high power consumption, the limited amount of power that can be transmitted through wireless transmission is a big limitation for potential autonomous robot applications. To avoid the need for interconnecting wires, designs based on solar cells have been proposed, as have low-power-consuming piezoelectric actuators [Ruffieux and Rooij, 1999; Ruffieux, 2000], electrostatic comb-drives [Yeh et al., 1996] or inch-worm actuators [Yeh and Pister, 2000] suited for such wireless robots. For wire-powered robots, a limited amount of wires is preferable, which implies that simple leg actuation schemes (i.e., on-off actuation as used for the walking robot platform in [Figure 28.6c](#)) are required if complex onboard steering electronics are to be avoided. Several proposals for making totally MEMS-based microrobots include the possibility of locomotion (e.g., walking) powered with or without wires.

#### 28.5.3.1 Examples of Walking Microrobots Designs

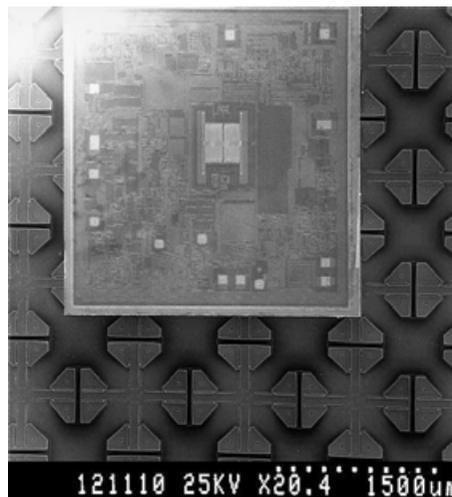

Several different principles used to actuate the different legs on a walking microrobot have been proposed, most of them mimicking principles used in nature. Some of the most feasible principles for walking MEMS microrobot platforms are listed below:

(a)

(b)

(c)

**FIGURE 28.15** (a) Principal of operation of an organic microactuator (bimorph polyimide legs) using thermal and electrostatic forces for actuation. Half of the upper polyimide and silicon nitride encapsulation/stiffening layer have been removed along the cilium's axis of symmetry to show the feature details. (b) SEM photograph of a polyimide cilia motion pixel. Four actuators in a common center configuration make up a motion pixel. Each cilium is  $430\ \mu\text{m}$  long and bends up to  $120\ \mu\text{m}$  out of the plane. (c) Micro cilia device moving an ADXL50 accelerometer chip. (d) The CMS-principle for two-dimensional conveyance (compare Figure 28.6). The state of the four actuators (north, east, west, south) is encoded with small letters (e.g., n) for down, and capital letters (e.g., S) for up. (e)–(h) Images (video frames) of a  $3 \times 3\text{-mm}^2$  IC chip rotating from a rotation demonstration. **FIGURE 28.17** (Color figure follows p. 12.26.) Photograph of the microrobot platform, used for walking, during a load test. The load of 2500 mg is equivalent to maximum 625 mg/leg (or more than 30 times the weight of the robot itself). The power supply is maintained through three 30- $\mu\text{m}$ -thin and 5- to 10-cm-long bonding wires of gold. The robot walks using the asynchronous ciliary motion principle described in Figure 28.6(c). The legs are actuated using the polyimide V-groove joint technology described in Figure 28.10. (Photograph by P. Westergård and published with permission.) (Note: Videos of various experiments performed using the microrobot shown here are available at [http://www.s3.kth.se/mst/research/gallery/microrobot\\_video.html](http://www.s3.kth.se/mst/research/gallery/microrobot_video.html).)

**FIGURE 28.18** The rotational leg walking principle. A few hundred cells (shown in the right picture) are arranged into a hexagonal array, inside a triangular grid frame that provides stiffness and room for interconnection. The simplest form of gait requires two phases so that half the actuators are in contact with the ground, where friction transmits their motion to the device, while the other half is preparing for the next step (compare to the CMS technique depicted in Figure 28.6). The bottom left figure illustrates the serial interconnections of the actuator resulting in six independent groups of beams (From Ruffieux, D. et al., in *Proc. IEEE 13th Int. Conf. on Micro Electromechanical Systems (MEMS '2000)*, pp. 662–667, 2000. With permission.)

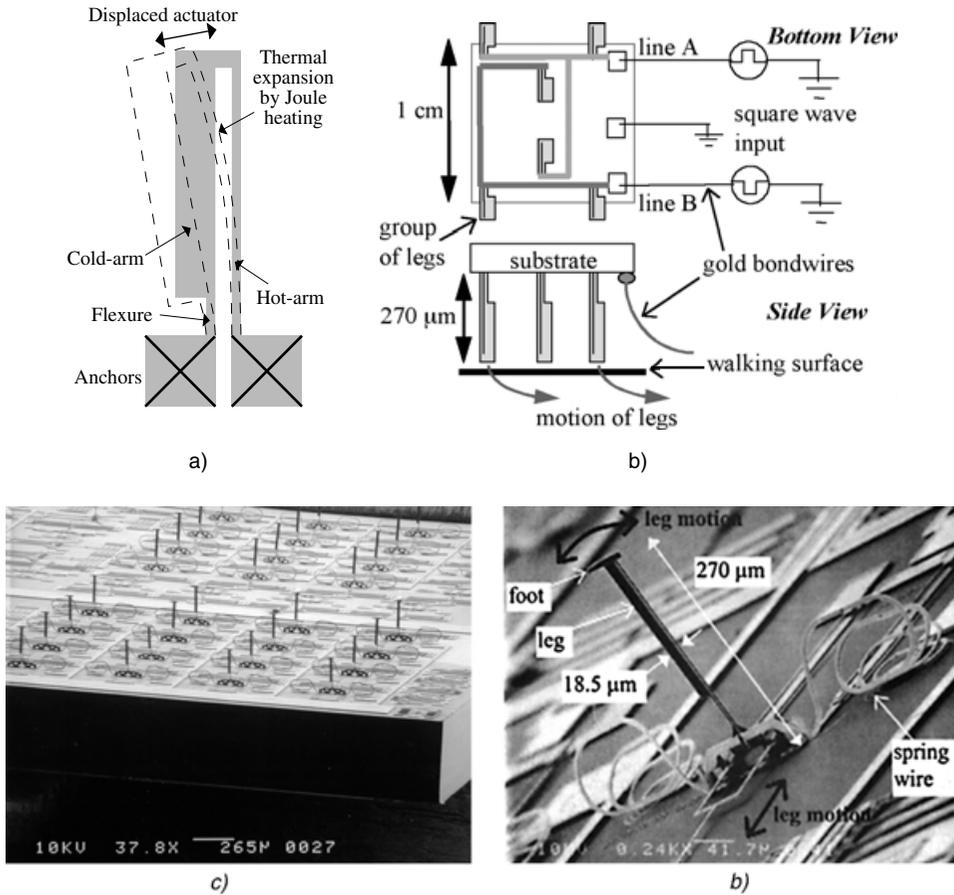

- *Ciliary motion* was used by Ebefors et al. (1999) for eight-legged robots, as illustrated in Figures 28.6 and 28.17.
- *Elliptical leg movements* adopted from the animal kingdom have been proposed by Ruffieux et al. [Ruffieux and Rooij, 1999; Ruffieux, 2000] and are illustrated in Figure 28.18. Similar to this concept is the principle used by Simu and Johansson (2001). Their microrobot concept consists of both a walking and a microtool unit for highly flexible micromanipulation. Instead of using thin-film piezolayers and silicon legs as did Ruffieux et al., Johansson and Simu have made robot

**FIGURE 28.19** First version of the microrobot prototype based on surface micromachined microhinges for joints; each leg has three degrees of freedom and is comprised of two 1.2-mm-long, rigid polysilicon links and electrostatic step motors for movement (not included in the SEM-photo). (Bottom) Concept for a new design based on a solar-powered silicon microrobot. Various components can be made separately and then assembled. Surface micromachined hinges are used for folding the legs (see Figures 28.3d and e). Each leg has two links, and each link will be actuated by an inchworm motor [Yeh and Pister, 2000]. (Published with permission and courtesy of K. Pister, BSAC-Berkeley, CA.)

legs in a solid, multilayer, piezoceramic material mounted on a glass body [Simu and Johansson, 1999] (see Figure 28.22).

- Gait mimicry of *six-legged* insects (similar to that of a crab [Zill and Seyfarth, 1996]) has been proposed by several research groups—for example, the six-legged microrobot by Yeh et al. [Yeh et al., 1996; Yeh and Pister, 2000] and the multilegged microrobot prototype by Kladitis et al. [Kladitis, 1999]. These concepts are illustrated in Figures 28.19 and 28.20.
- *Inch-worm* robots [Thornell, 1998] or *slip-and-stick* robots [Breguet and Renaud, 1996] that mimic an inch-worm or caterpillar are attractive microrobot walking principles, as these techniques take advantage of the frictional forces rather than trying to avoid them. The scratch-drive actuator principle [Mita et al., 1999] works according to this principle by firmly attaching to the surface only half of the robot or actuator body, then extending the spine (or middle part) of the body before anchoring the other half, releasing the first grip, shortening the spine, swapping the grip, and so on in a repeatable forward motion.
- Vibration fields and resonating thin-film silicon legs with polyimide joints have been used by Shimoyama et al. [Yasuda et al., 1993], as illustrated in Figure 28.21.

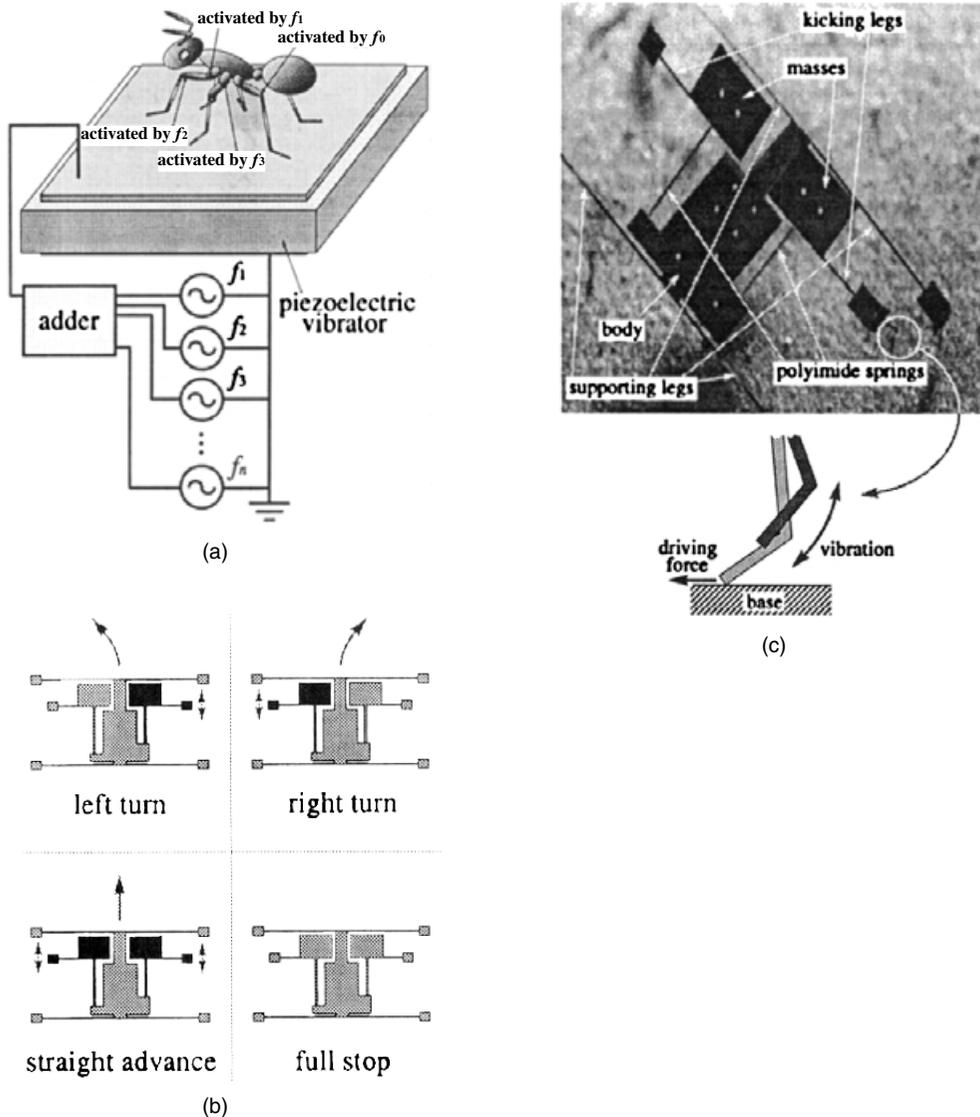

**FIGURE 28.20** (a) Schematic illustration of a single-material asymmetric thermal actuator for in-plane actuation (also called “heatuator”). The actuator structure was originally made of nickel in a LIGA process, although surface-micromachined polysilicon structures have also been used. (b) An out-of-plane folded heatuator for microrobotic applications. (c) Photograph of the microrobotic device in a conveyance mode (belly up). (d) Close-up of one of the heatuator legs photographed out of plane. (Part (a) from Guckel, H. et al. (1992) in *Technical Digest, Solid-State Sensor and Actuator Workshop*, pp. 73–75. With permission. Part (b) from Kladitis, P. et al. (1999) in *Proc. IEEE 12th Int. Conf. on Micro Electro Mechanical Systems (MEMS '99)*, pp. 570–575. With permission. Photographs courtesy of P. Kladitis and V. Bright, MEMS Group at the University of Colorado at Boulder.)

Because friction in many cases poses a restriction on microrobots due to their small size, solutions that take advantage of this effect (e.g., inch-worm robots) rather than trying to avoid it are the best suited for microgait. This trend can also be seen in the evolution of micromotors for microrobotic and other applications. Currently, many researcher try to avoid bearings or sliding contacts in their motors and instead make use of friction in wobble and inch-worm motors [Yeh and Pister, 2000] or actuators with flexible joints [Suzuki et al., 1992; Ebefors et al., 1999] without the drawback of wearing out.

The main problem associated with the fabrication of silicon robots is to achieve enough strength in the moveable legs and in the rotating joints. Most efforts to realize micromachined robots utilize surface micromachining techniques which results in relatively thin and fragile legs. Pister et al. [Yeh et al., 1996] have proposed the use of surface micromachined microhinges for joints, poly-Si beams for linkage to the triangular polysilicon legs and linear electrostatic stepper motor actuation for the realization of a microrobot, as illustrated in [Figure 28.19](#).

A similar approach for walking microrobots was used by Kladitis et al. (1999). They also used the microhinge technique to fold the leg out of plane, but instead of area-consuming comb drives for

**FIGURE 28.21** (a) The principle for a selective power supply through a vibrating energy field [Yasuda et al., 1993]. The microrobot has several resonant actuators with mutually exclusive resonance frequencies. The power and control signals to the robot are obtained via the vibrating table. (b) The four possible kinds of actions. (c) Photograph of the  $1.5 \times 0.7\text{-mm}^2$  surface micromachined microrobot. The legs have different spring constants and masses, resulting in different resonance frequencies. Polyimide is used for the soft springs and the polyimide joints are used for the erected leg. (From Yasuda et al. (1993) *Technical Digest, 7th Int. Conf. on Solid-State Sensors and Actuators* (Transducers '93), pp. 42–45, June 7–10, Yokohama, Japan. © 1993 IEEE/ASME. With permission.)

actuation they used the thermal “heatuator” principle integrated in the leg, as illustrated in Figure 28.20. To further improve the robustness and load capacity of their robot, they used 96 legs arranged in six groups instead of using a six-legged robot. However, that robot structure could “only” withstand a load four times the dead weight of the robot. That was not enough to obtain locomotive walking but was high enough for conveyance applications.

For both microrobots described above, which were based on surface micromachined polysilicon microhinges, the polysilicon legs were manually erected out of plane. The use of the microhinge technique

may cause problems because of wear after long-term actuation. Shimoyama et al. [Suzuki et al., 1992; Miura et al., 1995] introduced the concept of creating insect-like microrobots with exoskeletons made from surface-micromachined polysilicon plates and rigid polyimide joints that have low friction and therefore lower the risk for wearing out. These microrobots were powered externally by a vibrating field (i.e., no cables were needed) as illustrated in [Figure 28.21](#). By cleverly designed robot legs having different masses and spring constants and thus different mechanical resonance frequencies, the leg to be actuated can be selected by applying a certain external vibrating (resonance) frequency. The robot can then be “shaken” in a controlled way to walk forward and left or right, as illustrated in [Figure 28.21b](#). The need for a vibrating table to achieve the locomotion strongly limits the applications for this robot. Also, the thin legs cause the robot to stick easily to the vibrating table by surface forces, which means that the surface on which the robot walks must be insulating.

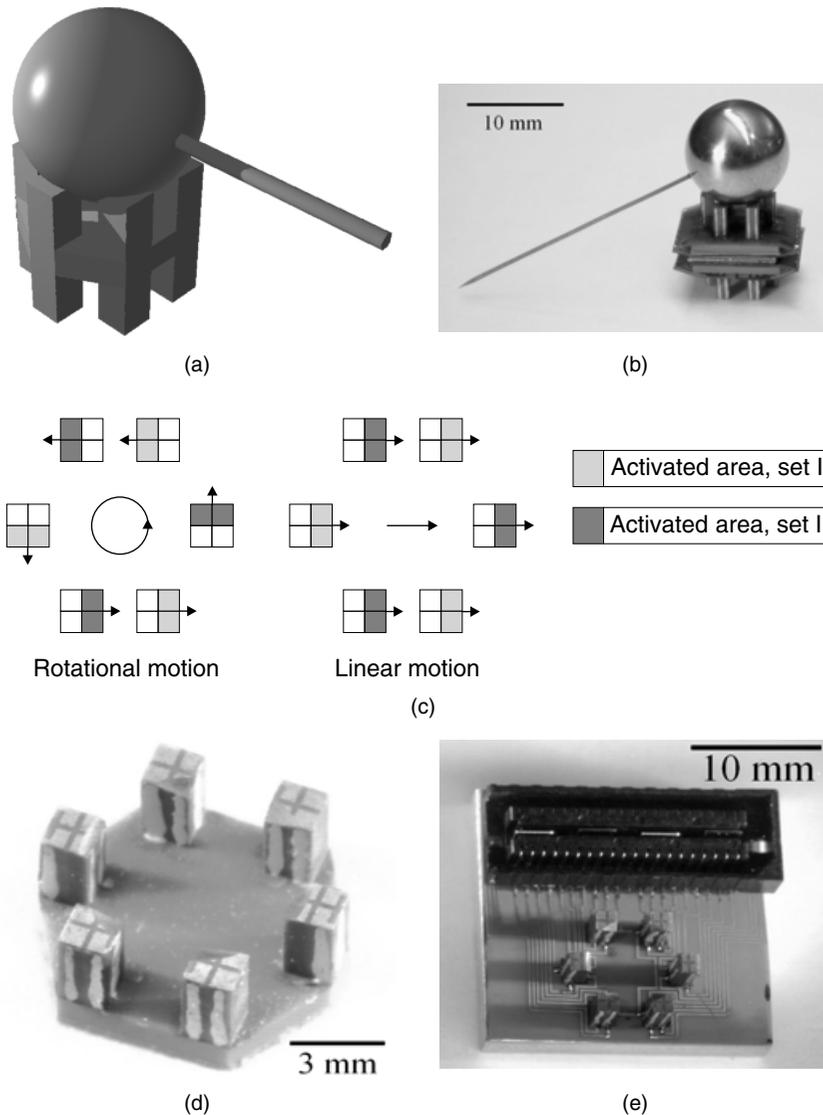

In a large European microrobot project, named MINIMAN, different miniaturized microrobots have been developed and more are under development. By the year 2000, a few demonstrators of minirobots and also a microrobot, having five degrees of freedom micromanipulation capability, had been fabricated. This prototype microrobot is illustrated in [Figure 28.22](#). Milling with a high-precision CNC (computer numerical controlled) machine tool in a green ceramic body has been used to make a stator unit where the drive elements are monolithically integrated with the base plate. The robot is made out of two almost identical piezoelectric stator units (shown in [Figure 28.22d](#)) which are put together back to back. One stator unit consists of six individually controlled legs. The lower stator, the micropositioning unit, should move laterally on a flat surface while the upper stator, the micromanipulating unit, will turn a ball equipped with a tool arbitrarily. [Figure 28.22c](#) illustrates the driving mechanism of the six-legged piezoceramic positioning and manipulating units to gain rotation and linear motion. Each three-axial element (leg) in the stator unit has four electrically separated parts able to produce the different motions needed for control of the robot. The elements are divided into two sets (different shading for sets I and II) phase-shifted 180°. Therefore, three elements are always in friction contact with the counter surface, producing a conveying (or walking) motion of the ball (or the robot itself).

The mechanical walking mechanism with solid multilayer piezoactuators is designed to give high handling speed, force and precision. A future version will include integration of the power drivers with the control circuitry and soldering the unit to a flexible printed circuit connecting the actuator elements in the stator unit. The electronic chip would then be placed between the two stator units.

[Figure 28.22e](#) shows the experimental setup for testing the first prototype of the micromanipulating stator unit. These stators in combination with prototypes of ICs intended for integration have been used to evaluate the performance. This setup will also be combined with a larger positioning platform, MINIMAN III (i.e., a walking minirobot platform), to obtain flexible microrobotic devices for micromanipulation.

### 28.5.3.2 Redundancy Criteria for Walking Microrobots

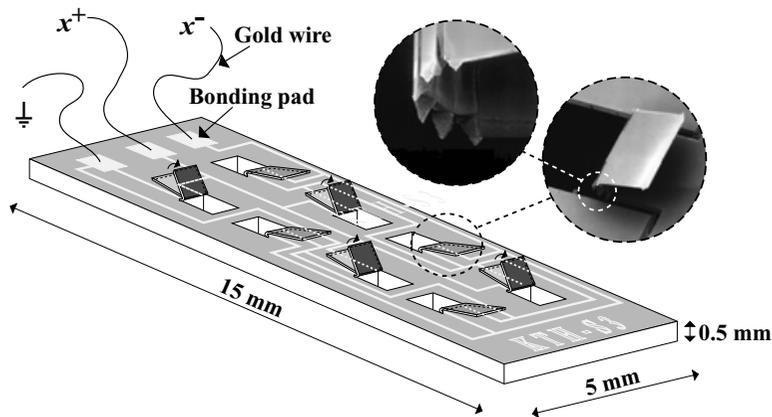

As was already pointed out in Section 28.4.3 one critical aspect when designing large distributed micro-motion systems based on arrayed actuators and distributed (or collective) actuation is the problem associated with the need for a very high yield of the actuators [Ruffieux and Rooij, 1999]. One nonworking actuator can undo the entire walking principle. Therefore, special attention has to be paid to achieve high redundancy by parallel designs wherever possible. The conveyer legs of the robot prototype design presented in [Figure 28.22](#) is fabricated by stacking several layers of thick-film piezoelectric layers on top of each other with metal electrodes in between. Because one layer is approximately 50  $\mu\text{m}$  thick, a piezostucture for a 1-mm-long leg consists of several layers and electrodes, which require very high yield in the fabrication. The metal electrodes are connected in parallel by the metal on the edges of the piezolegs to obtain higher redundancy for failure. Besides the need for parallel designs, the interconnecting wires must be kept at a minimum for walking microrobots (see [Figure 28.16](#)). For the piezorobot prototype shown in [Figure 28.22e](#), the stator unit is soldered to a flexible printed circuit board as it will be in the complete microrobot. The only difference is that the conductors do not lead to a surface-mounted connector, but instead to surface mounted integrated circuits. By using such a configuration, the number

**FIGURE 28.22** (a) Concept of a walking microrobot with a positioning unit (lower part) and micromanipulating unit (upper part) for turning the ball equipped with a tool. (b) A first prototype of the robot; this version is unable to walk. (c) Driving mechanism for the stator unit. (d) A photograph showing a six-legged piezoelement stator. (e) Experimental setup for the micropositioning unit. Note the amount of interconnection wires for this prototype. (Courtesy of U. Simu, Uppsala University, Sweden.)

of cables required to steer the robot will be minimized. In the current prototype version, the amount of interconnecting wires is quite large, as can be seen in [Figure 28.22e](#).

For the microrobots shown in [Figures 28.17](#) and [28.23](#), all the legs are connected in parallel so all of the actuators or legs are not needed to have perfect functionality. If one leg is broken, all the others are still functional, as the power supply line is connected in parallel (see [Figure 28.23](#)) instead of the serial connection, which is the most often used design for distributed microsystems. However, it is important that the nonfunctional (or broken) legs do not limit the walking function by blocking the action of the other legs. To further increase redundancy, each heating resistor in the PVG joint (see [Figures 28.10](#) and [28.14](#)) is divided into separate parts, allowing functional heating even if some part of the resistors (or the via contacts between the resistor and the metal) is not working.

**FIGURE 28.23** An upside-down view of the PVG joint-based microrobot platform used to study walking microrobots. The robot consists of two sets of legs (four of each  $x^+$  and  $x^-$ ). The metal interconnection is done in a parallel way to obtain the highest possible redundancy against failure. With three bonding pads the robot can walk forward and backward as well as lift up and down. By driving the legs on the left and right side at different speeds or stroke lengths, like a caterpillar (requires five wires), the robot can make left-right turns. The SEM photographs show the silicon leg and a close-up of a five-V-groove polyimide joint [Ebefors et al., 1999].

### 28.5.3.3 Steering of Microrobots

As shown in Figure 28.23, the simplest way to steer a CMS-based walking microrobot is by controlling the phase of the two rows of actuators on the robot. By driving one side forward and the other side backwards (or by not actuating it at all) the robot makes turns imitating a caterpillar. Other approaches to steer CMS microrobots to the left and right include:

- *Power*: Longer stroke lengths (changes in the  $x$  direction, or  $\Delta x$ ) on one side can be produced by increasing the power, but this would also produce higher steps (changes in the  $y$  direction, or  $\Delta y$ ), so the robot would walk with a stoop.
- *Frequency*: Increasing the number of steps on one side would produce smaller steps (both  $\Delta x$  and  $\Delta y$ ), so again the robot would walk with a stoop.
- *Combination of frequency and power*: Equal stroke lengths, but faster on one side, would allow “smooth” robot movements.

Another approach to obtain steerable walking robots is the use of large two-dimensional arrays with several rows of legs oriented in both the  $x$  and  $y$  directions. For these systems, based on the principle described in Figure 28.15, onboard electronics are probably required for minimizing the amount of wires required for the steering signals. Monolithic integration of CMOS electronics has been shown to work for conveyer systems [Suh et al., 1999], but the integration is not an easy task. Hybrid integration of electronics on a separate chip, as is planned for the microrobot shown in Figure 28.22, is not an easy task either, when many interconnect wires are needed.

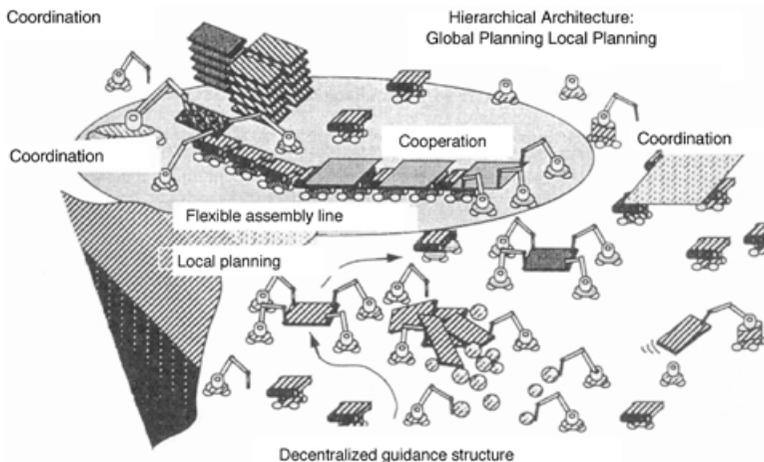

## 28.6 Multirobot System (Microfactories and Desktop Factories)

In the famous 1959 American Physical Society presentation by Feynman (1961), describing a new and exciting field of physics (e.g., miniaturization of systems, or “*there’s plenty of room at the bottom*”), the use of small machines to build smaller machines or systems was anticipated as a way to obtain miniaturization. However, this has not yet been realized in the MEMS field. Instead, we use larger and larger machines to achieve miniaturization and study physics at a very small scale (e.g., large vacuum chambers

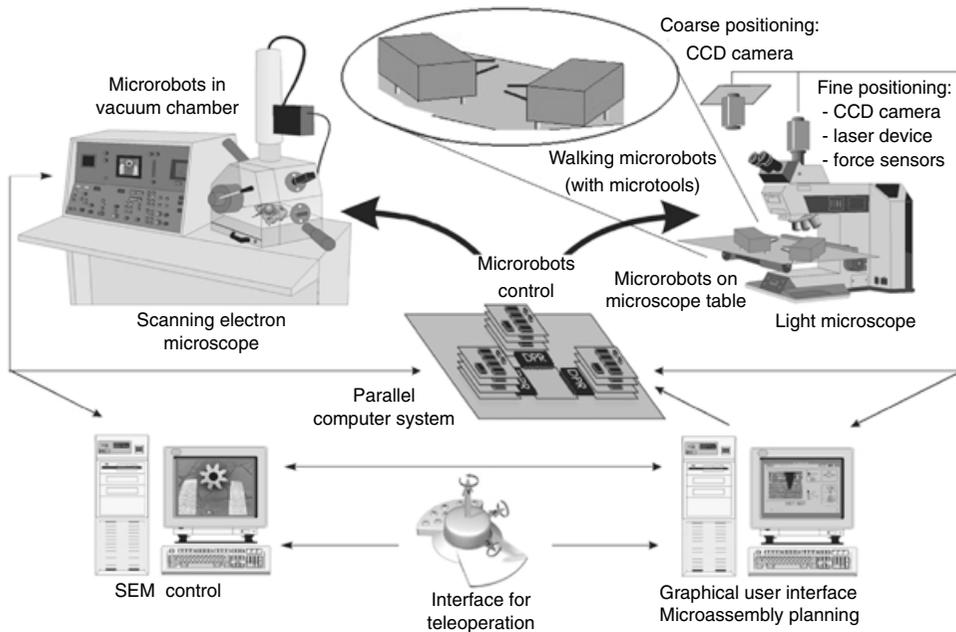

to evaporate the very thin films used in MEMS or the huge accelerator facilities used to study the smallest particles in the atom). However, at the research level, interest in such microfactories, where small machines build even smaller machines, has been growing since the mid-1990s.

Often MEMS is seen as the next step in the silicon system revolution (e.g., miniaturization) in that silicon integration breaks the confines of the electrical world and allows the ability to interact with the environment by means of sensors and actuators. Most of the commercially successful processes employed in MEMS technology have been adopted from the fabrication scheme of integrated circuits. This kind of processing equipment is usually very large and expensive but has the very attractive feature of batch fabrication, which allows production of low-cost devices in large quantities. However, as already described in this chapter, manufacturing concepts other than the IC-inspired batch silicon microfabrication are being developed today. All IC-based micromachining techniques require large volumes to be cost effective, as the equipment is large and expensive. Emerging alternative fabrication technologies allow for more flexible geometry (e.g., true three-dimensional structures) not feasible by planar IC process and integration of materials with properties other than those of semiconductors and thin metal films [Thornell and Johansson, 1998; Thornell, 1999]. These technologies utilize miniaturized versions of traditional tools typical for local processing (such as drilling, milling, etc. [Masuzawa, 1998]) rather than the parallel (batch) approach used in the IC industry. The main challenge in adopting these processes for commercial application is the slow processing time associated with high-precision machining. One potential solution to this problem might be to use microfactories, where a great number of microrobotic devices (conveyers and robots) are working in parallel to support the microtools with material [Hirai et al., 1993; Aoyama et al., 1995; Ishihara et al., 1995]. This kind of multirobot system, illustrated in Figure 28.24, introduces special requirements for the microrobots. These requirements include a wireless power supply (i.e., onboard power sources or telemetrically supplied power) and interrobot communication.

During the last decade, efforts have been made to develop various multi-(micro)robot system concepts, especially in Japan [Ishikawa and Kitahara, 1997; Kawahara et al., 1997], where the term *microfactories* is used, but also in Europe and U.S., where the most frequently used term is *desktop station fabrication*. The idea behind the microfactory approach is to allow production of small devices. Often, other factors such as saving energy, space and resources are also considered important, so the manufacturing process should also be cost effective for low-volume microsystems. It is still impossible to predict if these techniques will ever be competitive with standard parallel-batch MEMS processing, but two important advantages have already been demonstrated: flexibility and geometrical freedom.

**FIGURE 28.24** Concept for flexible decentralized multi-(micro)robot system. (Translated from Fatikow, S., *Mikroroboter and Mikromontage*, B. G. Tenbner, Stuttgart-Leipzig (in German). With permission.)

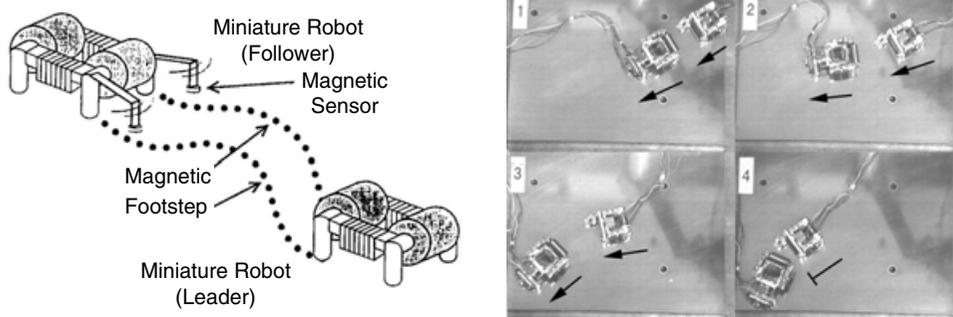

**FIGURE 28.25** Concept of the flexible microrobot-based microassembly station (FMMS). (Published with permission and courtesy of S. Fatikow, University of Kassel, Germany.)

Similar to the microfactory concept is the “automated desktop station using micromanipulation robots” proposed by Fatikow et al. [Fatikow and Rembold, 1996; 1997; Fatikow, 2000], as illustrated in Figure 28.25. Here, the focus is on assembly of different types of microdevices, fabricated by batch MEMS techniques, to build various microsystems rather than fabricate subcomponents in the systems.

### 28.6.1 Microrobot Powering

The ultimate goal for many microrobotics researchers is to achieve true autonomous microrobots like the ones shown in Figure 28.2o for work in multirobot systems such as microfactories. Some of the locomotive microrobot platforms presented in this chapter can be used as first steps toward that goal, but much research remains. Currently, there are no energy sources available to power a fully autonomous microrobot. Some robot actuators, such as the polyimide V-groove joint actuator shown in Figure 28.17 and other thermal actuators, have the drawback of high power consumption. Further research concerning the reduction of power is needed. This is a general problem: Robust and efficient microactuators usually have such high energy consumption that an onboard power supply cannot provide enough electric power over an extended period of time. Using cables to supply the energy to a microrobot obstructs the action (especially in multirobot systems) of the microrobot due to the stiffness of the cables; therefore, the robot has to be supplied with energy without using cables. Several research groups are working on developing microenergy sources—for example, various microgenerators, pyroelectric elements, solar batteries, fuel cells and other power-MEMS concepts [Lin et al., 1999]. An overview of thin-film batteries that may be suitable for microrobot applications is given by Kovacs (1998). Low-weight batteries have been used for a flying microrobot [Pornsin-Sirirak et al., 2000]. Even though the lifetime of such batteries and dc–dc converter systems is short, it demonstrates the possibilities for battery-powered microrobots. Solar cells made of a-Si–H junction for microrobot applications have also been proposed [Ruffieux and Rooij, 1999; Ruffieux, 2000]. By connecting several a-Si–H junctions a voltage of about 10 V is expected to be generated.

**FIGURE 28.26** Communication between miniature robots. The following robot follows the leader by a magnetic trace. (Published with permission and courtesy of H. Aoyama, University of Electro-Communications, Tokyo.)

## 28.6.2 Microrobot Communication

Besides the problems associated with the power sources, more research is required on the wireless transmission of steering signals to the microrobot and other means of communication between microrobots. Wireless microrobots and other microdevices can be achieved by using acoustic [Suzumori et al., 1999], optical [Ishihara and Fukuda, 1998], electromagnetic [Hierold et al., 1998] or thermal transmission of the control signal to the robot.

Common to all multirobot system concepts is the big challenge of how to obtain autonomous communication between different microrobotic devices. Normally, various telemetric solutions similar to those described in the previous section for wireless power transfer are also proposed for communication, but other approaches seem to be feasible as well. In nature, the ant creates an odor trail to guide fellow ants. Shimoyama (1995a,b) has been working on hybrid systems consisting of mechanical parts and living organisms. By using “living sensors” in the form of insect antennae, Shimoyama and co-workers were able to steer and control a mobile robot by pheromone stimulation [Kuwana et al., 1995]. Aoyama et al. [Aoyama et al., 1997] presented inch-sized robots who leave behind a magnetic footprint that can be detected by other robots for communication and motion guidance, as illustrated in [Figure 28.26](#). These footprints fade out with time, allowing continuous and advanced motion involving several miniature robots.

## 28.7 Conclusion and Discussion

Even though the microrobotic field and especially MEMS-based microrobotics are areas of constant expansion and we see a growing worldwide interest in the concept and possible applications, it still remains to be seen if these devices will come to practical and commercial use in applications such as hybrid assembling and manufacturing of microsystems. In this review, two fundamentally different aspects of microrobotics have been addressed: (1) MEMs for making microrobots, and (2) microrobots for making MEMs. The MEMs fabrication technology is an attractive approach for obtaining miniaturized robots. By scaling down the remaining robotic subsystems to the same scale as the control systems by integrating actuators, sensors, logic and power supplies onto a single piece of silicon, enormous advantages can be obtained in terms of mass producibility, lower costs and fewer connector problems encountered when interconnecting these discrete subsystems. The other aspect of MEMS and microrobotics is the application of these microrobots. Among several applications for microrobots, their use in medical applications (e.g., minimal invasive surgery) and biotechnology (e.g., cell-sorting) should be mentioned as the most promising for future commercial success of MEMS-based microrobotic devices. Further, the

use of various microrobotic devices and robot systems for assembling complex microsystems and perhaps also for more effective fabrication by hybrid technologies is an attractive approach for making more cost-effective devices and systems when low-volume or prototyping devices and systems are needed (i.e., microrobots for making MEMS). The micromanipulation tools, microconveyers and microrobots for locomotive mechanisms described in this chapter should be seen as the first steps in the long chain of developments needed to achieve autonomous microrobots for work in multirobotic systems such as microfactories for fabrication of other microsystems. However, much research remains in this field and it could be worth remembering the words of the great physicist Feynman when he “invented” the field of MEMS back in 1959:

*What are the possibilities of small but movable machines? They may or they may not be useful, but they surely would be fun to make.*

The devices described in this chapter illustrate the basic building blocks and some of the progress made in the young research field of MEMS-based microrobotics during the 1990s. Therefore, let us have fun, feel the wonder of microrobotics when “small movable machines” are fabricated and when new frontiers for science and research are explored. Beside the element of fun, there are tremendous opportunities for microrobotic applications, thus a large potential for industrial innovation and competition.

## Defining Terms

**Ciliary motion system (CMS):** A transportation system based on the ciliary motion principle adopted from nature. The CMS principle relies on an asynchronous driving technique that requires at least two spatially separated groups of actuators that are turned on and off at different times, alternately holding and driving the device. Higher speeds and smoother motions can be achieved with such asynchronous driving than with synchronous driving.

**Distributed micromotion systems (DMMS):** The concept of an array configuration of microactuators, where the cooperative work of many coordinated simple actuators generates interaction with the macroworld.

**Hybrid assembly:** Assembly of several individual microcomponents fabricated by different technologies and on different wafers. If microrobotic devices are used for the assembly (microrobots for making MEMS), extremely small components can be assembled.

**MEMS-based microrobotics:** A sort of “modified chip” fabricated by silicon MEMS-based technologies (such as batch-compatible bulk- or surface-micromachining or by micromolding and/or replication method) having features in the micrometer range.

**Microfactory:** A complete automatic factory containing conveyers, robot arms and other machine tools at a very small level. A synonym for microfactory is desktop factory.

**Microrobotics:** A general term for devices having dimensions smaller than classical watch-making parts (i.e.,  $\mu\text{m}$  to mm) with the ability to move, apply forces and manipulate objects in a workspace with dimensions in the micrometer or submicrometer range. Included in the term are both system aspects and more fundamental building-block aspects of a robot system. Examples of these fundamental building blocks in the microrobotic field are microgrippers, microconveyers and locomotive robots (arms for pick-and-place and/or legs for walking).

**Monolithic assembly:** All integration is done on one single (silicon) chip preferably using wafer-level assembly. This technology is preferable when fabricating microrobotic devices that rely on actuator arrays (MEMS for making microrobots).

**Parallel (batch) manufacturing:** Fabrication performed on several wafers at the same time (several-devices-at-a-time process) originally developed for the IC industry but now also commonly used for MEMS fabrication.

**Serial manufacturing:** One-device-at-a-time fabrication/assembly contrary to the monolithic approach where all integration is done on one single silicon chip using wafer-level assembly.

### 29.1 Introduction

---

Numerous potential applications for meso- and microscale sampling instruments are based on mass spectrometry [Nathanson et al., 1995; Ferran and Boumsellek, 1996; Orient et al., 1997; Piltingsrud, 1997; Wiberg et al., 2000; White et al., 1998; Freidhoff et al., 1999; Short et al., 1999] and gas chromatography [Terry et al., 1979]. Other miniaturized instruments utilizing electron optics [Chang et al., 1990; Park et al., 1997; Callas, 1999] will require both high-vacuum and repeated solid-sample transfers from higher pressure environments. The mushrooming interest in chemical laboratories on chips will likely evolve toward some manifestations requiring vacuum capabilities. At present, there are no microscale or mesoscale vacuum pumps to pair with the embryonic instruments and laboratories that are being developed. Certainly, small vacuum pumps will not always be necessary. Some of the new devices are attractive because of low quantities of waste and rapidity of analysis, not directly because they are small, energy efficient, or portable. However, for other applications involving portability and/or autonomous operations, appropriately small vacuum pumps with suitably low power requirements will be necessary. This chapter addresses the question of how to approach providing microscale and mesoscale vacuum pumping capabilities consistent with the volume and energy requirements of meso- and microscale instruments and processes in need of similarly sized vacuum pumps. It does not review existing microscale pumping devices because none are available with attractive performance characteristics (a review of the attempts has recently been presented by Vargo, 2000; see also NASA/JPL, 1999).

In the macroscale world, vacuum pumps are not very efficient machines, ranging in thermal efficiencies from very small fractions of one percent to a few percent. They generally do not scale advantageously to

**FIGURE 29.1** Representative performance ( $\dot{Q}/\dot{N}$ ) of selected macro- and mesoscale vacuum pumps (from Table 29.1) as a function of pressure ratio ( $\phi$ ).

small sizes, as is discussed in the section on pump scaling. Because of the continuing significant efforts to miniaturize instruments and chemical processes, it is a reasonable hypothesis that there is not much attraction in using oversized, power-intensive vacuum pumps to permit them to operate. This is probably generally true even for situations where pump size and power are not critical issues. More specifically, because microscale-generated vacuums are unavailable today, serious limits are imposed on the potential microscale applications of many high-performance analytical instruments and chemical processes where portability or autonomous operations are necessary.

To illustrate this point, the performance characteristics of several types of macroscale and mesoscale vacuum pumps are presented in Figure 29.1 and Table 29.1. Pumping performance is measured by  $\dot{Q}/\dot{N}$ , which is derived from the power required ( $\dot{Q}, W$ ) and the pump's upflow in molecules per unit time ( $\dot{N}, \#/s$ ). Representative vacuum pumping tasks are indicated by the inlet pressure  $p_I$  and the pressure ratio  $\phi$  through which  $\dot{N}$  is being pumped. Also shown in the figure is the reversible, constant-temperature compression power required per molecule of upflow ( $\dot{Q}/\dot{N}$ ) as a function of  $\phi$ . The adiabatic reversible (isentropic) compression power that would be required is also shown in Figure 29.1. The constant temperature comparison is most appropriate for vacuum systems. Note the 3- to 5-decade gap in the ideal  $\dot{Q}/\dot{N}$  and the actual values for the macroscale vacuum pumps. For low pump inlet pressures, the gases are very dilute and high volumetric flows are required to pump a given  $\dot{N}$ . The result is relatively large machines with significant size and frictional overheads. Unfortunately, scaling the pumps to smaller sizes generally increases the overhead relative to the upflow  $\dot{N}$ .

In addition to the power requirement, vacuum pumps tend to have large volumes, so that another indicator of relevance to miniaturized pumps is a pump's volume ( $V_p$ ) per unit upflow ( $V_p/\dot{N}$ ). The two measures  $\dot{Q}/\dot{N}$  and  $V_p/\dot{N}$  will be used throughout the following discussions for evaluating different approaches to the production of microscale vacuums.

The bias adopted in this chapter is to address only the production of appropriate vacuums where throughput or continuous gas sampling or, alternatively, multiple sample insertions are required. In some cases, so-called capture pumps (sputter ion pumps, getter pumps) may provide a convenient high- and ultra-high-vacuum pumping capacity. However, because of the finite capacity of these pumps before regeneration, they may or may not be suitable for long-duration studies. Because such trade-offs are very situation dependent, only the sputter ion and orbitron ion capture pumps are considered in the present

study. Both of these pump “active” ( $N_2$ ,  $O_2$ , etc.) and inert (noble and hydrocarbon) gases, whereas other nonevaporable and evaporable getters only pump the active gases efficiently [Lafferty, 1998].

## 29.2 Fundamentals

### 29.2.1 Basic Principles

Several basic relationships that are derived from the kinetic theory of gases [cf. Bird, 1994; Lafferty, 1998; Cercignani, 2000] are important to the discussion of both macroscale and microscale vacuum pumps. The conductance or volume flow in a channel under free molecule or collisionless flow conditions can be written as:

$$C_L = C_A \alpha \quad (29.1)$$

where  $C_L$  is the channel volume flow in one direction for a channel of length  $L$ . The conductance of the upstream aperture is  $C_A$  and  $\alpha$  is the probability that a molecule, having crossed the aperture into the channel, will travel through the channel to its end (this includes those that pass through without hitting a channel wall and those that have one or more wall collisions). Employing the kinetic theory expression for the number of molecules striking a surface per unit time per unit area ( $n_g \bar{C}'/4$ ) gives

$$C_A = (\bar{C}'/4)A_A = \{(8kT_g/\pi m)^{1/2}/4\}A_A \quad (29.2)$$

where:  $A_A$  is the aperture’s area;  $\bar{C}' = \{8kT_g/\pi m\}^{1/2}$  is the mean thermal speed of the gas molecules of mass  $m$ ;  $k$  is Boltzmann’s constant; and  $T_g$  and  $n_g$  are the gas temperature and number density, respectively. The probability,  $\alpha$ , can be determined from the length and shape of the channel and the rules governing the reflection at the channel’s walls [cf. Lafferty, 1998; Cercignani, 2000].

Several terms associated with wall reflection will be used. *Diffuse reflection* of molecules occurs when the angle of reflection from the wall is independent of the angle of incidence, with any reflected direction in the gas space equally probable per unit of projected surface area in that direction. The reflection is said to be *specular* if the angle of incidence equals the angle of reflection and both the incident and reflected velocities lie in the same plane and have equal magnitude.

The condition for effectively collisionless flow (no significant influence of intermolecular collisions) is reached when the mean free path ( $\lambda$ ) of the molecules between collisions in the gas is significantly larger than a representative lateral dimension ( $l$ ) of the flow channel. Usually this is expressed by the Knudsen number ( $Kn$ ), such that:

$$Kn_l = \lambda/l \geq 10 \quad (29.3)$$

The mean free path  $\lambda$  can have, for our purposes, the elementary kinetic theory form,

$$\lambda = 1/(\sqrt{2}\Omega n_g) \quad (29.4)$$

with  $\Omega$  being the temperature-dependent, hard-sphere, total-collision cross section of a gas molecule (for a hard-sphere gas of diameter  $d$ ,  $\Omega = \pi d^2$ ). As an example, the mean free path for air at 1 atm and 300 K is  $\lambda \approx 0.06 \mu\text{m}$ .

Expressions for conductance analogous to Eq. (29.1) can be obtained for transitional ( $10 > Kn_l > 0.01$ ) flows and continuum ( $Kn_l \leq 10^{-3}$ ) viscous flows [Cercignani, 2000, and references therein]. For our discussion, the major interest is in collisionless and early transitional flow ( $Kn_l \geq 0.1$ ).

The performance of a vacuum pump is conventionally expressed as its pumping speed or volume of upflow ( $S_p$ ) measured in terms of the volume flow of low-pressure gas from the chamber that is being pumped (see Lafferty, 1998, for details on the size and shape of the chamber). Following the recipe of Eq. (29.1), the pumping speed can be written as:

$$S_p = C_{AP}\alpha_p \quad (29.5)$$

Once a molecule has entered the pump's aperture of conductance  $C_{AP}$ , it will be "pumped" with probability  $\alpha_p$ . Clearly,  $(1 - \alpha_p)$  is the probability that the molecule will return or be backscattered to the low-pressure chamber. A pump's upflow in this chapter will generally be described in terms of the molecular upflow in molecules per unit time ( $\dot{N}$ , #/s). For a chamber pressure  $p_I$  and temperature  $T_b$ , the number density  $n_I$  is given by the ideal gas equation of state,  $p_I = n_I k T_b$ , and the molecular upflow is

$$\dot{N} = S_p n_I \quad (29.6)$$

## 29.2.2 Conventional Types of Vacuum Pumps

The several types of available vacuum pumps have been classified [*c.f.* Lafferty, 1998] into convenient groupings, from which potential candidates for microelectromechanical systems (MEMS) vacuum pumps can be culled. The groupings are

- *Positive-displacement* (vane, piston, scroll, Roots, claw, screw, diaphragm)
- *Kinetic* (vapor jet or diffusion, turbomolecular, molecular drag, regenerative drag)
- *Capture* (getter, sputter ion, orbitron ion, cryopump)

In systems requiring pressures  $<10^{-3}$  mbar, the positive-displacement, molecular and regenerative drag pumps are used as "backing" or "fore" pumps for turbomolecular or diffusion pumps. In their operating pressure range ( $<10^{-4}$  mbar), the capture pumps require no backing pump but have a more or less limited storage capacity before requiring "regeneration." Also, some means to pump initially to about  $10^{-4}$  mbar from the local atmospheric pressure is necessary. There is insufficient space here to discuss the details of

these pump types, and the interested reader is referred to J.M. Lafferty's excellent book [Lafferty, 1998]. The historical roots of this reference are also of interest [Dushman, 1949; Dushman and Lafferty, 1962]. Perhaps all that is necessary to remember at present is that the positive-displacement pumps mechanically trap gas in a volume at a low pressure, the volume decreases, and the trapped gas is rejected at a higher pressure. The kinetic pumps continuously add momentum to the pumped gas so that it can overcome adverse pressure gradients and be "pumped." The storage pumps trap gas or ions on and in a nanoscale lattice or, in the case of cryocondensation pumps, simply condense the gas. In either case, the storage pumps have a finite capacity before the stored gas has to be removed (pump regeneration) or fresh adsorption material supplied.

### 29.2.3 Pumping Speed and Pressure Ratio

For all pumps, except for the ion pumps, there is a trade-off between upflow  $S_p$  and the pressure ratio,  $\wp$ , that is being maintained by the pump. It has been found convenient to identify a pump's performance by two limiting characteristics [e.g., Bernhardt, 1983]: (1) the maximum upflow,  $S_{p,MAX}$ , which is achieved when the pressure ratio  $\wp = 1$ ; and (2) the maximum pressure ratio  $\wp_{MAX}$  which is obtained for  $S_p = 0$ . In many cases, a simple expression relating pumping speed ( $S_p$ ) and pressure ratio ( $\wp$ ) to  $S_{p,MAX}$  and  $\wp_{MAX}$  describes the trade-off between speed and pressure ratio:

$$S_p/S_{p,MAX} = \frac{(1 - \wp/\wp_{MAX})}{(1 - 1/\wp_{MAX})} \quad (29.7)$$

This relationship is not strictly correct because in many pumps the conductances that result in backflow losses relative to the upflow change dramatically as pressure increases. For the critical lower pressure ranges ( $10^{-1}$  mbar in macroscale pumps but significantly higher in microscale pumps), Eq. (29.7) is a reasonable expression for the trade-off between speed and pressure ratio. Equation (29.7) is convenient because  $\wp_{MAX}$  and  $S_{p,MAX}$  are identifiable and measurable quantities that can then be generalized by Eq. (29.7).

### 29.2.4 Definitions for Vacuum and Scale

The terms *vacuum* and *MEMS* have both flexible and strict definitions that depend on the beholders. For our discussion, the following categories of vacuum in reduced-scale devices will be used. The pressure range from  $10^{-2}$  to  $10^3$  mbar will be defined as *low* or *roughing vacuum*. The range from  $10^{-2}$  to  $10^{-7}$  mbar will be referred to as *high vacuum*, and for pressure below  $10^{-7}$  mbar, *ultra-high vacuum*.

For the foreseeable future most small-scale vacuum systems are unlikely to fall within the strict definition of MEMS devices (maximum component dimension <100  $\mu\text{m}$ ). Typically, device dimensions somewhat larger than 1 cm are anticipated. They will be fabricated using MEMS techniques but the total construct will be better termed *mesoscale*. Device scale lengths 10 cm and greater indicate macroscale devices.

## 29.3 Pump Scaling

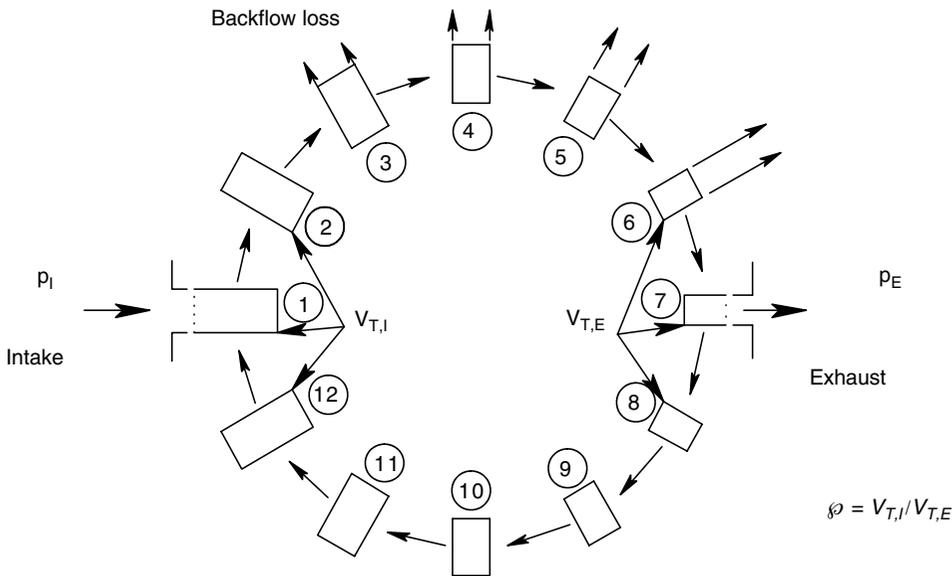

---

In this section, the sensitivities to size reduction of the performances of several generic, conventional vacuum pump configurations are discussed. Positive-displacement, turbomolecular (also molecular drag kinetic pumps), sputter and orbitron ion capture pumps are the major focus. Other possibilities, such as diffusion kinetic pumps, diaphragm positive-displacement pumps, getter capture pumps, cryocondensation and cryosorption pumps do not appear to be attractive for MEMS applications. This is due to vaporization and condensation of a separate working fluid (diffusion pumps), large backflow due to valve leaks relative to upflow (diaphragm pumps), low saturation gas loadings (getter capture pumps), an inability to pump the noble gases (getter capture pumps), and the difficulty in providing energy-efficient cryogenic temperatures for MEMS-scale cryocondensation or cryosorption pumps.

### 29.3.1 Positive-Displacement Pumps

Consider a generic positive-displacement pump that traps a volume  $V_T$  of low-pressure gas with a frequency of  $f_T$  trappings per unit time. In order to derive a phenomenological expression for pumping speed several inefficiencies must be taken into account: backflow due to clearances, which is particularly important for dry pumps and the volumetric efficiency of the pump's cycle, including both time-dependent inlet conductance effects and dead volume fractions. The generic positive-displacement pump is illustrated in Figure 29.2. Without going into detail, the pumping speed ( $S_p$ ) for an intake number density  $n_I$  and an exhaust number density  $n_E$  (or  $\wp$  corresponding to the pressures  $p_I$  and  $p_E$ , as the process gas temperature is assumed to be constant in the important low-pressure pumping range) can be derived:

$$S_p = (1 - \wp \wp_G^{-1})(1 - e^{-(C_{LI}/V_{T,I}f_T)\beta_1})V_{T,I}f_T - (\wp - 1)C_{LB}\beta_2 \quad (29.8)$$

- ① → ② Intake from  $p_I$  to  $V_{T,I}$  at pressure  $p_E/p_G$ , partial filling of  $V_{T,I}$  due to limited inlet time.  $V_{T,I}$  closed at  $\leq p_I$ .
- ② → ③ Volume decreases and backflow loss begins.
- ④ → ⑥ Volume continues to decrease to  $V_{T,E}$ , backflow increases, pressure in  $V_{T,E} > p_E$ .
- ⑦ Exhaust of excess pressure from  $V_{T,E}$  to  $p_E$ .
- ⑧  $V_{T,E}$  closed with pressure  $p_E$ .
- ⑦ → ⑫ Volume expands to  $V_{T,I}$ , pressure drops to  $p_E/\wp_G$ .
- ① Cycle repeats.

FIGURE 29.2 Generic positive-displacement vacuum pump.

where  $\wp$  is the pressure ratio  $p_E/p_I \equiv n_E/n_I$  (assuming  $T_I = T_E$ );  $C_{LI}$  is the pump's inlet conductance;  $V_{TI}$  is the trapping volume at the inlet;  $C_{LB}$  is the conductance of the backflow channels between exhaust and inlet pressures;  $\wp_G = V_{TI}/V_{TE}$  is the geometric trapped-volume ratio between inlet and exit;  $\beta_1$  is the fraction of the trapping cycle during which the inlet aperture is exposed; and  $\beta_2$  is the fraction of the cycle during which the backflow channels are exposed to the pressure ratio  $\wp$ .

The pumping speed expression of Eq. (29.8) applies most directly to a single compression stage. The backflow conductance is assumed to be approximately constant because the flow is in the "collisionless" flow regime that exists in the first few stages of a typical dry pumping system. The inlet conductance for a dry microscale system will be in the collisionless flow regime at low pressure (say  $10^{-2}$  mbar). The inlet conductance per unit area can increase significantly (amount depends on geometry) for transitional inlet pressures [Sone and Itakura, 1990; Lafferty, 1998; Sharipov and Seleznov, 1998]. The performance of macroscale (inlet apertures of several centimeters and larger) positive-displacement pumps at a given inlet pressure will thus benefit from the increased inlet conductance per unit area compared to their reduced scale counterparts in the important low-pressure range of  $10^{-3}$  to  $10^{-1}$  mbar.

The term  $(1 - \wp \wp_G^{-1})$  in Eq. (29.8) represents an inefficiency due to a finite dead volume in the exhaust portion of the cycle. The effect of incomplete trapped volume filling during the open time of the inlet aperture is represented by  $(1 - e^{-(C_{LI}/V_{TI})\beta_1})$ . The ideal (no inefficiencies) pumping speed is  $V_{TI}f_T$ . The backflow inefficiency is  $(\wp - 1)C_{LB}\beta_2$ . The dimensions of all groupings are volume per unit time. As in all pumps, a maximum upflow ( $S_{P,MAX}$ ) can be found by assuming  $\wp = 1$  in Eq. (29.8). Similarly, the maximum pressure ratio ( $\wp_{MAX}$ ) can be obtained from Eq. (29.8) by setting  $S_P = 0$ . With some manipulations, Eq. (29.8) can be rewritten as:

$$S_P = V_{TI}f_T \wp_G^{-1} \{1 + (C_{LB}\beta_2/V_{TI}f_T) \wp_G - \exp(-C_{LI}\beta_1/V_{TI}f_T)\} (\wp_{MAX} - \wp) \quad (29.9)$$

The relationship between  $\wp$ ,  $\wp_{MAX}$ ,  $S_P$  and  $S_{P,MAX}$  can be found by setting  $\wp = 1$  in Eq. (29.9). Substituting back into Eq. (29.9) gives the same expression as in Eq. (29.7).

For the purposes of the present discussions, the upflow of molecules per unit time ( $\dot{N} = S_P n_I$ ) is a useful measure of pumping speed. The form of Eq. (29.9) has been checked by fitting it successfully to observed pumping curves ( $S_P$  vs.  $p_I$ ) for several positive-displacement pumps (using data in Lafferty, 1998) between inlet pressures of  $10^{-2}$  and  $10^0$  mbar. This is done by following Eq. (29.9) and replotting the experimental results using  $S_P$  and  $(\wp_{MAX} - \wp)$  as the two variables. The variation of inlet conductance with  $Kn$ ,  $C_{LI}(Kn)$ , is important in matching Eq. (29.9) to the observed pumping performances.

At low inlet pressures, the energy use of positive-displacement pumps is dominated by friction losses due to the relative motion of their mechanical components. Taking the two possibilities of sliding and viscous friction as limiting cases, the frictional energy losses can be represented as:

$$\dot{Q}_{sf} = \bar{u} \mu_{sf} A_s \tilde{F}_N \quad (29.10a)$$

for sliding friction, and for viscous friction:

$$\dot{Q}_\mu = \bar{u} \mu A_s (\bar{u}/h) \quad (29.10b)$$

Here,  $\dot{Q}_{sf}$  and  $\dot{Q}_\mu$  are the powers required to overcome sliding friction and viscous friction, respectively. The coefficients are, respectively,  $\mu_{sf}$  and  $\mu$ ;  $A_s$  is the effective area involved;  $\tilde{F}_N$  is the normal force per unit area; and  $\bar{u}$  is a representative relative speed of the two surfaces that are in contact for sliding friction or separated by a distance  $h$  for the viscous case. The contribution to viscous friction in clearance channels exposed to the process gas at low pumping pressures is usually not important, but there may be significant viscous contributions from bearings or lubricated sleeves. An estimate of the power use per unit of upflow can be obtained by combining Eqs. (29.9) and (29.10) to give  $(\dot{Q}/\dot{N})$ , with units of power per molecule per second or energy per molecule.

Consider the geometric scaling to smaller sizes of a “reference system” macroscopic positive-displacement vacuum pump. The scaling is described by a scale factor  $s_i$  applied to all linear dimensions. Inevitable manufacturing difficulties when  $s_i$  is very small are put aside for the moment. As a result of the geometric scaling, the operating frequency  $f_{T,i}$  needs to be specified. It is convenient to set  $f_{T,i} = s_i^{-1} f_{T,R}$ , which keeps the component speeds constant between the reference and scaled versions. This may not be possible in many cases; another more or less arbitrary condition would be to have  $f_{T,i} = f_{T,R}$ . Using the scaling factor and Eq. (29.9), an expression for the scaled pump upflow,  $\dot{N}_i$ , can be written as a function of  $s_i$  and values of the pump’s important characteristics at the reference or  $s_i = 1$  scale (e.g.,  $V_{T,i} = s_i^3 V_{T,R} s_i^{-1} f_{T,R}$ ). For the case of  $f_{T,i} = s_i^{-1} f_{T,R}$ ,

$$\begin{aligned} \dot{N}_i = & n_I s_i^3 V_{T,R} s_i^{-1} f_{T,R} \wp_G^{-1} [1 + (s_i^2 C_{L,R} \beta_2 / s_i^3 V_{T,R} s_i^{-1} f_{T,R}) \wp_G \\ & - \exp\{-(s_i^2 C_{L,R} \beta_1 / s_i^3 V_{T,R} s_i^{-1} f_{T,R})\}] (\wp_{MAX} - \wp) \end{aligned} \quad (29.11)$$

Similarly, the scaled version of Eq. (29.10b) becomes:

$$\dot{Q}_{\mu,i} = \bar{u}^2 \mu s_i^2 A_{S,R} / s_i h_R \quad (29.12)$$

Forming the ratios  $(\dot{Q}_{\mu,i} / \dot{Q}_{\mu,R}) / (\dot{N}_i / \dot{N}_R) \equiv (\dot{Q}_{\mu,i} / \dot{N}_i) / (\dot{Q}_{\mu,R} / \dot{N}_R)$  eliminates many of the reference system characteristics and highlights the scaling. In this case, for the viscous energy dissipation per molecule of upflow in the scaled system compared to the same quantity in the reference system, a scaling relationship is obtained:

$$(\dot{Q}_{\mu,i} / \dot{N}_i) / (\dot{Q}_{\mu,R} / \dot{N}_R) = s_i^{-1} \quad (29.13)$$

A summary of the results of this type of scaling analysis applied to positive-displacements pumps is presented in [Table 29.2](#), along with all the other types of pumps that are considered below. In [Table 29.2](#) it is convenient to summarize the performance using  $\wp_{MAX}$  ( $S_p = 0$ ) and  $S_{p,MAX}$  or  $\dot{N}_{MAX}$  ( $\wp = 1$ ) in order to eliminate  $\wp$  appearing explicitly as a variable in the scaling expressions through the dependency of  $\dot{N}$  on the pressure ratio (refer to Eq. (29.11)).

### 29.3.2 Kinetic Pumps

Because of their sensitivity to orientation and their potential for contamination, diffusion pumps do not appear to be suitable for MEMS-scale vacuum pumps, except possibly for situations permitting fixed installations. The other major kinetic pumps, turbomolecular and molecular drag, require high-rotational-speed components but are dry and in macroscale versions can be independent of orientation, at least in time-independent situations. More or less arbitrarily, only the turbomolecular and molecular drag pumps are discussed in this chapter.

A simplified model of turbomolecular pumping has been developed by Bernhardt (1983). Following this description, the maximum pumping speed ( $\wp = 1$ ) of a turbomolecular pumping stage (rotating blade row and a stator row) can be written as:

$$S_{p,MAX} = A_I (\bar{C}' / 4) (v_c / \bar{C}') / [(1/q d_f) + (v_c / \bar{C}')] \quad (29.14)$$

In Eq. (29.14):  $A_I$  is the inlet area to the rotating blade row;  $v_c$  is an average tangential speed of the blades;  $q$  is the trapping probability of the rotating blade row for incoming molecules, and besides blade geometry it is a function of  $(v_c / \bar{C}')$ . The term,  $d_f$ , accounts for a reduction in transparency due to blade thickness. It is assumed in Eq. (29.14) that the blades are at an angle of  $45^\circ$  to the rotational plane of the blades. As an instructive convenience, write  $v_r = (v_c / \bar{C}')$ ;  $v_r$  is similar to but not identical with the Mach number.

Notes: For the case of  $f_{T,i} = f_{T,R}$  the expressions that result are sensitive to the particular importance of backflow and inlet losses in each case. Estimates have been made, using typical values for the losses, of the order of magnitude of these expressions in order to simplify the presentation. The detailed expressions appear below in Table 29.2b. The scaling of  $V_{p,i}/V_{p,R}$  is assumed to be as  $s_i^3$  when obtaining the  $(V_p/\dot{N}_{MAX})_i / (V_p/\dot{N}_{MAX})_R$  scaling.

The maximum pressure ratio ( $S_p = 0$ ) can be written as [Bernhardt, 1983]:

$$\wp_{MAX} = e^{\xi v_r} \quad (29.15)$$

where  $\xi$  is a constant that depends on blade geometry. Dividing Eq. (29.14) by  $A_i(\bar{C}'/4)$  gives the pumping probability:

$$\alpha_{P,MAX} = v_r / [(1/q_i d_f) + v_r] \quad (29.16)$$

The  $\wp_{MAX}$  for turbomolecular stages is generally large ( $>\mathcal{O}[10^5]$ ) for gases other than He and H<sub>2</sub> due to the exponential expression of Eq. (29.15). During operation in a multistage pump, the stages can be employed at pressure ratios of  $\wp \ll \wp_{MAX}$ . Thus, from Eq. (29.7) (which also applies to turbomolecular drag stages), the pumping speed approaches  $S_{P,MAX}$ .

The scaling characteristics of turbomolecular pumps can be derived using Eqs. (29.14) and (29.15). It is assumed that the pump blades remain similar during the scaling. The tangential speed ( $v_c$ ) will be written as  $2\pi R f_p$ , where  $R$  is a characteristic radius of the blade row and  $f_p$  is the rotational frequency in rps. From Eqs. (29.14) and (29.15):

$$\begin{aligned} (S_{P,MAX})_i &= s_i^2 A_{i,R} (\bar{C}'/4) \{ [2\pi s_i R_R f_{p,i} / \bar{C}'] / [(1/q_i d_{f,i}) + (2\pi s_i R_R f_{p,i} / \bar{C}')] \} \\ \wp_{MAX,i} &= \exp(\xi 2\pi s_i R_R f_{p,i} / \bar{C}') \end{aligned} \quad (29.17)$$

**TABLE 29.2b** Detailed Expressions for Size Scaling with  $f_{T,i} = f_{T,R}$

Type	$\frac{\phi_{MAX,i}}{\phi_{MAX,R}}$	$\frac{S_{P,MAX,i}}{S_{P,MAX,R}}$	$\frac{(\dot{Q}_{sf}/\dot{N}_{MAX})_i}{(\dot{Q}_{sf}/\dot{N}_{MAX})_R}$	$\frac{(\dot{Q}_u/\dot{N}_{MAX})_i}{(\dot{Q}_u/\dot{N}_{MAX})_R}$
Positive displacement	$\left\{ \frac{1 - \exp(-s_i^{-1}K_{I,R}) + s_i^{-1}K_{B,R}}{1 - \exp(-K_{I,R}) + K_{B,R}} \right\} \times$ $\left\{ \frac{1 - \exp(-K_{I,R}) + \phi_G K_{B,R}}{1 - \exp(-s_i^{-1}K_{I,R}) + s_i^{-1}\phi_G K_{B,R}} \right\}$	$s_i^3 \left\{ \frac{1 - \exp(-s_i^{-1}K_{I,R})}{1 - \exp(-K_{I,R})} \right\}$	$\left\{ \frac{1 - \exp(-K_{I,R})}{1 - \exp(-s_i^{-1}K_{I,R})} \right\}$	$\left\{ \frac{1 - \exp(-K_{I,R})}{1 - \exp(-s_i^{-1}K_{I,R})} \right\}$
Turbomolecular	$(\phi_{MAX,R})^{(s_i - 1)}$	$s_i^3 \left\{ \frac{(q_R d_{f,R})^{-1} + (v_{c,R}/\bar{C}')}{(q_R d_{f,R})^{-1} + s_i(v_{c,R}/\bar{C}')} \right\}$	$\left\{ \frac{(q_R d_{f,R})^{-1} + (s_i v_{c,R}/\bar{C}')}{(q_R d_{f,R})^{-1} + (v_{c,R}/\bar{C}')} \right\}$	$\left\{ \frac{(q_R d_{f,R})^{-1} + (s_i v_{c,R}/\bar{C}')}{(q_R d_{f,R})^{-1} + (v_{c,R}/\bar{C}')} \right\}$

*Notes:* The  $K_{I,R}$  and  $K_{B,R}$  are associated with the inlet losses and backflow losses, respectively (larger  $K_{I,R}$  leads to less inlet, losses, but the larger  $K_{B,R}$  the more serious the backflow loss).  $K_{I,R} = C_{LL,R} \beta_1 / V_{TL,R} f_{T,R}$ ,  $K_{B,R} = C_{LB,R} \beta_2 / V_{TL,R} f_{T,R}$ . The symbols are defined in the section on positive displacement pumps.

For example, the case of  $f_{P,i} = f_{P,R}$ ,  $d_{f,i} = d_{f,R}$ , gives

$$\frac{(S_{P,MAX})_i}{(S_{P,MAX})_R} = s_i^3 [(1/q_R d_{f,R}) + (v_{c,R}/\bar{C}')] / [(1/q_i d_{f,R}) + (s_i v_{c,R}/\bar{C}')] \quad (29.18)$$

$$\wp_{MAX,i} = (\wp_{MAX,R})^{s_i^{-1}} \quad (29.19)$$

For the case of  $f_{P,i} = s_i^{-1} f_{P,R}$  (constant  $v_c$ )

$$\frac{(S_{P,MAX})_i}{(S_{P,MAX})_R} = s_i^2, \quad \wp_{MAX,i} = \wp_{MAX,R} \quad (29.20)$$

A complete set of scaling results is presented in [Table 29.2](#).

### 29.3.3 Capture Pumps

#### 29.3.3.1 Sputter Ion Pumps

The sputter ion pump (SIP) is an option for high-vacuum MEMS pumping. The application of simple scaling approaches to these pumps is difficult; however, centimeter-scale pumps are already available. The SIP has the basic configuration illustrated in [Figure 29.3](#). A cold cathode discharge (Penning discharge), self-maintained by a several-thousand-volt potential difference and an externally imposed magnetic field that restricts the loss of discharge electrons, causes ions created in the discharge by electron-neutral collisions to bombard the cathodes. The energetic ions (with energy some fraction of the driving potential) both sputter cathode material (usually Ti) and imbed themselves in the cathodes. Sputtered material deposits on the anode and portions of the opposing cathodes. The freshly deposited material acts as a continuously refreshed adsorption pumping surface for “active” gases (most things other than the noble

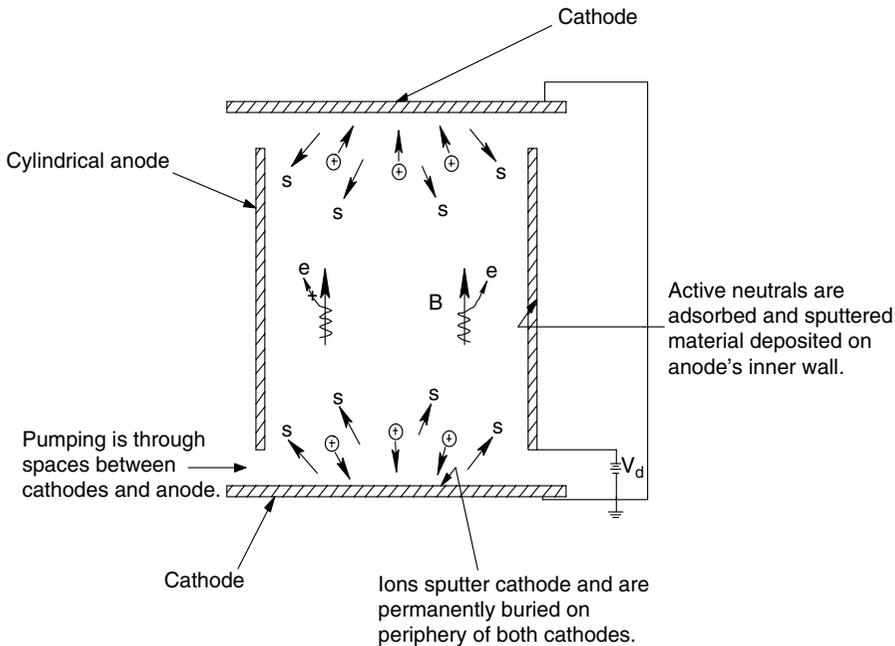

FIGURE 29.3 Sputter ion pump schematic.

gases and hydrocarbons). Small (down to an 8-mm-diameter anode cylinder and a cathode separation of 3.6 cm) pumps have been studied theoretically by Suetsugu (1993). His results compare reasonably well to experimental results for the particular case of a 1.5-cm-diameter anode. For a discharge voltage of 3000 V, a magnetic field strength of 0.3 T and a 0.8-cm-diameter anode, a pumping speed of slightly greater than 0.5 l/s is predicted at  $10^{-8}$  Torr. For these conditions, the discharge is operating in the high-magnetic-field (HMF) mode, which results in a maximum pumping speed. The pumping speed increases slowly as pressure increases.

SIPs have a finite but relatively long life and may be useful when ultra-high vacuums are required in small-scale systems. Their scaling to true MEMS sizes is uncertain because they require several thousand volts to operate reasonably effectively (ion impact energies approaching 1000 V are required for efficient sputtering and rare gas ion burial). The description of the SIP operation developed by Suetsugu (1993) can be used to provide a scaling expression (that needs to be employed cautiously). The power used by the discharge can be obtained knowing the applied potential difference,  $V_D$ , and the ion current,  $I_{ion}$ . Suetsugu (1993) gives for the pumping speed:

$$S_p = (K_G q \eta I_{ion}) / (3.3 \times 10^{19}) e p_I \quad (29.21)$$

where  $p_I$  is the pressure in Torr,  $\eta$  is the sputtering coefficient of cathode material due to the impact of energetic ions, and  $q$  is the sticking coefficient for active gases on the sputtered material. The charge on an electron is  $e$ , and  $K_G$  is a nondimensional geometric parameter derived from the electrode configuration that remains constant with geometric scaling. An expression for the power required per pumped molecule becomes:

$$(\dot{Q}/\dot{N})_i = (V_D I_{ion})_i / [\{(K_G q \eta I_{ion}) / ((3.3 \times 10^{19}) e p_I)\}_i \{10^{-3} n_i\}] \quad (29.22)$$

and

$$(\dot{Q}/\dot{N})_i / (\dot{Q}/\dot{N})_R = V_{D,i} / V_{D,R} \quad (29.23)$$

This assumes  $q_i = q_R$ ,  $\eta_i = \eta_R$ .

The scaling expression for pumping speed becomes:

$$S_{P,i} / S_{P,R} \equiv S_{P,MAX,i} / S_{P,MAX,R} = (I_{ion})_i / (I_{ion})_R \quad (29.24)$$

where the  $S_{P,MAX}$  is employed to be consistent with the previous usage for other pumps, although the Eq. (29.7) relationship does not really apply in this case.

The ion current is obtained by an iterative numerical solution involving the number density of trapped electrons [Suetsugu, 1993]. The scaling expression for  $\dot{Q}/\dot{N}$  in Eq. (29.23) is particularly simple because the ion currents cancel. The scaling represented by Eq. (29.23) appears reasonably valid providing  $\eta$  remains relatively constant, which implies that the ion energy should be relatively constant. Ion burial in the cathodes, which is the mechanism by which SIPs pump rare gases, is not discussed in detail here but can be considered within the framework of Suetsugu's analysis. Scaling results are summarized in [Table 29.2](#).

### 29.3.3.2 Orbitron Ion Pump

The orbitron ion pump [Douglas, 1965; Denison, 1967; Bills, 1967] was developed based on an electrostatic electron trap best known for application in ion pressure gauges. A sketch is presented in [Figure 29.4](#). Injected electrons orbit an anode; the triode version illustrated in [Figure 29.4](#) [Denison, 1967; Bills, 1967] has an independent sublimator that provides a continuous active getter (Ti) coating of the ion collector. The getter permits active gas pumping as well as permanent burial of rare gas and other ions that are

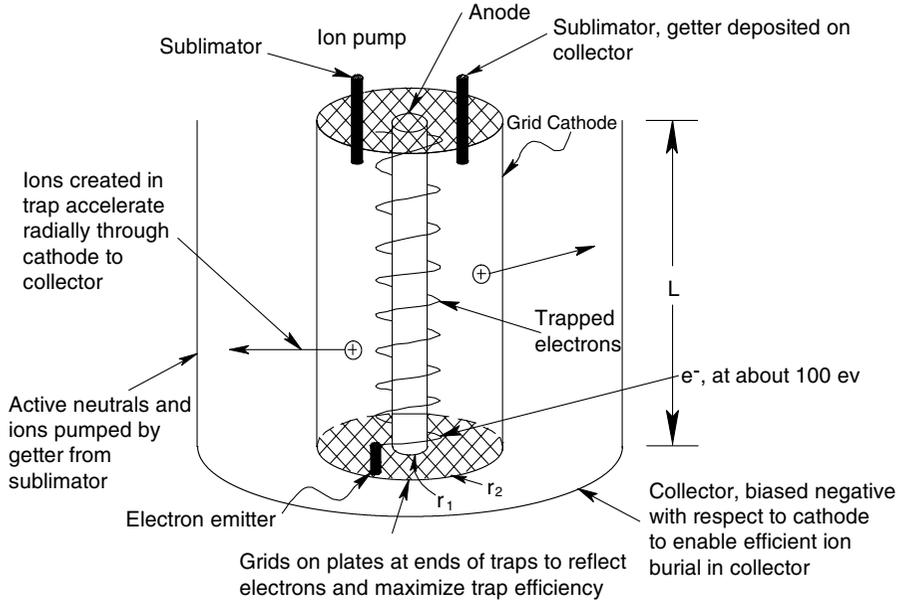

FIGURE 29.4 Orbitron pump schematic.

accelerated out of the trap through the cathode mesh by the radial electric fields. Initial work on reducing the size of an orbitron to MEMS scales has recently been reported by Wilcox (1999).

For a given geometry and potential difference between the anode and cathode mesh, the cylindrical capacitor represented by the trap geometry has a limiting maximum net negative charge of orbiting electrons. The corresponding ionization rate in the trap can be written as:

$$\dot{N}_{MAXions} = \frac{2X\pi\epsilon_0 V_D^{3/2} \Omega_t L n_g}{(em_e)^{1/2} \ln(r_2/r_1)^{3/2}} \quad (29.25)$$

where  $X$  is the fraction of the maximum charge that permits stable electron orbits (less than 0.5),  $V_D$  is the applied potential difference,  $m_e$  is the electron mass,  $\epsilon_0$  is the permittivity of free space,  $\Omega_t$  is the electron-neutral ionization cross section,  $L$  is the trap's length, and  $r_2$  and  $r_1$  are the radii of the trap's cathode and anode, respectively (Figure 29.4).

The orbitron's noble gas pumping speed and the trap's volume can be scaled based on the expression for ionization rate in Eq. (29.25):

$$\frac{(S_{P,MAXions})_i}{(S_{P,MAXions})_R} = s_i \frac{\Omega_i (V_D^{3/2})_i}{\Omega_R (V_D^{3/2})_R}; \quad \frac{(V_p/\dot{N}_{MAXions})_i}{(V_p/\dot{N}_{MAXions})_R} = s_i^2 \frac{\Omega_{I,i} (V_D)_i^{3/2}}{\Omega_{I,R} (V_D)_R^{3/2}} \quad (29.26)$$

Note that this is favorable scaling.

The sublimator's scaling, assuming the temperature of the sublimating getter is constant, can be written for neutrals and ions as:

$$\frac{(\dot{Q}_s/\dot{N}_{MAXneut})_i}{(\dot{Q}_s/\dot{N}_{MAXneut})_R} = 1; \quad \frac{(\dot{Q}_{ion}/\dot{N}_{MAXions})_i}{(\dot{Q}_{ion}/\dot{N}_{MAXions})_R} = 1 \quad (29.27)$$

Complete scaling results are presented in Table 29.2.

### 29.3.4 Pump-Down and Ultimate Pressures for MEMS Vacuum Systems

What is the consequence of size-scaling a vacuum system? Consider an elementary system made up of a pump and a vacuum chamber of volume  $V_c$  and surface area  $A_{sc}$ . The pump is modeled by writing the pumping speed as:

$$S_{p,i} = \{A_{I,P}(\bar{C}'/4)\alpha_p\}_i \quad (29.28)$$

where  $A_{I,P}$  is the area of the pump's inlet aperture from the chamber and  $\alpha_p$  is the probability that once through the aperture a molecule will be pumped. For a geometrically similar size change  $S_{p,i} = s_i^2(\alpha_{p,i}/\alpha_{p,R})S_{p,R}$ , and the pumping speed per unit surface area of the vacuum chamber is

$$(S_p/A_{sc})_i/(S_p/A_{sc})_R = \alpha_{p,i}/\alpha_{p,R} \quad (29.29)$$

Assuming equal outgassing rates per unit area for the reference and scaled systems, the ultimate system pressure will depend only on the pumping probability ratio,  $\alpha_{p,i}/\alpha_{p,R}$ . The pump-down time for the system can be measured using the ratio  $S_p/V_c = \tau_p$ :

$$\tau_{p,i}/\tau_{p,R} = s_i^{-1}(\alpha_{p,i}/\alpha_{p,R}) \quad (29.30)$$

For geometric scaling and the same outgassing rates, a MEMS vacuum system will have a significantly shorter pump-down time assuming  $\alpha_{p,i}/\alpha_{p,R}$  can be kept near one.

In practice MEMS-scale vacuum systems are likely to have pump apertures relatively much larger than their macroscopic counterparts. The economic deterrent to having large aperture pumps that exist at macroscales does not apply at the MEMS scale. At MEMS scales, it appears that technical issues associated with pump construction will favor making the pumps as large as possible. Consequently, relatively large pump apertures with areas about the same as the cross section of the pumped volume are anticipated.

### 29.3.5 Operating Pressures and $\dot{N}$ Requirements in MEMS Instruments

The selection of vacuum pumps for MEMS instruments and processes will depend on operating pressure and  $\dot{N}$  requirements. Because these can be determined reliably only when the task, instrument and detector or a particular process has been specified, it is virtually impossible to discuss significant, general size-scaling tendencies. For example, there has been speculation [Young, 1999] that a MEMS mass spectrometer sampling instrument might operate at upper pressures specified by keeping the Knudsen number based on, say, the quadrupole length constant compared to similar macroscale instruments. This can typically lead to tolerable upper operating pressures for microscale instruments of  $10^{-3}$  to  $10^{-2}$  mbar, depending on the scaling factor (see also Ferran and Boumsellek, 1996). On the other hand, the default response of many mass spectroscopists is  $10^{-5}$  mTorr, independent of scaling. Vargo (2000) based  $\dot{N}$  requirements for a miniaturized sampling mass spectrometer on the goal of replacing the entire volume of gas in the instrument ( $30 \text{ cm}^3$  in Vargo's case) every second at an operating pressure of  $10^{-4}$  mTorr, giving  $\dot{N} = 1.4 \times 10^{14}$  molecules/s. A point to remember is that for a constant  $Kn$  system the equilibrium quantity of adsorbed gas in the system increases compared to unadsorbed gas as the  $s_i$  decreases [Muntz, 1999].

A careful consideration of the operating pressure and  $\dot{N}$  requirements for a particular situation is obviously important, but impossible within the confines of the present discussion. It is clear that because of the difficulty in supplying volume- and power-compatible microscale vacuum systems, it will be important for overall system design to define operating conditions that are based on real needs.

### 29.3.6 Summary of Scaling Results

The scaling analyses outlined above have been applied to several pump types, with the results appearing in Table 29.2. The operating frequencies were selected to give two extremes: maintaining a constant average speed  $\bar{u}_i = \bar{u}_R$  (tangential for rotating devices or linear for reciprocating) by using the frequency scaling,  $f_{T,i} = s_i^{-1} f_{T,R}$ ; or maintaining a constant frequency,  $f_{T,i} = f_{T,R}$ , resulting in  $\bar{u}_i = s_i \bar{u}_R$ . Two alternative types of frictional drag, sliding and viscous, have been included, again as extremes of the likely possibilities.

The scaling expressions for the case  $\bar{u}_i = \bar{u}_R$  are simple when normalized by their respective reference scale values. For the second case, where  $\bar{u}_i = s_i \bar{u}_R$ , the expressions are more complex and the results depend on the relative magnitude of the quantities  $K_{L,R}$ ,  $K_{B,R}$ ,  $q_R d_{f,R}$ , etc. (see Table 29.2b). For the cases involving more complex expressions, order of magnitude estimates of the scaling based on typical pump characteristics have been included in Table 29.2a.

The sputter ion pumps have been included assuming that permanent magnets provide the required field strengths. Note that the mesoscale SIP performance presented in Figure 29.1 and Table 29.1 is for HMF operation.

In order to put the scaling results appearing in Table 29.2 in perspective it is important to remember that they are for geometrically accurate scale reductions. It is assumed that the relative dimensional accuracy of the components is the same in the reduced scale realization as in the reference macroscopic pumps. This is a very idealized assumption. The dimensional accuracy that can currently be attained in micromechanical parts as a function of size is illustrated in Figure 29.5, which is derived in part from Madou (1997). It is clear from Figure 29.5 that the scaling results of Table 29.2 may be very optimistic if true MEMS-scale pumps (component sizes 100  $\mu\text{m}$  or less) are required. On the other hand, the scalings do represent the best scaled performances that could be expected and as such are a useful guide. Note from Figure 29.5 that the smallest fractional tolerances can be achieved by precision machining techniques for approximately 1-cm size components. As a result, mesoscale pumps may be possible from a tolerance (although perhaps not economic) perspective using precision machining techniques.

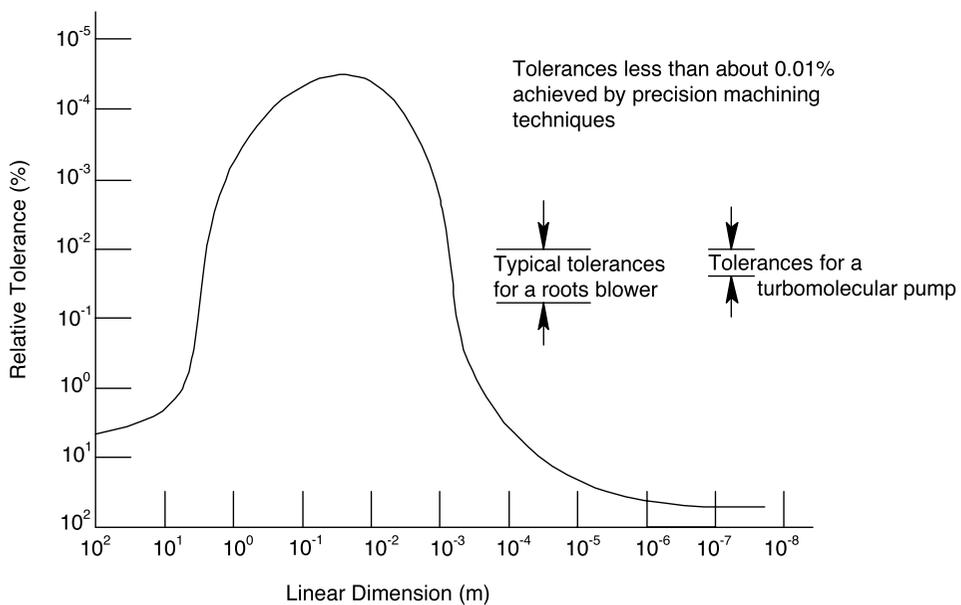

FIGURE 29.5 Dimensional accuracy of manufactured components as a function of size. (Adapted from Madou, 1997.)

Several points should be noted in the Table 29.2 results. For the case of  $\bar{u}_i = \bar{u}_R$ , the ideal scalings to small sizes are reasonable (remember  $s_i$  will range between  $10^{-1}$  and  $10^{-4}$ ). In the case of viscous friction losses, the energy use per molecule of upflow becomes large at small scales (increases as  $s_i^{-1}$ ) while the pump volume per unit upflow decreases as  $s_i$  decreases. For the case of positive-displacement pumps and  $\bar{u}_i = s_i \bar{u}_R$ , the energy use per molecule of upflow scales satisfactorily, but upflow scales as  $s_i^3$  so that the volume scaling is of  $\mathcal{O}[1]$  rather than the  $s_i^{-1}$  for the  $\bar{u}_i = \bar{u}_R$  case. The  $\phi_{MAX}$  scaling to small scales for  $\bar{u}_i = s_i \bar{u}_R$  is a disaster for turbomolecular pumps. Also, the upflow, energy and pump volume all scale badly for the turbomolecular pump with  $\bar{u}_i = s_i \bar{u}_R$ . These scalings are all a result of the trapping coefficient  $q \sim s_i$  for low peripheral speeds. Although not explicitly included, molecular drag pumps can be expected to scale similarly to the turbomolecular pump. For positive-displacement pumps, the pressure ratio scales well if there are no losses but can scale as badly as  $s_i$  depending on specific pump characteristics. For the cases where the pressure ratio scales badly, more pump stages would be required for a given task, leading to larger pumps as indicated by the > symbol in the energy use and pump volume per unit upflow columns.

The sputter ion pump scales well to smaller sizes. The major concern here for microscales will be the fundamental requirement for relatively high voltages. Also, thermal control will be difficult as it is complicated by the need for high field strengths (0.5–1 T) using co-located permanent magnets.

The orbitron ion pump scales well to smaller sizes but unfortunately, as seen in Figure 29.1 and Table 29.1, begins with a very poor performance as measured by  $\dot{Q}/\dot{N}$ .

Generally speaking, for the positive-displacement and turbomolecular pumps, the idealized geometric scaling results presented in Table 29.2 demonstrate that there is a mixed bag of possibilities, ranging from decreased performance to maintaining performance, with a few cases showing improvement on macro-scale performance by going to smaller scales. From a vacuum pump perspective, with ideal scaling there is little to no advantage based on performance to go to small scales, except for the ion pumps.

The actual performance of small-scale pumps is likely to be significantly poorer than the idealized scaling results shown in Table 29.2. For instance, it has proven to be very difficult to attain the high rotational speeds necessary to satisfy the  $\bar{u}_i = \bar{u}_R$  requirements in MEMS-scale devices; on the other hand, recent progress in air-bearing technology [Fr chet te et al., 2000] has been reported for mesoscale gas turbine wheels. Mesoscale sputter ion pumps have been operated, and the investigation of orbitron scaling is just beginning. Whether either can be scaled to true MEMS sizes is unclear, but they may be the only alternative for achieving high vacuum with MEMS pumps.

Keeping the preceding comments in mind, it is useful to re-visit the macroscale vacuum pump performances reviewed in Figure 29.1. Consider a typical energy requirement from Figure 29.1 of  $3 \times 10^{-15}$  W/molecule of upflow for macroscale systems, and assume that this can be maintained at mesoscales to pump through a pressure ratio of  $10^6$  ( $10^{-3}$  mbar to 1 bar). A typical upflow, assuming a 3-cm<sup>3</sup> volume at  $10^{-3}$  mbar is changed every second, is  $1.1 \times 10^{14}$  molecules/s and the required energy is 0.33 W. This is somewhat high but perhaps tolerable for a mesoscale system. However, with the expected degradation of the performance of complex macroscale pumps at meso- and microscales, it is clear that it is important to search for alternative, unconventional pumping technologies that will be buildable and operate efficiently at small scales.

## 29.4 Alternative Pump Technologies

The previous section on scaling indicates that searching for appropriate alternative technologies as a basis for MEMS vacuum pumps is necessary. There has been some effort in this regard during the past decade. In the fall of 1993, Muntz, Pham-Van-Diep and Shiflett hypothesized that the rarefied gas dynamic phenomenon of thermal transpiration might be particularly well suited for MEMS-scale vacuum pumps. Thermal transpiration is the application of a more general phenomenon, thermal creep, that can be used to provide a pumping action in flow channels for Knudsen numbers ranging from very large to about 0.05. The observation resulted in a publication [Pham-Van-Diep et al., 1995] and has very recently led to the construction of a prototype micromechanical pump stage by Vargo (2000). A MEMS thermal

transpiration pump has also been proposed by Young (1999). There is one fundamental problem with thermal transpiration or thermal creep pumps—for reasons explained later, they are staged devices that require part of each stage to have a minimum size corresponding to a dimension greater than about 0.2 molecular mean free paths ( $\lambda$ ) in the pumped gas. At 1 mTorr ( $1.32 \times 10^{-3}$  mbar)  $\lambda \approx 0.05$  m in air, resulting in required passages no smaller than about 1 cm. Thus, at low inlet pressures the pumps can be unacceptably large for MEMS applications.

An interestingly different version of a thermal creep pump has been suggested by Sone and his co-workers [Sone et al., 1996; Aoki et al., 2000], although it also has a low-pressure use limit similar to the one mentioned above.

Another alternative, the accommodation pump, which is superficially similar to thermal transpiration pumps but based on a different physical phenomenon, has been investigated [Hobson and Pye, 1972]. It can in principle be used to provide pumping at arbitrarily low pressures without minimum size restrictions.

### 29.4.1 Outline of Thermal Transpiration Pumping

Two containers, one with a gas at temperature  $T_L$  and one at  $T_H$  are separated by a thin diaphragm of area  $A_i$  having single or multiple apertures, each of which has an area  $A_a$  and a size  $\sqrt{A_a} \ll \lambda_L$  or  $\lambda_H$  (refer to Figure 29.6). The number of molecules hitting a surface per unit time per unit area in a gas is  $n\bar{C}'/4$ . In Figure 29.6 this means that there are  $(n_L\bar{C}'_L/4)A_a$  molecules passing from cold to hot through an aperture. Similarly, there are  $(n_H\bar{C}'_H/4)A_a$  molecules per unit time passing from hot into the cold chamber.

Assume  $m$  is the same for the molecules in both chambers, and assume that the inlet and outlet are adjusted so that  $p_L = p_H$ . Under these circumstances, the net number flow of molecules from cold to hot is, with the help of the equation of state:

$$\dot{N}_{MAX} = A_a(2\pi mk)^{-1/2}p_L[T_H^{1/2} - T_L^{1/2}]/(T_L T_H)^{1/2} \quad (29.31)$$

If, on the other hand, there is no net flow:

$$(p_H/p_L)_{\dot{N}=0} = \wp_{MAX} = (T_H/T_L)^{1/2} \quad (29.32)$$

For  $p_H$  between  $p_L$  and  $p_L(T_H/T_L)^{1/2}$  there will be both a pressure increase and a net flow, which are the necessary conditions for a pump! This effect is known as *thermal transpiration*. If there are  $\Gamma$  apertures

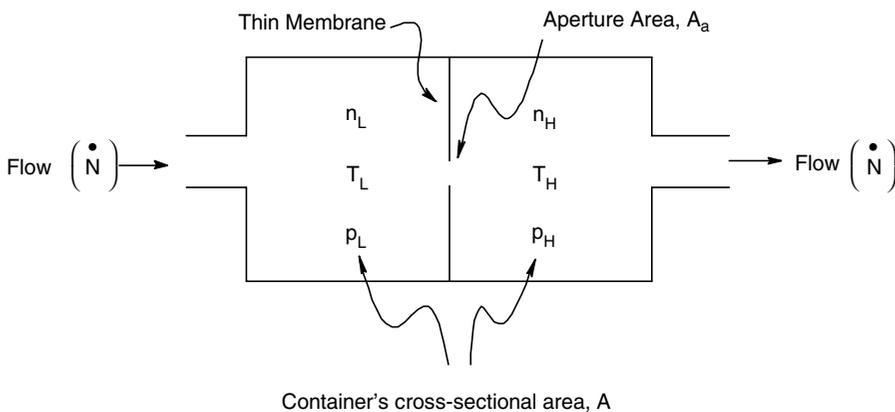

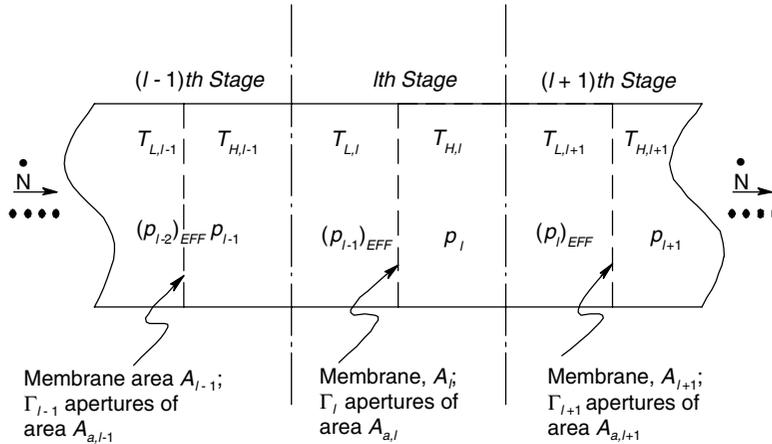

FIGURE 29.6 Elementary single stage of a thermal transpiration compressor.

**FIGURE 29.7** Cascade of thermal transpiration stages to form a Knudsen Compressor (the pressure difference,  $(p_{\ell})_{EFF} - p_{\ell}$ , drives the flow through the connector, as illustrated in [Figure 29.8](#)).

the total upflow of molecules is

$$\dot{N} = \Gamma A_a (2\pi mk)^{-1/2} [p_L/T_L^{1/2} - p_H/T_H^{1/2}] \quad (29.33)$$

If the hot gas at  $T_H$  is allowed to cool and is sent to another stage as indicated in [Figure 29.7](#), for the condition that  $\lambda \ll \sqrt{A_j}$  where  $A_j$  is the stage area (but also  $\lambda \gg \sqrt{A_{a,j}}$ ), the pressure  $p_{L,j+1} = P_{H,j}$ . Thus, a cascade of stages with net upflow is a pump with no net temperature increase over the pump cascade. This cascade of thermal transpiration pump stages has no moving parts and no close tolerances between shrouds and impellers, so it is an ideal candidate for a MEMS pump. However, the compressor stages sketched in [Figure 29.7](#) have a serious problem. The thin films containing the apertures are not practical in most applications because of heat-transfer considerations. A more practical stage is shown in [Figure 29.8](#), where the thin membrane has been replaced by a bundle of capillary tubes. The temperature and pressure profiles in the stage are also illustrated in [Figure 29.8](#) along with nomenclature that will be used below.

The stage configuration in [Figure 29.8](#) can be put in a cascade ([Figure 29.7](#)) to form a pump as proposed by Pham-Van-Diep et al. (1995) and called a Knudsen Compressor (after original work by Knudsen, 1910a; 1910b). Several investigations implementing thermal transpiration in macroscale pumps have been made over the years [Turner, 1966], but with no result beyond initial analysis and laboratory experimental studies. For the Knudsen Compressor, a performance analysis was presented for the case of collisionless flow in the capillaries and continuum flow in the connectors [Pham-Van-Diep et al., 1995]. Energy requirements per molecule of upflow ( $\dot{Q}/\dot{N}$ ) were estimated. Recently, Muntz and several collaborators [Muntz et al., 1998; Vargo, 2000] have extended the analysis to situations where the flow in both the capillaries and connector section can be in the transitional flow regime ( $10 > Kn > 0.05$ ). An initial look at the minimization of cascade energy consumption and volume has been conducted [Muntz et al., 1998; Vargo, 2000] by searching for minimums in  $\dot{Q}/\dot{N}$  and  $V_p/\dot{N}$ . Based on these studies, a preprototype micromechanical Knudsen Compressor stage has been constructed and tested [Vargo and Muntz, 1996; 1998; Vargo et al., 2000].

For transitional flow in a capillary tube with a longitudinal temperature gradient imposed on the tube's wall, flow is driven from the cold to hot ends, as illustrated in [Figure 29.9](#). The increased pressure at the hot end drives the return flow. For small temperature differences and thus small pressure increases, the Boltzmann equation can be linearized and results for the flow through a cylindrical capillary driven by small wall temperature gradients obtained [Sone and Itakura, 1990; Loyalka and Hamoodi, 1990;

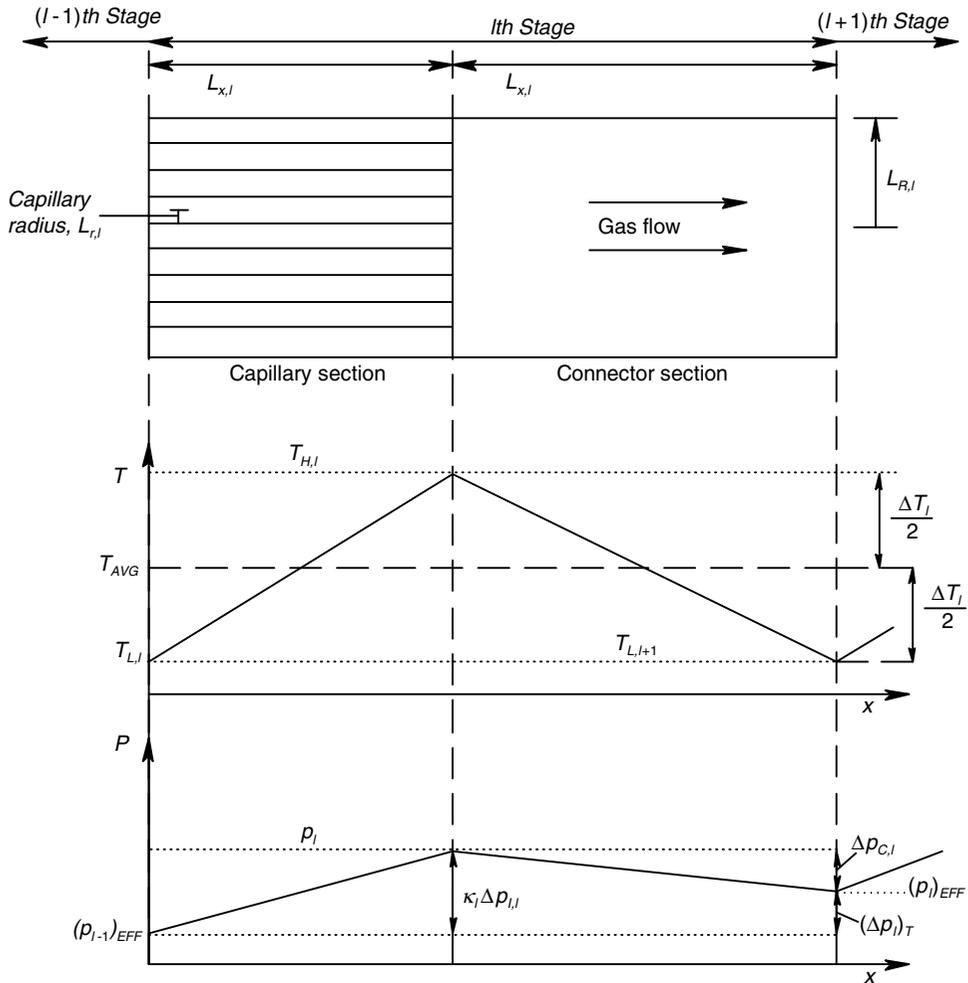

FIGURE 29.8 Capillary tube assembly as a model of a practical Knudsen Compressor.

Loyalka and Hickey, 1991]. The definition of the flow coefficients ( $Q_T$  and  $Q_P$ ) is implied in the following expression [Sone and Itakura, 1990]:

$$\dot{M} = p_{AVG} (2(k/m) T_{AVG})^{-1/2} A \left[ \frac{L_r}{T_{AVG}} \frac{dT}{dx} Q_T - \frac{L_r}{p_{AVG}} \frac{dp}{dx} Q_P \right] \quad (29.34)$$

Here,  $A$  is the cross-sectional area of the capillary,  $L_r$  is its radius,  $Q_P$  is the backflow due to the pressure increase, and  $Q_T$  is the thermally driven upflow near the walls. The sum determines the net mass flow through the tube from cold to hot. For large  $Kn$  ( $= \lambda/L_r$ ), the  $\dot{M} = 0$  pressure increase provided by a tube is  $p_H/p_C = Q_T/Q_P = (T_H/T_C)^{1/2}$ , identical to the aperture case discussed earlier. In the large  $Kn$  case, the backflow and upflow completely mingle over the entire tube cross section. For transitional  $Kn$ s the upflow is confined near the wall in a layer on the order of  $\lambda$  thick, as illustrated in Figure 29.9.

The values of  $Q_T$  and  $Q_P$  vary markedly throughout the transitional flow regime, as shown in Figure 29.10. The details of their functional variations as well as the ratio  $Q_T/Q_P$  are important to any pump using

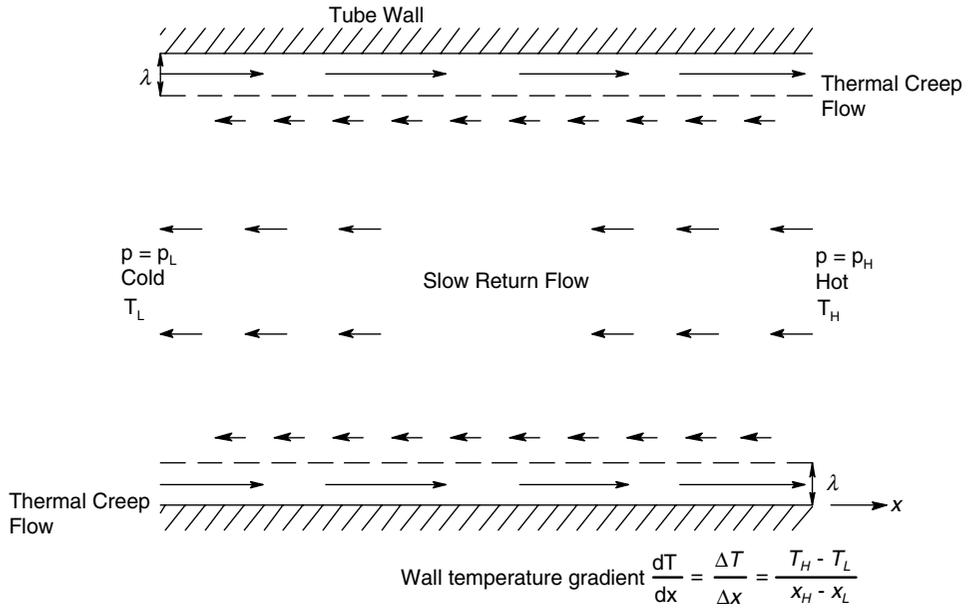

FIGURE 29.9 Transitional flow configuration in a capillary tube.

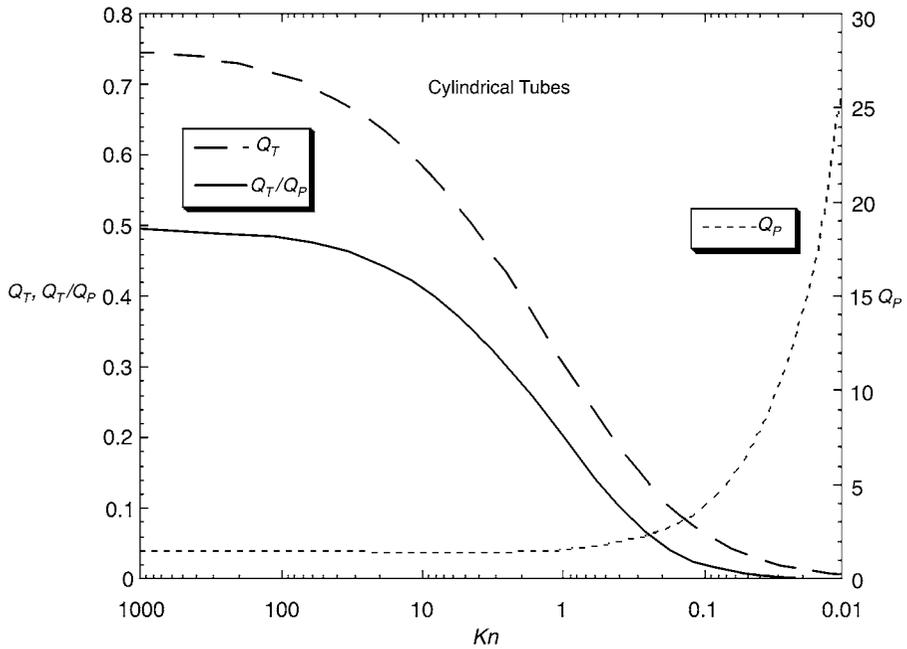

FIGURE 29.10 Transitional flow coefficients as a function of Knudsen number ( $Kn = \lambda/L_r$ ) for cylindrical capillaries. (Adapted from Vargo, 2000.)

thermal transpiration. Their roles are best illustrated by the expression for pumping speed and pressure ratio of the  $j$ th stage of a Knudsen Compressor [Muntz et al., 1998]:

$$S_{P,j} = \pi^{1/2} (1 - \kappa_j) \left| \frac{\Delta T}{T_{AVG}} \right| \left[ \frac{Q_T}{Q_P} - \frac{Q_{T,C}}{Q_{P,C}} \right] \left[ \frac{L_x/L_r}{F Q_P} + \frac{L_x/L_r}{F_C (A_c/A) Q_P} \right]^{-1} (C_A)_j \quad (29.35)$$

In Eq. (29.35), the  $\kappa_j$  is a parameter that sets the fraction of the  $\dot{M} = 0$  pressure rise that is realized in a finite upflow situation. The pressure ratio for the stage, assuming  $|\Delta T/T_{AVG}| \gg 1$  [Muntz et al., 1998], is

$$\wp_j = 1 + \kappa_j \left\{ \left| \frac{\Delta T}{T_{AVG}} \right| \left[ \frac{Q_T}{Q_P} - \frac{Q_{T,C}}{Q_{P,C}} \right] \right\} \quad (29.36)$$

In Eqs. (29.35) and (29.36),  $|\Delta T|$  is the temperature change across both the capillary section and the connector section;  $F$  is the fraction of the capillary section's area,  $A_p$ , that corresponds to the open area of the capillary tubes; and  $F_C$  is the fraction of the connector section's area,  $A_{C,j}$ , that is open (usually  $F_{C,j} = 1$ ). The dimensions  $L_{x,j}$ ,  $L_{r,j}$ ,  $L_{r,j}$ ,  $L_{R,j}$  are defined in Figure 29.8.

From Eq. (29.36), if  $\kappa_j = 0$  then  $\wp_j = 1$ . The corresponding maximum upflow is obtained by substituting  $\kappa_j = 0$  into Eq. (29.35) to give  $(S_{P,MAX})_j$ . The result is

$$S_{P,j}/(S_{P,MAX})_j = (1 - \kappa_j) \quad (29.37)$$

which can be combined with the expression for  $\wp_{j,MAX,j}$  (using  $\kappa_j = 1$  in Eq. (29.35)) to give the familiar relationship for a vacuum pumping system, Eq. (29.7), between  $S_{P,j}$ ,  $S_{P,MAX,j}$ ,  $\wp_j$  and  $\wp_{MAX,j}$ .

The expression for pumping speed in Eq. (29.35) can also be used to compute the pumping probability  $\alpha_{P,j}$ , where from Eq. (29.5)  $\alpha_{P,j} = S_{P,j}/C_{A,j}$ . Using Eqs. (29.35) and (29.36) and remembering that  $N_j = S_{P,j} n_{I,j}$ , where  $n_{I,j}$  is the number density at the inlet to the stage, cascade performance calculations can be accomplished. The approach is presented in detail in Muntz et al. (1998). The results of several cascade simulations are given by Vargo (2000). As shown by Muntz, the majority of the energy required is the thermal conduction loss across the capillary tube bundle. The physical realization of the capillary section of a Knudsen Compressor is frequently not a bundle of capillary tubes, but rather a porous membrane. Nevertheless, the theoretical behavior based on "equivalent" capillary tubes appears to be consistent with the results obtained experimentally [*c.f.* Vargo, 2000, and the discussions presented therein].

Selected results of micro/meso and macroscale pump cascade simulations reported by Vargo (2000) are plotted in Figure 29.11 and presented in Table 29.3. It is important to note that all the Knudsen Compressor cascade results are from simulations; a micromechanical cascade has yet to be constructed, although several mesoscale stages have been operated in series [Vargo and Muntz, 1996]. In his thesis, Vargo (2000) describes the construction of a laboratory prototype micromechanical Knudsen Compressor stage and the experimental results obtained from it. A scheme for constructing a cascade is also presented, along with predicted energy requirements, but this has yet to be built and tested. The Knudsen Compressor performance presented in Figure 29.11 is based on a significant body of preliminary work but has not yet been demonstrated experimentally. The results are for varying initial pressures  $p_i$  and pumping to 1 atm (the detailed conditions are presented in Table 29.3. In MEMS devices, pressures below 10 mTorr extract a significant energy penalty, tending to preclude Knudsen Compressor applications to lower pressures at MEMS scale. This restriction, however, depends on the  $\dot{N}$  that is required. The energy penalty originates from the difficulty in effectively reaching continuum flow in the connector section for a reasonable size. Note that the macroscale simulations presented in Figure 29.11 give efficient pumping to significantly lower  $p_i$  (higher  $\wp$ ).

Notes: Micro-/mesoscale cascade:  $L_r = 500 \mu\text{m}$ ,  $L_R/L_r = 5$  from  $p_I$  to 50 mTorr, then constant  $Kn_p$ ; Macroscale cascade:  $L_r = 5 \text{ mm}$ ,  $L_R/L_r = 20$  from  $p_I$  to 10 mTorr, then constant  $Kn_p$ .

**FIGURE 29.11** Simulation results for several macro- and microscale pumping tasks from  $p_I$  to  $p_E = 1 \text{ atm}$  using Knudsen Compressors (as presented in Table 29.3).

The size scaling of Knudsen Compressors at low inlet pressures is dominated by the ratio  $L_R/L_r$ , which can be achieved in the early stages of a particular design. The ratio  $L_R/L_r$  determines the Knudsen number ratio, which in turn determines the  $Q_T/Q_p$  ratio (Figure 29.10). By referring to Eq. (29.36), the effects on the stage  $\wp_j$  are immediately clear. In the limit of  $L_R/L_r \rightarrow 1$ ,  $\wp = 1$ . For  $L_R/L_r \gg 1$ ,  $Q_{T,C}/Q_{R,C} \ll 1$  and  $\wp_j$  reaches a maximum value that depends only on  $\kappa_j$  and  $|\Delta T/T_{AVG}|$ .

Minimizing the energy requirement of a Knudsen Compressor cascade depends on a number of important parameters describing the individual stage configurations. The results reported by Vargo (2000)

**FIGURE 29.12** Comparison of macro- and microscale Knudsen Compressor performances from simulations [Vargo, 2000] to representative available macro- and mesoscale vacuum pumps.

are only a beginning attempt at optimizing Knudsen Compressor performance (there are extended discussions of optimization issues in Muntz et al., 1998). The predicted Knudsen Compressor performance presented in Figure 29.11 is quite promising. Generally, as illustrated in Figure 29.12, the energy requirement for the micro-/mesoscale version is at least an order of magnitude better than macroscale, positive-displacement mechanical backing pumps. It also appears very competitive with the macroscale molecular drag kinetic backing pumps used in conjunction with turbomolecular pumps.

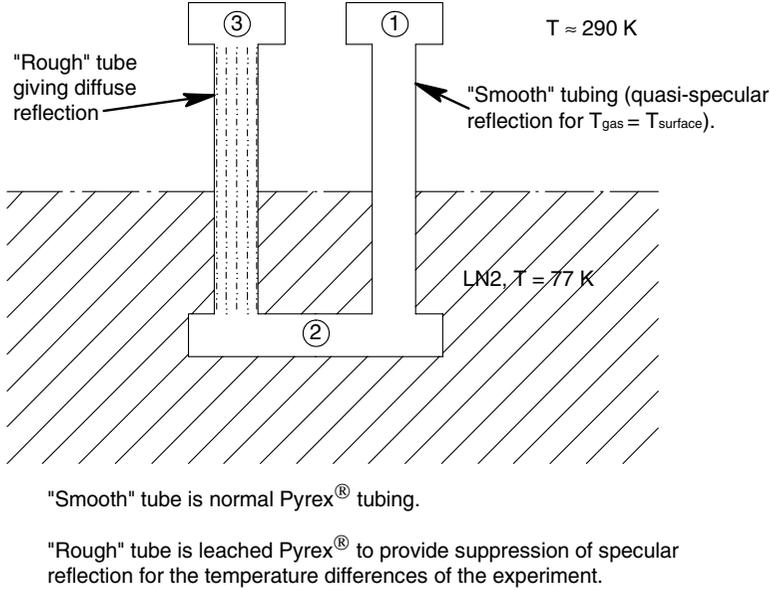

Another MEMS thermal transpiration compressor has been proposed by Young (1999). Its configuration is different from the Knudsen Compressor, relying on temperature gradients established in the gas rather than along a wall. No experimental or theoretical analysis of the flow or pressure-rise characteristics of this configuration has been reported. There are theoretical reasons to believe that the flow effects induced by thermal gradients in a gas are significantly smaller than the effects supported by wall thermal gradients [Cercignani, 2000].

### 29.4.2 Accommodation Pumping

In 1970, Hobson introduced the idea of high-vacuum pumping by employing a characteristic of surface scattering that had been observed in molecular beam experiments [*cf.* the review by Smith and Saltzburg, 1964]. For some surfaces that give quasi-specular reflection under controlled conditions, when the beam temperature differs from the surface temperature, the quasi-specular scattering lobe moves toward the surface normal for cold beams striking hot surfaces. For hot beams striking cold surfaces, the lobe moves away from the normal. Hobson's initial study was followed in short order by several investigations adopting the same approach [Hobson and Pye, 1972; Hobson and Salzman, 2000; Doetsch and Ryce, 1972; Baker et al., 1973]. Other investigators, relying on the same phenomenon, have used different geometrical arrangements [Tracy, 1974; Hemmerich, 1988]. Recently Hudson and Bartel (1999) analyzed a sampling of previous experiments with the Direct Simulation Monte Carlo technique. To date, the most successful pumping arrangement, which is sketched in Figure 29.13, has been that of Hobson.

Following Hobson's lead it is easy to write expressions for  $\phi_{MAX,j} = p_3/p_1$  and  $S_{P,MAX,j}$  for the stage in Figure 29.13. The accommodation pump works best under collisionless flow conditions, so assume  $\lambda \geq 10d$ , where  $d$  is the tube diameter. Assuming steady-state conditions, conservation of molecule flow equations for each volume can be solved simultaneously for zero net upflow to give:

$$\phi_{MAX,j} = \frac{\alpha_{23}}{\alpha_{32}} \cdot \frac{\alpha_{12}}{\alpha_{21}} = \frac{\alpha_{12}}{\alpha_{21}} \quad (29.38)$$

**FIGURE 29.13** Schematic representation of Hobson's accommodation pump configuration. (Adapted from Hobson, 1970).

Here,  $\alpha_{kl}$  is the probability for a molecule having entered a tube from the  $k$ th chamber reaching the  $l$ th chamber. In this case, because the tube joining chambers 2 and 3 is assumed always to reflect diffusely,  $\alpha_{23} = \alpha_{32}$ .

The same molecule flow equations can be solved along with Eq. (29.38) to provide maximum upflow or pumping speed ( $\phi_j = 1$ ):

$$S_{P,MAX,j} = \frac{\bar{C}'_H A_j}{4} \{ (\phi_{MAX,j} - 1) \alpha_{2,1} / [1 + (\alpha_{2,1}) / (8L_r / 3L_x)] \} \quad (29.39)$$

From the earlier discussions, it is reasonable to anticipate that  $\alpha_{2,1}$  will have a value that approximately corresponds to diffuse reflection, which for a long tube is  $(8L_r / 3L_x)$ . A simple approximate expression for maximum pumping speed becomes:

$$S_{P,MAX,j} = (\bar{C}'_H / 4) A_j (4L_r / 3L_x) (\phi_{MAX,j} - 1) \quad (29.40)$$

If  $\phi_{MAX,j}$  is known from experiments,  $S_{P,MAX,j}$  can be found from Eq. (29.40).

Scaling accommodation pumping is not difficult because, unlike the Knudsen Compressor, the flow is collisionless everywhere. If the minimum radius of the two channels in a stage is such that  $L_r \geq 100$  nm, there is little reason to believe that  $\phi_{MAX,j}$  or the transmission probabilities will vary with scale. For geometric scaling:

$$\frac{S_{P,MAX,j}}{S_{P,MAX,R}} = s_i^2 \quad (29.41)$$

No analysis or measurements of the energy requirements of accommodation pumping are available, but the temperature differences required to obtain an effect are quite large (the temperature ratio in various experiments ranges from 3 to 4). Careful thermal management would be required at MEMS scales. Additionally, the stage  $\phi_{MAX,j}$  values are quite low (Hobson's are typically around 1.15). For an upflow of  $S_{P,MAX,j} / 2$ , to pump through a pressure ratio of  $10^2$  would require about 125 stages. For comparison, a Knudsen Compressor operating between the same temperatures would require 10 stages. Of course, as

outlined earlier, the Knudsen Compressor could not pump effectively at very low pressures, whereas accommodation pumps can.

Using the miniature Creare turbomolecular pump scaled down with constant  $f_{Bi}$  to a 2-cm diameter, the authors have estimated an air pumping probability of about 0.05. A Hobson-type accommodation pump with 2-cm-diameter,  $L_r/L_x = 0.05$  Pyrex® tubes and operating between room and  $LN_2$  temperatures would have, from Eq. (29.40), a pumping probability of about 0.01.

Scaling Hobson's pump to MEMS scales would permit operation with molecular flow up to pressures much greater than  $10^{-2}$  mbar, providing the surface reflection characteristics were not negatively affected by adsorbed gases. This is a serious uncertainty, as all of the available experiments have been reported for pressures between 1 and several orders of magnitude less than  $10^{-2}$  mbar.

## 29.5 Conclusions

---

The performances of a representative sampling of macroscale vacuum pumps have been reviewed based on parameters relevant to micro- and mesoscale vacuum requirements. If the macroscale performances of these generally complex devices could be maintained at meso- and microscales, they might be barely compatible with the energy and volume requirements of meso- and microsampling instruments. A general scaling analysis of macroscale pumps considered as possible candidates for scaling (although going to microscales with these scaled pumps is currently beyond the state of the manufacturing art) is presented and provides little to no incentive for simply trying to scale existing pumps, with the possible exception of ion pumps. When the difficulty in developing MEMS manufacturing techniques with adequate tolerances is considered, the possibility of maintaining the macroscale performance at microscales is remote. As a consequence, two alternative pump technologies are examined. The first, the Knudsen Compressor, is based on thermal creep flow or thermal transpiration and appears attractive as a result of both analysis and initial experiments. The second, also a thermal creep pump, is under study but requires further analysis before its microscale suitability can be established. Both, however, have a characteristic that prevents them from operating efficiently when pumping high vacuums ( $<10^{-3}$  to  $10^{-2}$  mbar).

The second possibility, accommodation pumping, although superficially similar to the Knudsen Compressor, is based on surface molecular reflection characteristics and will pump to ultra-high vacuums. Further analysis and experiments are required to be able to provide performance estimates of accommodation pumping in meso- and microscale contexts.

The alternative technology pumps have no moving parts; no liquids are required for seals, pumping action or lubrication. These are characteristics shared with the ion pumps. They all have the capability of providing mesoscale pumping and the potential for truly MEMS-scale pumping. To realize these alternative technology pumps, significant and focused research and development efforts will be required.

## Acknowledgments

---

The authors thank Andrew Jamison for preparing the figures and Tariq El-Atrache and Tricia Harte for patiently working on the manuscript through many revisions. Dr. Andrew Ketsdever, Professor Geoff Shiflett, and Mr. Dean Wiberg have provided helpful comments. Discussions with Dr. David Salzman over several years have been both entertaining and informative.

## Defining Terms

**Capture pumps:** Vacuum pumps where pumping action relies on sequestering pumped gas in a solid matrix until it can be removed in a separate, off-line operation.

**Conductance:** Measure of the capability of a vacuum system component (tube, channel) for handling gas flows; has units of gas volume per unit time.

**Knudsen number:** Indication of the degree of rarefaction of flow in a vacuum system component; for  $Kn > 10$ , molecules collide predominantly with the walls, and, for  $Kn < 10^{-3}$ , intermolecular collisions dominate.

**Microscale, mesoscale and macroscale:** In reference to a device, these terms as used in this chapter correspond to the following typical dimensions:

- *Microscale:* Smallest components <100  $\mu\text{m}$ , device <1 cm
- *Mesoscale:* Smallest component 100  $\mu\text{m}$  to 1 mm, device 1 cm to 10 cm
- *Macroscale:* Smallest components >1 mm, device >10 cm

**Pumping speed:** Measure of the pumping ability of a vacuum pump in terms of volume per unit time of inlet pressure gas that can be pumped.

**Regeneration:** Off-line removal of sequestered gas from a capture pump.

**Vacuum:** For the purposes of this chapter, the pressure ranges corresponding to various descriptions attached to vacuums are

- *Low or roughing:*  $10^3$  to  $10^{-2}$  mbar
- *High:*  $10^{-2}$  to  $10^{-7}$  mbar
- *Ultra-high:*  $<10^{-7}$  mbar

## Further Information

A concise up-to-date review of the mathematical background of internal rarefied gas flow is presented in the book, *Rarefied Gas Dynamics*, by Carlo Cercignani [Cercignani, 2000]. Vacuum terminology and important considerations for the description of vacuum system performance and pump types are presented in the excellent publication by J. M. Lafferty, *Foundations of Vacuum Science and Technology* [Lafferty, 1998]. A detailed presentation of work on rarefied transitional flows is documented by the proceedings of the biannual International Symposia on Rarefied Gas Dynamics (various publishers over the last 45 years, all listed in Cercignani, 2000). This reference source is generally only useful for those with the time and inclination for academic study of undigested research, although there are several review papers in each publication.

### 30.1 Introduction

---

Microdroplet generators are becoming an important research area in microelectromechanical systems (MEMS), not only because of the valuable marketing device—inkjet printhead—but also because of the many other emerging applications for precise or micro-amount fluidic control. There has been a long history of development of microdroplet generators ever since the initial inception by Sweet (1964, 1971), who used piezo actuation, and by Hewlett-Packard and Cannon [Nielsen et al., 1985] in the late 1970s, who used thermal bubble actuation. Tremendous research activities regarding inkjet applications have been devoted to this exciting field. Emerging applications in the biomedical, fuel-injection, chemical, pharmaceutical, electronic fabrication, microoptical device, integrated circuit cooling, and solid freeform fields have fueled these research activities. Thus, many new operation principles, designs, fabrication processes and materials related to microdroplet generation have been explored and developed recently, supported by micromachining technology.

In this chapter, microdroplet generators are defined as droplet generators generating micro-sized droplets in a controllable manner; that is, droplet size and number can be accurately controlled and counted. Thus, atomizer, traditional fuel-injector or similar droplet-generation devices that do not offer such control are not discussed here.

Microdroplet generators usually employ mechanical actuation to generate high pressure to overcome liquid surface tension and viscous force for droplet ejection. Depending on the droplet size, the applied pressure is usually greater than several atmospheres. The operation principles, structure/process designs and materials often play key roles in the performance of droplet generators.

The applications of microdroplet generators, in addition to the well-known application of inkjet printing, cover a wide spectrum of fields, including direct writing, fuel injection, solid freeform, solar cell fabrication, light emitting polymer display (LEPD) fabrication, packaging, microoptical components, particle sorting, microdosage, plasma spraying, drug screening/delivery/dosage, micropropulsion, integrated circuit cooling and chemical deposition. Many of these applications may become key technologies for integrated microsystems in the near future.

This chapter provides the reader with an overview of the operation principles, physical properties, design issues, fabrication process and issues, characterization methods and applications of microdroplet generators.

## 30.2 Operation Principles of Microdroplet Generators

Many attempts have been made to generate controllable microdroplets [Buehner et al., 1977; Twardeck, 1977; Carmichael, 1977; Ashley et al., 1977; Bugdayci et al., 1983; Darling et al., 1984; Lee et al., 1984; Myers and Tamulis, 1984; Nielsen, 1985; Bhaskar and Aden, 1985; Allen et al., 1985; Krause et al., 1995; Chen and Wise, 1995; Tseng et al., 1996; Hirata et al., 1996; Zhu et al., 1996]. Most of these methods have employed the principle of creating pressure differences, either by lowering the outer pressure or increasing the inner pressure of a nozzle, to push or pull liquid out of the nozzle to form droplets. Typical examples are pneumatic, piezoelectric, thermal bubble, thermal buckling, focused acoustic-wave and electrostatic actuations. The basic principles of those droplet generators are introduced in the following sections. An ejection method by acceleration is also included in the last section, in which inertial force is employed for droplet generation.

### 30.2.1 Pneumatic Actuation

The spray nozzle is one of the most commonly used devices for generating droplets nowadays for airbrush or sprayer applications. Two types of spray nozzles are shown in Figure 30.1. Figure 30.1a shows that the air brush generates lower pressure at the outer edge of the capillary tube by blowing air across the tube

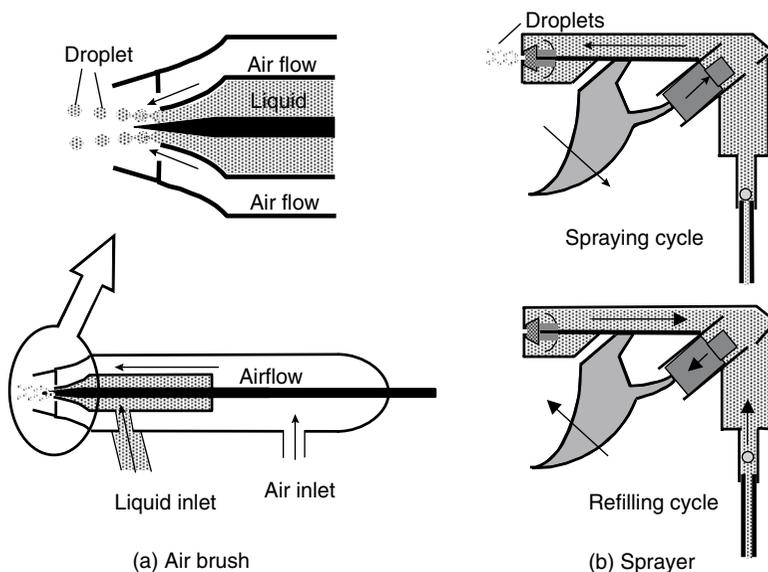

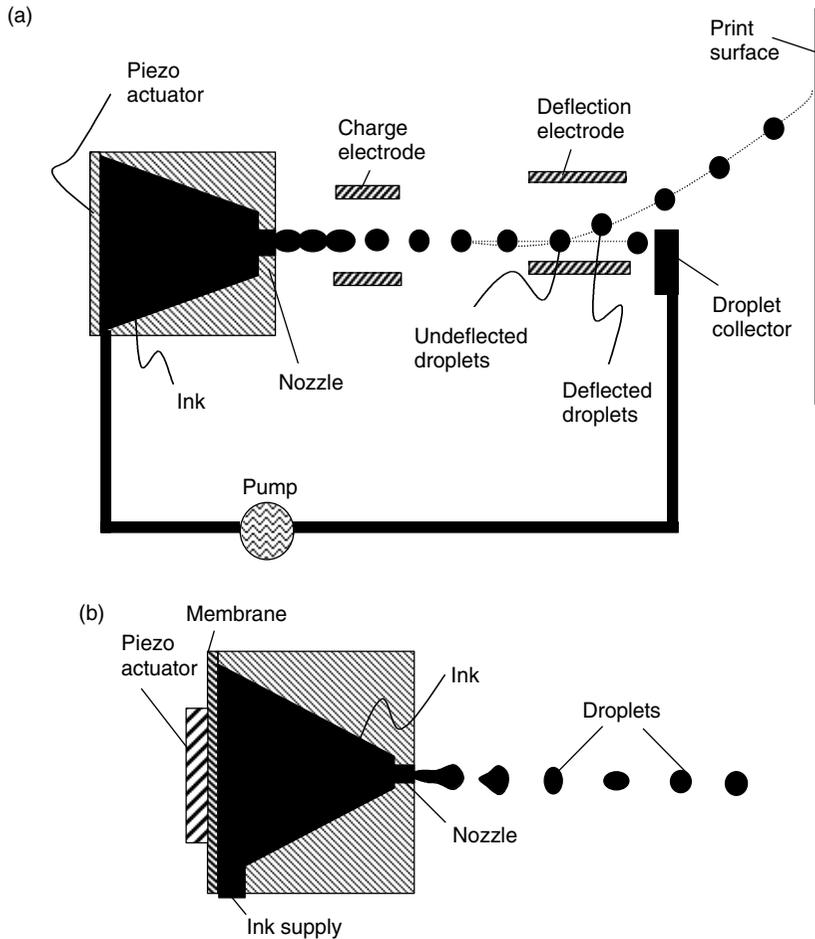

FIGURE 30.1 Operation principle of airbrush and sprayer. (After Tseng, 1998.)

**FIGURE 30.2** (a) Operation principle of a piezoelectric-actuated continuous droplet generator. (After Buehner et al., 1977.) (b) Operation principle of a piezoelectric-actuated droplet-on-demand droplet generator. (After Lee et al., 1984.)

end, which forces liquid to move out of the tube and form droplets. The sprayer shown in [Figure 30.1b](#) employs high pressure to push liquid through a small nozzle to form droplets. Typical sizes of the droplets generated by the spray nozzle range from tens to hundreds of microns in diameter. The device can be fabricated in microsize using micromachining technology, however, it is difficult to control each nozzle separately in an array format.

### 30.2.2 Piezoelectric Actuation

The droplet ejection by piezoelectric actuation was invented by Sweet in 1964. Based on the piezoelectric technology, there are two types of piezoelectric devices. One is called the *continuous inkjet* [Buehner et al., 1977; Twardeck, 1977; Carmichael, 1977; Ashley et al., 1977]. [Figure 30.2a](#) shows the operation principle of this type of inkjet. Conductive ink is forced out of the nozzles by pressure. The jet breaks up continuously into droplets with random sizes and spacing. Uniformity of the size and spacing of the droplets can be controlled by applying an ultrasonic wave with fixed frequency to the ink through a piezoelectric transducer. The continuously generated droplets pass through a charge plate, and only the desired ones are charged by the electric field and deflected to printout, while the nondesired ones are collected in a

gutter and recycled. One piezoelectric transducer can support multiple nozzles, so the nozzle spacing can be as small as desired for high-resolution arrays, however, the complexity of the droplet charging and collecting system is a major obstacle to practical use of this device.

The other device, called droplet-on-demand inkjet, utilizes a piezoelectric tube or disc for droplet ejection only when printing a spot is desired [Bugdayci et al., 1983; Darling et al., 1984; Lee et al., 1984]. Figure 30.2b shows a typical drop-on-demand drop generator. The operational principle is based on the generation of an acoustic wave in a fluid-filled chamber by a piezoelectric transducer through the application of a voltage pulse. The acoustic wave interacts with the free meniscus surface at the nozzle to eject a single drop. The major advantage of the drop-on-demand method is that a complex system for droplet deflection and collection is not required. However, the main drawback is that the size of the piezoelectric transducer tube or disc, on the order of submillimeters to several millimeters, is too large for high-resolution applications. It has been reported that the typical frequency for stable operation of a piezoelectric inkjet would be tens of kilohertz [Chen et al., 1999].

### 30.2.3 Thermal-Bubble Actuation

The thermal bubble jet was developed by Hewlett-Packard in the U.S. and by Canon in Japan in the early 1980s [Nielsen, 1985; Bhaskar and Aden, 1985; Allen et al., 1985]. There are also many other designs reported in the literature [e.g., Krause et al., 1995; Chen and Wise, 1995; Tseng et al., 1996; Tseng, 1998]. Figure 30.3 shows the cross section of a thermal bubble jet. Liquid in the chamber is heated by a pulse current applied to the heater under the chamber. The temperature of the liquid covering the surface of the heater rises to around the liquid critical point in microseconds, and then a bubble grows on the surface of the heater, which serves as a pump. The bubble pump pushes liquid out of the nozzle to form a droplet. After the droplet is ejected, the heating pulse is turned off and the bubble starts to collapse. Liquid refills the chamber by surface tension on the free surface of the meniscus for recovery to the original position. The second pulse starts again to generate another droplet. The energy consumption for ejecting each droplet is around 0.04 mJ for the H-P ThinkJet printhead. Because bubbles can deform freely, the chamber size of the thermal bubble jet would be smaller than that of other actuation means, which is important for high-resolution applications. The resolution reported in the literature ranges from 150 to

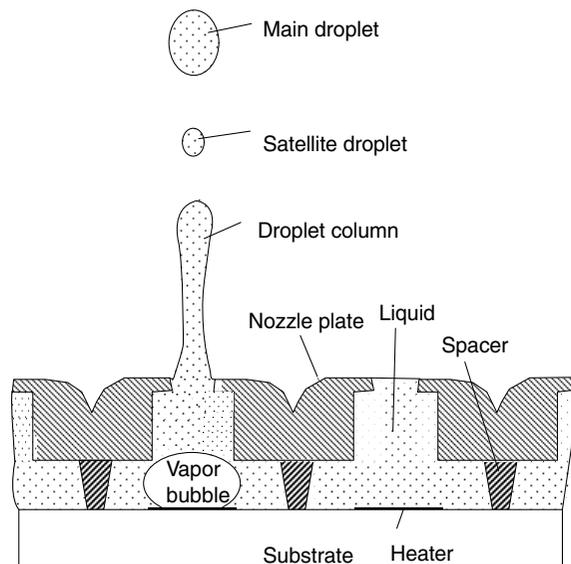

FIGURE 30.3 Operation principle of a thermal-bubble-actuated droplet generator. (After Allen et al., 1985.)

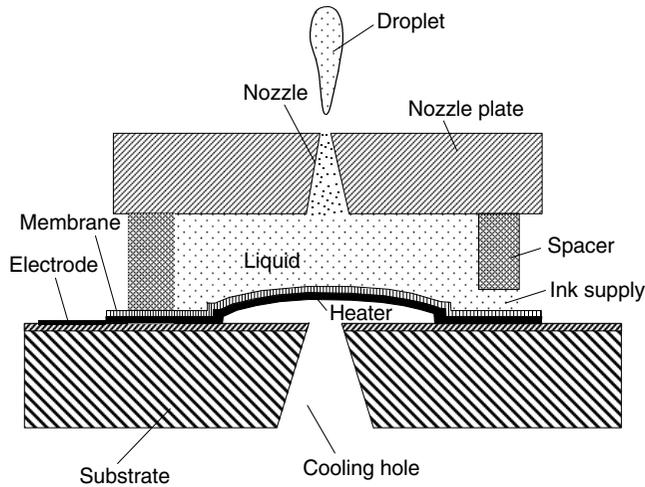

FIGURE 30.4 Operation principle of a thermal-buckling-actuated droplet generator. (After Hirata et al., 1996.)

600 dpi [Krause et al., 1995] and 1016 dpi [Chen and Wise, 1995]. The typical operational frequency for the contemporary thermal bubble jets is from several to tens of kilohertz.

### 30.2.4 Thermal-Buckling Actuation

Hirata et al. (1996) employed a buckling diaphragm for droplet generation. Figure 30.4 shows the basic operation principle. A composite circular membrane, consisting of silicon dioxide and nickel layers, is fixed on the border with a small gap between it and the substrate. A heater is placed at the center of the composite membrane and electrically isolated from it. Pulsed current is sent to the heater and then the membrane is heated for several microseconds. When the thermally induced stress is greater than the critical stress, the diaphragm buckles up abruptly and ejects a droplet out of the nozzle. The power required to generate a droplet at a speed of 10 m/s is around 0.1 mJ for a 300- $\mu\text{m}$ -diameter diaphragm. The power consumption and the device size of buckling membrane inkjet are much larger than those of the thermal bubble jet. The reported frequency response of membrane buckling jet ranges from 1.8 to 5 kHz, depending on the desired droplet velocity.

### 30.2.5 Acoustic-Wave Actuation

Figure 30.5 shows a lensless liquid ejector using a constructive interference of acoustic waves to generate droplets [Zhu et al., 1996]. A PZT thin-film actuator with the help of an on-chip Fresnel lens was employed to generate and focus acoustic waves on the air-liquid interface for droplet formation. The actuation comes from excitation of a piezoelectric film under a burst of radio-frequency (RF) signal. The device does not require a nozzle to define droplets, thus reducing the troublesome clogging problem occurring in most of the droplet generators employing nozzles. Droplet size can also be controlled by acoustic waves with specific frequencies, however, due to vigorous agitation of the acoustic wave in the liquid, it is difficult to maintain a quiet interface for reliable and repeatable droplet generation. As a result, a “nozzle area” is still desired to maintain the interface at a stable level. The applied RF ranges from 100 to 400 MHz and the burst period is 100  $\mu\text{s}$ . The power consumption for one droplet is around 1 mJ, which is high compared to other principles. The droplet size ranges from 20 to 100  $\mu\text{m}$ , depending on the RF. The reported size of the device is  $1 \times 1 \text{ mm}^2$ , which is much larger than other droplet generators mentioned in the previous sections.

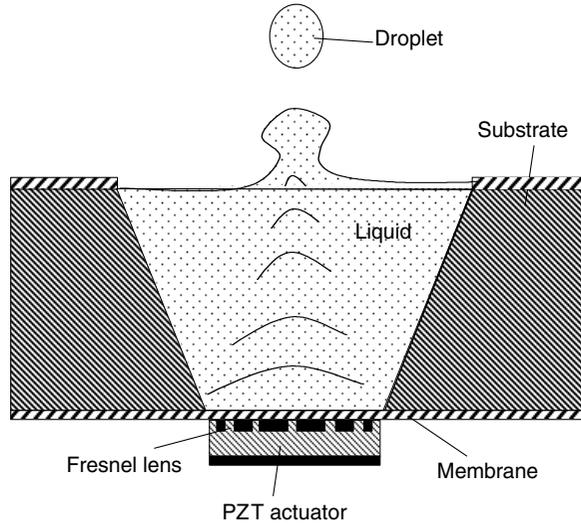

FIGURE 30.5 Operation principle of an acoustic-wave-actuated droplet generator. (After Zhu et al., 1996.)

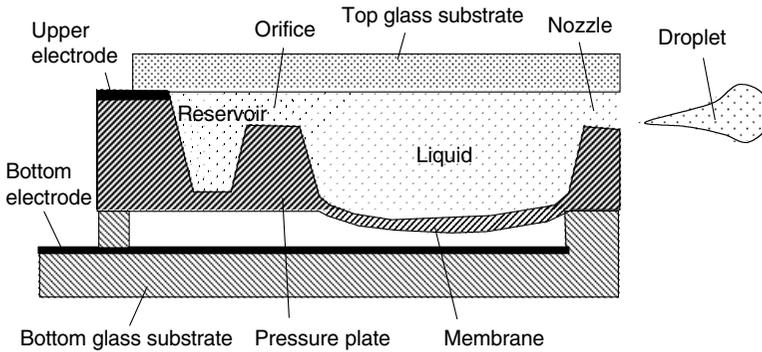

FIGURE 30.6 Operation principle of an electrostatic-actuated droplet generator. (After Kamisuki et al., 1998.)

### 30.2.6 Electrostatic Actuation

The electrostatically driven inkjet printhead was first introduced by Seiko–Epson Corp. [Kamisuki et al., 1998, 2000] for commercial printing purposes. As shown in Figure 30.6, the actuation beings by application of a dc voltage between the electrode plate and pressure plate to deflect the pressure plate for ink filling. When the voltage turns off, the pressure plate reflects back to push the droplet out of the nozzle. This device was developed for use in electric calculators, as it offers low power consumption of less than 0.525 mW/nozzle. The driving voltage for a SEAJet™ is 26.5 V and the driving frequency can be up to 18 kHz with uniform ink ejection. A device with 128 nozzles/chip with 360-dpi pitch resolution has also been demonstrated to have high printing quality (for bar coding), high-speed printing, low power consumption, a long lifetime under heavy-duty usage (lifetime more than 4 billion ejections) and low acoustic noise. However, the fabrication comprises complex bonding processes among three different micromachined pieces. Besides, the pressure plate requires a very precise etching process to control the accuracy and uniformity of the thickness. Due to the deformation limitation of solid materials and alignment accuracy required in the bonding process, the nozzle pitch may not easily be reduced further for higher resolution applications.

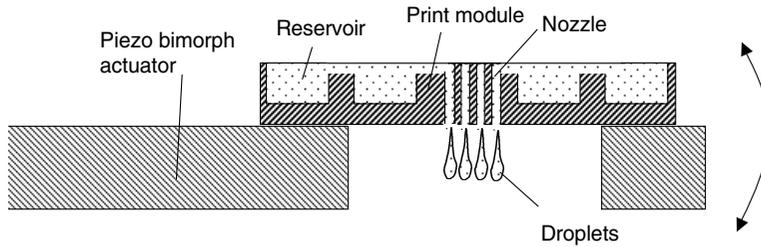

FIGURE 30.7 Operation principle of an inertia-actuated droplet generator. (After Gruhler et al., 1999.)

### 30.2.7 Inertial Actuation

Inertial droplet actuators apply high acceleration to the nozzle chip for droplet ejection. Such an apparatus is shown in Figure 30.7 [Gruhler et al., 1999]. The print module consists of large reservoirs on the top plate, which connects to the nozzles on the bottom plate. The print module is mounted on a long cantilever beam with a piezo–bimorph actuator for acceleration generation. It requires 500  $\mu\text{s}$  to generate 1 nl of droplets from 100- $\mu\text{m}$ -diameter nozzles. Twenty-four liquid droplets of different solution types were demonstrated to be ejected simultaneously from the nozzles in a 500- $\mu\text{m}$ -pitch. The smallest droplet claimed to be generated is 100 pl from 50- $\mu\text{m}$ -diameter nozzles. This principle provides a gentle ejection process for bioreagent applications. However, the ejection of smaller droplets may encounter strong surface tension and flow drag forces at the microscale that are much larger than the droplet inertial. Also, the droplets cannot be selectively and individually ejected from the desired nozzles which limits its applications.

## 30.3 Physical and Design Issues

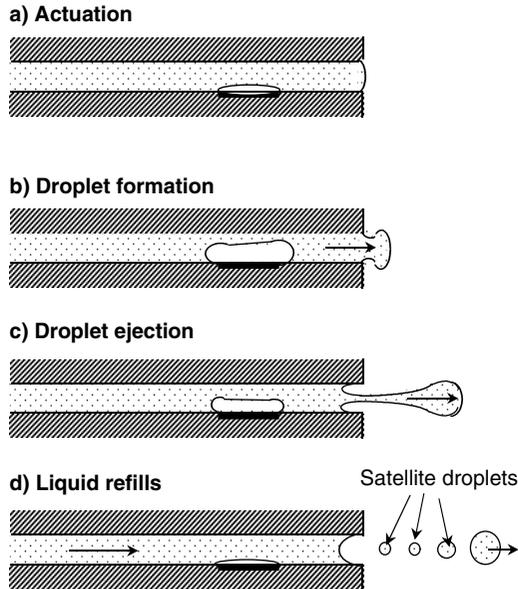

The sequence of droplet generation involves wide ranges of physical issues and design concerns, including microfluid flow, heat transfer, wave propagation, surface properties, material properties and structure strength. The following sections discuss frequency response, thermal cross-talk, hydraulic cross-talk, over-fill, satellite droplets, puddle formation and material issues commonly seen in microdroplet generators.

### 30.3.1 Frequency Response

The frequency response of droplet generators is an important measure for assessing the performance of a device. The reported typical frequency response for thermal bubble jets, piezo jets, thermal buckling jets, acoustic wave jets and electrostatic and inertial jets ranges from a kilohertz to tens of kilohertz. Piezo and acoustic wave jets typically have higher frequency responses than the others. Recently, the novel design by Tseng (1998) improved the frequency response of thermal bubble jets by about three times (35 kHz), which is comparable to the speed of piezo jets. Higher speed devices (in the range of hundreds of kilohertz) are currently under development by major inkjet printer makers and further breakthroughs will follow in the next few years.

The three important time constants related to the frequency response of microdroplet generators are actuation, droplet ejection and liquid refilling, as shown in Figure 30.8.

The typical time constant from heating to bubble formation in a thermal bubble jet is around 5 to 10  $\mu\text{s}$  for a chamber size ranging from 20 to 100  $\mu\text{m}$  [Tseng, 1998]. Thermal buckling and electrostatic microdroplet generators have actuation times of tens to hundreds of microseconds (estimated from Hirata et al., 1996), due to the large actuation plate required for sufficient displacement for droplet formation. The inertial type required even longer actuation time (estimated from Gruhler et al., 1999), typically hundreds to thousands of microseconds, due to the large cantilever structure necessary for generating large droplets with sufficient inertial force to overcome liquid surface tension and viscosity. The actuation

**FIGURE 30.8** The sequence of droplet generation.

time for piezo or acoustic wave types of generators may be shorter [Darling et al., 1984; Zhu et al., 1996], around one microsecond to tens of microseconds.

After application of actuation pressure to the liquid, the droplet starts to eject. The ejection sequence usually takes a couple to hundreds of microseconds for a droplet volume of 1 pl to 1 nl [Tseng, 1998], which does not vary much for different operation principles.

The liquid refills back automatically by surface tension force after the droplet ejection. Liquid refilling time can vary by three orders of magnitude (e.g., from less than 10  $\mu\text{s}$  to over 1 s), depending on the length and geometry of the refilling path. In most of the commercial inkjet printhead designs, a chamber neck [Nielsen, 1985], elongated chamber channel [Nielsen, 1985] or physical valve [Karz et al., 1994] is used to prevent hydraulic cross-talk and maintain a high pressure in the firing chamber. However, those designs, if not arranged properly, may greatly increase the refilling time, causing a reduction in the frequency response. As a result, how to prevent the hydraulic cross-talk without sacrificing the device speed becomes an important issue in the design of super-high-speed and high-resolution droplet generators. Tseng et al. (1998a; 1998b; 1998c) introduced the concept of a virtual chamber neck to speed up the refilling process of thermal bubble jets and to suppress cross-talk. The virtual neck consists of vapor bubbles that provide sealing pressure while the droplet is ejecting and opens up to reduce flow resistance while liquid is refilling, thus increasing the frequency response. The concept is shown in [Figure 30.9](#).

For simulation of droplet actuation and the formation sequence, much work [Curry and Portig, 1977; Lee, 1977; Levanoni, 1977; Pimbley and Lee, 1977; Fromm, 1984; Bogoy and Talke, 1984; Asai et al., 1987; 1988; Asai, 1989; 1991; 1992; Mirfakhraee, 1989; Chen et al., 1997a; 1997b; 1988a; 1988b; 1999; Rembe et al., 2000] has been conducted on the bubble formation sequence, droplet generation, and aerodynamics of droplets traveling in the atmosphere for thermal bubble as well as piezo jets. Interested readers can refer to those works for details.

### 30.3.2 Thermal/Hydraulic Cross-Talk and Overfill

When nozzle pitch becomes small, two types of cross-talk—hydraulic and thermal (for thermal bubble jet)—become significant in multiple-nozzle droplet generators. Hydraulic cross-talk relates to the transportation of a pressure wave from the firing chamber to the neighboring chambers, as shown in [Figure 30.10](#). The vibration of the meniscus of the neighboring chambers may result in poor droplet volume control

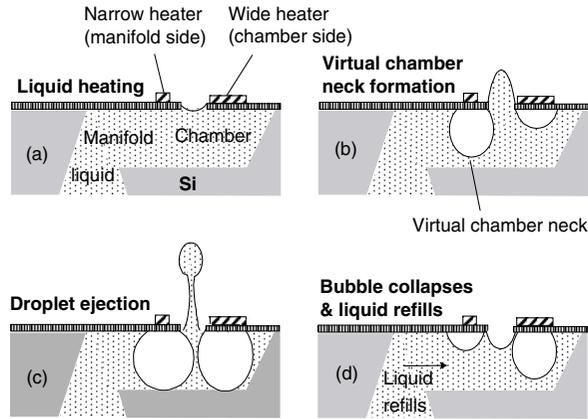

FIGURE 30.9 Operation principle of virtual chamber neck. (After Tseng et al., 1998c.)

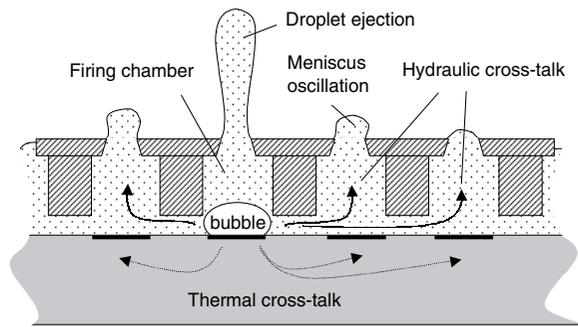

FIGURE 30.10 Cross-talk among neighboring microchambers.

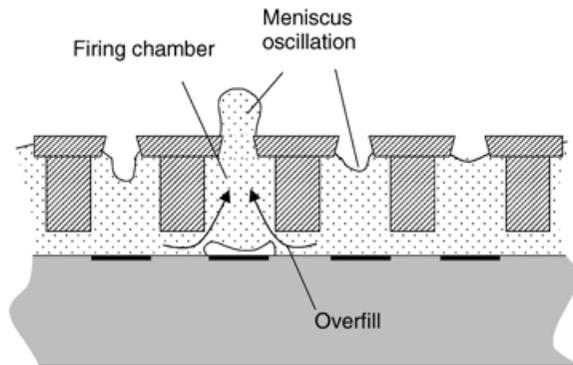

FIGURE 30.11 Overfill phenomenon.

or, even worse, unexpected droplet ejection. Thermal cross-talk, which only appears in the thermal bubble jet, is the phenomenon of thermal energy transportation from the firing chamber to neighboring chambers, resulting in poor droplet volume control. After droplet ejection, the refilling process of liquid sometimes causes meniscus oscillation, posing another issue of overfill. Overfill, similar to cross-talk, increases the waiting time for the next droplet ejection and even causes undesired droplet ejection. The phenomenon of overfill is illustrated in Figure 30.11.

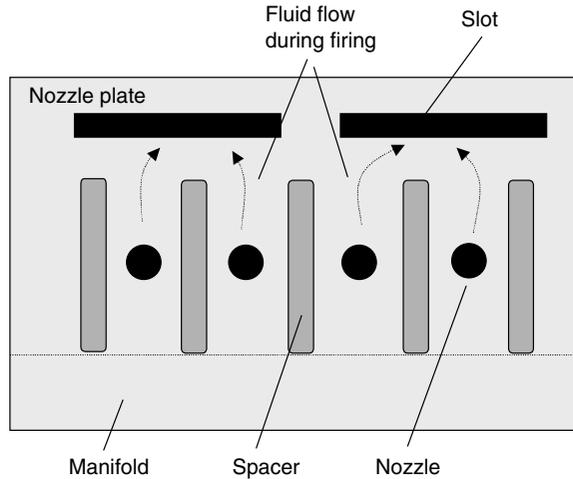

FIGURE 30.12 Method of applying parallel compliant (reservoir) to overcome cross-talk.

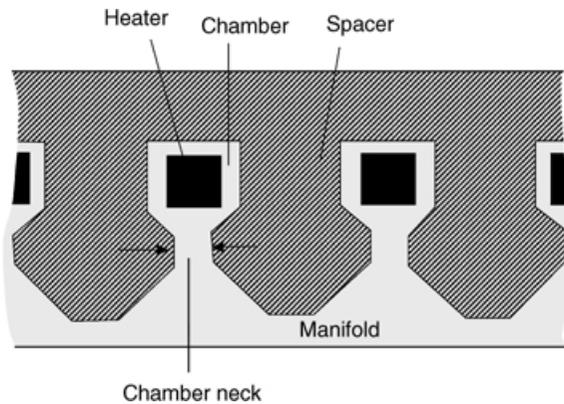

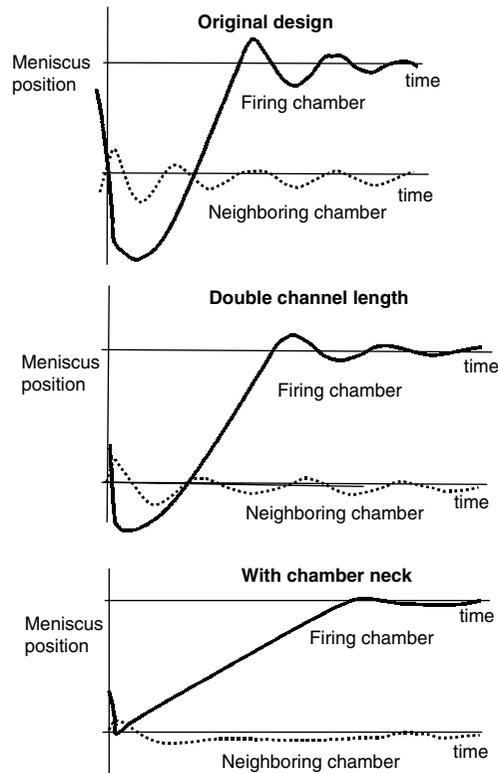

FIGURE 30.13 The cross-talk overcome by employing a chamber neck.

These issues stem from the fact that there is not enough flow compliance among nozzles. One of the solutions developed by IBM [Nielsen, 1985] is to increase the channel length for each chamber. However, the increased serial compliance of the lengthened channel between the reservoir and chamber increases the flow resistance and inertia significantly, increasing the liquid refilling time.

HP tried to solve this problem by using either a parallel compliant (reservoir) or a chamber neck. Figure 30.12 shows a slot used as a reservoir beside the nozzles to store energy while the bubble is exploding and to release energy while the bubble is collapsing [Nielsen, 1985]. Figure 30.13 shows the second approach by narrowing the inlet of the chamber to form a chamber neck [Buskirk et al., 1988].

The effects from the aforementioned methods were simulated by Buskirk et al. (1988). Figure 30.14 shows the simulation results of the meniscus position of the firing chamber and neighboring chamber for various chamber designs. In the first figure, without any design of flow compliance, the menisci on both the firing chamber and the neighboring chamber show huge fluctuations. Doubling the channel length (series compliance) damped down some of the fluctuation, but not completely. Only the chamber neck design almost completely damped down the meniscus fluctuation; however, it has the slowest rising response among the three methods.

In contrast to fixed chamber neck design, Xerox [Karz et al., 1994] has used a flexible plate as a valve to address the cross-talk issue. However, this design may suffer from low frequency response and material

**FIGURE 30.14** Meniscus oscillation in various chamber structures. (Data from Buskirk et al., 1988.)

reliability problems. Tseng et al. (2000) used a novel design of a virtual chamber neck, employing the bubble as a virtual valve to reduce the cross-talk problem while maintaining the high frequency response of the droplet generator, as shown in Figure 30.9. Their work demonstrated that the bubble has faster response and more reliable operation performance in the microscale than do solid valves.

In addition to hydraulic cross-talk, thermal cross-talk, in Tseng’s work, was also reduced by placing the heater on the chamber top of a thin film with low thermal conduction, instead of leaving it on the thick substrate through which heat can be conducted to the neighbors [Tseng et al., 1998c; 2001a]. It is clear that as the nozzle pitch becomes closer, the cross-talk problem becomes more severe in the operation of very-high-resolution and high-speed droplet generators.

### 30.3.3 Satellite Droplets

Satellite droplets result from the breakdown of the long ejected liquid column by the interaction among surface tension, air drag force and inertial force. The velocity mismatch along the liquid column, resulting from the variation of actuation velocity, promotes the breakdown. The droplet ejection sequence captured from a commercial inkjet reveals the detailed steps of satellite droplet formation, as shown in Figure 30.15 [Tseng et al., 1998c]. When applied to printing, the quality is degraded from the occurrence of satellite drops, as revealed in Figure 30.16. Satellite droplets also reduce the accuracy for precise liquid dispensing control.

A literature survey reveals that there have been many attempts to predict the droplet formation. Asai et al. (1987; 1988; Asai, 1989; 1991; 1992) conducted both numerical simulation and experimental measurements to obtain the temporal variation of droplet length at a thermal bubble jet. However, the formation process of satellite droplets is not included. In the drop-on-demand inkjet, Fromm (1984)

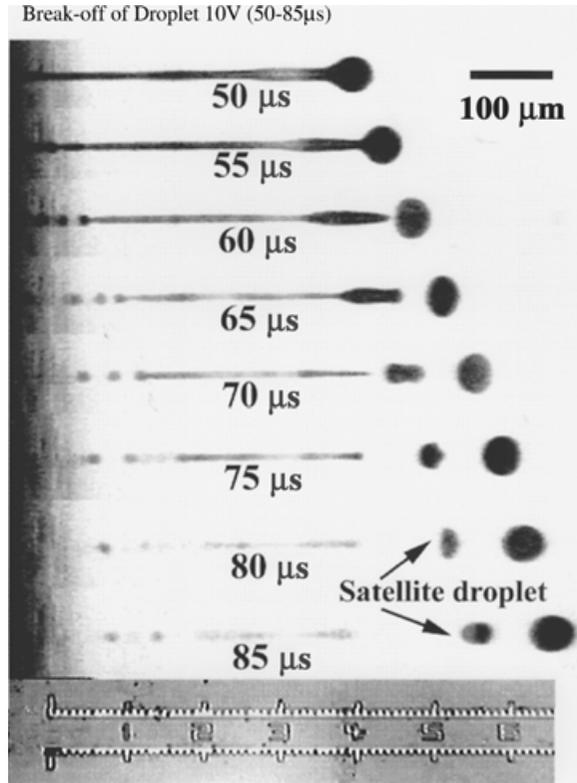

FIGURE 30.15 Droplet ejection sequence of HP 51626A printhead. (After Tseng et al., 1998c.)

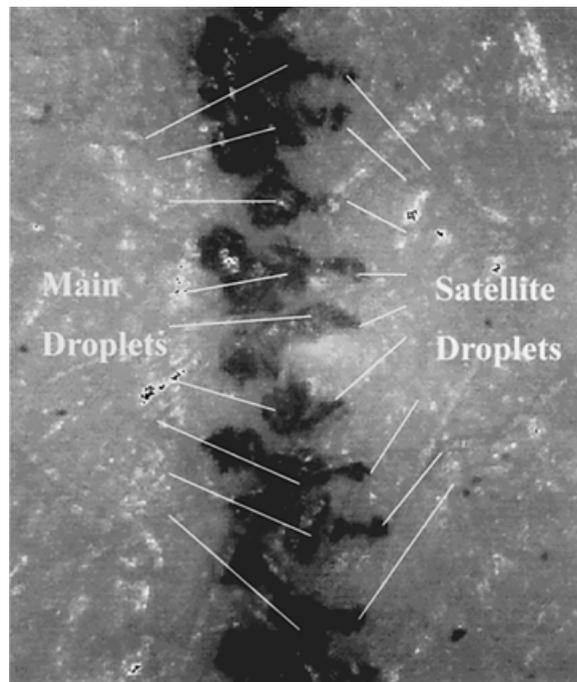

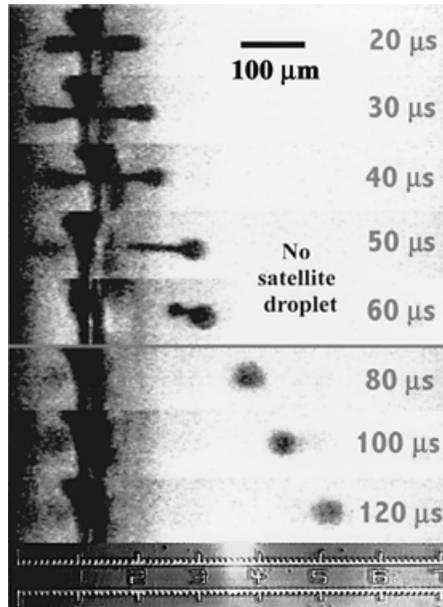

FIGURE 30.16 A printed vertical line smeared by satellite droplets. (After Tseng et al., 1998c.)

**FIGURE 30.17** Droplet ejection without satellite droplets. (After Tseng et al., 1998a.)

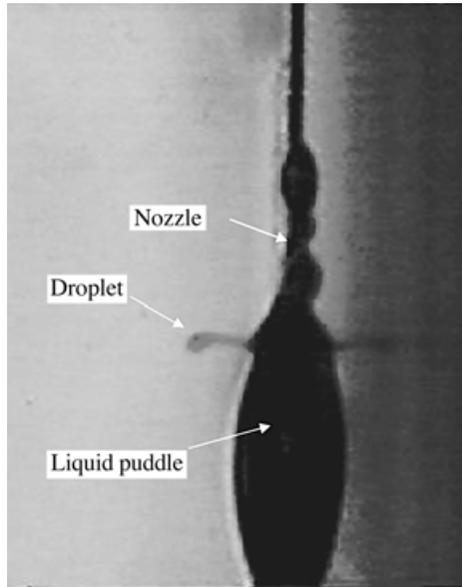

and Chen et al. (1997a; 1997b; 1998a; 1998b; 1999) solved the Navier–Stokes equation to predict the droplet formation, and showed the process of satellite droplet formation. Pimbley and Lee (1977) and Chen et al. (1997b) demonstrated the evolution of the droplet as well as satellite droplet formation by flow visualization, however, the detailed method for eliminating the separation of satellite droplet from the main droplet was not discussed.

Various efforts have been made to eliminate satellite droplets from the commercial product. In piezo droplet generators, triangular waves were used to eliminate satellite drops [Chen et al., 1999]. For thermal bubble jets, Tseng et al. (1998a; 1998c; 2000) proposed a novel method employing the bubble as a trimmer to cut off the long droplet tail to eliminate satellite droplets, as shown in Figure 30.17. The tail of the liquid column, shortened by the bubble trimmer in Tseng’s work, is drawn back by surface tension into the main droplet, thus eliminating satellite drops.

### 30.3.4 Puddle Formation

A liquid puddle forms when liquid is pushed to flow outward and accumulates on the outside surface of the nozzle. Puddles impose a great blocking force on droplet ejection, causing distortion or even disruption of droplet ejection. One of the major causes of puddle formation is the hydrophilic nozzle surface. When it comes into contact with working fluid from the chamber, the liquid accumulates on the outer surface of the nozzle. It was observed by (Tseng, 1998) that the puddle appears after several continuous operations; that is, the chamber surface does not acquire a puddle until getting wet after several runs. If the operation of droplet ejection stops, the puddle is drawn back into the chamber by surface tension. However, once the chamber surface becomes wet, puddle formation always occurs when operation starts again. Figure 30.18 shows the formation of a puddle during the running of a microinjector [Tseng, 1998]. Notice that the droplet ejection position is away from the nozzle, due to distortion by the liquid puddle.

One way to eliminate puddle formation is to coat the chamber outer surface with a nonwetting material to prevent the wetting process of the working fluid, the inner surface of the chamber must remain hydrophilic

**FIGURE 30.18** Liquid puddle formation outside the micro nozzles. (After Tseng, 1998.)

for liquid refill. Even with the coating, however, there is still no guarantee that the puddle will not form. More research is under way to fully understand the mechanism of the puddle formation process.

### 30.3.5 Material Issues

Material issues, including stress, erosion, durability and compatibility, are very complex issues in the design of microdroplet generators. Material compatibility, stress and durability problems are commonly discussed from the processing perspective. Material compatibility issues result from the processing temperature, processing environment (oxidation, reactive gas, etc.), etching method used and adhesion ability; stress issues are usually a result of processing temperature as well as doping conditions; material durability issues either are material intrinsic properties or are due to the mechanical forces induced during the process (i.e., fluid flow force, surface tension force, vacuum forces or handling force). Lots of care needs to be taken in the process flow design to eliminate the material issues, such as compensating material stress during or after the fabrication process, conducting the high-temperature process earlier than the low-temperature material, finishing aggressive wet etching before metal film deposition or using low-temperature bonding material and processes to protect integrated circuit and microdevices.

From the operation aspect, durability, stress and erosion issues are the major concerns. Due to the cycling nature of the droplet generation process, the materials chosen for actuation face challenges not only from stress but also from fatigue. HP reported that possible reasons for failure of the heater passivation materials are cavitation and thermal stress [Bhaskar and Aden, 1985]. Silicon, low-stress silicon nitride, silicon carbide, silicon dioxide and some metals are usually used to overcome the aforementioned problems. In addition to proper material selection, reducing sharp corners in the design is also an important key to preventing the material from cracking by eliminating stress concentration points. Moreover, the erosion of structure materials from the working fluid is another serious issue. Lee et al. (1999) reported the erosion of spacer material in a commercial inkjet head when diesel fuel was used as the working fluid. In contrast, materials, including silicon and silicon nitride, used by Tseng et al. [Tseng et al., 1998c; Tseng, 1998] and Lee et al. (1999b) in the microinjector are free of this problem and can be applied to a wide variety of fluids, including solvents and chemicals. Selecting materials wisely, arranging them correctly in process and properly designing the materials in the microstructures are the three important concepts in reducing material issues.

## 30.4 Fabrication of Microdroplet Generators

The common structures in most of the microdroplet generators include a manifold for liquid storage, microchannels for liquid transportation, microchambers for holding liquid, nozzles for droplet size and direction definition and actuation mechanisms for droplet generation. Occasionally, droplet generators may not have nozzles but instead use energy focusing as a means to generate droplets locally, such as acoustic wave droplet generators [Zhu et al., 1996]. Before micromachining processes became popular, most of the fabrication processes of microdroplet generators stemmed from the same concept: Nozzle plates, fluid-handling plates and actuation plates are manufactured separately and then integrated into one final device. However, as the nozzle resolution becomes finer, bonding processes pose severe alignment, yield, material and integrated-circuit compatibility problems. Also, interconnection lines may not have enough space to pull out individually from each chamber when nozzle resolution is higher than 600 dpi. As a result, monolithic ways to fabricate high-resolution integrated circuit droplet generators have become very important. In the following sections, examples of different fabrication means are introduced.

### 30.4.1 Multiple Pieces

Figure 30.19 shows the traditional fabrication of microdroplet generators by the bonding of fabricated structure pieces [Tseng, 1999]. Actuation plates are fabricated separately from the nozzle plates. In the thermal bubble jet, heaters are usually sputtered or evaporated and then patterned with an integrated circuit on the bottom plate, while piezo, thermal buckling, electrostatic and inertial actuators consist of

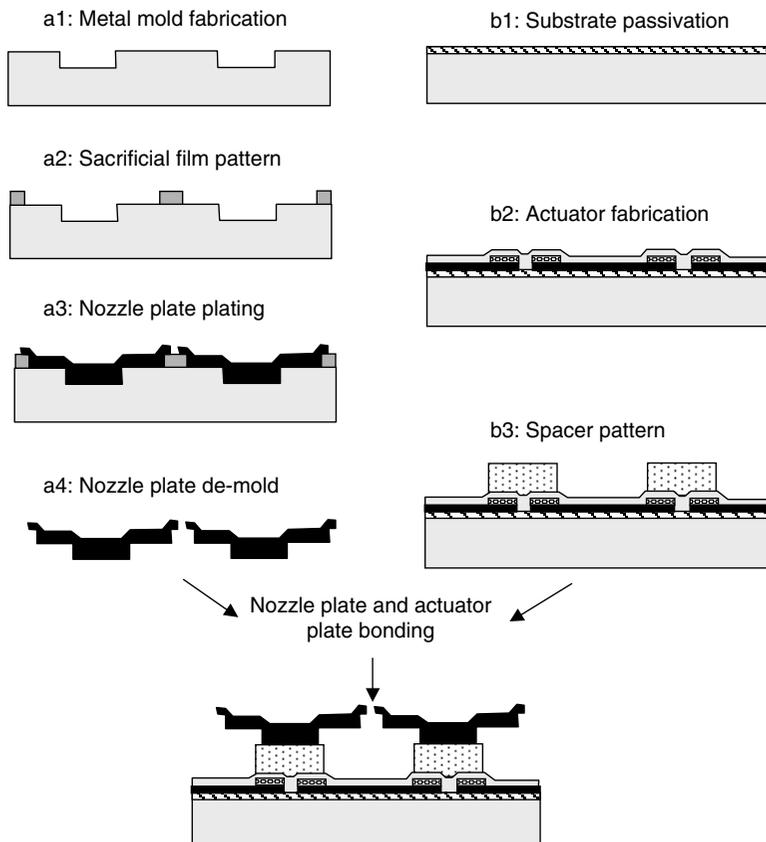

FIGURE 30.19 Conventional fabrication process flow of microdroplet generators.

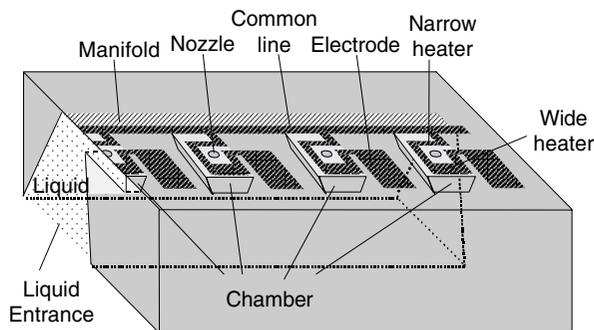

more complex structures, such as piezo disc, thin plate structure, or cantilever beam. Parallel to the actuator fabrication, nozzles are fabricated by electroforming [Ta et al., 1988], molding or laser drilling [Keefe et al., 1997]. The combination of those processed pieces is assembled either by using polymer spacer material as intermediate layers [Siewell et al., 1985; Askeland et al., 1988; Hirata et al., 1996; Keefe et al., 1997] or by directly adhering several pieces through anodic bonding [Kamisuki et al., 1998; 2000], fusion bonding [Gruhler et al., 1999], eutectic bonding or low-temperature chemical bonding. However, most of the bonding means are chip-level not wafer-level processes and face the similar challenges of alignment, bonding quality and material/process compatibility. As the nozzle resolution becomes higher than 600 dpi, alignment accuracy of 4  $\mu\text{m}$  (10% of the nozzle pitch) is difficult to achieve. Higher alignment accuracy significantly increases the fabrication cost, especially for the chip-level process. Bonding quality is another important issue corresponding to the fabrication yield of large-array and high-resolution devices. The bonding materials (mostly polymers) chosen may not be suitable for the application environments and working fluids. Also, the bonding process, involving heat, pressure, high voltage or chemical situations, restricts integrated circuit integration with the droplet generators which is essential for large-array and high-resolution applications.

### 30.4.2 Monolithic Fabrication

In order to address the aforementioned issues, monolithic processes utilizing micromachining technology have been widely employed since the early 1990s. Two major methods have been introduced: One is the combination of bulk and surface micromachining and the other is the use of bulk micromachining and deep-ultraviolet (UV) lithography associated with electroforming (or UV lithography only).

For example, Tseng, (1998) combined surface and bulk micromachining to fabricate a microdroplet generator array with potential nozzle resolution up to 1200 dpi (printing resolution can be 2400 dpi or higher). In this design, double bulk-micromachining processes were utilized to fabricate a fluid-handling system that included a manifold, microchannels and microchambers. Surface micromachining was used for heater, interconnection line and nozzle fabrication. The whole process was finished on (100)-crystal-orientation silicon wafers. Figures 30.20 and 30.21 show the three-dimensional structure of the microinjectors and the monolithic fabrication process, respectively. The ejection of 0.9-pl droplets has also been demonstrated by Tseng et al. (2001b) for high-resolution microinjectors. The structure materials used in the microinjector are silicon silicon nitride and silicon oxide, durable in high temperature and suitable for various liquids (even some harsh chemicals). Integrated circuits can be easily integrated with this device on the same silicon substrate.

The second case can be found in Lee et al.'s (1999a) work. In this design, the multi-exposure and signal development (MESD) lithography method was used to define microchannel and microchamber structures

**FIGURE 30.20** Schematic three-dimensional structure view of microinjectors. (After Tseng et al., 1998c.)

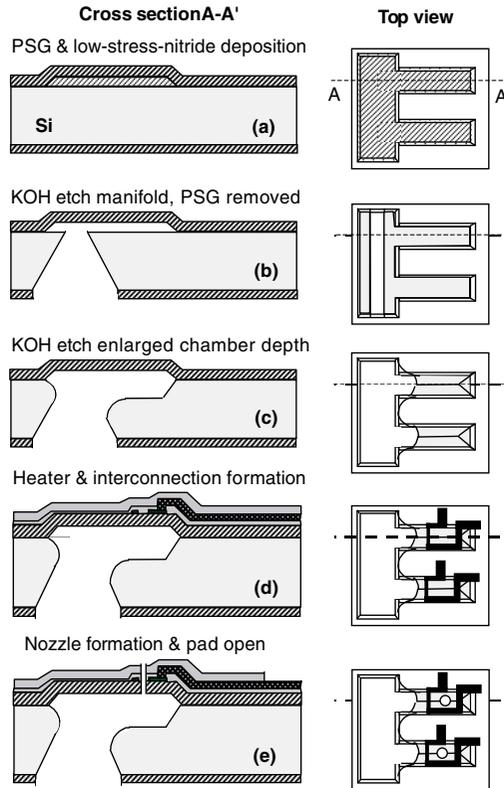

FIGURE 30.21 Fabrication process flow of monolithic micro injectors. (After Tseng et al., 1998c.)

(using a photoresist as the sacrificial layer), and the physical structures were constructed by electroformed metal. The manifold was manufactured from the wafer backside by electrochemical methods [Lee et al., 1995]. This device demonstrated compatibility with the very-high-resolution array and integrated circuit process. Another method, using a photoresist as the sacrificial layer and polyimide as the structure layer, was introduced by Chen et al. (1998b) for applications compatible with high-resolution and integrated circuit applications.

## 30.5 Characterization of Droplet Generation

Droplet trajectory, volume, ejection direction and ejection sequence/velocity are four important quantitative measures for assessing the ejection quality of microdroplet generators. The following sections briefly introduce the basic methods for the testing of droplet generation.

### 30.5.1 Droplet Trajectory

Droplet trajectory visualized by utilizing a flashing light on the ejection stream, as shown in Figure 30.22, was introduced by Tseng et al. (1998a). The white dots in Figure 30.23 indicate the droplet stream. The visualized droplet trajectory follows an exponential curve, very different from the parabolic one expected for normal-size objects with similar initial horizontal velocity. The droplet trajectory was also estimated by Tseng et al. (1998a) by solving a set of ordinary differential equations from the force balance, in both horizontal and vertical direction, of a single droplet flying through air.

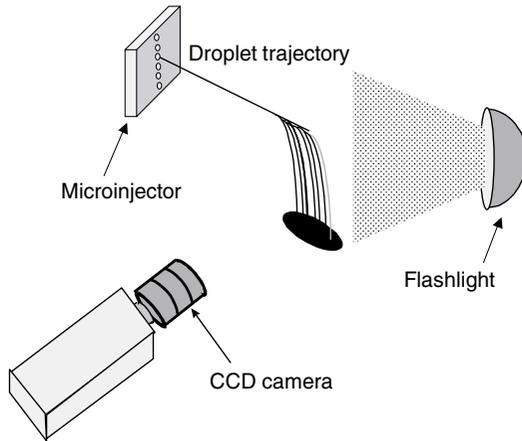

FIGURE 30.22 Experimental setup for droplet stream visualization.

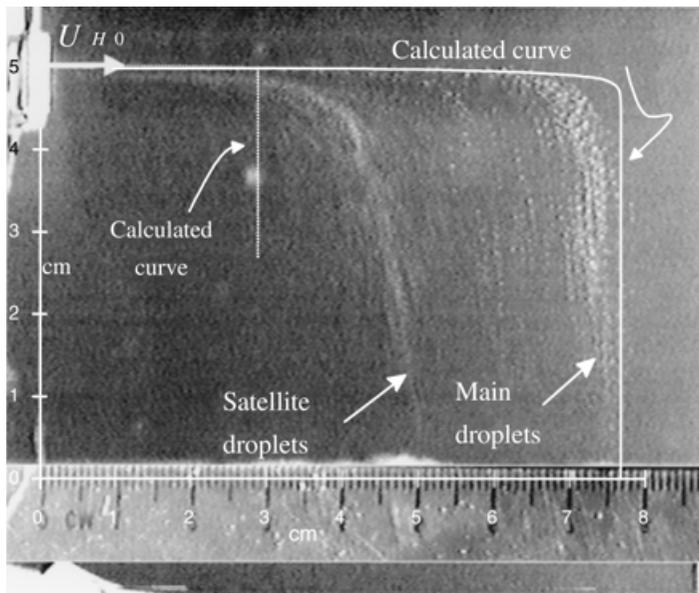

FIGURE 30.23 Visualized droplet stream and estimated trajectory of a microdroplet generator. (After Tseng et al., 1998a.)

From the analysis, the vertical position  $Y$  and horizontal position  $X$  of the droplet can be expressed by:

$$Y = U_{v\infty} \left[ t - \frac{U_{v\infty}}{g} \left( 1 - e^{-\frac{6\pi\mu r_0}{m} t} \right) \right] \quad (30.1)$$

$$X = \frac{U_{H0} m}{6\pi\mu r_0} \left( 1 - e^{-\frac{6\pi\mu r_0}{m} t} \right) \quad (30.2)$$

where  $g$  is the acceleration due to gravity,  $t$  is the time,  $m$  is the mass,  $r_0$  is the radius of the droplet,  $\mu$  is the viscosity of air,  $U_{v\infty} = \frac{mg}{6\pi\mu r_0}$  is the droplet terminal velocity, and  $U_{H0}$  is the initial horizontal velocity.

The trajectory is drawn in [Figure 30.23](#) with the experimental result and fits the visualized trajectory well except at the end, suggesting an interaction among droplets. From this simple analysis, the maximum flying distance of a droplet with a known diameter can be estimated as:

$$X_{\max} = \frac{U_{H0}m}{6\pi\mu r_0} = \frac{2\rho_{\text{liquid}}}{9\mu_{\text{air}}}(U_{H0}r_0^2), \text{ when } t \sim \infty \quad (30.3)$$

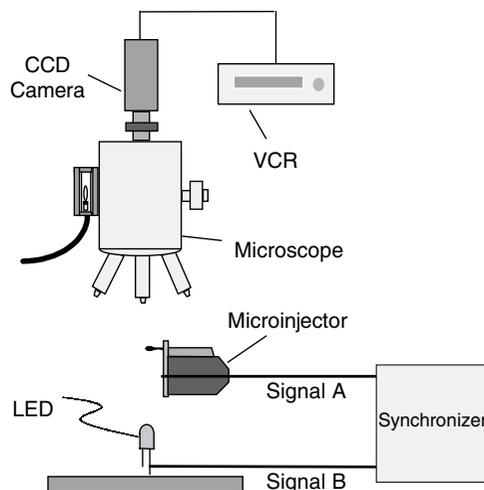

Here, the maximum distance is proportional to the droplet velocity and droplet radius to the second power. For droplets of varying sizes and the same initial velocity, the maximum flying distance is reduced quickly for the smaller ones. To obtain 1-mm flying distance, a droplet with 10-m/s initial velocity must have a minimum radius of 2.7  $\mu\text{m}$ . From the above estimation, droplet size should be maintained beyond a certain value to ensure enough flying distance for printing. Printing with very fine droplets (diameter smaller than a couple of micrometers) requires either increasing the initial velocity of the droplets or printing in a special vacuum environment to overcome the resistant force from air drag.

### 30.5.2 Ejection Direction

Droplet direction can be decided by the visualized trajectory. Many parameters, including nozzle shape, roughness, aspect ratio and wetting property, as well as actuation direction and chamber design, affect droplet direction. In general, symmetric structure design and accurate alignment can help control droplet direction.

### 30.5.3 Ejection Sequence/velocity and Droplet Volume

To characterize the detailed droplet ejection sequence, a visualization system [Chen et al., 1997b; Tseng et al., 1998c], as shown in [Figure 30.24](#), has been widely used. In this system, an LED was placed under the droplet generator to back-illuminate the droplet stream. Two signals, synchronized with adjustable time delay, were sent to a microinjector and an LED, respectively. Droplets were ejected from a droplet generator continuously, and the droplet images were frozen by the flashlight from the LED at specified time delays, as shown in [Figure 30.15](#). Droplet volume can be determined from the images by assuming the droplet is axisymmetric or by weighing certain numbers of droplets. Droplet velocity can be estimated by measuring the flying distance difference of the droplet fronts in two successive images.

**FIGURE 30.24** Experimental setup for droplet ejection sequence visualization.

## 30.5.4 Flow Field Visualization

To better understand flow properties such as cross-talk, actuation sequence, liquid refill and droplet formation inside microdroplet generators, flowfield visualization is one of the most direct and effective ways. Flow visualization at a small scale has some difficulties that do not occur at a large scale, such as limited viewing angles, hard-to-apply light sheet reflection from the particles trapped on the wall, short response time and small spatial scale. Meinhart and Zhang (2000) adopted a micrometer-resolution particle image velocimetry system to measure instantaneous velocity fields in an electrostatically actuated inkjet head. In the setup, 700-nm-diameter fluorescent particles were introduced for flow tracing. The spatial as well as temporal resolutions of the image velocimetry were found to be 5 to 10  $\mu\text{m}$  and 2 to 5  $\mu\text{s}$ , respectively. The four primary phases of the injection operation, including infusion, inversion, ejection and relaxation, were clearly captured and quantitatively analyzed.

## 30.6 Applications

More than a hundred applications have been explored employing microdroplet generators. This section provides a summary of some of the applications.

### 30.6.1 Inkjet Printing

Inkjet printing involves arranging small droplets on a printing medium to form texts, figures or images and is the most well-known application. The smaller and cleaner the droplets are, the sharper the printing is, however, smaller droplets cover a smaller printing area and thus increase the printing time. Therefore, in printing applications, high-speed microdroplet generation with stable and clean microsized droplets is desired for fast, high-quality printing. The printing media can be paper, textile, skin, cans or other surfaces that can adsorb or absorb printing solutions. Inkjet printing generated a more than \$10 billion worldwide market in 2000 and continues to grow.

### 30.6.2 Biomedical and Chemical Sample Handling

The application of microdroplet generators to biomedical sample handling is an emerging field and is drawing much attention. Much research effort has been focused on droplet volume control, droplet size miniaturization, compatibility issues, variety of samples and high-throughput parallel methods.

Luginbuhl et al. (1999), Miliotis et al. (2000) and Wang et al. (1999) developed piezo- and pneumatic-type droplet injectors, for mass spectrometry. Figure 30.25 shows the design of the injectors, which are utilized to generate submicron- to micron-sized bioreagent droplets for sample separation and analysis in a mass spectrometer, as shown in Figure 30.26. Luginbuhl et al. (1999) employed silicon bulk micro-machining to fabricate a silicon nozzle plate and Pyrex® glass actuation plate, while Wang et al. (1999)

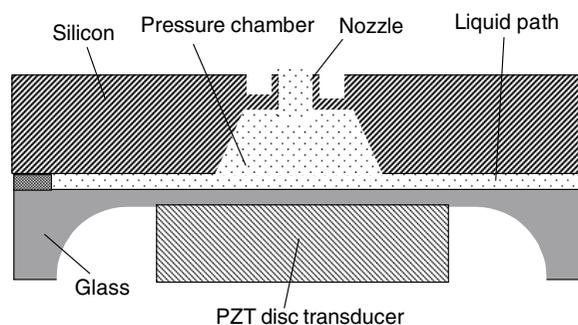

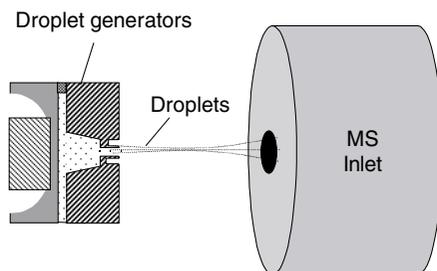

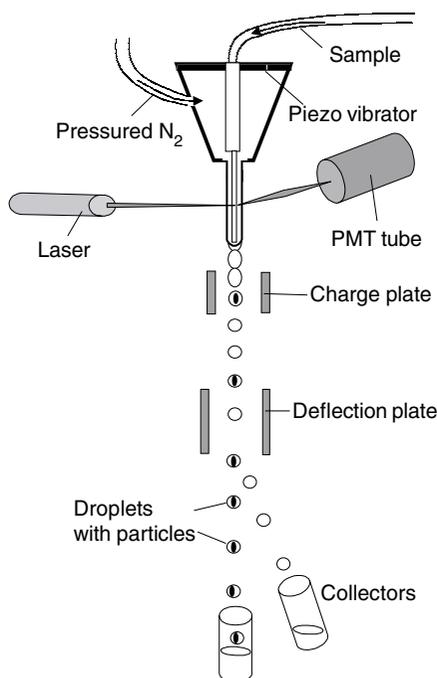

FIGURE 30.25 The injector design for mass spectrometry. (After Luginbuhl et al., 1999).

**FIGURE 30.26** Operation principle of mass spectrometry using microdroplet generators.

**FIGURE 30.27** Particle sorting using droplet generators. (After Asano et al., 1995.)

employed the combination of surface and bulk micromachining to fabricate a droplet generator. These injectors are part of the lab-on-a-chip system for incorporating a microchip with a macro-instrument.

Microdroplet generators were also used by Koide et al. (2000), Nilsson et al. (2000), Goldmann and Gonzalez (2000) and Szita et al. (2000), for the accurate dispensing of biological solutions. Piezo- and thermal-type injectors were used in this research for protein, peptide, enzyme or DNA dispensing. In those applications, the operation principles of the employed devices are similar to those for inject printing. A single biological droplet can be precisely dispensed and deposited onto a desired medium, and the dispensing of droplet arrays can also be carried out. The arrayed bioreagents can be further bioprocessed for high-throughput analysis.

Continuous-jet-type droplet generators were reported by Asano et al. (1995) to effectively focus and sort particles by electrostatic force. The experimental setup is shown in Figure 30.27. A syringe pump pressurizes the sample fluid containing the particles, which pass through a nitrogen sheath flow for focusing. The sample is then ejected from a piezoelectric-transducer-disturbed nozzle to form a droplet. The droplets containing the desired particles are charged at the breakup point and deflected into collectors. The reported separation probability for 5-, 10-, and 15- $\mu\text{m}$  particle can be as high as 99%. However, the

inner jet diameter limits the particle size for separation. Other than solid particle separation, this method can potentially also be applied to cell sorting for biomedical applications.

In addition to biomedical reagent handling, microdroplet generators have been widely used in chemical handling. For example, Shah et al. (1999) used an inkjet to print catalyst patterns for electroless metal deposition. In their system, a Pt solution was employed and ejected by a commercial inkjet printhead as a seed layer for Cu electroless plating. The lines produced by this method were reported to be 100  $\mu\text{m}$  wide and 0.2 to 2  $\mu\text{m}$  high.

### 30.6.3 Fuel Injection and Mixing Control

Microdroplet generators can be used for fuel injection to dispense controllable and uniform droplets, important for mixing and combustion applications. Combustion efficiency depends on the mixing rate of the reactants. The reactants in a shear flow are first entrained by large vortical structures (Brown and Roshko, 1974) and then mixed by fine-scale eddies. The entrainment can be greatly enhanced by controlling the evolution of large-scale vortices either actively (Ho and Huang, 1982) or passively (Ho and Gutmark, 1987). The effectiveness of controlling large-scale vortical structures by increasing the combustion efficiency has also been experimentally demonstrated (Shadow et al., 1987). Although much work has been done on improving the mixing efficiency in combustion chambers, a significant challenge in combustion research is to improve the small-scale mixing and to reduce the evaporation time of the liquid fuel.

Traditional injectors with a nozzle diameter of tens to hundreds of microns can neither supply uniform microdroplets for reducing evaporation time and fine-scale mixing nor eject droplets which can be controlled individually to modulate vortex structure [Lee et al., 1999b]. To overcome those limitations, Tseng et al. (1996) proposed a microdroplet injector array fabricated using micromachining technologies for fuel injection. The droplets ejected from microinjectors are uniform and the size can be one to tens of microns in diameter, which is close to the microscale of low-turbulence eddies. The fine-scale mixing can be carried out by the reaction of the low-turbulence eddies directly with the microdroplets. The evaporation time is also greatly reduced by increasing the evaporation surface from the reduced and unformed droplet size. In addition, appropriate selection of microinjectors distributed around the nozzle of a dump combustor (Figure 30.28) provides spatial coherent perturbations to control the large vortices. Two types of coherent structures (i.e., spanwise and streamwise vortices) can be influenced by imposing subharmonics of the most unstable instability frequency of the air jet. Control of the spanwise vortices can be accomplished by applying temporal amplitude modulation on the injection. If the ejecting phases of the

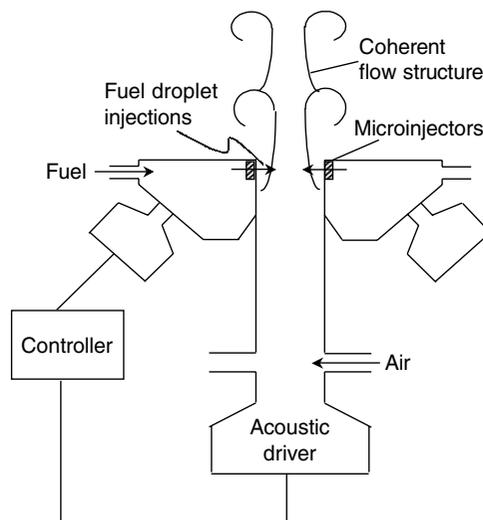

FIGURE 30.28 Control of mixing and fuel injection by microdroplet generators. (After Tseng et al., 1996.)

microdroplets along the azimuthal direction are the same, the mode zero instability (Brown and Roshko, 1974) is enhanced. When a certain defined phase lag is imposed on these microinjectors, higher mode instability (Brown and Roshko, 1974) waves are generated which are usually beneficial for mass transfer enhancement. Because about a thousand injectors are placed around the nozzle, the spatial modulation in the azimuthal direction can perturb the streamwise vortices. The interaction of streamwise and spanwise vortices by microinjectors brings forth fine-scale mixing.

### 30.6.4 Direct Writing and Packaging

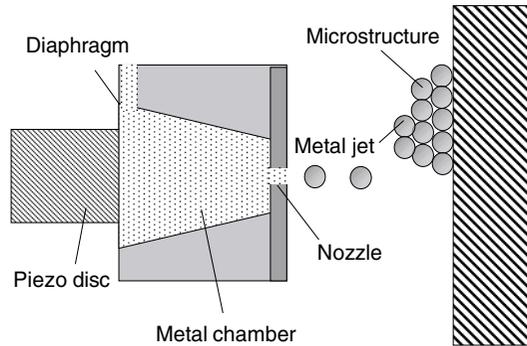

Microdroplet generators offer an alternative to the lithography process for electronics and optoelectronics manufacturing. This approach has the advantages of precise volume control of dispensed materials, data-driven flexibility, low cost, high speed and low environmental impact, as mentioned by Hayes and Cox (1998). Materials used with this process include adhesives for component bonding, filled polymer systems for direct resistor writing and oxide deposition and solder for solder-bumping of flip-chip ball grid arrays (BGAs), printed circuit boards (PCBs), and chip-scale packages (CSPs) [Teng et al., 1988; Hays et al., 1999]. In these printing applications, the temperature should be elevated to 100 ~ 200°C, and the viscosity of fluids should be around 40 cps; in some cases, an inert process environment, such as nitrogen flow, is required to prevent oxidation of the materials.

Direct writing by inkjet printing can eliminate the fabrication difficulty inherent in photolithography or screen-printing processes for solar-cell metallization and light-emitting polymer (LEP) deposition of light-emitting polymer displays (LEPDs). In solar-cell metallization, metallo-organic decomposition (MOD) silver ink is used to inkjet print directly onto solar-cell surfaces for avoidance of p-n junction degradation under the traditional screenprinting method requiring 600 to 800°C for firing process. Inkjet printing also allows formation of a uniform line of film on rough solar-cell surfaces [Tang and Vest, 1988a; 1988b; Somberg, 1990] which is not easily achieved by traditional photolithography.

Organic light-emitting devices that require deposition of many organic layers to perform full-color operation face similar problems. Due to the solubility of those organic layers in many solvents and aqueous solutions, conventional methods such as photolithography, screen printing and evaporation, which require a wet patterning process, are not suitable [Hebner et al., 1998; Shimoda et al., 1999; Kobayashi et al., 2000]. Thus, direct writing of organic materials by inkjet printing has become a promising solution to provide a safe, patternable process without a wet etching procedure. However, due to pinholes appearing on the patterned materials, high-quality polymer devices may not be easily inkjet printed. Yang's group proposed a hybrid way of combining an inkjet-printed layer with another uniform spin-coated polymer layer to overcome the problem [Bharathan and Young, 1998]. In such a system, the uniform layer serves as a buffer to seal the pinholes and the inkjet-printed layer contains the desired patterns [Bharathan and Young, 1998].

### 30.6.5 Optical Component Fabrication and Integration

Integrated microoptics has become a revolutionized concept in the optics field, as it provides the advantages of low cost, miniaturization, improved spatial resolution and time response and reduction of the assembly process on optical systems, which is not possible by traditional means. As a result, fabricating and integrating miniaturized optical components with performance similar or even better than traditional components are critical issues in integrated microoptics systems. Standard bulk or surface micromachining provides various ways to fabricate active/passive micromirrors, wave-guides and Fresnel lenses, but fabrication of refractive lenses with curved surfaces is not easy. Compared to photolithography, which utilizes patterned and melted photoresist columns as lenses, the inkjet printing method provides more flexibility as far as the process, material choices and system integration. Cox et al. [Cox et al., 1994; Hays and Cox, 1998] employed inkjet printing technology to eject heated polymer material to fabricate a microlenslet array. The shape of the lens was controlled by the viscosity of the droplets at the impact point, the substrate wetting condition and the cooling/curing rate of the droplets [Hays et al., 1998]. A 70- to 150- $\mu\text{m}$ -diameter lens with a density greater than 15,000/cm<sup>2</sup> has been successfully fabricated and

**FIGURE 30.29** Operation principle of three-dimensional structure fabrication by microdroplet generator. (After Yamaguchi et al., 2000.)

has focal lengths between 50 and 150  $\mu\text{m}$ . Besides the lens, wave-guides have also been demonstrated by Cox et al. (1994) using inkjet technology.

Because the optical components can be selectively deposited onto the desired region with varying properties, integration of those components with fabricated integrated circuit or other devices is possible and efficient.

### 30.6.6 Solid Freeforming

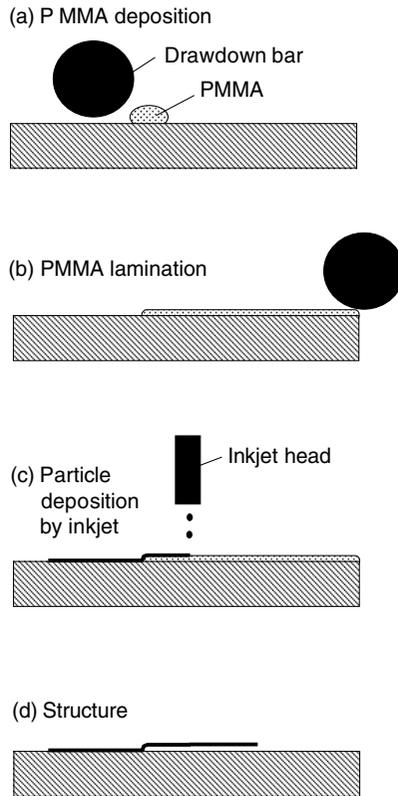

Two-dimensional patterns and three-dimensional solid structures can be generated by microdroplet generators. Orme and Huang (1993) and Marusak (1993) reported the application of molten metal drops for solid freeform fabrication. Evans' group demonstrated the application of continuous and drop-on-demand inkjets for ceramic printing to fabricate three-dimensional structures as well as functionally graded materials [Mott and Evans, 1999; Blasdell and Evans, 2000; Yamaguchi et al. 2000] used a metal jet to print functional three-dimensional microstructures, and Figure 30.29 shows the operation principle. Employing multijets for structure and sacrificial material deposition to print an overhanging structure was also proposed by Yamaguchi et al. (2000), while Fuller and Jacobson (2000) used laminated poly(methyl methacrylate) (PMMA) film as the supporting material for ejection of metal cantilever beams. The fabrication principle is shown in Figure 30.30.

### 30.6.7 Manufacturing Process

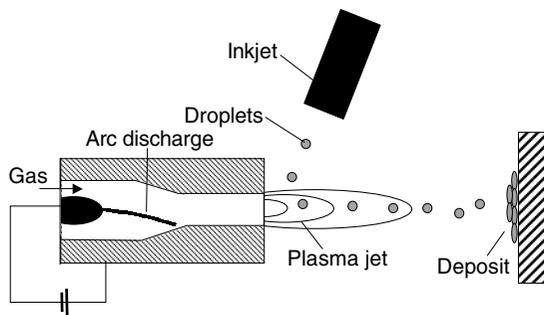

Droplet generators also provide novel material processing. For example, submicron ceramic particles can be plasma sprayed, as introduced by Blasdell and Juroda, for surface coating [Blasdell and Kuroda, 2000]. The operation principle is shown in Figure 30.31. A continuous-jet printer was used for droplet formation from ceramic solution. The produced ceramic stream was delivered into the hottest part of the plasma jet and then sprayed onto the working piece. The splats produced by the plasma spray are similar in morphology to those produced using conventional plasma spraying of a coarse powder but are significantly smaller in size, which may provide unique characteristics such as extension of solid-state solubility, refinement of grain size, formation of metastable phases and a high concentration of point defects [Blasdell and Kuroda, 2000].

### 30.6.8 Integrated Circuit Cooling

Conventionally, blowing fans and fins are widely used to cool integrated-circuit chips, especially for central processing unit (CPUs). Recently, as the heating power has increased greatly with increasing CPU size, more advanced methods, such as heat pipes, CPL and impinging air jets, have been introduced for quick heat removal. However, no matter how the designs improve, the limitation of heat removal ability

**FIGURE 30.30** Fabrication of three-dimensional structures by droplet ejection and polymer lamination. (After Fuller and Jacobson, 2000.)

**FIGURE 30.31** Operation principle of plasma spraying by microdroplet generators. (After Blazdell and Kuroda, 2000.)

for those devices is on the order of tens of watts per square centimeter. In addition, being able to detect hot spots and selectively remove the heat only from hot regions to preserve energy is highly desired but not easy to perform by traditional ways. As a result, the concept of transporting latent heat through the droplet evaporation process holds promise. This method can, in principle, remove three to four orders more heat than conventional methods. Also, the cooling spot can be selected and monitored through the integrated micro-temperature sensor and integrated circuit array. The conceptual design by Tseng (2001), as shown in [Figure 30.32](#), used a two-dimensional array of microinjectors to selectively deposit liquid droplets onto the chip surface. The applied droplet frequency and numbers can be adjusted to maintain a dry chip surface with constant temperature. The estimated maximum heat removed by this device is

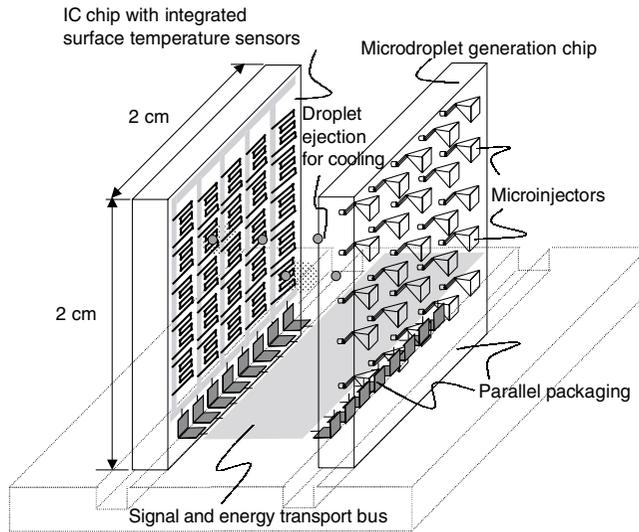

FIGURE 30.32 Conceptual design of integrated circuit cooling by microdroplet injections.

around  $300,000 \text{ W/cm}^2$ , more than 1000 times greater than by conventional means. Temperature sensors as well as a control circuit can also be fabricated on the same chip to form a self-contained smart system.

## 30.7 Concluding Remarks

The droplet generator is an important fluid-handling device for precise liquid-dosing control. MEMS technology makes microsized droplet generators possible and popular for many applications. Various methods of droplet generation, including piezoelectric, thermal bubble, thermal buckling, focused acoustic wave, electrostatic and inertial actuation, have been employed. Compared to other methods, the thermal bubble approach has greater actuation deformation, simpler design/fabrication and less limitation on the chamber volume, but it has the drawbacks of being temperature sensitivity and influenced by liquid properties. The piezo-type jet has the advantage of high frequency response, controllable droplet size, and no satellite drops, but it has the limitation of finite actuation deformation, thus limiting miniaturization of the chamber volume. The electrostatic and thermal buckling jets have size limitations similar to the piezo type. Despite the electrostatic generator having the benefit of low power consumption, both have limited frequency response due to size limitations. The acoustic-wave droplet generator, on the other hand, is not mature and stable enough for commercial applications, while the inertial actuation method offers limited miniaturization due to its operation principle. More types of microdroplet generators are under development and may one day replace the ones we have been using for decades.

Physical properties, design issues and manufacturing aspects are important concerns in the design and fabrication of microdroplet generators. The associated issues, including frequency response, cross-talk, satellite droplets, puddle formation, material selection and integration, require great care at the various design and fabrication levels. MEMS technology provides some of the key solutions to those practical issues.

Many aspects of the applications have made microdroplet generators important and exciting ever since their inception. Inkjet printing is the traditional application and has generated a significant amount of revenue in the printing market. Moreover, hundreds of applications are yet emerging, including bioreagent handling, fine chemical handling, drug delivery, direct writing, solid freeform, integrated circuit cooling and fuel injection, which show promising results and many potential markets. Many exciting applications of microdroplet generators are yet to be discovered.

### 31.1 Introduction

---

As described by Peterson (1994), a heat pipe operates on a closed two-phase cycle in which heat added to the evaporator region causes the working fluid to vaporize and move to the cooler condenser region, where the vapor condenses, giving up its latent heat of vaporization. In traditional heat pipes, the capillary forces existing in a wicking structure pump the liquid back to the evaporator. While the concept of utilizing a wicking structure as part of a device capable of transferring large quantities of heat with a minimal temperature drop was first introduced by Gaugler (1944), it was not until much more recently that the concept of combining phase-change heat transfer and microscale fabrication techniques (i.e., microelectromechanical systems, or MEMS, devices for the dissipation and removal of heat) was first proposed by Cotter (1984). This initial introduction envisioned a series of very small “micro” heat pipes incorporated as an integral part of semiconductor devices. While no experimental results or prototype designs were presented, the term *micro heat pipe* was first defined as one “so small that the mean curvature of the liquid–vapor interface is necessarily comparable in magnitude to the reciprocal of the hydraulic radius of the total flow channel” [Babin et al., 1990]. Early proposed applications of these devices included the removal of heat from laser diodes [Mráček, 1988] and other small localized heat-generating devices [Peterson, 1988a; 1988b]; thermal control of photovoltaic cells [Peterson, 1987a; 1987b]; removal or dissipation of heat from the leading edge of hypersonic aircraft [Camarda et al., 1997]; applications involving the nonsurgical treatment of cancerous tissue through either hyper- or hypothermia [Anon., 1989; Fletcher and Peterson, 1993]; and space applications in which heat pipes are embedded in silicon radiator panels to dissipate the large amounts of waste heat generated [Badran et al., 1993].

While not all of these applications have been implemented, micro heat pipes ranging in size from 1 mm in diameter and 60 mm in length to 30  $\mu\text{m}$  in diameter and 10 mm in length have been analyzed, modeled and fabricated, and the larger of these are currently commonplace in commercially available products, such as laptop computers or high-precision equipment where precise temperature control is essential. More recently, this work has been expanded to include micro heat spreaders fabricated in silicon or in new metallized polymeric materials, which can be used to produce highly conductive, flexible heat spreaders capable of dissipating extremely high heat fluxes over large areas, thereby reducing the source heat flux by several orders of magnitude.

Since the initial introduction of the micro heat pipe concept, the study of microscale heat transfer has grown enormously and has encompassed not only phase-change heat transfer, but also the entire field of heat transfer, fluid flow and, particularly for a large number of fundamental studies, thin film behavior, as described elsewhere in this book. Microscale fluid behavior and heat transfer at the microscale, along with the variations between the behavior of bulk thermophysical properties and those that exist at the micro- or nanoscale levels are all areas of considerable interest. While the division between micro- and macroscale phase-change behavior is virtually indistinguishable, in applications involving phase-change heat transfer devices, such as micro heat pipes and micro heat spreaders, it can best be described by applying the dimensionless expression developed by Babin and Peterson (1990) and described later in this chapter. This expression relates the capillary radius of the interface and the hydraulic radius of the passage and provides a good indicator of when the forces particular to the microscale begin to dominate.

A number of previous reviews have summarized the literature published prior to 1996 [Peterson and Ortega, 1990; Peterson, 1992; Peterson et al., 1996]; however, significant advances have been made over the past several years, particularly in the development of a better understanding of the thin-film behavior that governs the operation of these devices. The following review begins with a very brief overview of the early work in this area and then looks at advances made in individual micro heat pipes, arrays of micro heat pipes and more recent investigations of flat-plate microscale heat spreaders.

For heat pipes operating in steady state, there are a number of fundamental mechanisms that limit the maximum heat transfer. These have been summarized and described in a concise format (which will be summarized here) by Marto and Peterson (1988) and include the capillary wicking limit, viscous limit, sonic limit, entrainment and boiling limits. The first two of these deal with the pressure drops occurring in the liquid and vapor phases. The sonic limit results from pressure-gradient-induced vapor velocities that may result in choked vapor flow, while the entrainment limit focuses on the entrainment of liquid droplets in the vapor stream, which inhibits the return of the liquid to the evaporator and ultimately leads to dryout. Unlike these limits, which depend upon the axial transport, the boiling limit is reached when the heat flux applied in the evaporator portion is high enough that nucleate boiling occurs in the evaporator wick, creating vapor bubbles that partially block the return of fluid.

While a description of the transient operation and start-up dynamics of these devices is beyond the scope of this work, it is appropriate to include a brief description of the methods for determining the steady-state limitations. For additional information on the theory and fundamental phenomena that cause each of these limitations, readers are referred to Tien et al. (1975), Chi (1976), Dunn and Reay (1982) and Peterson (1994).

### 31.1.1 Capillary Limitation

The operation and performance of heat pipes are dependent on many factors, including the shape, working fluid and wick structure. The primary mechanism by which these devices operate results from the difference in the capillary pressure across the liquid–vapor interfaces in the evaporator and condenser. To operate properly, this pressure difference must exceed the sum of all the pressure losses throughout the liquid and vapor flow paths. This relationship can be expressed as:

$$\Delta P_c \geq \Delta P_+ + \Delta P_- + \Delta P_l + \Delta P_v \quad (31.1)$$

where

- $\Delta P_c$  = net capillary pressure difference.
- $\Delta P_+$  = normal hydrostatic pressure drop.
- $\Delta P_-$  = axial hydrostatic pressure drop.
- $\Delta P_l$  = viscous pressure drop occurring in the liquid phase.
- $\Delta P_v$  = viscous pressure drop occurring in the vapor phase.

As long as this condition is met, liquid is returned to the evaporator. For situations where the summation of the viscous pressure losses,  $\Delta P_l$  and  $\Delta P_v$ , and the hydrostatic pressure losses,  $\Delta P_+$  and  $\Delta P_-$ , is greater than the capillary pressure difference between the evaporator and condenser, the wicking structure becomes starved of liquid and dries out. This condition, referred to as the capillary wicking limitation, varies according to the wicking structure, working fluid, evaporator heat flux and operating temperature.

### 31.1.1.1 Capillary Pressure

The capillary pressure difference at a liquid–vapor interface,  $\Delta P_c$ , is defined by the LaPlace–Young equation, which for most heat pipe applications reduces to:

$$\Delta P_{c,m} = \left( \frac{2\sigma}{r_{c,e}} \right) - \left( \frac{2\sigma}{r_{c,c}} \right) \quad (31.2)$$

where  $r_{c,e}$  and  $r_{c,c}$  represent the radii of curvature in the evaporator and condenser regions, respectively.

During normal heat pipe operation, the vaporization occurring in the evaporator causes the liquid meniscus to recede into the wick, reducing the local capillary radius,  $r_{c,e}$ , while condensation in the condenser results in increases in the local capillary radius,  $r_{c,c}$ . It is this difference in the two radii of curvature that “pumps” liquid from the condenser to the evaporator. During steady-state operation, it is generally assumed that the capillary radius in the condenser,  $r_{c,c}$ , approaches infinity, so that the maximum capillary pressure for a heat pipe operating at steady state can be expressed as a function of only the capillary radius of the evaporator wick,

$$\Delta P_{c,m} = \left( \frac{2\sigma}{r_{c,e}} \right) \quad (31.3)$$

Values for the effective capillary radius,  $r_{c,e}$ , can be found theoretically for simple geometries [Chi, 1976] or experimentally for other more complicated structures.

### 31.1.1.2 Hydrostatic Pressure Drops

The normal and axial hydrostatic pressure drops,  $\Delta P_+$  and  $\Delta P_-$ , are the result of the local gravitational body force. The normal and axial hydrostatic pressure drops can be expressed as:

$$\Delta P_+ + \rho_l g d_v \cos \Psi \quad (31.4)$$

and

$$\Delta P_- = \rho_l g L \sin \Psi \quad (31.5)$$

where  $\rho_l$  is the density of the liquid,  $g$  is the gravitational acceleration,  $d_v$  is the diameter of the vapor portion of the pipe,  $\Psi$  is the angle the heat pipe makes with respect to the horizontal, and  $L$  is the length of the heat pipe.

In a gravitational environment, the axial hydrostatic pressure term may either assist or hinder the capillary pumping process depending upon whether the tilt of the heat pipe promotes or hinders the flow of liquid back to the evaporator (i.e., the evaporator lies either below or above the condenser). In a zero- $g$  environment or for cases where the surface tension forces dominate, such as micro heat pipes, both of these terms can be neglected.

### 31.1.1.3 Liquid Pressure Drop

As the liquid returns from the condenser to the evaporator, it experiences a viscous pressure drop,  $\Delta P_l$ , which can be written in terms of the frictional drag,

$$\frac{dP_l}{dx} = -\frac{2\tau_l}{(r_{h,l})} \quad (31.6)$$

where  $\tau_l$  is the frictional shear stress at the liquid–solid interface and  $r_{h,l}$  is the hydraulic radius, defined as twice the cross-sectional area divided by the wetted perimeter.

This pressure gradient is a function of the Reynolds number,  $Re_l$ , and drag coefficient,  $f_l$ , defined as:

$$Re_l = \frac{2(r_{h,l})\rho_l V_l}{\mu_l} \quad (31.7)$$

and

$$f_l = \frac{2\tau_l}{\rho_l V_l^2} \quad (31.8)$$

respectively, where  $V_l$  is the local liquid velocity which is related to the local heat flow,

$$V_l = \frac{q}{\varepsilon A_w \rho_l \lambda} \quad (31.9)$$

$A_w$  is the wick cross-sectional area,  $\varepsilon$  is the wick porosity, and  $\lambda$  is the latent heat of vaporization.

Combining these expressions yields an expression for the pressure gradient in terms of the Reynolds number, drag coefficient and the thermophysical properties:

$$\frac{dP_l}{dx} = \left( \frac{(f_l Re_l) \mu_l}{2\varepsilon A_w (r_{h,l})^2 \lambda \rho_l} \right) q \quad (31.10)$$

which in turn can be written as a function of the permeability,  $K$ , as:

$$\frac{dP_l}{dx} = \left( \frac{\mu_l}{K A_w \lambda \rho_l} \right) q \quad (31.11)$$

where the permeability expressed as:

$$K = \frac{2\varepsilon (r_{h,l})^2}{f_l Re_l} \quad (31.12)$$

For steady-state operation with constant heat addition and removal, Eq. (31.11) can be integrated over the length of the heat pipe to yield:

$$\Delta P_l = \left( \frac{\mu_l}{K A_w \lambda \rho_l} \right) L_{eff} q \quad (31.13)$$

where  $L_{eff}$  is the effective heat pipe length defined as:

$$L_{eff} = 0.5 L_e + L_a + 0.5 L_c \quad (31.14)$$

### 31.1.1.4 Vapor Pressure Drop

The methods for calculating the vapor pressure drop in heat pipes is similar to that used for the liquid pressure drop described above but is complicated by the mass addition and removal in the evaporator and condenser, respectively, and by the compressibility of the vapor phase. As a result, accurate computation of the total pressure drop requires that the dynamic pressure be included. In-depth discussions of the methodologies for determining the overall vapor pressure drop have been presented previously by Chi (1976), Dunn and Reay (1982) and Peterson (1994). The resulting expression is similar to that developed for the liquid:

$$\Delta P_v = \left( \frac{C(f_v Re_v) \mu_v}{2(r_{h,v})^2 A_v \rho_v \lambda} \right) L_{eff} q \quad (31.15)$$

where  $(r_{h,v})$  is the hydraulic radius of the vapor space and  $C$  is a constant that depends on the Mach number.

Unlike the liquid flow, which is driven by the capillary pressure difference and hence is always laminar, the vapor flow is driven by the temperature gradient and for high heat-flux applications may result in turbulent flow conditions. As a result, it is necessary to determine the vapor flow regime as a function of the heat flux by evaluating the local axial Reynolds number, defined as:

$$Re_v = \frac{2(r_{h,v})q}{A_v \mu_v \lambda} \quad (31.16)$$

Due to compressibility effects, it is also necessary to determine if the flow is compressible. This is accomplished by evaluating the local Mach number, defined as:

$$Ma_v = \left( \frac{q}{A_v \rho_v \lambda (R_v T_v \gamma_v)} \right)^{1/2} \quad (31.17)$$

where  $R_v$  is the gas constant,  $T_v$  is the vapor temperature, and  $\gamma_v$  is the ratio of specific heats, which is equal to 1.67, 1.4 or 1.33 for monatomic, diatomic and polyatomic vapors, respectively (Chi, 1976).

Previous investigations summarized by Kraus and Bar-Cohen (1983) have demonstrated that the following combinations of these conditions can be used with reasonable accuracy:

$$\begin{aligned} Re_v < 2300, \quad Ma_v < 0.2 \\ (f_v Re_v) &= 16 \\ C &= 1.00 \end{aligned} \quad (31.18)$$

$$\begin{aligned} Re_v < 2300, \quad Ma_v > 0.2 \\ (f_v Re_v) &= 16 \\ C &= \left[ 1 + \left( \frac{\gamma_v - 1}{2} \right) Ma_v^2 \right]^{-1/2} \end{aligned} \quad (31.19)$$

$$\begin{aligned} Re_v > 2300, \quad Ma_v < 0.2 \\ (f_v Re_v) &= 0.038 \left( \frac{2(r_{h,v})q}{A_v \mu_v \lambda} \right)^{3/4} \\ C &= 1.00 \end{aligned} \quad (31.20)$$

$$\begin{aligned}
Re_v &> 2300, \quad Ma_v > 0.2 \\
(f_v Re_v) &= 0.038 \left( \frac{2(r_{h,v}) q}{A_v \mu_v \lambda} \right)^{3/4} \\
C &= \left[ 1 + \left( \frac{\gamma_v - 1}{2} \right) Ma_v^2 \right]^{-1/2}
\end{aligned} \tag{31.21}$$

The solution procedure is to first assume laminar, incompressible flow and then to compute the Reynolds and Mach numbers. Once these values have been found, the initial assumptions of laminar, incompressible flow can be evaluated and the appropriate modifications made.

### 31.1.2 Viscous Limitation

At very low operating temperatures, the vapor pressure difference between the closed end of the evaporator (the high-pressure region) and the closed end of the condenser (the low-pressure region) may be extremely small. Because of this small pressure difference, the viscous forces within the vapor region may prove to be dominant and hence limit the heat pipe operation. Dunn and Reay (1982) discuss this limit in more detail and suggest the criterion:

$$\frac{\Delta P_v}{P_v} < 0.1 \tag{31.22}$$

for determining when this limit might be of a concern. For steady-state operation, or applications in the moderate operating temperature range, the viscous limitation will normally not be important.

### 31.1.3 Sonic Limitation

The sonic limitation in heat pipes is the result of vapor velocity variations along the length of the heat pipe due to the axial variation of the vaporization and condensation. Much like the effect of decreased outlet pressure in a converging–diverging nozzle, decreased condenser temperature results in a decrease in the evaporator temperature up to but not beyond that point where choked flow occurs in the evaporator, causing the sonic limit to be reached. Any further decreases in the condenser temperature do not reduce the evaporator temperature or the maximum heat transfer capability, due to the existence of choked flow.

The sonic limitation in heat pipes can be determined as:

$$q_{s,m} = A_v \rho_v \lambda \left( \frac{\gamma_v R_v T_v}{2(\gamma_v + 1)} \right)^{1/2} \tag{31.23}$$

where  $T_v$  is the mean vapor temperature within the heat pipe [Chi, 1976].

### 31.1.4 Entrainment Limitation

In an operating heat pipe, the liquid and vapor typically flow in opposite directions, resulting in a shear stress at the interface. At very high heat fluxes, liquid droplets may be picked up or entrained in the vapor flow. This entrainment results in dryout of the evaporator wick due to excess liquid accumulation in the condenser. The Weber number,  $We$ , which represents the ratio of the viscous shear force to the force resulting from the liquid surface tension, can be used to determine at what point this entrainment is likely to occur:

$$We = \frac{2(r_{h,w}) \rho_v V_v^2}{\sigma} \tag{31.24}$$

To prevent the entrainment of liquid droplets in the vapor flow, the Weber number must therefore be less than one, which implies that the maximum transport capacity based on the entrainment limitation may be determined as:

$$q_{e,m} = A_v \lambda \left( \frac{\sigma \rho_v}{2(r_{h,w})} \right)^{1/2} \quad (31.25)$$

where  $(r_{h,w})$  is the hydraulic radius of the wick structure (Dunn and Reay, 1983).

### 31.1.5 Boiling Limitation

As mentioned, all of the limits discussed previously depend upon the axial heat transfer. The boiling limit, however, depends upon the evaporator heat flux and occurs when the nucleate boiling in the evaporator wick creates vapor bubbles that partially block the return of fluid. The presence of vapor bubbles in the wick requires both the formation of bubbles and also the subsequent growth of these bubbles. Chi (1976) has developed an expression for the boiling limit, which can be written as

$$q_{b,m} = \left( \frac{2\pi L_{eff} k_{eff} T_v}{\lambda \rho_v \ln(r_i/r_v)} \right) \left( \frac{2\sigma}{r_n} - \Delta P_{c,m} \right) \quad (31.26)$$

where  $k_{eff}$  is the effective thermal conductivity of the liquid–wick combination,  $r_i$  is the inner radius of the heat pipe wall, and  $r_n$  is the nucleation site radius [Dunn and Reay, 1982].

### 31.1.6 Heat Pipe Thermal Resistance

Once the maximum transport capacity is known, it is often useful to determine the temperature drop between the evaporator and condenser. The overall thermal resistance for a heat pipe is comprised of nine resistances of significantly different orders of magnitude, arranged in a series/parallel combination. These resistances can be summarized as follows:

- $R_{pe}$  = radial resistance of the pipe wall at the evaporator.
- $R_{we}$  = resistance of the liquid–wick combination at the evaporator.
- $R_{ie}$  = resistance of the liquid–vapor interface at the evaporator.
- $R_{ya}$  = resistance of the adiabatic vapor section.
- $R_{pa}$  = axial resistance of the pipe wall.
- $R_{wa}$  = axial resistance of the liquid–wick combination.
- $R_{ic}$  = resistance of the liquid–vapor interface at the condenser.
- $R_{wc}$  = resistance of the liquid–wick combination at the condenser.
- $R_{pc}$  = radial resistance of the pipe wall at the condenser.

Previous investigations have indicated that typically the resistance of the vapor space, the axial resistances of the pipe wall and liquid–wick combinations, can all be neglected. In addition, the liquid–vapor interface resistances and the axial vapor resistance can, in most situations, be assumed to be negligible. This leaves only the pipe wall radial resistances and the liquid–wick resistances at both the evaporator and condenser.

As presented by Peterson (1994), the radial resistances at the pipe wall can be computed from Fourier's law as:

$$R_{pe} = \frac{\delta}{k_p A_e} \quad (31.27)$$

for flat plates, where  $\delta$  is the plate thickness and  $A_e$  is the evaporator area, or

$$R_{pe} = \frac{\ln(d_o/d_i)}{2\pi L_e k_p} \quad (31.28)$$

for cylindrical pipes, where  $L_e$  is the evaporator length. An expression for the equivalent thermal resistance of the liquid–wick combination in circular pipes is

$$R_{we} = \frac{\ln(d_o/d_i)}{2\pi L_e k_{eff}} \quad (31.29)$$

where  $k_{eff}$  is the effective conductivity of the liquid–wick combination.

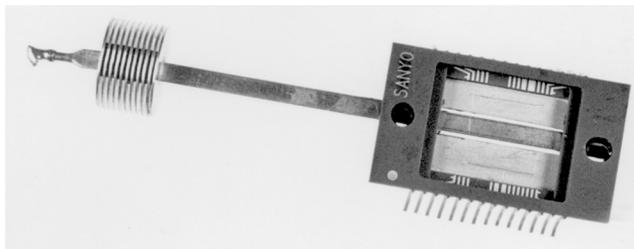

Combining these individual resistances allows the overall thermal resistance to be determined, which when combined with the maximum heat transport found previously will yield an estimation of the overall temperature drop.

## 31.2 Individual Micro Heat Pipes

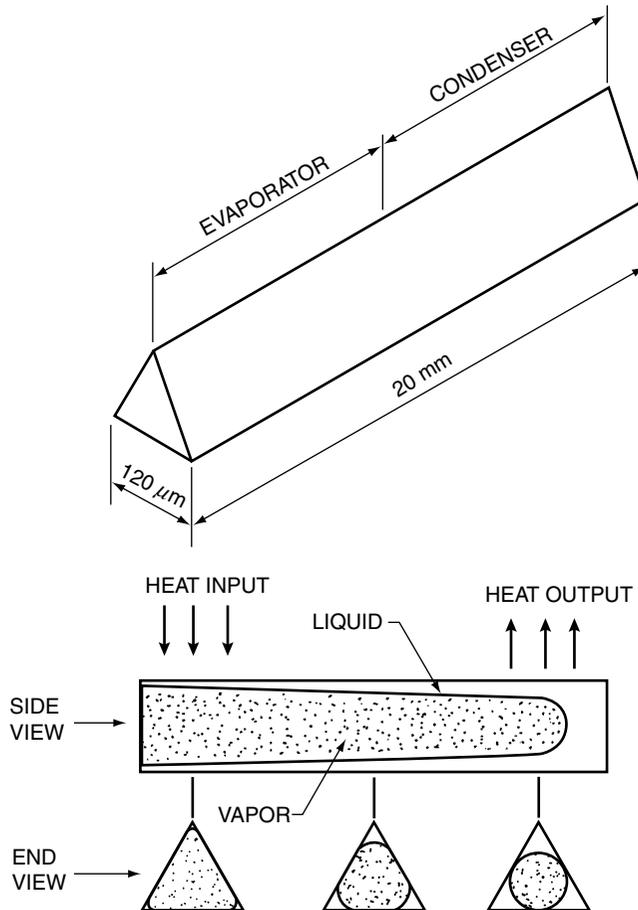

The earliest embodiments of micro heat pipes typically consisted of a long thin tube with one or more small noncircular channels that utilized the sharp-angled corner regions as liquid arteries. While initially quite novel in size (see [Figure 31.1](#)), it was soon apparent that devices with characteristic diameters of approximately 1 mm functioned in nearly the same manner as larger, more conventional liquid artery heat pipes. Heat applied to one end of the heat pipe vaporizes the liquid in that region and forces it to move to the cooler end, where it condenses and gives up the latent heat of vaporization. This vaporization and condensation process causes the liquid–vapor interface in the liquid arteries to change continually along the pipe, as illustrated in [Figure 31.2](#) and results in a capillary pressure difference between the evaporator and condenser regions. This capillary pressure difference promotes the flow of the working fluid from the condenser back to the evaporator through the triangular-shaped corner regions. These corner regions serve as liquid arteries, thus no wicking structure is required [Peterson, 1990; 1994]. The following sections present a summary of the analytical and experimental investigations conducted on individual micro heat pipes, arrays of micro heat pipes, flat-plate microscale heat spreaders, and the latest advances in the development of highly conductive, flexible, phase-change heat spreaders.

### 31.2.1 Modeling Micro Heat Pipe Performance

The first steady-state analytical models of individual micro heat pipes utilized the traditional pressure-balance approach developed for use in more conventional heat pipes and described earlier in this chapter. These models provided a mechanism by which the steady-state and transient performance characteristics of micro heat pipes could be determined and indicated that, while the operation was similar to that observed in larger more conventional heat pipes, the relative importance of many of the parameters is quite different. Perhaps the most significant difference was the relative sensitivity of the micro heat pipes

**FIGURE 31.1** Micro-heat-pipe-cooled ceramic chip carrier. (From Peterson, G.P. (1994) *An Introduction to Heat Pipes: Modeling, Testing and Applications*, John Wiley & Sons, New York. With permission.)

**FIGURE 31.2** Micro heat pipe operation. (From Peterson, G.P. et al. (1996) in *Microscale Energy Transport* (C.L. Tien et al., Eds.), Taylor & Francis, Washington, D.C. Reproduced by permission of Routledge, Inc.)

to the amount of working fluid present. These early steady-state models later led to the development of both transient numerical models and three-dimensional numerical models of the temperature and pressure distribution within individual micro heat pipes [Peterson, 1992; 1994; Peterson et al., 1996].

### 31.2.1.1 Steady-State Modeling

The first steady-state model specifically designed for use in the modeling of micro heat pipes was developed by Cotter (1984). Starting with the momentum equation and assuming uniform cross-sectional area and no-slip conditions at the boundaries, this expression was solved for both the liquid and vapor pressure differentials and then combined with the continuity expression. The result was a first-order ordinary differential equation, which related the radius of curvature of the liquid–vapor interface to the axial position along the pipe. Building upon this model, Peterson (1988a) and Babin et al. (1990) developed a steady-state model for a trapezoidal micro heat pipe, using the conventional steady-state modeling techniques outlined by Chi (1976) and described earlier in this chapter. The resulting model demonstrated that the capillary pumping pressure governed the maximum heat transport capacity of these devices.

A comparison of the performance limitations resulting from the models presented by Cotter (1984) and by Babin et al. (1990) indicated significant differences in the capillary limit predicted by the two models. These differences have been analyzed and found to be the result of specific assumptions made in the initial formulation of the models [Peterson, 1992].

A comparative analysis of these two early models was performed by Gerner et al. (1992), who indicated that the most important contributions of Babin et al. (1990) were the inclusion of the gravitational body force and the recognition of the significance of the vapor pressure losses. In addition, the assumption that the pressure gradient in the liquid flow passages was similar to that occurring in Hagen–Poiseuille flow was questioned, and a new scaling argument for the liquid pressure drop was presented. In this development, it was assumed that the average film thickness was approximately one fourth the hydraulic radius, resulting in a modified expression for the capillary limitation.

A significant contribution made by Gerner et al. (1992) was the recognition that the capillary limit may never actually be reached due to Kelvin–Helmholtz-type instabilities occurring at the liquid–vapor interface. Using stability analysis criteria for countercurrent flow in tubes developed by Tien et al. (1979) and minimizing the resulting equations, the wavelength was found to be approximately 1 cm for atmospheric water and methanol. Because this length was long with respect to the characteristic wavelength, it was assumed that gravity was the dominant stabilizing mechanism. The decision as to whether to use the traditional capillary limit proposed by Babin et al. (1990) or the interfacial instability limit proposed by Gerner et al. (1992) should be governed by evaluating the shape and physical dimensions of the specific micro heat pipe being considered.

### 31.2.1.2 Transient Modeling

As heat pipes diminish in size, the transient nature becomes of increasing interest. The ability to respond to rapid changes in heat flux coupled with the need to maintain constant evaporator temperature in modern high-powered electronics necessitates a complete understanding of the temporal behavior of these devices. The first reported transient investigation of micro heat pipes was conducted by Wu and Peterson (1991). This initial analysis utilized the relationship developed by Collier (1981) and was used later by Colwell and Chang (1984) to determine the free-molecular-flow mass flux of evaporation. The most interesting result from this model was the observation that reverse liquid flow occurred during the startup of micro heat pipes. As explained in the original reference [Wu et al., 1991], this reverse liquid flow is the result of an imbalance in the total pressure drop and occurs because the evaporation rate does not provide an adequate change in the liquid–vapor interfacial curvature to compensate for the pressure drop. As a result, the increased pressure in the evaporator causes the meniscus to recede into the corner regions, forcing liquid out of the evaporator and into the condenser. During startup, the pressure of both the liquid and vapor is higher in the evaporator and gradually decreases with position, promoting flow away from the evaporator. Once the heat input reaches full load, the reverse liquid flow disappears and the liquid mass flow rate into the evaporator gradually increases until a steady-state condition is reached. At this time, the change in the liquid mass flow rate is equal to the change in the vapor mass flow rate for any given section [Wu and Peterson, 1991].

Several, more detailed transient models have been proposed. Badran et al. (1993) developed a conjugate model to account for the transport of heat within the heat pipe and conduction within the heat pipe case. This model indicated that the specific thermal conductivity of micro heat pipes (effective thermal conductivity divided by the density) could be as high as 200 times that of copper and 100 times that of Gr/Cu composites. Longtin et al. (1994) developed a one-dimensional, steady-state model that indicated that the maximum heat transport capacity varied with respect to the cube of the hydraulic diameter, and Khrustalev and Faghri (1994) presented a detailed mathematical model of the heat- and mass-transfer processes in micro heat pipes which described the distribution of the liquid and the thermal characteristics as a function of the liquid charge. The liquid flow in the triangular-shaped corners of a micro heat pipe with a polygonal cross section was considered by accounting for the variation of the curvature of the free liquid surface and the interfacial shear stresses due to the liquid–vapor interaction. A comparison of the predicted results with the experimental data obtained by Wu and Peterson (1991) and Wu et al. (1991) indicated the importance of the liquid charge, the contact angle and the shear stresses at the liquid–vapor interface in predicting the maximum heat-transfer capacity and thermal resistance of these devices.

Ma et al. (1996) developed a closed mathematical model of the liquid friction factor for flow occurring in triangular grooves. This model, which built upon the earlier work of Ma et al. (1994), considered the

interfacial shear stresses due to liquid–vapor frictional interactions for countercurrent flow. Using a coordinate transformation and the Nachtsheim–Swigert iteration scheme, the importance of the liquid–vapor interactions on the operational characteristics of micro heat pipes and other small phase-change devices was demonstrated. The solution resulted in a method by which the velocity distribution for countercurrent liquid–vapor flow could be determined and allowed the governing liquid flow equations to be solved for cases where the liquid surface is strongly influenced by the vapor flow direction and velocity. The results of the analysis were verified using an experimental test facility constructed with channel angles of 20, 40 and 60 degrees. The experimental and predicted results were compared and found to be in good agreement [Ma and Peterson 1996a; 1996b; Peterson and Ma, 1996a].

## **31.2.2 Testing of Individual Micro Heat Pipes**

As fabrication capabilities have developed, experimental investigations on individual micro heat pipes have been conducted on progressively smaller and smaller devices, beginning with early investigations on what now appear to be relatively large micro heat pipes, approximately 3 mm in diameter, and progressing to micro heat pipes in the 30- $\mu$ m-diameter range. These investigations have included both steady-state and transient investigations.

### **31.2.2.1 Steady-State Experimental Investigations**

In the earliest experimental tests of this type reported in the open literature by Babin et al. (1990), several micro heat pipes approximately 1 mm in external diameter were evaluated. The primary purpose of this investigation was to determine the accuracy of the previously described steady-state modeling techniques, to verify the micro heat pipe concept, and to determine the maximum heat-transport capacity. The fabrication techniques used to produce these test articles were developed by Itoh Research and Development Company, Osaka, Japan [Itoh, 1988]. As reported previously, four test articles were evaluated, two each from silver and copper. Two of these test pipes were charged with distilled, deionized water and the other two were used in an uncharged condition to determine the effect of the vaporization–condensation process on the overall thermal conductivity of these devices. Steady-state tests were conducted over a range of tilt angles to determine the effect of the gravitational body force on the operational characteristics. An electrical resistance heater supplied the heat into the evaporator. Heat rejection was achieved through the use of a constant-temperature ethyl–glycol solution, which flowed over the condenser portion of the heat pipe. The axial temperature profile was continuously monitored by five thermocouples bonded to the outer surface of the heat pipe using a thermally conductive epoxy. Three thermocouples were located on the evaporator: one on the condenser and one on the outer surface of the adiabatic section. Throughout the tests, the heat input was systematically increased and the temperature of the coolant bath adjusted to maintain a constant adiabatic wall temperature [Babin et al., 1990].

The results of this experiment have been utilized as a basis for comparison with a large number of heat pipe models. As previously reported [Peterson et al., 1996], the steady-state model of Babin et al. (1990) overpredicted the experimentally determined heat-transport capacity at operating temperatures below 40°C and underpredicted it at operating temperatures above 60°C. These experimental results represented the first successful operation of a “micro” heat pipe that utilized the principles outlined in the original concept of Cotter (1984) and as such paved the way for numerous other investigations and applications.

### **31.2.2.2 Transient Experimental Investigations**

While the model developed by Babin et al. (1990) was shown to predict the steady-state performance limitations and operational characteristics of the trapezoidal heat pipe reasonably well for operating temperatures between 40 and 60°C, little was known about the transient behavior of these devices. As a result, Wu et al. (1991) undertook an experimental investigation of the transient characteristics of these devices. This experimental investigation again utilized micro heat pipe test articles developed by Itoh (1988); however, this particular test pipe was designed to fit securely under a ceramic chip carrier and

had small fins at the condenser end of the heat pipe for removal of heat by free or forced convection, as shown in Figure 31.1. Startup and transient tests were conducted in which the transient response characteristics of the heat pipe as a function of incremental power increases, tilt angle, and mean operating temperature were measured.

Itoh and Polásek (1990a; 1990b) presented the results of an extensive experimental investigation on a series of micro heat pipes ranging in size and shape from 1 to 3 mm in diameter and 30 to 150 mm in length that utilized both cross-sectional configurations, similar to those presented previously, and a conventional internal wicking structure (Polásek, 1990; Fejfar et al., 1990). The unique aspect of this particular investigation was the use of neutron radiography to determine the distribution of the working fluid within the heat pipes [Itoh and Polásek, 1990a; 1990b; Ikeda, 1990]. Using this technique, the amount and distribution of the working fluid and noncondensable gases were observed during real-time operation along with the boiling and/or re-flux flow behavior. The results of these tests indicated several important results [Peterson, 1992]:

- As is the case for conventional heat pipes, the maximum heat-transport capacity is principally dependent upon the mean adiabatic vapor temperature.
- Micro heat pipes with smooth inner surfaces were found to be more sensitive to overheating than those with grooved capillary systems.
- The wall thickness of the individual micro heat pipes had a greater effect on the thermal performance than did the casing material.
- The maximum transport capacity of heat pipes utilizing axial channels for return of the liquid to the evaporator was found to be superior to that of those utilizing a formal wicking structure.

## 31.3 Arrays of Micro Heat Pipes

### 31.3.1 Modeling of Heat Pipe Arrays

The initial conceptualization of micro heat pipes by Cotter (1984) envisioned fabricating micro heat pipes directly into semiconductor devices as shown schematically in Figure 31.3. While many of the previously discussed models can be used to predict the performance limitations and operational characteristics of individual micro heat pipes, it is not clear from the models or analyses how the incorporation of an array of these devices might affect the temperature distribution or the resulting thermal performance. Mallik et al. (1991) developed a three-dimensional numerical model capable of predicting the thermal performance of an array of parallel micro heat pipes constructed as an integral part of semiconductor chips, similar to that illustrated in Figure 31.4. In order to determine the potential advantages of this concept, several different thermal loading configurations were modeled, and reduction in maximum surface temperature, the mean chip temperature and the maximum temperature gradient across the chip was determined [Peterson, 1994].

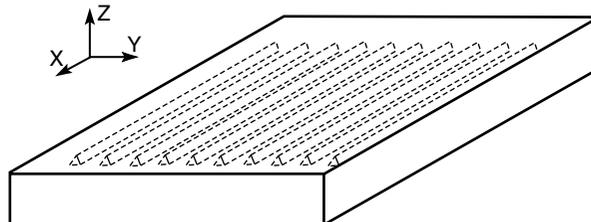

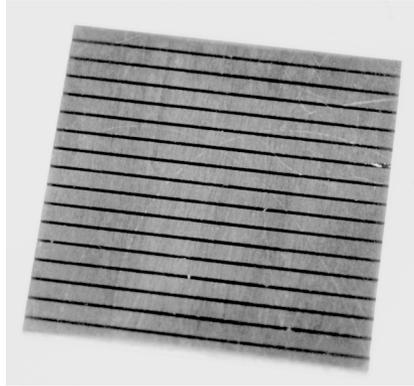

FIGURE 31.3 Array of micro heat pipes fabricated as an integral part of a silicon wafer.

**FIGURE 31.4** Silicon wafer into which an array of micro heat pipes has been fabricated.

Although the previous investigations of Babin et al. (1990), Wu and Peterson (1991) and Wu et al. (1991) indicated that an effective thermal conductivity greater than 10 times that of silicon could be achieved, additional analyses were conducted to determine the effect of variations in this value. Steady-state analyses were performed using a heat pipe array comprised of 19 parallel heat pipes. Using an effective thermal conductivity ratio of 5, the maximum and mean surface temperatures were 37.69 and 4.91°C, respectively. With an effective thermal conductivity ratio of 10, the maximum and mean surface temperatures were 35.20 and 4.21°C, respectively. Using an effective thermal conductivity ratio of 15, the maximum and mean surface temperatures were 32.67 and 3.64°C, respectively [Peterson, 1994]. These results illustrate how the incorporation of an array of micro heat pipes can reduce the maximum wafer temperature, reduce the temperature gradient across the wafers and eliminate localized hot spots. In addition, this work highlighted the significance of incorporating these devices into semiconductor chips, particularly those constructed in materials with thermal conductivities significantly less than that of silicon, such as gallium arsenide.

This work was further extended to determine transient response characteristics of an array of micro heat pipes fabricated into silicon wafers as a substitute for polycrystalline diamond or other highly thermally conductive heat spreader materials [Mallik and Peterson, 1991; Mallik et al., 1992]. The resulting transient, three-dimensional, numerical model was capable of predicting the time-dependent temperature distribution occurring within the wafer when given the physical parameters of the wafer and the locations of the heat sources and sinks and indicated that significant reductions in the maximum localized wafer temperatures and thermal gradients across the wafer could be obtained through the incorporation of an array of micro heat pipes. Utilizing heat sinks located on the edges of the chip perpendicular to the axis of the heat pipes and a cross-sectional area porosity of 1.85%, reductions in the maximum chip temperature of up to 40% were predicted.

### **31.3.2 Testing of Arrays of Micro Heat Pipes**

Peterson et al. (1991) fabricated, charged and tested micro heat pipe arrays incorporated as an integral part of semiconductor wafers. These tests represented the first successful operation of these devices reported in the open literature. In this investigation, several silicon wafers were fabricated with distributed heat sources on one side and an array of micro heat pipes on the other, as illustrated in Figure 31.4. Since that time, a number of experimental investigations have been conducted to verify the micro heat pipe array concept and determine the potential advantages of constructing an array of micro heat pipes as an integral part of semiconductor devices [Peterson et al., 1993; Peterson, 1994]. The arrays tested have typically been fabricated in silicon and have ranged in size from parallel rectangular channels, 30 μm wide, 80 μm deep and 19.75 mm long, machined into a silicon wafer 20 mm square and 0.378 mm thick with an interchannel spacing of 500 μm, to etched arrays of triangular channels, 120 μm wide and 80 μm

## CONSTRUCTION PROCESS

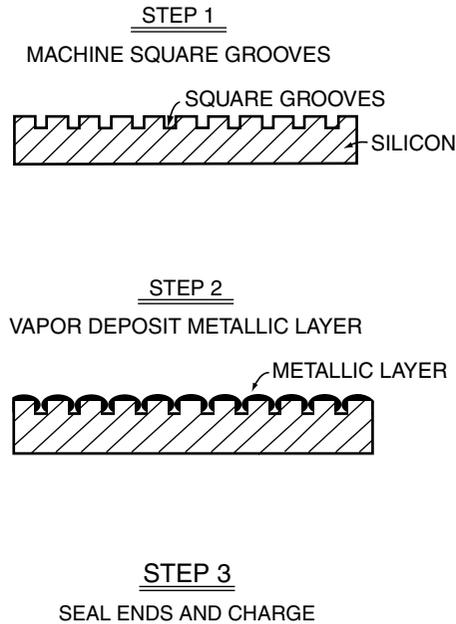

FIGURE 31.5 Vapor deposition process for fabricating micro heat pipes.

deep machined into 20-mm-square silicon wafers 0.5 mm thick [Peterson et al., 1993]. In addition, arrays of micro heat pipes fabricated using a vapor deposition process first proposed by Peterson (1990) and illustrated in Figure 31.5 were tested by Mallik et al. (1995).

In this work, wafers with arrays of 34 and 66 micro heat pipes were evaluated using an infrared thermal imaging system in conjunction with a VHS video recorder. These arrays occupied 0.75% and 1.45% of the wafer cross-sectional area, respectively. The wafers with micro heat pipe arrays demonstrated a 30 to 45% reduction in the thermal time constant when compared to that obtained for plain silicon wafers, which led to a significant reduction in the maximum wafer temperature. The experimental results were then used to validate the transient numerical model described previously [Peterson and Mallik, 1995].

### 31.3.3 Fabrication of Arrays of Micro Heat Pipes

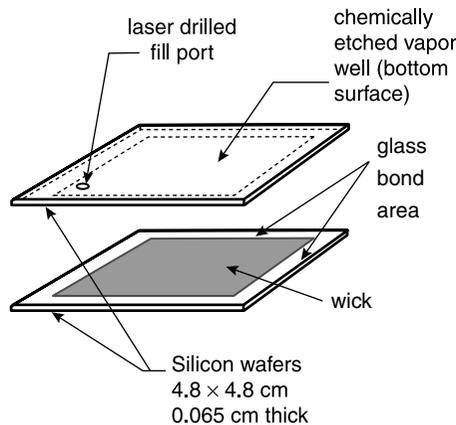

Considerable information is available on the methods used to fabricate micro heat pipes with hydraulic diameters on the order of 20 to 150  $\mu\text{m}$  into silicon or gallium arsenide wafers. These early investigations included the use of conventional techniques such as the machining of small channels [Peterson, 1988b; Peterson et al., 1991], the use of directionally dependent etching processes to create rectangular- or triangular-shaped channels [Peterson, 1988b; Gerner, 1990; Mallik et al., 1991; Gerner et al., 1992] or other more elaborate techniques that utilize the multisource vapor deposition process illustrated in Figure 31.5 [Mallik et al., 1991; Weichold et al., 1993] to create an array of long, narrow channels of triangular cross section lined with a thin layer of copper. Peterson (1994) has summarized these. The earliest fabricated arrays were machined into a silicon wafer 2 cm square and 0.378 mm thick, with an inter-channel spacing of 500  $\mu\text{m}$ . Somewhat later, Adkins et al. (1994) reported on a different fabrication process used for an array of heat pipes with a segmented vapor space. Peterson (1988b), Gerner (1990), Peterson et al. (1993), Ramadas et al. (1993) and Gerner et al. (1994) have described other processes. All of these techniques are similar in nature and typically utilize conventional photolithography masking techniques, coupled with an orientation-dependent etching technique.

Perhaps the most important aspects of these devices are the shape and relative areas of the liquid and vapor passages. A number of investigations have been directed at the optimization of these grooves. These include investigations by Ha and Peterson (1994) that analytically evaluated the axial dryout of the evaporating thin liquid film, one by Ha and Peterson (1996) that evaluated the interline heat transfer and others that examined other important aspects of the problem. [Ha and Peterson, 1998a; 1998b; Peterson and Ha, 1998; Ma and Peterson, 1998]. These studies and others have shown both individual and arrays of micro heat pipes to be extremely sensitive to flooding [Peterson, 1992], and for this reason several different charging methods have been developed and described in detail [Duncan and Peterson, 1995]. These vary from those that are similar to the methods utilized on larger more conventional heat pipes to a method in which the working fluid is added and then the wafer is heated to above the critical temperature of the working fluid so that the working fluid is in the supercritical state and exists entirely as a vapor. The array is then sealed and allowed to cool to below the critical temperature, allowing the vapor to cool and condense. Because, when in the critical state, the working fluid is uniformly distributed throughout the individual micro heat pipes, the exact charge can be carefully controlled and calculated.

### 31.4 Flat-Plate Micro Heat Spreaders

While arrays of micro heat pipes have the ability to significantly improve the effective thermal conductivity of silicon wafers and other conventional heat spreaders, they are of limited value in that they only provide heat transfer along the axial direction of the individual heat pipes. To overcome this problem, flat-plate heat spreaders, capable of distributing heat over a large two-dimensional surface have been proposed by Peterson (1992; 1994). In this application, a wicking structure is fabricated in silicon multichip module substrates to promote distribution of the fluid and vaporization of the working fluid (Figure 31.6). This wick structure is the key element in these devices and several methods for wick manufacture have been considered [Peterson et al. 1996].

In the most comprehensive investigation of these devices to date, a flat-plate micro heat pipe similar to that described by Peterson et al. (1996) was fabricated in silicon multichip module substrates 5 mm × 5 mm square [Benson et al., 1996a; 1996b]. These devices, which are illustrated in Figure 31.6, utilized two separate silicon wafers. On one of the two wafers, the wick pattern was fabricated leaving a small region around the perimeter of the wafer unpatterned to allow the package to be hermetically sealed. The other silicon wafer was etched in such a manner that a shallow well was formed that corresponded to the wick area. The two pieces were then wafer-bonded together along the seal ring. Upon completion

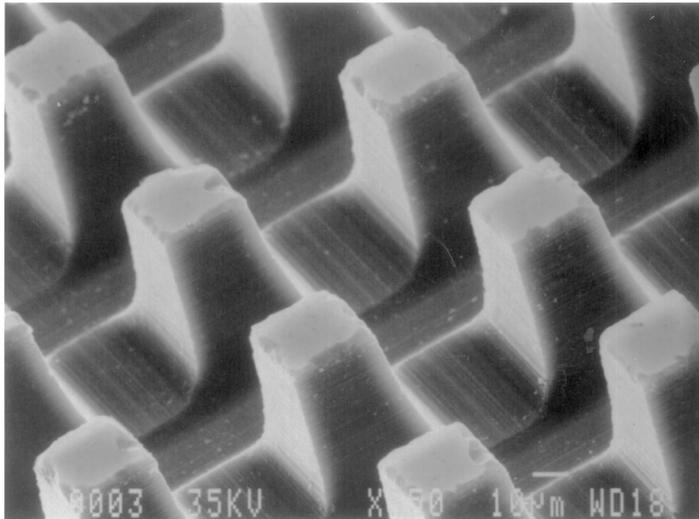

**FIGURE 31.6** Flat-plate micro heat spreader. (From Benson, D.A. et al. (1996a) *Proc. IEEE Multichip Module Conf.*, Santa Clara, CA. © 1996 IEEE. With permission.)

of the fabrication, the flat-plate micro heat pipe was filled through a small laser-drilled port located in one corner of the wafer. Because the entire wicking area was interconnected, the volume of the liquid required to charge was of sufficient volume that conventional charging techniques could be utilized [Benson et al., 1996b].

### 31.4.1 Modeling of Micro Heat Spreaders

Analytical investigations of the performance of these micro heat spreaders or flat-plate heat pipes have been underway for some time; Benson et al. (1996a; 1996b) and Peterson (1996) have summarized the results. These investigations have demonstrated that these devices can provide an effective mechanism for distributing the thermal load in semiconductor devices and reducing the localized hot spots resulting from active chip sites [Peterson, 1996]. The models indicate that the performance of these devices is excellent. In addition, because these devices can be made from silicon, Kovar or a wide variety of other materials, an excellent match between the coefficient of thermal expansion (CTE) can be achieved, while keeping the material and fabrication costs very low. A number of different wicking structures have been considered. Among these are wicks fabricated using a silicon dicing saw (Figure 31.7), wicks fabricated using conventional anisotropic etching techniques (Figure 31.8) and wicks fabricated using a deep plasma etching technique (Figure 31.9). Recent modeling has focused on the development of optimized wicking structures that could be fabricated directly into the wafer and provide maximum capillary pumping while optimizing the thin-film region of the meniscus in order to maximize the heat flux [Wayner et al., 1976; Peterson and Ma, 1996b; 1999].

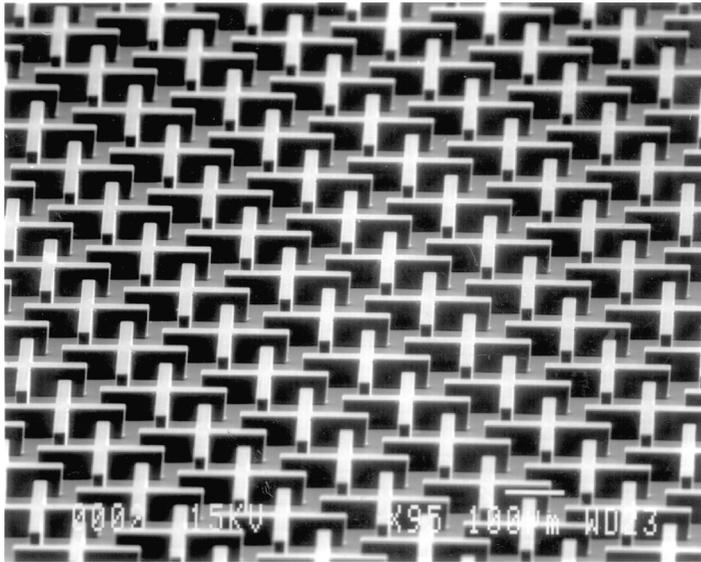

**FIGURE 31.7** Wick pattern prepared with bidirectional saw cuts on a silicon wafer. (From Benson, D.A. et al. (1996b) *Advances in Design, Materials and Processes for Thermal Spreaders and Heat Sinks Workshop*, April 19–21, Vail, CO. © 1996 IEEE. With permission.)

**TABLE 31.1** Thermal Conductivity, Coefficient of Thermal Expansion, Cost Estimates and Scaling Trends of Current and Potential Substrate Materials

Materials	Thermal Conductivity (W/cm-K)	Coefficient of Thermal Expansion ( $10^{-6}/K$ )	Cost of Substrate (\$/in <sup>2</sup> )	Scaling with Area Cost Trend
Alumina	0.25	6.7	0.09	6" limit
FR-4	Depends on copper	13.0	0.07	Constant to 36"
AlN	1.00–2.00	4.1	0.35	6" limit
Silicon	1.48	4.7	1.00	6–10" limit
Heat pipe in silicon	8.00 → 20.00 (?)	4.7	3.00	6–10" limit
Al	2.37	41.8	0.0009	Scales as area
Cu	3.98	28.7	0.0015	Scales as area
Diamond	10.00–20.00	1.0–1.5	1000.00	Scales as area <sup>2</sup>
Kovar	0.13	5.0	0.027	Scales as area
Heat pipe in Kovar	>8.00	5.0	0.10	Scales as area
AlSiC	2.00 (at 70%)	7.0 (?)	1.00	Casting size limited

**FIGURE 31.9** Wick pattern on silicon prepared by a photomask and deep plasma etch technique; 25- $\mu\text{m}$ -wide  $\times$  50- $\mu\text{m}$ -deep wafer. (From Benson, D.A. et al. (1996b) *Advances in Design, Materials and Processes for Thermal Spreaders and Heat Sinks Workshop*, April 19–21, Vail, CO. © 1996 IEEE. With permission.)

The results of these optimization efforts have demonstrated that these microscale flat-plate heat spreaders allow the heat to be dissipated in any direction across the wafer surface, thereby vastly improving performance. The resulting effective thermal conductivities can approach and perhaps exceed those of diamond coatings of equivalent thicknesses. Table 31.1 [Benson et al., 1998] illustrates the relative comparison of these flat-plate heat pipes and other types of materials traditionally utilized in the electronics industry for heat spreading. In this comparison, it is important to note that the ideal heat spreader would have the thermal conductivity of diamond, a coefficient of thermal expansion of silicon, and a cost comparable to aluminum. As shown, flat-plate heat pipes fabricated in either silicon or Kovar compare very favorably with diamond in terms of thermal conductivity and have a coefficient of thermal expansion relatively close to silicon (or exactly, in the case of silicon), and a projected cost that is quite low. Based upon this comparison, it would appear that these flat-plate heat pipes have tremendous commercial potential.

### 31.4.2 Testing of Micro Heat Spreaders

As described by Benson et al. (1998), a number of different flat-plate micro heat pipe test articles have been evaluated using an infrared camera to determine the spatially resolved temperature distribution. Using this information and a technique initially described by Peterson (1993) for arrays of micro heat pipes, the effective thermal conductivities of charged and uncharged flat-plate micro heat pipes and a series of micro heat spreaders were evaluated experimentally. The results indicated that an effective thermal conductivity between 10 and 20 W/cm-K was possible over a fairly broad temperature range. These values of thermal conductivity approach those of polycrystalline diamond substrates, or are more than five times that of a solid silicon substrate even at elevated temperatures (50°C) and power levels (15 W/cm<sup>2</sup>). The cost of such advanced silicon substrates is estimated at \$.60/cm<sup>2</sup> (see Table 31.1). Any other inexpensive material with a CTE close to that of the chip may also be a potential option for the heat pipe case material. For example, many alloys in the Fe/Ni/Co family have CTEs closely matching those of semiconductor materials [Benson et al., 1996].

As noted by Peterson (1992), several aspects of the technology remain to be examined before flat-plate micro heat spreaders can come into widespread use, but it is clear from the results of these early experimental tests that spreaders such as the ones discussed here, fabricated as integral parts of silicon chips, present a feasible alternative cooling scheme that merits serious consideration for a number of heat-transfer applications.

### 31.4.3 Fabrication of Micro Heat Spreaders

The fabrication of these micro heat spreaders is basically just an extension of the methods used by several early investigations to fabricate individual micro heat pipes with hydraulic diameters on the order of 20 to 150 μm. As discussed previously, a number of different wicking structures have been utilized. These wicking structures have been Kovar, silicon or gallium arsenide and include the use of conventional techniques such as machining, directionally dependent etching and deep plasma etching multisource vapor deposition processes. Charging of these devices is somewhat easier than for the individual arrays of micro heat pipes and, while these devices are still sensitive to undercharge, they can accommodate an overcharge much more readily.

## 31.5 New Designs

---

In addition to the designs described above, several new designs are currently being developed and evaluated for use in conventional electronic applications and for advanced spacecraft applications. The function of these designs is to provide lightweight, flexible flat-plate heat pipes capable of collecting heat from high heat-flux sources and transporting it to large surface areas where it can be dissipated. In electronic applications, this may entail the collection of heat from a microprocessor and transport of it to a conventional heat spreader or to a more readily available heat sink, such as the screen of a laptop computer. In advanced spacecraft applications, these devices may be used to fabricate highly flexible radiator fin structures for use on long-term spacecraft missions.

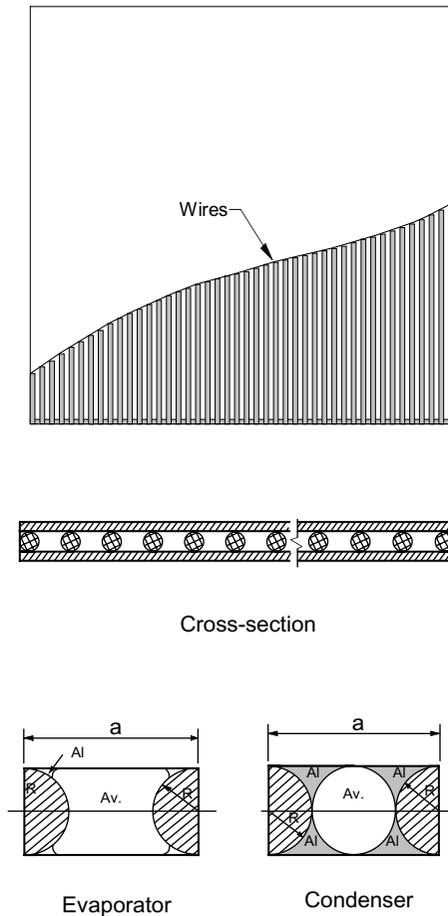

To date, several new designs have been proposed. The first of these consists of a flexible, micro heat pipe array, fabricated by sintering an array of aluminum wires between two thin aluminum sheets as shown in Figure 31.10. In this design, the sharp corner regions formed by the junction of the plate and the wires act as the liquid arteries. When made of aluminum with ammonia or acetone as the working fluid, these devices become excellent candidates for use as flexible radiator panels for long-term spacecraft missions and can have a thermal conductivity that greatly exceeds the conductivity of an equivalent thickness of any known material.

A numerical model, combining both conduction and radiation effects, has been developed to predict the heat-transfer performance and temperature distribution of these types of radiator fins in a simulated space environment [Wang et al., 2000]. Three different configurations were analyzed and experimentally

**TABLE 31.2** Configurations of Microheat Pipes

	Prototype		
	No. 1	No. 2	No. 3
Material	Aluminum	Aluminum	Aluminum
Working fluid	Acetone	Acetone	Acetone
Total dimension (mm)	152 × 152.4	152 × 152.4	152 × 152.4
Thickness of sheet (mm)	0.40	0.40	0.40
Diameter of wire (mm)	0.50	0.80	0.50
Number of wires	43	43	95

Source: From Wang, Y. et al. (2000) Paper No. AIAA-2000-0969, 38th Aerospace Sciences Meeting, January 10–13, Reno, NV. With permission.

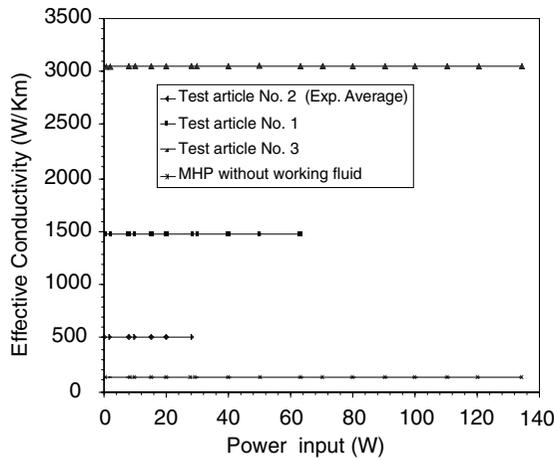

**FIGURE 31.10** Flexible wire bonded heat pipe. (From Wang, Y. et al. (2000) Paper No. AIAA-2000-0696, 38th Aerospace Sciences Meeting, January 10–13, Reno, NV. With permission.)

evaluated, and the results were compared. Each of the three configurations was modeled both with and without a working fluid charge in order to determine the reduction in the maximum temperature, mean temperature and temperature gradient on the radiator surface. Table 31.2 lists the physical specifications of the three micro heat pipe arrays fabricated. Acetone was used as the working fluid in both the modeling effort and also in the actual experimental tests.

**FIGURE 31.11** Temperature difference of micro heat pipe arrays with or without working fluid. (From Wang, Y. et al. (2000) Paper No. AIAA-2000-0696, 38th Aerospace Sciences Meeting, January 10–13, Reno, NV. With permission.)

**FIGURE 31.12** Effective thermal conductivity of micro heat pipe arrays. (From Wang, Y. et al. (2000) Paper No. AIAA-2000-0696, 38th Aerospace Sciences Meeting, January 10–13, Reno, NV. With permission.)

The results of the preliminary tests conducted on these configurations are shown in [Figure 31.11](#). As indicated, the heat transport was proportional to the temperature difference between the evaporator and condenser; i.e., the effective thermal conductivity of the micro heat pipe array was constant with respect to the temperature. From the temperature difference and heat transport obtained as shown in [Figure 31.11](#) the effective conductivity was obtained. As illustrated in [Figure 31.12](#), the effective thermal conductivities of micro heat pipe arrays No.1, 2 and 3 were 1446.2, 521.3 and 3023.1 W/Km, respectively. For the micro heat pipe arrays without any working fluid, the effective conductivities in the  $x$ -direction were 126.3, 113.0 and 136.2 W/Km, respectively. Comparison of the predicted and experimental results indicated that these flexible radiators, with the arrays of micro heat pipes, have an effective thermal conductivity between 15 and 20 times that of the uncharged version. This results in a more uniform temperature distribution, which could significantly improve the overall radiation effectiveness, reduce the overall size, and meet or exceed the baseline design requirements for long-term manned missions to Mars.

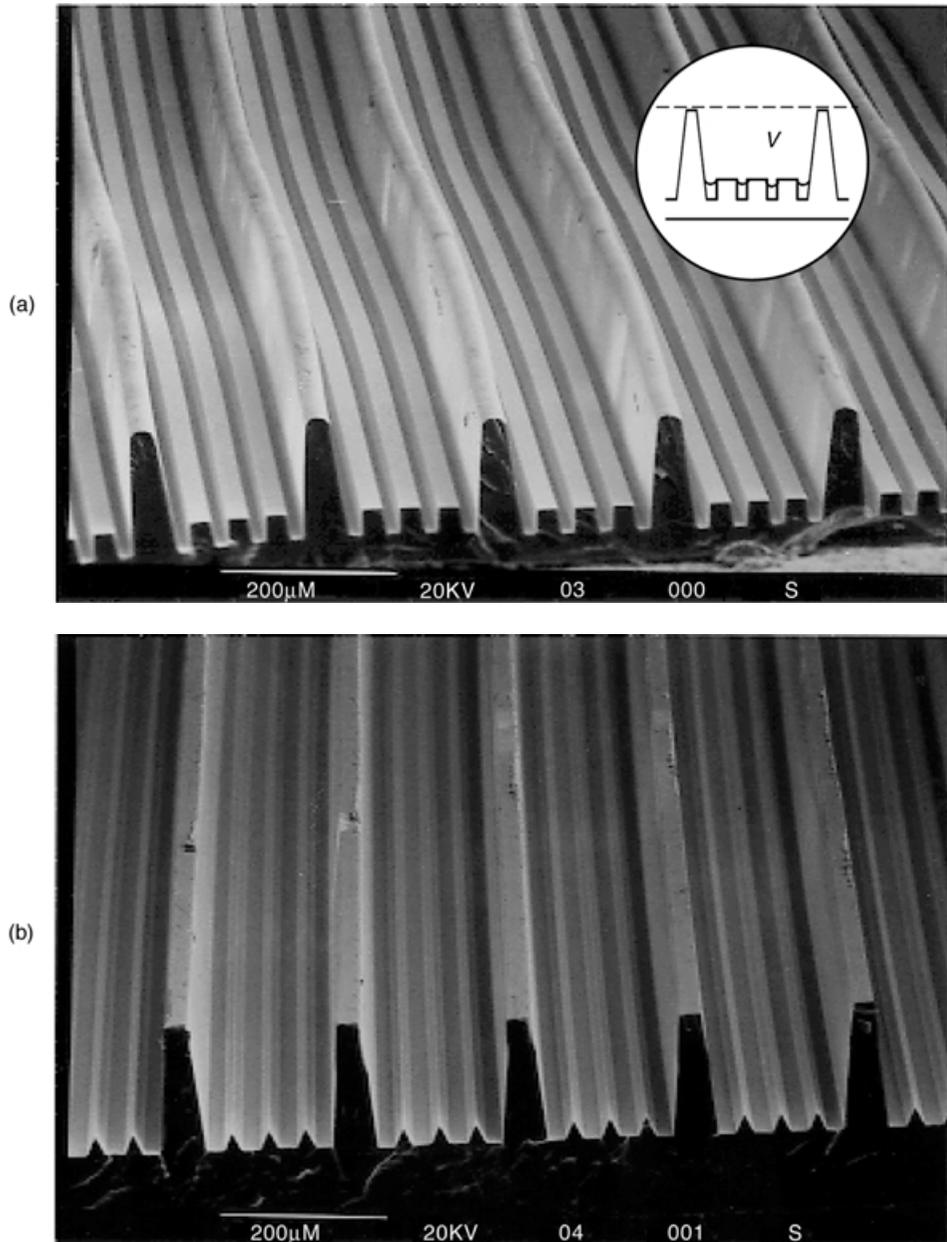

FIGURE 31.13 Flexible polymer micro heat pipe. (a) Rectangular grooves; (b) trapezoidal grooves.

The second design currently being considered consists of an array of flexible micro heat pipes fabricated in a polymer material, as illustrated in Figure 31.13a. This material is extruded in such a fashion that it has a series of large rectangular grooves that serve as the actual heat pipes, each approximately 200  $\mu\text{m}$  wide. Within each of these micro heat pipes is a series of smaller grooves that serve as the liquid arteries (see inset). As shown in Figure 31.13a, these grooves can be rectangular in nature or, as shown in Figure 31.13b, they can be trapezoidal. In both cases, the material is polypropylene, and the internal dimension of the individual heat pipes is approximately 200  $\mu\text{m}$ . The smaller grooves within each of the individual heat pipes are designed to transport the fluid from the evaporator to the condenser. While only preliminary

experimental test data are available, this design appears to hold great promise for both spacecraft radiator applications and also for flexible heat spreaders for use in Earth-based electronic applications.

## 31.6 Summary and Conclusions

---

It is clear from the preceding review that the concept of using microscale heat pipes and/or flat-plate micro heat spreaders is feasible, practical and cost effective. A number of different concepts and sizes have been shown to be acceptable from both an experimental and theoretical perspective, and a number of these devices are already in widespread use. Steady-state and transient models have been developed and verified experimentally and are capable of predicting the operational limits and performance characteristics of micro heat pipes with diameters less than 100 microns with a high degree of reliability. These models are currently being expanded for use in both individual heat pipes and also with arrays of heat pipes constructed as an integral part of semiconductor devices.

In addition to the analytical work, experimental evaluation has indicated that these devices can be effective in dissipating and transporting heat from localized heat sources and are presently being used in a number of commercial applications. Arrays of micro heat pipes on the order of 35 microns have been successfully fabricated, charged and tested, and incorporated as an integral part of semiconductor devices. Extensive testing has indicated that these heat pipes can provide an effective method for dissipating localized heat fluxes, eliminating localized hot spots, reducing the maximum wafer temperatures and thereby improving the wafer reliability.

Finally, several new designs have been and continue to be developed that have applications ranging from spacecraft radiator applications to land-based electronics applications. These new designs incorporate optimized wicking structures and clever new fabrication schemes, along with materials not previously utilized for heat pipe applications.

### Nomenclature

- $A$  = area ( $\text{m}^2$ )
- $C$  = constant (defined in text)
- $d$  = diameter (m)
- $f$  = drag coefficient (dimensionless)
- $k$  = thermal conductivity (W/m-K)
- $K$  = wick permeability ( $\text{m}^2$ )
- $L$  = length (m)
- $Ma$  = Mach number (dimensionless)
- $P$  = pressure ( $\text{N/m}^2$ )
- $q$  = heat flow rate (W)
- $R$  = thermal resistance (K/W) or universal gas constant (J/kg-K)
- $Re$  = Reynolds number (dimensionless)
- $r$  = radius (m)
- $T$  = temperature (K)
- $V$  = velocity (m/s)
- $w$  = groove width (m) or wire spacing (m)
- $We$  = Weber number (dimensionless)

### Greek Symbols

- $\lambda$  = latent heat of vaporization (J/kg)
- $\mu$  = dynamic viscosity (kg/m-s)
- $\rho$  = density ( $\text{kg/m}^3$ )

$\sigma$  = surface tension (N/m)  
 $\tau$  = shear stress (N/m<sup>2</sup>)  
 $\Psi$  = angle of inclination (degrees or radians)

### Subscripts

$b$  = boiling  
 $c$  = capillary, capillary limitation, condenser  
 $e$  = entrainment, evaporator section  
 $eff$  = effective  
 $f$  = fin  
 $h$  = hydraulic  
 $i$  = inner  
 $l$  = liquid  
 $m$  = maximum  
 $o$  = outer  
 $p$  = pipe  
 $s$  = sonic  
 $v$  = vapor  
 $w$  = wire spacing, wick  
– = axial hydrostatic pressure  
+ = normal hydrostatic pressure

### 32.1 Introduction

---

The last decade has witnessed impressive progress in micromachining technology enabling the fabrication of micron-sized mechanical devices, which have become more prevalent in both commercial applications and scientific research. These micromachines have had a major impact on many disciplines, including biology, chemistry, medicine, optics, aerospace and mechanical and electrical engineering. This emerging field not only provides miniature transducers for sensing and actuation in a domain that we could not examine in the past but also allows us to venture into research areas in which the surface effects dominate most of the physical phenomena [Ho and Tai, 1998]. Fundamental heat-transfer problems posed by the development and processing of advanced integrated circuits (ICs) and microelectromechanical systems (MEMS) are becoming a major consideration in the design and application of such systems. The demands on heat-removal and temperature-control functions in modern devices that have highly transient thermal loads require an approach providing high cooling rates and uniform temperature distributions.

As the field of microfluidics and micro heat transfer continues to grow, it becomes increasingly important to understand the mechanisms and fundamental differences involved with heat transfer in single- and two-phase flow in microducts. The idea of fabricating microchannel heat sinks is not new. As early as two decades ago, Tuckerman and Pease (1981) pioneered the use of microchannels for the cooling of planar integrated circuits. They demonstrated that by flowing water through small cooling channels etched in a silicon substrate, heat-transfer rates of about  $10^5 \text{ W/m}^2\text{K}$  could be achieved. This rate is about two orders of magnitude higher than that in the state-of-the-art commercial technologies

for cooling arrays of ICs. Subsequently, similar experiments were conducted by, among others, Goldberg (1984), Wu and Little (1984), Mahalingam (1985), and Nayak et al. (1987), who passed either liquids or gases in channels ranging in cross-sectional size from 100  $\mu\text{m}$  to 1000  $\mu\text{m}$ . The heat-transfer performance of flows in microchannels has been theoretically analyzed by a number of researchers [e.g., Keyes, 1984; Samalam, 1989; Weisberg et al., 1992]. These works include a number of simplifications and approximations; the major ones are that the heat-transfer coefficient along the channel walls is uniform, the heat transport occurs through the vertical fins, the fluid temperature at each cross section is uniform, and the gas flow is incompressible. In reality, however, the heat-transfer coefficient is a function of the local velocity profile and varies appreciably along the walls. A significant amount of heat is likely to be transported through the channel top or bottom. The fluid temperature field is not one but is at least two dimensional. Most of these early studies dealt with single-phase flow, either liquid or gas, through microchannels, as it proved to be complicated enough. However, it is clear that utilizing the latent heat associated with phase change can dramatically enhance the performance of microchannel heat sinks.

The area of two-phase forced convection heat transfer in microchannels is relatively young and most of the work has been carried out within the last decade [Stanley et al., 1995]. By far, the majority of the reported research work in this area has been empirical in nature. Peng and Wang (1993) investigated the flow boiling through microchannels with a cross section of 0.6 mm  $\times$  0.7 mm. They reported that no partial nucleate boiling existed, and that the velocity and liquid subcooling had no obvious effect on the flow nucleate boiling. Moreover, no bubbles were observed throughout the investigation. Peng et al. (1995) argued that the flow boiling was initiated at once and that immediately fully developed nucleate boiling took place. The liquid species and concentration were all found to affect the boiling heat-transfer coefficients [Peng et al., 1996]. Bowers and Mudawar (1994) investigated the pressure drop and critical heat flux in mini- and microchannels. They found that the thermal resistance in a microchannel was lower; however, in the nucleation regime, the pressure drop along the microchannel rose drastically with the increased heat flux. They modeled the pressure drop using a homogeneous equilibrium model to account for acceleration and friction effects. Ravigururajan (1998) studied the impact of channel geometry on two-phase flow in microchannels. The diamond cross section resulted in a lower heat-transfer coefficient but higher critical heat flux compared to the triangular cross section. Only recently have efforts to derive analytical models from basic principles rather than empirical correlations been reported. Peles and Haber (2000) calculated the steady-state, one-dimensional, evaporating, two-phase flow in a triangular microchannel. Although the physical model has been simplified to render the mathematical model tractable, it is the first serious attempt to calculate such a complex flow field.

In this article, the discussion is limited to microchannel heat sinks under steady-state operation. The supplied heat is removed by either single- or two-phase flow forced through microducts, while the single phase can be either water or vapor. Unsteady phenomena in the operation of microchannel heat sinks are naturally of great interest and should be covered in a separate article, as the aim here is to highlight size effects on heat and mass transport in microchannels.

## 32.2 Fundamentals of Convective Heat Transfer in Microducts

---

In the science of thermodynamics, which deals with energy in its various forms and with its transformation from one form to another, two particularly important transient forms are defined: work and heat. These energies are termed transient since, by definition, they exist only when there is an exchange of energy between two systems or between a system and its surrounding. When such an exchange takes place without the transfer of mass from the system and not by means of a temperature difference, the energy is said to have been transferred through the performance of work. If the exchange of energy between the systems is the result of a temperature difference, the exchange is said to have been accomplished via the transfer of heat. The existence of a temperature difference is the distinguishing feature of the energy exchange form known as heat transfer. Microchannel heat sinks, of which a typical schematic is shown in [Figure 32.1](#), are a class of devices that can be applied for the removal of thermal energy from very small areas.

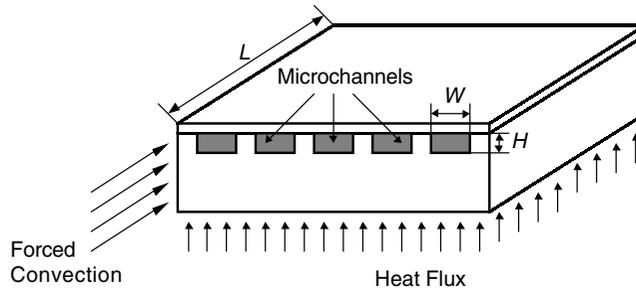

FIGURE 32.1 A schematic of a typical microchannel heat sink.

### 32.2.1 Modes of Heat Transfer

The mechanism by which heat is transferred in an energy conversion system is complex; however, three basic and distinct modes of heat transfer have been classified: conduction, convection and radiation [Sadik and Yaman, 1995]. Convection is the heat-transfer mechanism, which occurs in a fluid by the mixing of one portion of the fluid with another portion due to gross movements of the mass of fluid. Although the actual process of energy transfer from one fluid particle or molecule to another is still heat conduction, the energy may be transported from one point in space to another by the displacement of the fluid itself. An analysis of convective heat transfer is, therefore, more involved than that of heat transfer by conduction alone, as the motion of the fluid must be studied simultaneously with the energy transfer process. The fluid motion may be caused by external mechanical means (e.g., pump), in which case the process is called forced convection. If the fluid motion is caused by density differences created by the temperature differences existing in the fluid mass, the process is termed free or natural convection. The important heat transfers in liquid–vapor phase-change processes (i.e., boiling and condensing) are also classified as convective mechanisms, as fluid motion is still involved, with the additional complication of a latent heat exchange. Hence, heat transfer in microchannel heat sinks belongs to this class of forced convection heat transfer with or without phase change [Stephan, 1992].

### 32.2.2 The Continuum Hypothesis

In an analysis of convective heat transfer in a fluid, the motion of the fluid must be studied simultaneously with the heat transport process. In its most fundamental form, the description of the motion of a fluid involves a study of the behavior of all the discrete particles (e.g., molecules) that make up the fluid. The most fundamental approach in analyzing convective heat transfer, therefore, would be to apply the laws of mechanics and thermodynamics to each individual particle, or a statistical group of particles, subsequent to some initial conditions. Such an approach, kinetic theory or statistical mechanics, would give an insight into the details of the energy transfer processes; however, it is not practical for most scientific problems and engineering applications.

In most applications, the primary interest lies not in the molecular behavior of the fluid, but rather in the average or macroscopic effects of many molecules. It is these macroscopic effects that we ordinarily perceive and measure. In the study of convective heat transfer, therefore, the fluid is treated as an infinitely divisible substance, a continuum, while the molecular structure is neglected. The continuum model is valid as long as the size and the mean free path of the molecules are small enough compared with other dimensions existing in the medium such that a statistical average is meaningful.

However, the continuum assumption breaks down whenever the mean free path of the molecules becomes the same order of magnitude as the smallest significant dimension of the problem. In gas flows, the deviation of the state of the fluid from continuum is represented by the Knudsen number, defined as  $Kn \equiv \lambda/L$ . The mean free path,  $\lambda$ , is the average distance traveled by the molecules between successive collisions, and  $L$  is the characteristic length scale of the flow. The appropriate flow and heat-transfer

models depend on the range of the Knudsen number, and a classification of the different gas flow regimes is as follows [Schaaf and Chambre, 1961]:

$Kn < 10^{-3}$	continuum flow
$10^{-3} < Kn < 10^{-1}$	slip flow
$10^{-1} < Kn < 10^{+1}$	transition flow
$10^{+1} < Kn$	free molecular flow

In the slip-flow regime, the continuum flow model is still valid for the calculation of the flow properties away from solid boundaries. However, the boundary conditions have to be modified to account for the incomplete interaction between the gas molecules and the solid boundaries. Under normal conditions,  $Kn$  is less than 0.1 for most gas flows in microchannel heat sinks with a characteristic length scale on the order of 1  $\mu\text{m}$ . Therefore, only the regime of slip flow, but neither transition nor free molecular flow, will be discussed. The continuum assumption is of course valid for liquid flows in microchannel heat sinks.

### 32.2.3 Thermodynamic Concepts

The most convenient framework within which heat-transfer problems can be studied is the system, which is a quantity of matter, not necessarily constant, contained within a boundary. The boundary can be physical, partly physical and partly imaginary, or wholly imaginary. The physical laws to be discussed are always stated in terms of a system. A control volume is any specific region in space across the boundaries of which mass, momentum and energy may flow and within which mass, momentum and energy storage may take place and on which external forces may act. The complete definition of a system or a control volume must include, implicitly at least, the definition of a coordinate system, as the system may be moving or stationary. The characteristic of a system of interest is its state, which is a condition of the system described by its properties. A property of a system can be defined as any quantity that depends on the state of the system and is independent of the path (i.e., previous history) by which the system arrived at the given state. If all the properties of a system remain unchanged, the system is said to be in an equilibrium state.

A change in one or more properties of a system necessarily means that a change in the state of the system has occurred. The path of the succession of states through which the system passes is called the process. When a system in a given initial state goes through a number of different changes of state or processes and finally returns to its initial state, the system has undergone a cycle. The properties describe the state of a system only when it is in equilibrium. If no heat transfer takes place between any two systems when they are placed in contact with each other, they are said to be in thermal equilibrium. Any two systems are said to have the same temperature if they are in thermal equilibrium with each other. Two systems that are not in thermal equilibrium have different temperatures, and heat transfer may take place from one system to the other. Therefore, temperature is a property that measures the thermal level of a system.

When a substance exists as part liquid and part vapor at a saturation state, its quality is defined as the ratio of the mass of vapor to the total mass. The quality  $\chi$  may be considered a property ranging between 0 and 1. Quality has meaning only when the substance is in a saturated state (i.e., at saturated pressure and temperature). The amount of energy that must be transferred in the form of heat to a substance held at constant pressure so that a phase change occurs is called the latent heat. It is the change in enthalpy, which is a property of the substance at the saturated conditions, of the two phases. The heat of vaporization, boiling, is the heat required to completely vaporize a unit mass of saturated liquid.

### 32.2.4 General Laws

The general laws when referring to an open system (e.g., microchannel heat sink) can be written in either an integral or a differential form. The law of conservation of mass simply states that in the absence of any mass–energy conversion the mass of the system remains constant. Thus, in the absence of a source or sink,  $Q = 0$ , the rate of change of mass in the control volume (CV) is equal to the mass flux through

the control surface (CS). Newton's second law of motion states that the net force,  $\mathbf{F}$ , acting on a system in an inertial coordinate system is equal to the time rate of change of the total linear momentum of the system. Similarly, the law of conservation of energy for a control volume states that the rate of change of the total energy  $E$  of the system is equal to the sum of the time rate of change of the energy within the control volume and the energy flux through the control surface.

The first law of thermodynamics, which is a particular statement of conservation of energy, states that the rate of change in the total energy of a system undergoing a process is equal to the difference between the rate of heat transfer to the system and the rate of work done by the system. The second law of thermodynamics leads to the introduction of entropy,  $S$ , as a property of the system. It states that the rate of change in the entropy of the system is either equal to or larger than the rate of heat transfer to the system divided by the system temperature during the heat-transfer process. Even in cases where entropy calculations are not of interest, the second law of thermodynamic is still important as it is equivalent to stating that heat cannot pass spontaneously from a lower to a higher temperature system.

### 32.2.5 Particular Laws

Fourier's law of heat conduction, based on the continuum concept, states that the heat flux due to conduction in a given direction (i.e., the heat-transfer rate per unit area) within a medium (solid, liquid or gas) is proportional to temperature gradient in the same direction, namely:

$$\mathbf{q}'' = -k\nabla T \quad (32.1)$$

where  $\mathbf{q}''$  is the heat flux vector,  $k$  is the thermal conductivity, and  $T$  is the temperature.

Newton's law of cooling states that the heat flux from a solid surface to the ambient fluid by convection,  $q''$ , is proportional to the temperature difference between the solid surface temperature,  $T_w$ , and the fluid free-stream temperature,  $T_\infty$ , as follows:

$$q'' = h(T_w - T_\infty) \quad (32.2)$$

where  $h$  is the heat transfer coefficient.

### 32.2.6 Governing Equations

The integral form of the conservation laws is useful for the analysis of the gross behavior of the flowfield. However, detailed point-by-point knowledge of the flowfield can be obtained only from the equations of fluid motion in differential form. Microchannel heat sinks typically incorporate arrays of elongated microchannels varying in cross-sectional shape; therefore, it is most convenient to use the governing equations derived either in a rectangular or cylindrical coordinate system. The governing equations for forced convection heat transfer in differential form include conservation of mass, momentum and energy as follows:

$$\frac{D\rho}{Dt} + \rho(\nabla \cdot \mathbf{U}) = 0 \quad (32.3)$$

$$\rho \frac{D\mathbf{U}}{Dt} = -\nabla P + \rho \mathbf{B} + \mu \nabla^2 \mathbf{U} + (\mu + \eta) \nabla(\nabla \cdot \mathbf{U}) \quad (32.4)$$

$$\rho c_p \frac{DT}{Dt} = k \nabla^2 T + \frac{DP}{Dt} + \phi + \theta \quad (32.5)$$

In this set of equations,  $\rho$  is the density;  $P$  is the thermodynamic pressure;  $\mathbf{B}$  is the body force (e.g., gravity);  $\mu$  and  $\eta$  are the shear and the bulk viscosity coefficients, respectively;  $c_p$  is the specific heat;  $\theta$  is the heat

source or sink; and  $\phi$  is the viscous dissipation given by:

$$\phi = 2\mu \left[ \left( \frac{\partial u}{\partial x} \right)^2 + \left( \frac{\partial v}{\partial y} \right)^2 + \left( \frac{\partial w}{\partial z} \right)^2 + \frac{1}{2} \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 + \frac{1}{2} \left( \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right)^2 + \frac{1}{2} \left( \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right)^2 \right] \quad (32.6)$$

where  $u$ ,  $v$  and  $w$  are the three components of the velocity vector  $\mathbf{U}$  in a rectangular coordinate system  $(x, y, z)$ . The state of a simple compressible pure substance, or a mixture of gases, is defined by two independent properties. From experimental observations, it has been established that the behavior of gases at low density is closely given by the ideal-gas equation of state:

$$P = \rho RT \quad (32.7)$$

where  $R$  is the specific gas constant. At very low density, all gases and vapors approach ideal-gas behavior; however, the behavior may deviate substantially from that at higher densities. Nevertheless, due to its simplicity, the ideal gas equation of state has been widely used in thermodynamic calculations.

## 32.2.7 Size Effects

Length scale is a fundamental quantity that dictates the type of forces or mechanisms governing physical phenomena. Body forces are scaled to the third power of the length scale. Surface forces depend on the first or the second power of the characteristic length. This difference in slopes means that a body force must intersect a surface force as a function of the length scale. Empirical observations in biological studies and MEMS show that 1 mm is approximately the order of the demarcation scale [Ho and Tai, 1998]. The characteristic scale of microsystems is smaller than 1 mm; therefore, body forces such as gravity can be neglected in most cases, even in liquid flows, in comparison with surface forces. The large surface-to-volume ratio is another inherent characteristic of microsystems. This ratio is typically inversely proportional to the smaller length scale of the device cross section and is about 1  $\mu\text{m}$  in surface-micromachined devices. The large surface-to-volume ratio in microdevices accentuates the role of surface effects.

### 32.2.7.1 Noncontinuum Mechanics

The characteristic length scale of a microchannel (i.e., the hydraulic diameter) is typically on the order of a few micrometers. When gas is the working fluid, the mean free path is about 10 to 100 nm, resulting in a Knudsen number of about 0.05. Thus, the flow is considered to be in the slip regime,  $0.001 < Kn < 0.1$ , where deviations from the state of continuum are relatively small. Consequently, the flow is still governed by Eqs. (32.3) to (32.5), derived and based on the continuum assumption. The rarefaction effect is modeled through Maxwell's velocity-slip and Smoluchowski's temperature-jump boundary conditions [Beskok and Karniadakis, 1994]:

$$U_s - U_w = \frac{2 - \sigma_U}{\sigma_U} \lambda \left. \frac{\partial U}{\partial n} \right|_w \quad (32.8a)$$

$$T_j - T_w = \frac{2 - \sigma_T}{\sigma_T} \frac{2\gamma}{\gamma + 1} \frac{k}{\mu c_p} \lambda \left. \frac{\partial T}{\partial n} \right|_w \quad (32.8b)$$

$U_w$  and  $T_w$  are the wall velocity and temperature, respectively;  $U_s$  and  $T_j$  are the gas flow velocity and temperature at the boundary;  $n$  is the direction normal to the solid boundary;  $\gamma = c_p/c_v$  is the ratio of specific heats; and  $\sigma_U$  and  $\sigma_T$  are the momentum and energy accommodation coefficients, respectively, which model the momentum and energy exchange of the gas molecules impinging on the solid boundary. Experiments with gases over various surfaces show that both coefficients are approximately 1.0. This essentially means a diffuse reflection boundary condition, where the impinging molecules are reflected at a random angle uncorrelated with the incident angle.

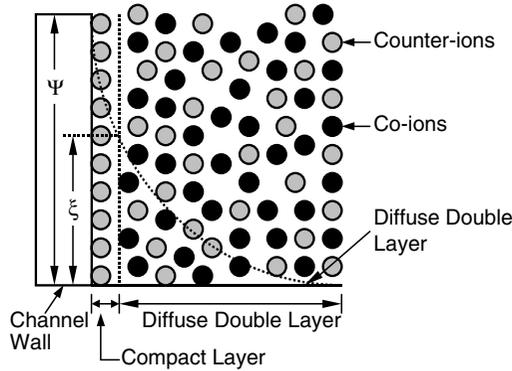

FIGURE 32.2 A schematic representation of an electric double layer (EDL) at the channel wall.

### 32.2.7.2 Electric Double Layer

Most solid surfaces are likely to carry electrostatic charge (i.e., an electric surface potential) due to broken bonds and surface charge traps. When a liquid containing a small amount of ions is forced through a microchannel under hydrostatic pressure, the solid-surface charge will attract the counter-ions in the liquid to establish an electric field. The arrangement of the electrostatic charges on the solid surface and the balancing charges in the liquid is called the electric double layer (EDL), as illustrated in Figure 32.2. Counter-ions are strongly attracted to the surface and form a compact layer, about 0.5 nm thick, of immobile counter-ions at the solid–liquid interface due to the surface electric potential. Outside this layer, the ions are affected less by the electric field and are mobile. The distribution of the counter-ions away from the interface decays exponentially within the diffuse double layer, with a characteristic length inversely proportional to the square root of the ion concentration in the liquid. The thickness of the diffuse EDL ranges from a few up to several hundreds of nanometers, depending on the electric potential of the solid surface, the bulk ionic concentration and other properties of the liquid. Consequently, EDL effects can be neglected in macrochannel flow. In microchannels, however, the EDL thickness is often comparable to the characteristic size of the channel, and its effect on the fluid flow and heat transfer may not be negligible.

Consider a liquid between two parallel plates, separated by a distance  $H$ , containing positive and negative ions in contact with a planar positively charged surface. The surface bears a uniform electrostatic potential  $\psi_0$ , which decreases with the distance from the surface. The electrostatic potential,  $\psi$ , at any point near the surface is approximately governed by the Debye–Huckel linear approximation [Mohiuddin Mala et al., 1997]:

$$\frac{d^2\psi}{dy^2} = \frac{2n_0\zeta^2 e^2}{\epsilon\epsilon_0 k_b T} \psi \quad (32.9)$$

where  $\epsilon$  is the dielectric constant of the medium, and  $\epsilon_0$  is the permittivity of vacuum;  $\zeta$  is the valence of negative and positive ions;  $e$  is the electron charge;  $k_b$  is the Boltzmann constant; and  $n_0$  is the ionic concentration. The characteristic thickness of the EDL is the Debye length given by  $k_d^{-1} = (\epsilon\epsilon_0 k_b T / 2n_0 \zeta^2 e^2)^{1/2}$ . For the boundary conditions when  $\psi = 0$  at the midpoint,  $y = 0$ , and  $\psi = \xi$  on both walls,  $y = \pm H/2$ , the solution is

$$\psi = \frac{\xi}{\sinh(k_d H/2)} |\sinh(k_d y)| \quad (32.10)$$

where  $\xi$  is the electric potential at the boundary between the diffuse double layer and the compact layer.

### 32.2.7.3 Polar Mechanics

In classical nonpolar mechanics, the mechanical action of one part of a body on another is assumed to be equivalent to a force distribution only. However, in polar mechanics, the mechanical action is assumed to be equivalent to not only a force but also a moment distribution. Thus, the state of stress at a point in nonpolar mechanics is defined by a symmetric second-order tensor, which has six independent components. On the other hand, in polar mechanics, the state of stress is determined by a stress tensor and a couple-stress tensor. The most important effect of couple stresses is to introduce a size-dependent effect that is not predicted by the classical nonpolar theories [Stokes, 1984].

In micropolar fluids, rigid particles contained in a small volume can rotate about the center of the volume element described by the microrotation vector. This local rotation of the particles is in addition to the usual rigid body motion of the entire volume element. In micropolar fluid theory, the laws of classical continuum mechanics are augmented with additional equations that account for conservation of microinertia moments. Physically, micropolar fluids represent fluids consisting of rigid, randomly oriented particles suspended in a viscous medium, where the deformation of the particles is ignored. The modified momentum, angular momentum and energy equations are

$$\rho \frac{DU}{Dt} = \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{f} \quad (32.11)$$

$$\rho I \frac{D\boldsymbol{\Omega}}{Dt} = \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} + \boldsymbol{\tau}_x \quad (32.12)$$

$$\rho c_p \frac{DT}{Dt} = k \nabla^2 T + \boldsymbol{\tau} : (\nabla \mathbf{U}) + \boldsymbol{\sigma} : (\nabla \boldsymbol{\Omega}) - \boldsymbol{\tau}_x \cdot \boldsymbol{\Omega} \quad (32.13)$$

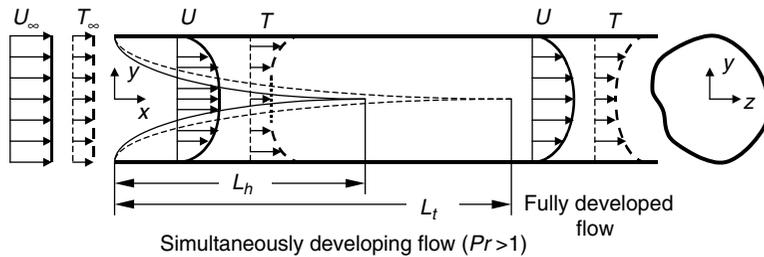

where  $\boldsymbol{\Omega}$  is the microrotation vector and  $I$  is the associated micro-inertia coefficient;  $\mathbf{f}$  and  $\mathbf{g}$  are the body and couple force vectors, respectively, per unit mass;  $\boldsymbol{\tau}$  and  $\boldsymbol{\sigma}$  are the stress and couple-stress tensors;  $\boldsymbol{\tau} : (\nabla \mathbf{U})$  is the dyadic notation for  $\tau_{ji} U_{i,j}$ , the scalar product of  $\boldsymbol{\tau}$  and  $\nabla \mathbf{U}$ . If  $\boldsymbol{\sigma} = 0$  and  $\mathbf{g} = \boldsymbol{\Omega} = 0$ , then the stress tensor  $\boldsymbol{\tau}$  reduces to the classical symmetric stress tensor, and the governing equations reduce to the classical model [Lukaszewicz, 1999].

## 32.3 Single-Phase Convective Heat Transfer in Microducts

Flows completely bounded by solid surfaces are called internal flows and include flows through ducts, pipes, nozzles, diffusers, etc. External flows are flows over bodies in an unbounded fluid. Flows over a plate, a cylinder or a sphere are examples of external flows, and they are not within the scope of this article. Only internal flows, in either liquid or gas phase, in microducts will be discussed, with an emphasis on size effects, which may potentially lead to different behavior in comparison with similar flows in macroducts.

### 32.3.1 Flow Structure

Viscous flow regimes are classified as laminar or turbulent on the basis of flow structure. In the laminar regime, flow structure is characterized by smooth motion in laminae, or layers. The flow in the turbulent regime is characterized by random, three-dimensional motions of fluid particles superimposed on the mean motion. These turbulent fluctuations enhance the convective heat transfer dramatically. However, turbulent flow occurs in practice only as long as the Reynolds number,  $Re = \rho U_m D_h / \mu$ , is greater than a critical value,  $Re_{cr}$ . The critical Reynolds number depends on the duct inlet conditions, surface roughness, vibrations imposed on the duct walls and the geometry of the duct cross section. Values of  $Re_{cr}$  for various duct cross-section shapes have been tabulated elsewhere [Bhatti and Shah, 1987]. In practical applications,

**FIGURE 32.3** A schematic of hydrodynamically and thermally developing flow, followed by hydrodynamically and thermally fully developed flow.

though, the critical Reynolds number is estimated to be

$$Re_{cr} = \frac{\rho U_m D_h}{\mu} \cong 2300 \quad (32.14)$$

where  $U_m$  is the mean flow velocity, and  $D_h = 4A/S$  is the hydraulic diameter, with  $A$  and  $S$  being the cross-section area and the wetted perimeter, respectively. Microchannels are typically larger than  $1000 \mu\text{m}$  in length with a hydraulic diameter of about  $10 \mu\text{m}$ . The mean velocity for gas flow under a pressure drop of about  $0.5 \text{ MPa}$  is less than  $100 \text{ m/s}$ , and the corresponding Reynolds number is less than  $100$ . The Reynolds number for liquid flow will be even smaller due to the much higher viscous forces. Thus, in most applications, the flow in microchannels is expected to be laminar. Turbulent flow may develop in short channels with large hydraulic diameter under high-pressure drop and therefore will not be discussed here.

### 32.3.2 Entrance Length

When a viscous fluid flows in a duct, a velocity boundary layer develops along the inside surfaces of the duct. The boundary layer fills the entire duct gradually, as sketched in [Figure 32.3](#). The region where the velocity profile is developing is called the hydrodynamics entrance region, and its extent is the hydrodynamic entrance length. An estimate of the magnitude of the hydrodynamic entrance length,  $L_h$ , in laminar flow in a duct is given by Shah and Bhatti (1987):

$$\frac{L_h}{D_h} = 0.056 Re \quad (32.15)$$

The region beyond the entrance region is referred to as the hydrodynamically fully developed region. In this region, the boundary layer completely fills the duct and the velocity profile becomes invariant with the axial coordinate.

If the walls of the duct are heated (or cooled), a thermal boundary layer will also develop along the inner surfaces of the duct, shown in [Figure 32.3](#). At a certain location downstream from the inlet, the flow becomes fully developed thermally. The thermal entrance length,  $L_t$ , is then the duct length required for the developing flow to reach fully developed condition. The thermal entrance length for laminar flow in ducts varies with the Reynolds number, Prandtl number ( $Pr = \mu c_p/k$ ) and the type of the boundary condition imposed on the duct wall. It is approximately given by:

$$\frac{L_t}{D_h} \cong 0.05 Re Pr \quad (32.16)$$

More accurate discussion on thermal entrance length in ducts under various laminar flow conditions can be found elsewhere [e.g., Shah and Bhatti, 1987].

In most practical applications of microchannels, the Reynolds number is less than 100 while the Prandtl number is on the order of 1. Thus, both the hydrodynamic and thermal entrance lengths are less than 5 times the hydraulic diameter. Because the length of microchannels is typically two orders of magnitude larger than the hydraulic diameter, both entrance lengths are less than 5% of the microchannel length and can be neglected.

### 32.3.3 Governing Equations

Representing the flow in rectangular ducts as flow between two parallel plates, the two-dimensional governing equations can be simplified as follows (Sadik and Yaman, 1995):

Continuity:

$$\frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} = 0 \quad (32.17)$$

$x$ -momentum:

$$\frac{\partial(\rho uu)}{\partial x} + \frac{\partial(\rho vu)}{\partial y} = -\frac{\partial P}{\partial x} + \mu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) + \frac{\mu}{3} \frac{\partial}{\partial x} \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \quad (32.18)$$

$y$ -momentum:

$$\frac{\partial(\rho uv)}{\partial x} + \frac{\partial(\rho vv)}{\partial y} = -\frac{\partial P}{\partial y} + \mu \left( \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) + \frac{\mu}{3} \frac{\partial}{\partial y} \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \quad (32.19)$$

Energy:

$$u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} = \frac{k}{\rho c_p} \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} \right) + \frac{2\mu}{\rho c_p} \left[ \left( \frac{\partial u}{\partial x} \right)^2 + \left( \frac{\partial v}{\partial y} \right)^2 + \frac{1}{2} \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 \right] \quad (32.20)$$

### 32.3.4 Fully Developed Gas Flow Forced Convection

Analytical solution of Eqs. (32.17) to (32.20) is not available. Some solutions can be obtained upon further simplification of the mathematical model. Indeed, incompressible gas flows in macroducts with different cross sections subjected to a variety of boundary conditions are available [Shah and Bhatti, 1987]. However, the important features of gas flow in microducts are mainly due to rarefaction and compressibility effects. Two more effects due to acceleration and nonparabolic velocity profile were found to be of second order compared to the compressibility effect (van den Berg et al., 1993). The simplest system for demonstration of the rarefaction and compressibility effects is the two-dimensional flow between parallel plates separated by a distance  $H$ , with  $L$  being the channel length ( $L/H \gg 1$ ). If  $MaKn \ll 1$ , all streamwise derivatives can be ignored except the pressure gradient, which is the driving force. The Mach number,  $Ma = U/a$ , is the ratio between the fluid speed and the speed of sound  $a$ . In such a case, the momentum equation reduces to:

$$-\frac{dP}{dx} + \mu \frac{d^2 u}{dy^2} = 0 \quad (32.21)$$

with the symmetry condition at the channel centerline,  $y = 0$ , and the slip boundary conditions at the walls,  $y = \pm H/2$ , as follows:

$$\frac{du}{dy} = 0 \quad @ \quad y = 0 \quad (32.22)$$

$$u = -\lambda \frac{du}{dy} \Big|_{y=H/2} \quad @ \quad y = \pm H/2 \quad (32.23)$$

Integration of Eq. (32.21) twice with respect to  $y$ , assuming  $P = P(x)$ , yields the following velocity profile [Arkilic et al., 1997]:

$$u(y) = -\frac{H^2}{8\mu} \frac{dP}{dx} \left[ 1 - \left( \frac{y}{H/2} \right)^2 + 4Kn(x) \right] \quad (32.24)$$

where  $Kn(x) = \lambda(x)/H$ . The streamwise pressure distribution,  $P(x)$ , calculated based on the same model is given by:

$$\frac{P(x)}{P_o} = -6Kn_o + \sqrt{\left( 6Kn_o + \frac{P_i}{P_o} \right)^2 - \left[ \left( \frac{P_i^2}{P_o^2} - 1 \right) + 12Kn_o \left( \frac{P_i}{P_o} - 1 \right) \right] \left( \frac{x}{L} \right)} \quad (32.25)$$

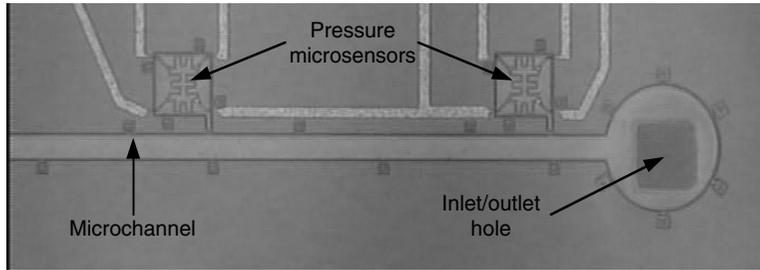

where  $P_i$  is the inlet pressure,  $P_o$  the outlet pressure, and  $Kn_o$  is the outlet Knudsen number. It is difficult to verify experimentally the cross-stream velocity distribution,  $u(y)$ , within a microchannel. However, detailed pressure measurements have been reported [Liu et al., 1993; Pong et al., 1994]. A picture of a microchannel integrated with pressure sensors for such experiments is shown in [Figure 32.4a](#). Indeed, the calculated pressure distributions based on Eq. (32.25) were found to be in a close agreement with the measured values as shown in [Figure 32.4b](#) [Li et al., 2000]. Furthermore, the mass flow rate,  $Q_m$ , as a function of the inlet and outlet conditions is obtained by integrating the velocity profile with respect to  $x$  and  $y$  as follows:

$$Q_m = \frac{H^3 W P_o^2}{24\mu R T L} \left[ \left( \frac{P_i}{P_o} \right)^2 - 1 + 12Kn_o \left( \frac{P_i}{P_o} - 1 \right) \right] \quad (32.26)$$

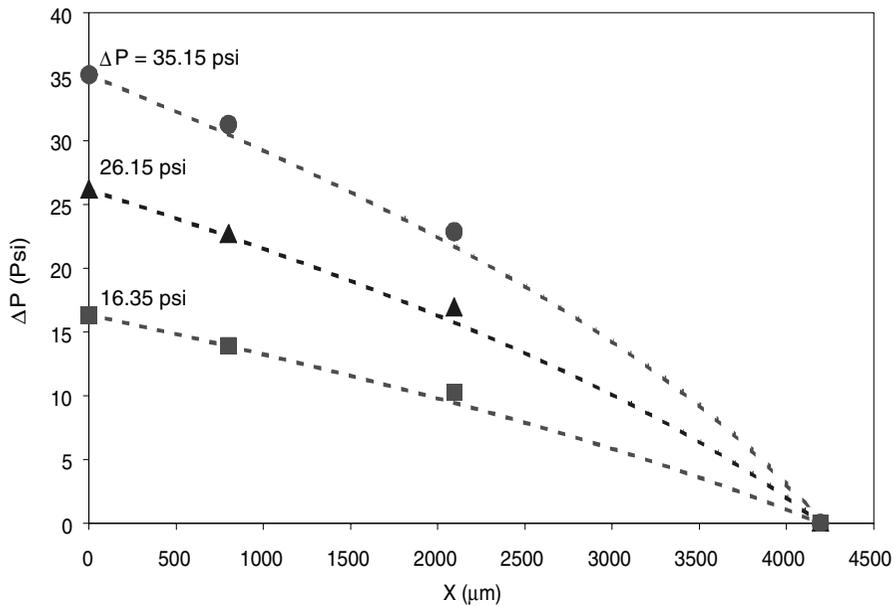

where  $W$  is the width of the channel. This simple equation was found to yield accurate results for three different working gasses: nitrogen, helium and argon, with ambient temperatures ranging from 20 to 60°C, as demonstrated in [Figure 32.5](#) [Jiang et al., 1999a].

The microchannel flow temperature distribution and heat flux depend on the boundary conditions, and extensive analytical work has been conducted (Harley et al., 1995; Beskok et al., 1996). However, closed-form analytical solutions in general are still not available. Numerical simulations of Eqs. (32.17) to (32.20) were carried out for constant wall temperature and constant heat flux boundary conditions by Kavehpour et al. (1997), and the results are summarized in [Figure 32.6](#). The heat transfer rate from the wall to the gas flow decreases while the entrance length increases due to the rarefaction effect (i.e., increasing Knudsen number). This may not be a universal result, however, as the slip flow conditions include two competing effects (Zohar et al., 1994). The velocity slip at the wall increases the flow rate, thus enhancing the cooling efficiency. On the other hand, the temperature jump at the boundary acts as a barrier to the flow of heat to the gas, thus reducing the cooling efficiency. The net result of these effects depends on the specific material properties and specific geometry of the system.

A microchannel integrated with suspended temperature sensors was constructed, [Figure 32.7a](#), for an initial attempt to experimentally assess the slip flow effects on heat transfer in microchannels

(a)

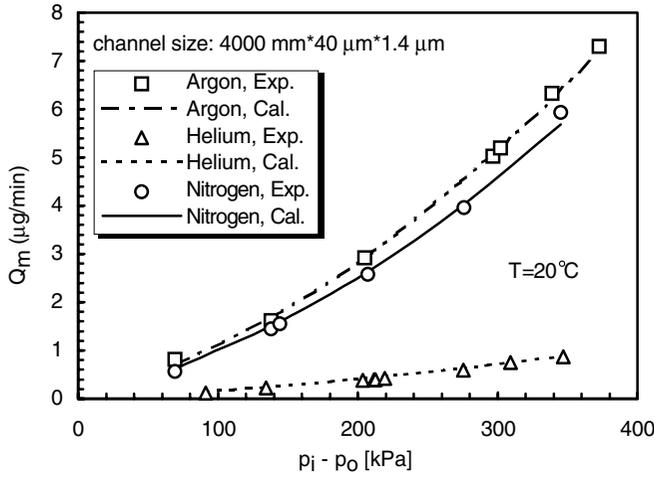

(b)

**FIGURE 32.4** Slip flow effect on a microchannel flow: (a) microchannel, 40 μm wide, integrated with pressure microsensors; (b) a comparison between calculated (dash lines) and measured (symbols) streamwise pressure distributions. (Reprinted from Li, X. et al. (2000) *Sensors and Actuators A*, **83**, 277–283. With permission from Elsevier Science.)

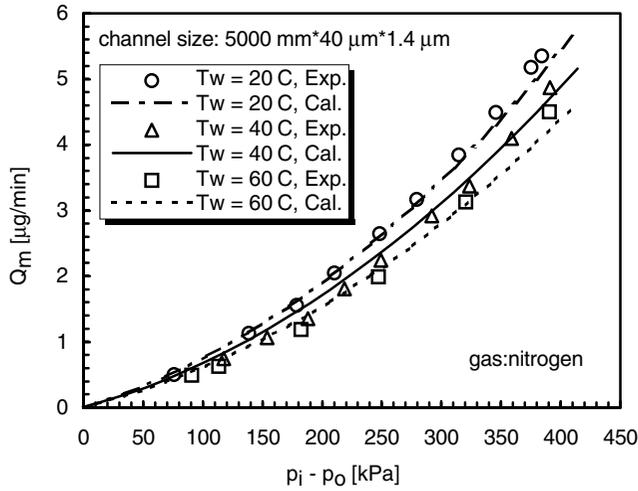

[Jiang et al., 1999a]. The resulting temperature distributions along the microchannel are shown in Figure 32.7b for different wall temperatures and pressure drops. In all cases, the temperature along the channel is almost uniform and equal to the wall temperature, and no cooling effect has been observed. Indeed, on one hand, the slip flow effects are small, but, on the other hand, the sensitivity of the experimental system is not sufficient. Thus, experiments with higher resolution and greater sensitivity are required to accurately verify the weak slip flow effects on the temperature and the heat-transfer coefficient predicted by theoretical analyses and numerical simulations.

### 32.3.5 Fully Developed Liquid Flow Forced Convection

Liquid flow is considered to be incompressible even in microducts, as the distance between the molecules is much smaller than the characteristic scale of the flow. Hence, no rarefaction effect is encountered, and the classical model in Eq. (32.21) should be valid. Again, in such a case, extensive data are readily available [Shah and Bhatti, 1987]. However, two unique features of liquid flow in microducts, polarity and EDL, could affect the flow behavior.

(a)

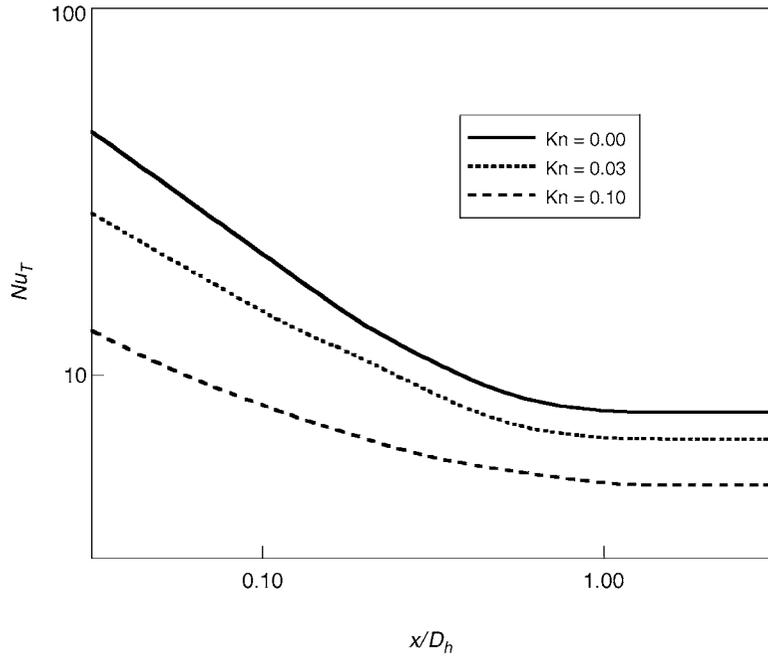

(b)

**FIGURE 32.5** Slip flow effect on microchannel mass flow rate as a function of the total pressure drop for various working gases (a) and wall temperatures (b). (From Jiang, L. et al. (1999) *J. Micromech. Microeng.*, **9**, 422–428. With permission.)

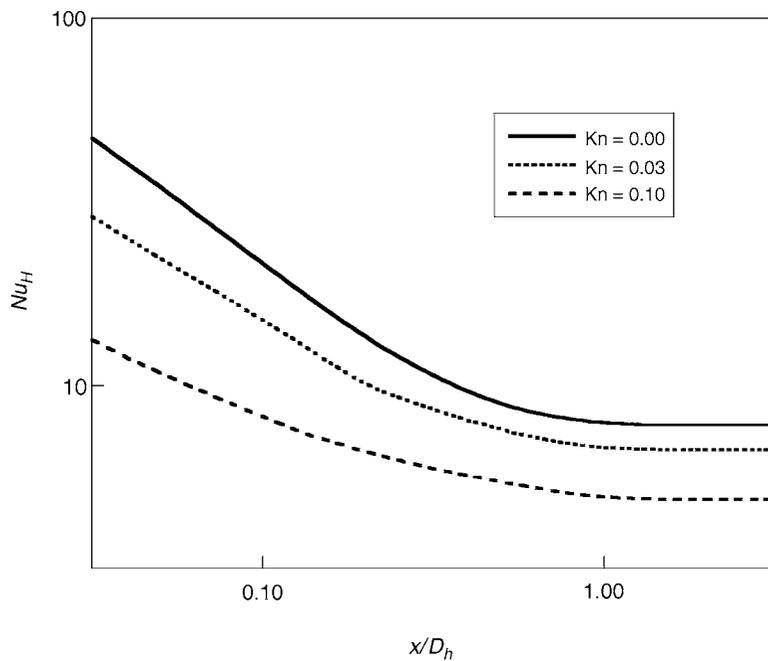

The characteristic length scale of the electric double layer is inversely proportional to the square root of the ion concentration in the liquid. For example, in pure water the scale is about 1  $\mu\text{m}$ , while in 1 mole of NaCl solution the EDL length scale is only 0.3 nm. Thus, in microducts, liquid flow with low ionic concentration and the associated heat transfer can be affected by the presence of the EDL. The  $x$ -momentum and energy equations for a two-dimensional duct flow can be reduced to (Mohiuddin Mala et al., 1997):

$$\mu \frac{d^2 u}{dy^2} - \frac{dP}{dx} - \epsilon \epsilon_0 \frac{E_s}{L} \frac{d^2 \Psi}{dy^2} = 0 \quad (32.27)$$

$$\rho c_p \left( u \frac{\partial T}{\partial x} \right) = k \left( \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial x^2} \right) + \mu \left( \frac{\partial u}{\partial y} \right)^2 \quad (32.28)$$

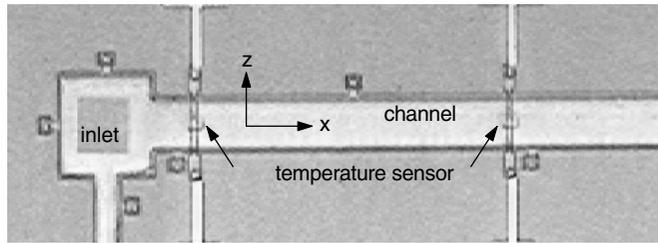

(a)

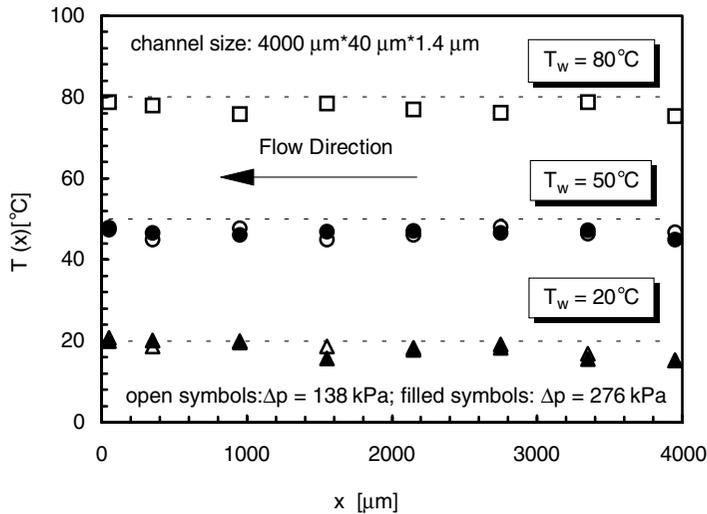

(b)

**FIGURE 32.6** Numerical simulations of the effect of the inlet Knudsen number,  $Kn_i$ , on the Nusselt number,  $Nu$ , along a microchannel for uniform wall temperature ( $Nu_T$ ) (a) and heat flux ( $Nu_H$ ) (b) boundary conditions. (From Kavehpour, H.P. et al. (1997) *Numerical Heat Transfer A*, 32, 677–696. Reproduced by permission of Taylor & Francis, Inc.)

(a)

(b)

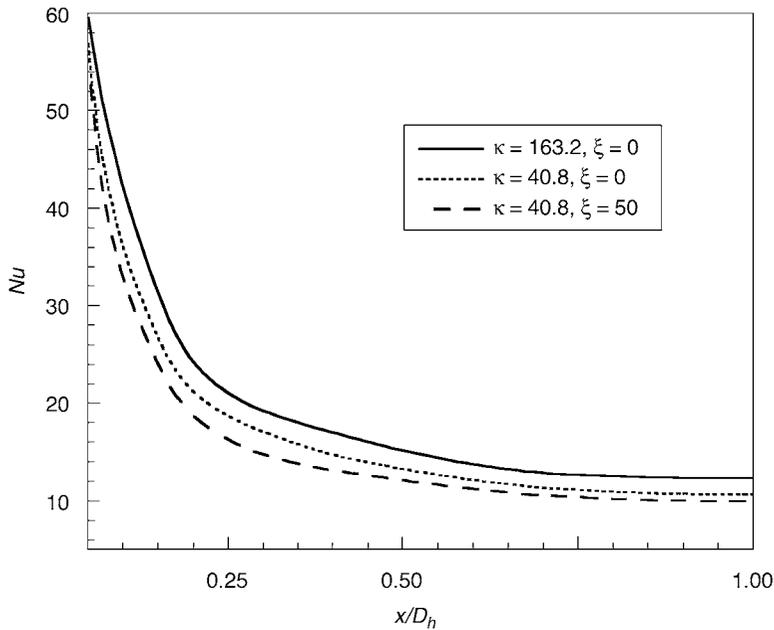

**FIGURE 32.7** Slip flow effect on microchannel flow: (a) microchannel integrated with suspended temperature sensors; (b) measured streamwise temperature distributions for different ambient temperature and pressure drop. where  $E_s$  is the streaming potential and  $L$  is the duct length. Equation (32.27) was solved analytically, and Eq. (32.28) was solved numerically for constant wall temperature boundary condition for a given inlet liquid temperature. The results showed that both the temperature gradient at the wall and the difference between the wall and the bulk temperature decrease with downstream distance. The value of the temperature gradient decreases much faster, resulting in a decreasing Nusselt number,  $Nu = hD_h/k$ , along the channel, as plotted in Figure 32.8. However, with no double layer effects (i.e.,  $\xi = 0$ ) a higher heat-transfer rate (higher  $Nu$ ) is obtained. The EDL results in a reduced flow velocity (higher apparent viscosity), thus decreasing the heat-transfer rate.

In order to evaluate micropolar effects on microchannel heat transfer, Jacobi (1989) considered the steady, fully developed, laminar flow in a cylindrical microtube with uniform heat flux, for which the energy equation is given by:

$$\rho c_p \left( u \frac{\partial T}{\partial x} \right) = \frac{k}{r} \left( \frac{\partial T}{\partial r} + r \frac{\partial^2 T}{\partial r^2} \right) \quad (32.29)$$

where  $r$  is the radial coordinate. Both the velocity and temperature radial distributions were analytically estimated. Based on the temperature field, the heat-transfer rate was calculated and the results are shown in Figure 32.9 for different values of  $\Gamma$ , a length scale that depends on the viscosity coefficients of the micropolar fluid. The Nusselt number is smaller than the classical value of  $Nu = 4.3636$  by as much as

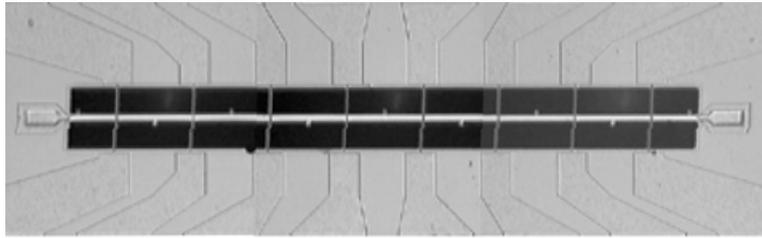

**FIGURE 32.8** Electric double layer effect on the variation of the local Nusselt number,  $Nu$ , along the channel length. (Reprinted from Mohiddin Mala, G. et al. (1997) *Int. J. Heat Mass Transfer*, **40**, 3079–3088. With permission from Elsevier Science.)

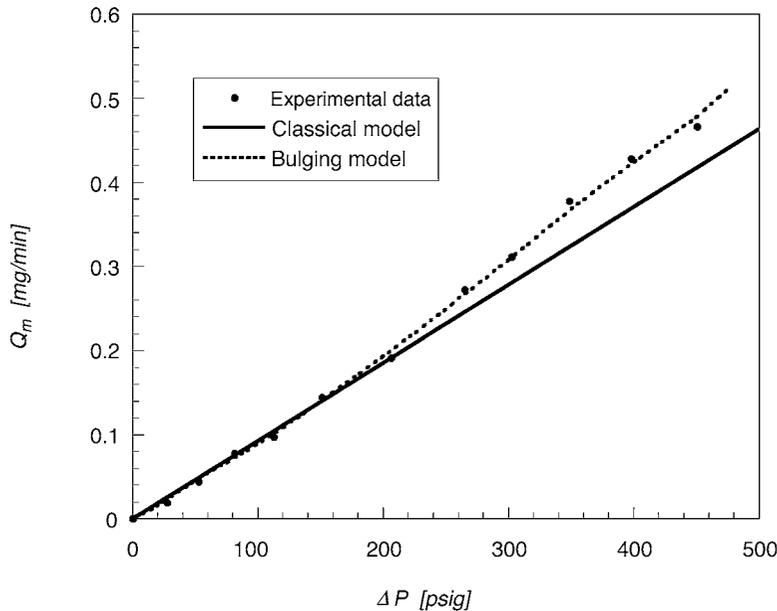

**FIGURE 32.9** Micropolar fluid effect on the Nusselt number,  $Nu$ , as a function of the viscosity ratio,  $k_v/\mu_v$ , for different values of  $\Gamma$ . (From Jacobi, A.M. (1989) *J. Heat Transfer*, **111**, 1083–1085. With permission.)

7% for this micropolar flow. Although the micropolar fluid theory has been applied to many situations, however, the drawback to these analyses is still the unknown viscosity coefficients.

Clearly, the EDL and micropolar fluid effects on liquid forced convection in microducts are indirect; namely, the velocity is modified due to these effects and, as a consequence, the heat-transfer rate is affected.

(a)

(b)

**FIGURE 32.10** Microchannel liquid flow: (a) microchannel integrated with temperature sensors on the channel roof; (b) a comparison between liquid flow rate measurements as a function of the pressure drop and theoretical calculations based on classical and bulging models. (From Wu, P. et al. (1998) in *Proc. 11th Int. Workshop on Micro Electro Mechanical Systems (MEMS'98)*, pp. 87–92. ©1998/2000 IEEE. With permission.)

Thus, it is important to first verify the hydrodynamic effects. Indeed, it has been suggested in a few reports that theoretical calculations based on the classical model did not agree with experimental measurements of liquid flow properties in microchannels [Pfahler et al., 1990; Peng et al., 1994; Peng and Peterson, 1996]. An experimental study of water flow in a microchannel with a cross-section area of  $600 \mu\text{m} \times 30 \mu\text{m}$  was carried out specifically to evaluate micropolar effects by Papautsky et al. (1998). They concluded that micropolar fluid theory provides a better approximation to the experimental data than the classical theory. However, a close examination of the results shows that the difference between the results of the two theories is smaller than the difference between the experimental data and the predictions of either theory.

In carefully conducted experiments of water flow through a suspended microchannel (Figure 32.10a) with a cross-section area of  $20 \mu\text{m} \times 2 \mu\text{m}$  and under a pressure drop of up to 500 psi, none of these effects has been observed [Wu et al., 1998]. The slight mismatch between theory and experiment was found to be a result of the bulging effect of the channel roof under the high pressure. The deformation of the channel roof can be measured accurately. Once the corrected cross-section area has adequately been accounted for in the calculations, the classical theory results agree well with the experimental measurements as evident in Figure 32.10b. However, more research work is required to verify these observations, as these discrepancies may have to do more with experimental errors rather than true size effects.

## 32.4 Two-Phase Convective Heat Transfer in Microducts

Micro heat sinks have been constructed as micro heat exchangers for cooling of thermal microsystems, which were developed and investigated either experimentally or theoretically. It is a common finding that the cooling rates in such microchannel heat exchangers should increase significantly due to a decrease in the convective resistance to heat transport caused by a drastic reduction in the thickness of the thermal boundary layers. The potentially high heat-dissipation capacity of such a micro heat sink is based on the large heat-transfer surface-to-volume ratio of the microchannel heat exchanger. In order to increase the heat flux from a microchannel with single-phase flow while maintaining practical limits on surface temperature, it is necessary to increase the heat-transfer coefficient by either increasing the flow rate or decreasing the hydraulic diameter. Both are accompanied by a large increase in the pressure drop. However, forced-convection flow with phase change can achieve a very high heat-removal rate for a constant flow rate, while maintaining a relatively constant surface temperature determined by the saturation properties of the cooling fluid. The advantage of using two-phase over single-phase micro heat sinks is clear. Single-phase heat sinks compensate for high heat flux by a large streamwise increase in both coolant and heat sink temperature. Two-phase heat sinks, in contrast, utilize latent heat exchange, which maintains streamwise uniformity both in the coolant and the heat sink temperature at a level set by the coolant saturation temperature. Therefore, it is expected that two-phase heat transfer may lead to significantly more efficient heat transfer, and a two-phase micro heat exchanger would be the most promising approach for cooling in microsystems [Stanley et al., 1995].

Heat transfer during boiling of a liquid in free convection is essentially determined by the difference between the heating-surface and boiling temperatures, the properties of the liquid, and the properties of the heating surface. Thus, the heat-transfer coefficient can be represented by a simple empirical correlation of the form  $h \propto q''$ . During boiling in forced convection, however, the flow velocities of the vapor and liquid phases and the phase distribution play additional roles. Consequently, the mass flow rate and the quality are additional limiting quantities, giving rise to a correlation of the form  $h \propto q'' Q_m^n f(\chi)$ . Forced convection boiling is complex not only due to the co-existence of two separate phases having different properties but also, especially, due to the existence of a highly convoluted vapor–liquid interface resulting in a variety of flow patterns. Typical patterns that have experimentally been observed in macroducts, such as bubble, slug, churn, annular and drop flow, are sketched in Figure 32.11. Accordingly, flow pattern maps have been suggested in which the duct orientation on heat-transfer boiling is significant due to gravity effects [Stephan, 1992].

### 32.4.1 Boiling Curves

Forced convection boiling is attractive as it ensures low device temperature for high power dissipation or, alternatively, it allows higher power dissipation for a given device temperature. Measurements of either the inner wall or the fluid bulk temperature distributions along a microduct under forced convection boiling are not available yet, due to the difficulty in integrating sensors at the desired locations.

**FIGURE 32.13** Flow rate effect on the temperature distribution along the microchannel heat sink centerline. (From Jiang, L. et al. (1999) *J. MEMS*, **8**, 358–365. © 1999/2000 IEEE. With permission.)

However, measurements of the surface temperature of a microchannel heat sink device have been reported [Jiang et al., 1999b]. A picture of the integrated microsystem, consisting of an array of microducts, a local micro heater and an array of temperature microsensors, is shown in Figure 32.12. The 35 diamond-shaped microducts, each with a hydraulic diameter of about 40  $\mu\text{m}$ , are buried between two bonded silicon wafers. A significant reduction of the device temperature is demonstrated in Figure 32.13. Initially, the device temperature and its temperature gradient, for a given power dissipation (3.6 W), is high. The maximum temperature of about 230°C is measured close to the heater. The device temperature drops sharply to about 115°C even for the low flow rate of 0.25 mL/min (average liquid velocity of about 6.7 cm/s within each duct). Increasing the water flow rate leads to further reduction of the device temperature to a level below the saturation temperature of about 100°C. This is expected, as a higher flow rate results in a higher heat-transfer rate. Consequently, the device internal energy (i.e., the device temperature) decreases. Furthermore, the temperature distribution becomes more uniform as well, which suggests that the local heat-transfer rate is highly nonuniform. It should be emphasized, though, that the flow is in

**FIGURE 32.14** Boiling curves of device temperature as a function of the input power for microchannels with: (a) water and  $D_h = 40 \mu\text{m}$  or  $80 \mu\text{m}$  [Jiang et al., 1999b], and (b) R-113 and  $D_h = 510 \mu\text{m}$  [Bowers and Mudawar, 1994]. (Reprinted with permission from Elsevier Science.)

single-liquid phase for the high-flow-rate case and in two-phase for the low-flow-rate case, as indicated by the exit fluid quality. Hence, the heat-transfer mechanism changes character as the flow rate varies.

The measured spanwise temperature distributions were found to be uniform, similar to the streamwise temperature distributions plotted in Figure 32.13. Thus, the average temperature along the device centerline can characterize the device temperature. In order to obtain a complete boiling curve, the device temperature was recorded as the input power increased by small increment while maintaining the inlet water

flow rate constant at room temperature (22°C). This experiment was repeated several times for different devices with varying flow rate [Jiang et al., 1999b], and the results are summarized in Figure 32.14a. In all curves, the device average temperature increases monotonically, almost linearly, with the power level. At a certain input power, known as critical heat flux (CHF), the temperature increases sharply. The exit flow changes from single-liquid phase, quality zero, through two-phase flow of liquid–vapor, to a single vapor phase, quality one, under CHF conditions. These boiling curves are in contrast to the previously reported data of Bowers and Mudawar (1994), plotted in Figure 32.14b for a microchannel 510 μm in diameter. The typical boiling plateau illustrated at the inset of Figure 32.14a has not been observed under all tested conditions. The plateau in the boiling curve is due to the saturated nucleate boiling, where bubbles continuously form, grow and detach such that the temperature is kept uniform and constant although the heat dissipation is increasing until the CHF condition is approached. The curves in Figure 32.14a suggest that the saturated nucleate boiling does not develop in such microducts due to size effect, which could be verified by flow visualization of the boiling pattern.

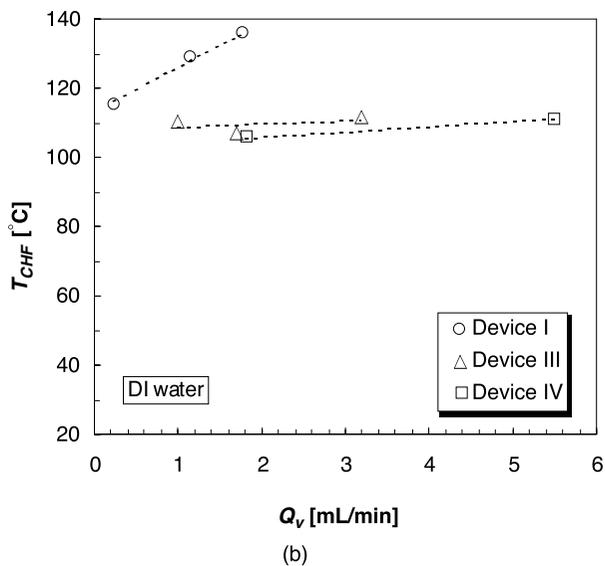

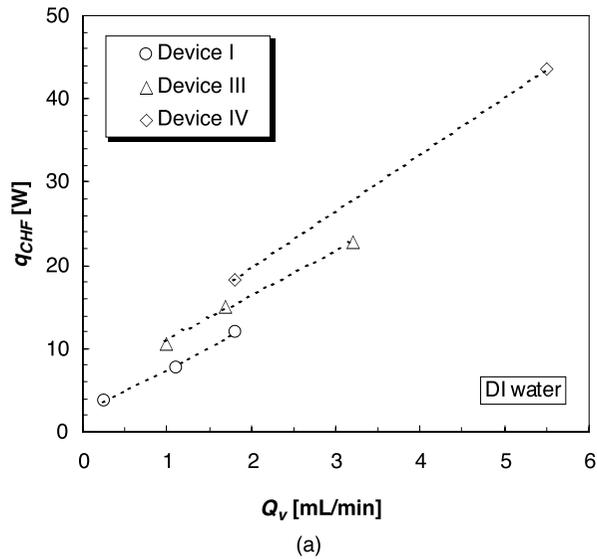

### 32.4.2 Critical Heat Flux

The critical heat flux is the most important factor used to determine the upper limit of the heat sink cooling ability. When the CHF condition is approached, a sudden dryout takes place at the heat-transfer surface. This is accompanied by a drastic reduction of the heat-transfer coefficient and a sharp rise in surface temperature. The exit flow quality is one, as the entire liquid passing through the heat sink changes phase into vapor. Therefore, it is reasonable that the critical heat flux,  $q_{CHF}$ , increases linearly with the flow rate (Figure 32.15a), as most of the input power is converted into latent heat at about the saturation temperature (Jiang et al., 1999b). An important parameter associated with the CHF condition is the corresponding device temperature. The dependence of the average temperature under the CHF condition,  $T_{CHF}$ , on the water flow rate,  $Q_v$ , is shown in Figure 32.15b for three different devices. For the large heat sinks,  $D_h = 80 \mu\text{m}$ , the CHF temperature depends neither on the flow rate nor on the number of channels. Furthermore,  $T_{CHF}$  is slightly higher than the saturation temperature of water under atmospheric pressure, 100°C. The higher CHF temperature may be due to the higher pressure, larger than 1 atm, throughout the microducts. However, for the small heat sink,  $D_h = 40 \mu\text{m}$ , the CHF temperature increases almost linearly with the water flow rate, which cannot be attributed to the higher pressure. The difference between the two heat sinks is puzzling, and more experiments with wider flow rate ranges are required to confirm this observation.

Bowers and Mudawar (1994) reported similar dependence of the critical heat flux on liquid flow rate in a study comparing the performance of mini- and microchannel heat sinks. The data exhibited a lack of subcooling effect on the CHF for both heat sinks and all operating conditions. This was attributed to fluid reaching the saturation temperature within a short distance into the heated section of the channel. However, they did notice a distinct separation between mini- and microchannel curves, which was explained as a result of the large difference in  $L/D$  ratio ( $L$  and  $D$  being the channel length and diameter, respectively): 3.94 for the minichannel and 19.6 for the microchannel. Consequently, they proposed the following CHF correlation:

$$\frac{q_{mp}}{Gh_{fg}} = 0.16 We^{-0.19} \left(\frac{L}{D}\right)^{-0.54} \quad (32.30)$$

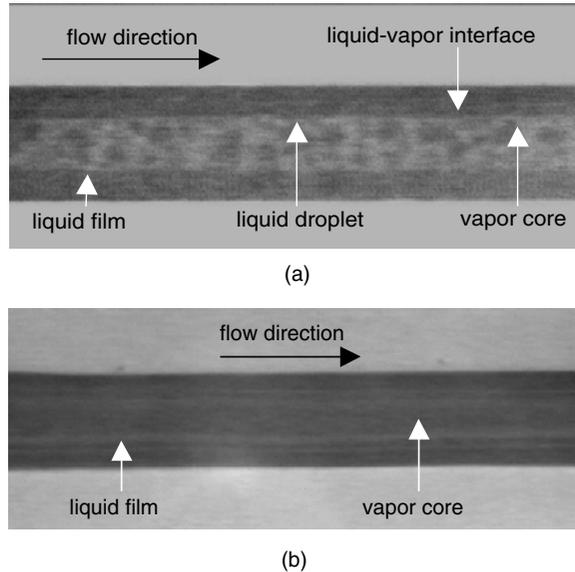

where  $q_{mp}$  is the CHF based upon the heated channel inside area,  $G$  is the mass velocity, and  $h_{fg}$  is the latent heat of evaporation.  $We = G^2L/\beta\rho$  is the Weber number, where  $\beta$  and  $\rho$  are the liquid surface tension and density, respectively. The authors argued that the small diameter of the channels resulted in an increased frequency and effectiveness of droplet impact on the channel wall. This could have increased the heat-transfer coefficient and enhanced the CHF compared to droplet flow regions in larger tubes. The small overall size of the heat sinks seemed to contribute to delaying CHF by conducting heat away from the downstream region undergoing partial or total dryout to the boiling region of the channel. Thus, a higher heat-transfer rate is required to trigger CHF conditions along the entire microchannel rather than just at the downstream region.

**FIGURE 32.15** Flow rate effect on the critical heat flux (a) and the corresponding device temperature (b). (From Jiang, L. et al. (1999) *J. MEMS*, **8**, 358–365. © 1999/2000 IEEE. With permission.)

### 32.4.3 Flow Patterns

Two-phase flow patterns in ducts are the result of the detailed heat transfer between the solid boundary and the working fluid. The flow patterns are important, as the temperature distributions in both the solid boundary and the fluid flow are directly determined by these patterns. Mudawar and Bowers (1999) suggested that low- and high-velocity flows are characterized by drastically different flow patterns as well as unique CHF trigger mechanisms. Whereas the low flow exhibits a succession of bubbly, slug and annular flow, the high flow is characterized by a bubbly flow near the wall with a liquid core. Unfortunately, limited results of flow patterns have been reported thus far, so it is not clear whether this distinction is valid for microchannel heat sinks.

**FIGURE 32.16** Pictures of flow patterns during forced convection boiling: (a) unstable annular flow with liquid droplets in the vapor core ( $q/q_{CHF} = 0.6$ ), and (b) stable annular flow ( $q/q_{CHF} = 0.8$ ) (channel width, 50  $\mu\text{m}$ ; 35 channels in the microdevice). (From Jiang, L. et al. (2001) *J. MEMS*, **10**, pp. 80–87. © 2000 IEEE. With permission.)

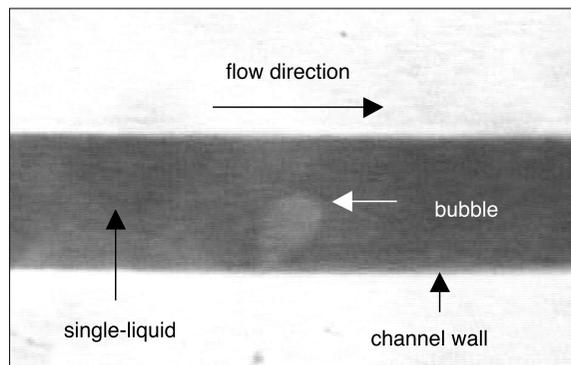

An integrated microsystem, similar to the one shown in Figure 32.12, has been fabricated to study the forced convection boiling flow patterns [Jiang et al., 2000]. The triangular-shaped grooves etched in the silicon wafer were covered by a bonding glass wafer, rather than a silicon wafer, in order to facilitate flow visualizations. In microducts, body forces such as gravity are negligible with respect to surface forces (i.e., surface tension or capillary forces). Consequently, the microduct orientation has little effect on forced convection boiling, and no difference between the flow patterns in horizontal and vertical microducts could be detected experimentally. Furthermore, the boiling modes identified in these microducts are different from the classical patterns sketched in Figure 32.11. At moderate power levels, an annular flow mode with liquid droplets within the vapor core could be observed, as shown in Figure 32.16a, while the vapor–liquid interface in the channel appears to be wavy. This mode should be regarded as an unstable, transition stage, as it was not always detected. Moreover, when it did appear, it was short lived. An annular flow mode, shown in Figure 32.16b, was observed to be a stable pattern for a wide range of input power levels,  $0.6 < q/q_{CHF} < 0.9$ . A thin liquid film coated each channel wall, and an interface between the liquid film and the vapor core was clearly distinguishable. No liquid droplets existed within the vapor core, indicating that the vapor-core temperature was higher than the liquid saturation temperature.

Evaporation at the liquid film–vapor core interface dominated the heat transfer from the channel wall to the fluid in the annular flow mode. Because the heat is conducted through the liquid film to the interface, the temperature at the wall has to increase to allow a higher heat-transfer rate enforced by the increased input power. The temperature would increase linearly with the input power if the film thickness stays constant. However, the film thickness decreased with increased power, due to the evaporation process, resulting in higher quality of the two-phase exit flow. Thus, the input power is converted into: (1) latent heat required for evaporation at the liquid–vapor interface due to the phase change, and (2) internal energy of the liquid film manifested by the increased liquid and wall temperature. The combination of the two mechanisms resulted in a monotonic temperature increase with decreasing slope as the input power increased. It is not clear whether the annular flow is a general pattern in microchannels due to size effect, or if it is unique only to triangular channel cross sections due to the strong capillary forces at the sharp corners (similar to micro heat pipes).

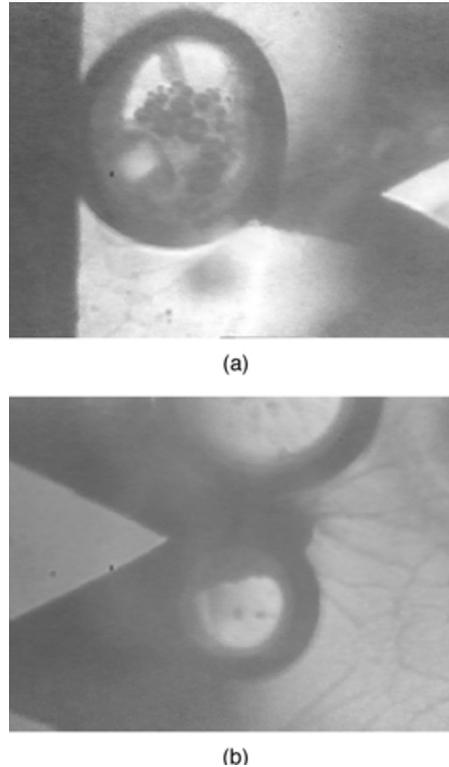

### 32.4.4 Bubble Dynamics

Boiling is a phase-change process in which vapor bubbles are formed either on a heated surface or in a superheated liquid layer adjacent to the heated surface. It differs from evaporation at predetermined vapor–liquid interfaces because it also involves creation of these interfaces at discrete sites on the heated surface. Nucleate boiling is a very efficient mode of heat transfer, and it is used in various energy-conversion systems. The number density of sites that become active increases as wall heat flux or wall superheat increases. Clearly, addition of new nucleation sites influences the heat-transfer rate from the solid surface to the working fluid. Knowledge of the nucleation site density as a function of wall superheat is, therefore, needed to develop a credible model for prediction of the heat flux. Several other parameters also affect the site density, including the surface finish, surface wettability and material thermophysical properties. After inception, a bubble continues to grow until forces causing it to detach from the surface exceed those pushing the bubble against the wall. Bubble dynamics, which plays an important role in determining the heat-transfer rate, includes the processes of bubble growth, bubble departure and bubble release frequency [Dhir, 1998].

Jiang et al. (2000) reported that the first experimentally observed mode of phase change, local nucleation boiling, was detected in the microchannel heat sink at an input power level as low as  $q/q_{CHF} \cong 0.5$ . The working fluid was water and the corresponding device temperature was about 70°C. Bubbles could be seen forming at specific locations along the channel walls at a few active nucleation sites. Bubble generation, growth and explosion at a fairly high frequency inside the microducts were recorded; a mature bubble is shown in Figure 32.17. However, there were very little, if any, active nucleation sites along the channel walls. Furthermore, most of the nucleation sites became inactive after one or two runs, suggesting that they may have been residues of the fabrication process. Therefore, no attempt was made to characterize the bubble release frequency. At slightly higher input power level,  $0.5 < q/q_{CHF} < 0.6$ , large bubbles were generated at the inlet/outlet common passages, which connect the microchannel array to the device common inlet/outlet. The boiling activity at these larger passages, shown in Figure 32.18, became more intense with increasing input power. Furthermore, the upstream bubbles were forced through the microducts as shown in Figure 32.19. The bubbles typically grew to a size larger than the microduct cross section. Therefore, upon departure from their nucleation sites, these bubbles blocked the duct entrances, as pictured in Figure 32.19a, until the upstream pressure was high enough to force them into the microduct. In some cases, the bubbles traveled slowly along the channel as slug flow as shown in Figure 32.19b. In most instances, however, the bubbles were ejected at high speed through the microduct and could not be detected until they reappeared at the channel exit, as shown in Figure 32.19c. Further increase of the input power level,  $q/q_{CHF} > 0.7$ , resulted in the annular flow pattern, and the nucleation sites on the duct walls could no longer be observed. The corresponding device temperature was about 90°C. It seems very likely that suppression of the nucleation sites within the microduct was the result of the activity of the

**FIGURE 32.17** Active nucleation site within the microchannel exhibiting bubble formation, growth and explosion. (From Jiang, L. et al. (2001) *J. MEMS*, **10**, pp. 80–87. © 2001 IEEE. With permission.)

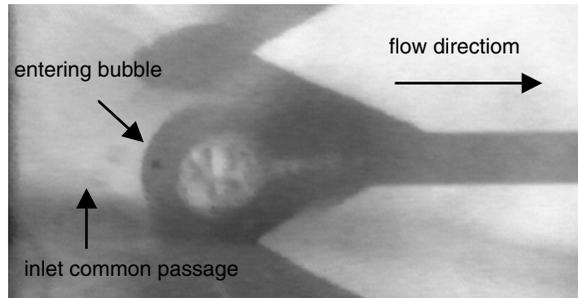

**FIGURE 32.18** Bubble formation and growth at inlet (a) and outlet (b) common passages of a microchannel array ( $q/q_{CHF} = 0.5$ ; 35 channels, each 50  $\mu\text{m}$  in width). (From Jiang, L. et al. (2001) *J. MEMS*, **10**, pp. 80–87. © 2001 IEEE. With permission.)

upstream bubbles as they passed through the ducts rather than a genuine size effect. Similar bubble activity was reported by Peles et al. (1999), who conducted experiments with an almost identical micro-channel heat sink.

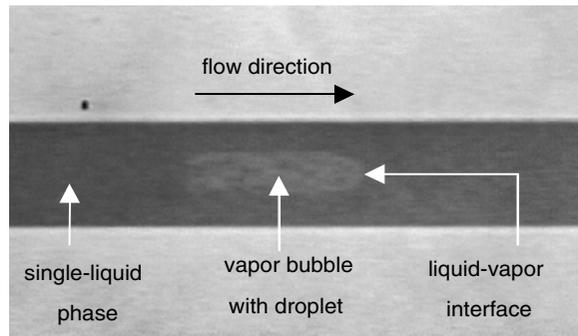

It is reasonable to expect the bubble dynamics after inception, unlike the nucleation site density, to be affected by the channel size. However, it is clear that in channels with a hydraulic diameter as small as 25  $\mu\text{m}$ , bubble growth and departure have been observed. Thus, the lack of partial nucleate boiling of subcooled liquid flowing through microchannels cannot be attributed to a direct fundamental size effect suppressing bubble dynamics (i.e., bubbles cannot grow and detach due to the small size of the channel). However, it is very plausible that the absence of partial nucleate boiling is an indirect size effect. Namely, another boiling mode such as annular flow becomes dominant due to small channel size (i.e., strong capillary forces), and as a result the bubble dynamics mechanisms are suppressed.

### 32.4.5 Modeling of Forced Convection Boiling

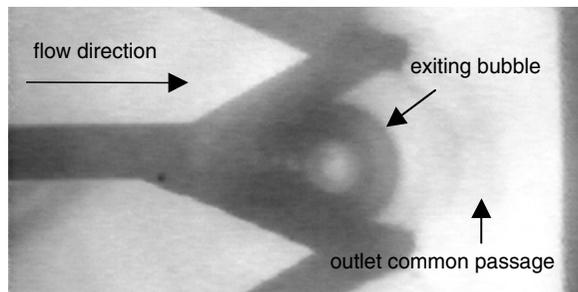

Phase change from liquid to gas within a microchannel presents a formidable challenge for physical and mathematical modeling. It is not surprising, therefore, that very little work has been reported on this subject. One of the first attempts to address this problem is the derivation of Peles et al. (2000), which was based on fundamental principles rather than empirical formulations. The idealized pattern of the flow in a heated microduct is depicted in Figure 32.20. In this model, the microchannel entrance flow is in single-liquid phase and the exit flow in single-vapor phase. The two phases are separated by a meniscus at a location determined by the heat flux. Such a flow is characterized by a number of specific properties due to the existence of the interfacial surface, which is infinitely thin with a jump in pressure and velocity while the temperature is continuous. Within the single-liquid or vapor phase, heat transfer

(b)

(c)

**FIGURE 32.19** Sequence of pictures of a bubble entering into (a), traveling through (b), and exiting out of (c) a microchannel 50  $\mu\text{m}$  in width ( $q/q_{CHF} = 0.5$ ). (From Jiang, L. et al. (2001) *J. MEMS*, **10**, pp. 80–87. © 2001 IEEE. With permission.)

**FIGURE 32.20** Physical model of forced convection boiling in a microchannel showing the single-liquid and single-vapor phases separated by an interface. (Reprinted from Peles, Y.P. et al. (2000) *Int. J. Multiphase Flow*, **26**, 1063–1093. With permission from Elsevier Science.)

from the wall to the fluid is accompanied by a streamwise increase of the liquid or vapor temperature and velocity. At the liquid–vapor interface, heat flux causes the liquid to move downstream and evaporate.

The mathematical model includes, on top of the standard equations of conservation and state for each phase, conditions corresponding to the interface surface. For stationary capillary flow, these conditions

can be expressed by the equations of continuity of mass, thermal flux across the interface and the balance of all forces acting on the interface. For a capillary with evaporative meniscus, the governing equations take the following form [Peles et al., 2000]:

$$\sum_{b=1}^2 \rho^{(b)} \mathbf{U}^{(b)} n_i^{(b)} = 0 \quad (32.31)$$

$$\sum_{b=1}^2 \left( c_p^{(b)} \rho^{(b)} \mathbf{U}^{(b)} T^{(b)} + k^{(b)} \frac{\partial T^{(b)}}{\partial x_i} \right) n_i^{(b)} = 0 \quad (32.32)$$

$$\sum_{b=1}^2 (P^{(b)} + \rho^{(b)} u_i^{(b)} u_j^{(b)}) n_i^{(b)} = (\sigma_{ij}^{(2)} - \sigma_{ij}^{(1)}) n_j + \beta \left( \frac{1}{r_1} + \frac{1}{r_2} \right) n_i^{(2)} + \frac{\partial \beta}{\partial x_i} \quad (32.33)$$

where  $n_i$  and  $n_j$  correspond to the normal and tangent directions, respectively, and  $\sigma_{ij}$  is the tensor of viscous tension. The superscript  $b$  represents either vapor ( $b = 1$ ) or liquid ( $b = 2$ ). When the interface surface is expressed by a function  $x = f(y, z)$ , the general radii of curvature,  $r_i$ , are found from the equation:

$$A_2 r_i^2 + A_1 r_i + A_0 = 0 \quad (32.34)$$

The coefficients  $A_i$  depend on the shape of the interface. This model, though simplified a great deal, clearly demonstrates the complexity of the theoretical models, which will have to be developed in order to obtain meaningful results. Peles et al. further assumed a quasi-one-dimensional flow and derived a set of equations for the average parameters in order to solve the system of equations. A comparison between the calculations and measurements will not be very useful at this stage, as the physical model, on which the mathematical model is based, has not been observed experimentally in microducts. However, the reported flow patterns could be the result of the specific triangular cross section used in the experiment [Peles et al., 1999; Jiang et al., 2000]. It may well be that with a different cross-section shape (e.g., square or triangular) the flow pattern depicted in [Figure 32.20](#) could develop as a stable phase-change mode.

## 32.5 Summary

Single-phase forced convection heat transfer in macrosystems has been investigated and well documented. The theoretical calculations and the empirical correlations should be applied to microsystems as well, unless a clear size effect has been identified to require modification of these results. Most known size effects—velocity slip, electric double layer and micropolar fluid—affect the thermal performance indirectly by modifying the velocity field. The only size effect directly related to the heat-transfer mechanism is the temperature jump boundary condition for gas flow, which is the result of incomplete energy exchange between the impinging molecules and the solid boundary due to the size of the channel. Therefore, research in this area should first concentrate on the size effect on the velocity field. Theoretical calculations of size effects on the velocity and temperature distributions are available to some extent. With the advent of micromachining technology, it is possible to fabricate microchannels integrated with microsensors to collect precise experimental data, which can lead to sharp conclusions. Very few studies have been reported to date, and more work is required. Although solid experimental verification is still lacking, initial results show that most size effects are quite small and oftentimes are within the measurement experimental errors.

Two-phase convective heat transfer in microchannels appears to be a technology that can satisfy the demand for the dissipation of high fluxes associated with electronic and laser devices. However, in this area, both experimental and theoretical research related to phase change in microchannels is still very limited. Bubble dynamics during boiling is a complex phenomenon, and size effects can be very significant, much more so than in single-phase forced convection. It is, therefore, vital to establish a credible

set of experimental data to provide guidance for theoretical modeling. Initial results show that classical bubble dynamics could still be observed in microchannels, but not classical flow patterns related to bubble activity. Again, this might be an indirect effect, as other phase-change modes become more dominant in microchannels. Clearly, local as well as global measurements are required to supply adequate information in order to understand the heat-transfer mechanisms in microchannels. The integration of microsensors (temperature, pressure, capacitance, etc.) in microchannel systems and flowfield visualizations (flow patterns, bubble dynamics, phase-change evolution) are becoming key components in the march to understand microscale forced convection heat transfer.

The author would like to thank Dr. Linan Jiang for her help with the assembling of the material and the critical review of the manuscript.

## Defining Terms

**Annular flow:** A flow pattern in which liquid flow coats the solid boundaries while vapor flows in the central core of duct.

**Boiling:** A phase-change process in which vapor bubbles are formed either on a heated surface or in a superheated liquid layer adjacent to the heated surface; involves the creation of vapor–liquid interfaces at discrete sites on the heated surface.

**Boiling curves:** Curves of the heating surface temperature as a function of the heat-transfer rate.

**Bubble dynamics:** The processes of bubble formation at specific locations, growth and departure at certain frequencies.

**Capillary force:** The force balance between adhesion (attraction between solid and liquid molecules) and cohesion (mutual attraction of liquid molecules) forces at a liquid–gas–solid interface.

**Convective heat transfer (convection):** The process of energy transport by the combined effect of heat conduction and the movement of fluid.

**Critical heat flux:** A critical value beyond which an incremental increase of the heat flux results in a drastic increase of the heating surface temperature.

**Entrance length:** The entry section of a duct where either the velocity or temperature profile is still developing.

**Forced convection:** Convective heat transfer where the fluid motion involved in the process is induced by external means (e.g., pump or fan).

**Fully developed flow:** The duct section in which either the temperature or velocity profile is invariant with the axial coordinate along the duct.

**Latent heat:** The amount of energy that must be transferred in the form of heat to a substance held at constant pressure in order for a phase change to occur.

**Mean free path:** The average distance a molecule travels before it collides with another molecule.

**Microchannel heat sink:** A device comprising a microchannel array to remove heat utilizing forced convection heat transfer with or without boiling.

**Nucleation sites:** Vapor/gas trapped in imperfections such as cavities and scratches on a heated surface, which serve as nuclei for bubbles.

*I would like to shock you by stating that I believe that with today's technology we can easily—I say easily—construct motors one fortieth of this size on each dimension. That's sixty-four thousand times smaller than the size of McLellan's motor [400 microns on a side]. And in fact, with our present technology, we can make thousands of these motors at a time, all separately controllable. Why do you want to make them? I told you there's going to be lots of laughter, but just for fun, I'll suggest how to do it—it's very easy.*

(From the talk “Infinitesimal Machinery,” delivered by Richard P. Feynman at the Jet Propulsion Laboratory, Pasadena, CA, February 23, 1983.)

### 33.1 Introduction

---

The subject of flow control—particularly, reactive flow control—is broadly introduced in this chapter, leaving some of the details to other chapters which will deal with the issues of control theory, distributed and optimal control, soft computing tools such as neural networks, genetic algorithms and fuzzy logic, diagnostics and control of turbulent flows and futuristic control specifically targeting the coherent

structures in turbulent flows. Distributed flow control can greatly benefit from the availability of inexpensive microsensors and microactuators, hence the relevance of this topic to the *Handbook of MEMS*. In reactive control of turbulent flows, large arrays of minute sensors and actuators form feedback or feedforward control loops whose performance can be enhanced by employing optimized control algorithms and soft computing tools, thus the inclusion in this book of chapters on these specialized topics.

The ability to manipulate a flowfield actively or passively to effect a desired change is of immense technological importance, and this undoubtedly accounts for the fact that the subject is more hotly pursued by scientists and engineers than any other topic in fluid mechanics. The potential benefits of realizing efficient flow-control systems range from saving billions of dollars in annual fuel costs for land, air and sea vehicles to achieving economically and environmentally more competitive industrial processes involving fluid flows. Methods of control to effect transition delay, separation postponement, lift enhancement, drag reduction, turbulence augmentation and noise suppression are considered. Prandtl (1904) pioneered the modern use of flow control in his epoch-making presentation to the Third International Congress of Mathematicians held at Heidelberg, Germany. In just eight pages, Prandtl introduced the boundary-layer theory, explained the mechanics of steady separation, opened the way for understanding the motion of real fluids and described several experiments in which the boundary layer was controlled. He used active control of the boundary layer to show the great influence such a control exerted on the flow pattern. Specifically, Prandtl used suction to delay boundary-layer separation from the surface of a cylinder.

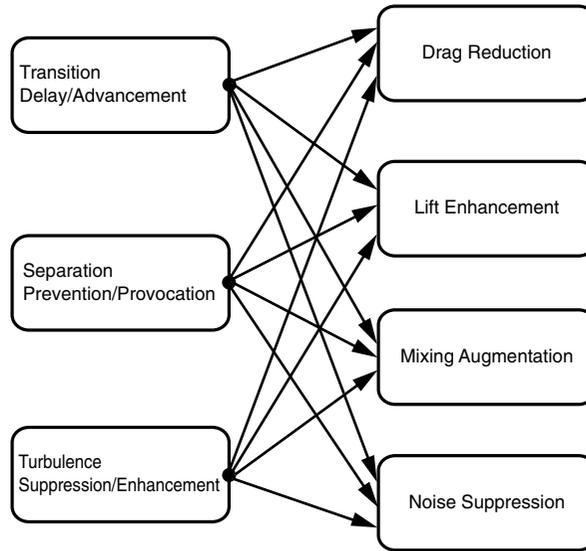

Notwithstanding Prandtl's success, aircraft designers in the three decades following his convincing demonstration were accepting lift and drag of airfoils as predestined characteristics with which no man could or should tamper [Lachmann, 1961]. This predicament changed mostly due to the German research in boundary-layer control pursued vigorously shortly before and during World War II. In the two decades following the war, extensive research on laminar flow control, where the boundary layer formed along the external surfaces of an aircraft is kept in the low-drag laminar state, was conducted in Europe and the U.S., culminating in the successful flight test program of the X-21 where suction was used to delay transition on a swept wing up to a chord Reynolds number of  $4.7 \times 10^7$ . The oil crisis of the early 1970s brought renewed interest in novel methods of flow control to reduce skin-friction drag even in turbulent boundary layers. In the 1990s, the need to reduce the emissions of greenhouse gases and to construct supermaneuverable fighter planes, faster/quieter underwater vehicles and hypersonic transport aircraft (e.g., the U.S. National Aerospace Plane) provides new challenges for researchers in the field of flow control.

The books by Gad-el-Hak et al. (1998) and Gad-el-Hak (2000) provide up-to-date overviews of the subject of flow control. In this chapter, following a description of the unifying principles of flow control, we focus on the concept of targeted control in which distributed arrays of microsensors and microactuators, connected in open or closed control loops, are used to target the coherent structures in turbulent flows in order to effect beneficial flow changes such as drag reduction, lift enhancement, noise suppression, etc.

## 33.2 Unifying Principles

---

A particular control strategy is chosen based on the kind of flow and the control goal to be achieved. Flow control goals are strongly, often adversely, interrelated, and therein lies the challenge of making tough compromises. There are several different ways for classifying control strategies to achieve a desired effect. The presence or lack of walls, Reynolds and Mach numbers, and the character of the flow instabilities are all important considerations for the type of control to be applied. All these seemingly disparate issues are what place the field of flow control in a unified framework. They will each be discussed in turn in the following.

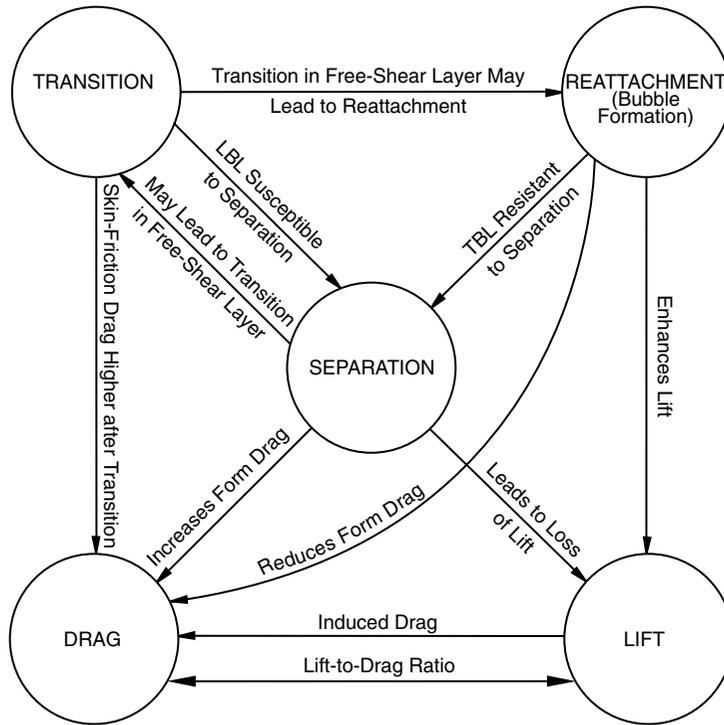

**FIGURE 33.1** Engineering goals and corresponding flow changes. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

### 33.2.1 Control Goals and Their Interrelation

What does the engineer want to achieve when attempting to manipulate a particular flowfield? Typically, engineers aim at reducing the drag; enhancing the lift; augmenting the mixing of mass, momentum or energy; suppressing the flow-induced noise or a combination thereof. To achieve any of these useful end results, for either free-shear or wall-bounded flows, transition from laminar to turbulent flow may have to be either delayed or advanced, flow separation may have to be either prevented or provoked and, finally, turbulence levels may have to be either suppressed or enhanced. All of those engineering goals and the corresponding flow changes intended to effect them are depicted in [Figure 33.1](#). None of them is particularly difficult if taken in isolation, but the challenge is to achieve a goal using a simple device that is inexpensive to build as well as to operate and, most importantly, has minimum side effects. For this latter hurdle, the interrelation between control goals must be elaborated, and this is what is attempted below.

Consider the technologically very important boundary layers. An external wall-bounded flow, such as that developing on the exterior surfaces of an aircraft or a submarine, can be manipulated to achieve transition delay, separation postponement, lift increase, skin-friction and pressure<sup>1</sup> drag reduction, turbulence augmentation, heat-transfer enhancement or noise suppression. These objectives are not necessarily mutually exclusive. The schematic in [Figure 33.2](#) is a partial representation of the interrelation between one control goal and another. To focus the discussion further, consider the flow developing on a lifting surface such as an aircraft wing. If the boundary layer becomes turbulent, its resistance to separation is enhanced and more lift could be obtained at increased incidence. On the other hand, the skin-friction drag for a laminar boundary layer can be as much as an order of magnitude less than that for a turbulent one. If transition is delayed, lower skin friction as well as lower flow-induced noise are achieved. However, the laminar boundary layer can support only a very small adverse pressure gradient without separation, and subsequent loss of lift and increase in form drag occur. Once the laminar boundary layer separates, a free-shear layer forms, and for moderate Reynolds numbers transition to turbulence takes place. Increased entrainment of high-speed fluid due to the turbulent mixing may result

<sup>1</sup>Pressure drag includes contributions from flow separation, displacement effects, induced drag, wave drag and, for time-dependent motion of a body through a fluid, virtual mass.

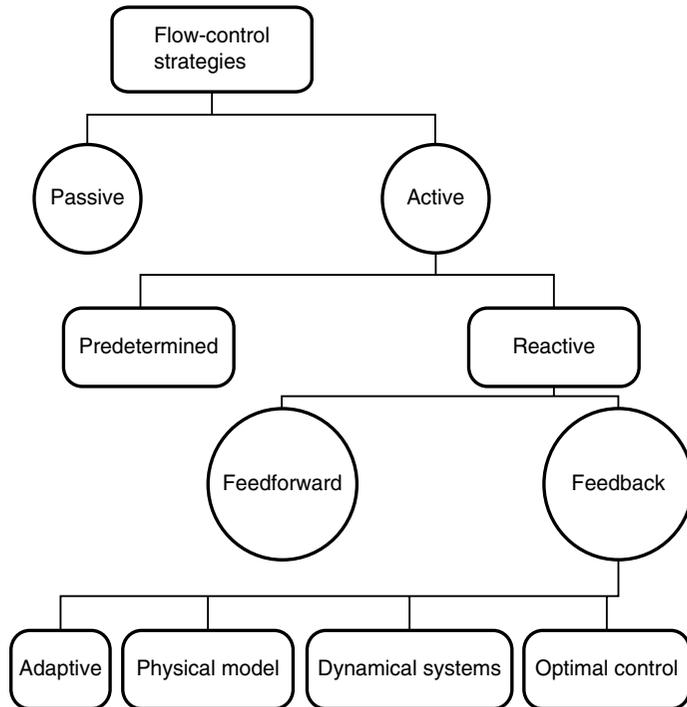

**FIGURE 33.2** Interrelations among flow control goals. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

in reattachment of the separated region and formation of a laminar separation bubble. At higher incidence, the bubble breaks down, either separating completely or forming a longer bubble. In either case, the form drag increases and the slope of the lift curve decreases. The ultimate goal of all this is to improve the performance of the airfoil by increasing the lift-to-drag ratio. However, induced drag is caused by the lift generated on a lifting surface with a finite span. Moreover, more lift is generated at higher incidence, but form drag also increases at these angles.

All of the above point to potential conflicts as one tries to achieve a particular control goal only to adversely affect another goal. An ideal method of control that is simple, inexpensive to build and operate and does not have any trade-offs does not exist, and the skilled engineer has to make continuous compromises to achieve a particular design goal.

### 33.2.2 Classification Schemes

Various classification schemes exist for flow control methods. One is to consider whether the technique is applied at the wall or away from it. Surface parameters that can influence the flow include roughness, shape, curvature, rigid-wall motion, compliance, temperature and porosity. Heating and cooling of the surface can influence the flow via the resulting viscosity and density gradients. Mass transfer can take place through a porous wall or a wall with slots. Suction and injection of primary fluid can have significant effects on the flowfield, influencing particularly the shape of the velocity profile near the wall and thus the boundary layer susceptibility to transition and separation. Different additives, such as polymers, surfactants, microbubbles, droplets, particles, dust or fibers, can also be injected through the surface in water or air wall-bounded flows. Control devices located away from the surface can also be beneficial. Large-eddy breakup devices (LEBUs; also called outer-layer devices, or OLDs), acoustic waves bombarding a shear layer from outside, additives introduced in the middle of a shear layer, manipulation of freestream

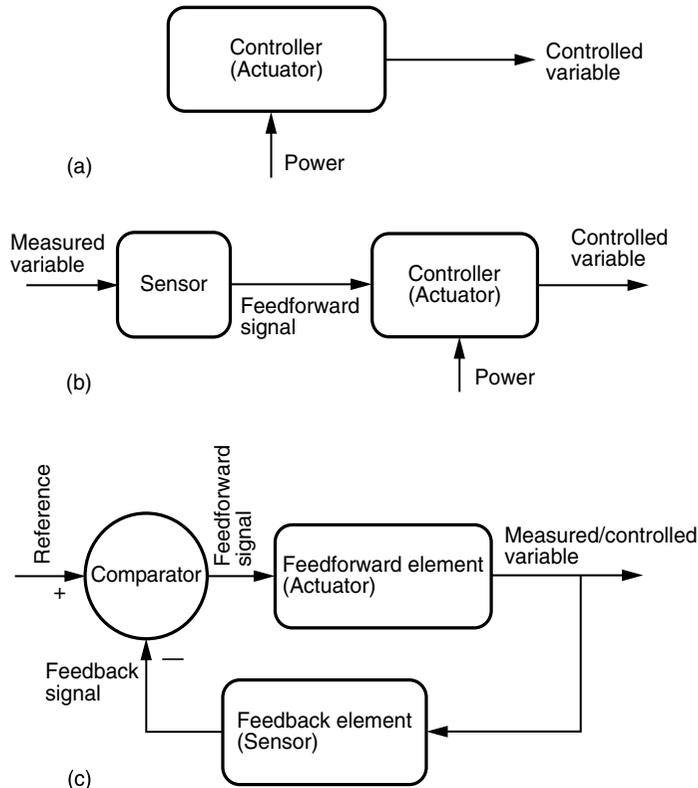

**FIGURE 33.3** Classification of flow control strategies. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

turbulence levels and spectra, gust and magneto- and electrohydrodynamic body forces are examples of flow control strategies applied away from the wall.

A second scheme for classifying flow control methods considers energy expenditure and the control loop involved. As shown in Figure 33.3, a control device can be passive, requiring no auxiliary power and no control loop, or active, requiring energy expenditure. As for the action of passive devices, some prefer to use the term *flow management* rather than *flow control* [Fiedler and Fernholz, 1990], reserving the latter terminology for dynamic processes. Active control requires a control loop and is further divided into predetermined or reactive. Predetermined control includes the application of steady or unsteady energy input without regard to the particular state of the flow. The control loop in this case is open, as shown in Figure 33.4a, and no sensors are required. Because no sensed information is being fed forward, this open control loop is not a feedforward one. This subtle point is often confused in the literature, blurring predetermined control with reactive, feedforward control. Reactive control is a special class of active control where the control input is continuously adjusted based on measurements of some kind. The control loop in this case can either be an open, feedforward one (Figure 33.4b) or a closed, feedback loop (Figure 33.4c). Classical control theory deals, for the most part, with reactive control.

The distinction between feedforward and feedback is particularly important when dealing with the control of flow structures that convect over stationary sensors and actuators. In feedforward control, the measured variable and the controlled variable differ. For example, the pressure or velocity can be sensed at an upstream location, and the resulting signal is used together with an appropriate control law to trigger an actuator which in turn influences the velocity at a downstream position. Feedback control, on the other hand, requires that the controlled variable be measured, fed back and compared with a reference input. Reactive feedback control is further classified into four categories: adaptive, physical model based, dynamical systems based and optimal control [Moin and Bewley, 1994].

Yet another classification scheme considers whether the control technique directly modifies the shape of the instantaneous/mean velocity profile or selectively influence the small dissipative eddies. An inspection

**FIGURE 33.4** Different control loops for active flow control: (a) predetermined, open-loop control; (b) reactive, feedforward, open-loop control; (c) reactive, feedback, closed-loop control. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

of the Navier–Stokes equations written at the surface [Gad-el-Hak, 2000] indicates that the spanwise and streamwise vorticity fluxes at the wall can be changed, either instantaneously or in the mean, via wall motion/compliance, suction/injection, streamwise or spanwise pressure gradient, normal viscosity gradient or a suitable streamwise or spanwise body force. These vorticity fluxes determine the fullness of the corresponding velocity profiles. For example, suction (or downward wall motion), a favorable pressure gradient or lower wall viscosity results in vorticity flux away from the wall, making the surface a source of spanwise and streamwise vorticity. The corresponding fuller velocity profiles have negative curvature at the wall and are more resistant to transition and to separation but are associated with higher skin-friction drag. Conversely, an inflectional velocity profile can be produced by injection (or upward wall motion), an adverse pressure gradient or higher wall viscosity. Such a profile is more susceptible to transition and to separation and is associated with lower, even negative, skin friction. Note that many techniques are available to effect a wall-viscosity gradient—for example, surface heating/cooling, film boiling, cavitation, sublimation, chemical reaction, wall injection of lower/higher viscosity fluid and the presence of a shear thinning/thickening additive.

Flow control devices can target certain scales of motion rather than globally changing the velocity profile. Polymers, riblets and LEBUs, for example, appear to selectively damp only the small dissipative eddies in turbulent wall-bounded flows. These eddies are responsible for the (instantaneous) inflectional profile and the secondary instability in the buffer zone, and their suppression leads to increased scales, a delay in the reduction of the (mean) velocity-profile slope and consequent thickening of the wall region. In the buffer zone, the scales of the dissipative and energy-containing eddies are roughly the same; hence, the energy-containing eddies will also be suppressed, resulting in reduced Reynolds stress production, momentum transport and skin friction.

### 33.2.3 Free-Shear and Wall-Bounded Flows

Free-shear flows, such as jets, wakes and mixing layers, are characterized by inflectional mean-velocity profiles and are therefore susceptible to inviscid instabilities. Viscosity is only a damping influence in this case, and the prime instability mechanism is vortical induction. Control goals for such flows include transition delay/advancement, mixing enhancement and noise suppression. External and internal wall-bounded flows, such as boundary layers and channel flows, can also have inflectional velocity profiles but, in the absence of an adverse pressure gradient and similar effects, are characterized by noninflectional profiles, and viscous instabilities are then to be considered. This kind of viscosity-dominated, wall-bounded flow is intrinsically stable and therefore is generally more difficult to control. Free-shear flows and separated boundary layers, on the other hand, are intrinsically unstable and lend themselves more readily to manipulation.

Free-shear flows originate from some kind of surface upstream, be it a nozzle, a moving body or a splitter plate, and flow control devices can therefore be placed on the corresponding walls, albeit far from the fully developed regions. Examples of such control include changing the geometry of a jet exit from circular to elliptic [Gutmark and Ho, 1986], using periodic suction/injection in the lee side of a blunt body to affect its wake [Williams and Amato, 1989] and vibrating the splitter plate of a mixing layer [Fiedler et al., 1988]. These and other techniques are extensively reviewed by Fiedler and Fernholz (1990), who offer a comprehensive list of appropriate references, and more recently by Gutmark et al. (1995), Viswanath (1995) and Gutmark and Grinstein (1999).

### 33.2.4 Regimes of Reynolds and Mach Numbers

The Reynolds number ( $Re$ ) is the ratio of inertial to viscous forces and, absent centrifugal, gravitational, electromagnetic and other unusual effects,  $Re$  determines whether the flow is laminar or turbulent. It is defined as  $Re \equiv v_o L / \nu$ , where  $v_o$  and  $L$  are, respectively, suitable velocity and length scales, and  $\nu$  is the kinematic viscosity. For low-Reynolds-number flows, instabilities are suppressed by viscous effects and the flow is laminar, as can be found in systems with large fluid viscosity, small length scale or small velocity. The large-scale motion of the highly viscous volcanic molten rock and air/water flow in capillaries and microdevices are examples of laminar flows. Turbulent flows seem to be the rule rather than the exception, occurring in or around most important fluid systems such as airborne and waterborne vessels, gas and oil pipelines, material processing plants and the human cardiovascular and pulmonary systems.

Because of the nature of their instabilities, free-shear flows undergo transition at extremely low Reynolds numbers as compared to wall-bounded flows. Many techniques are available to delay laminar-to-turbulence transition for both kinds of flows, but none would do that to indefinitely high Reynolds numbers. Therefore, for Reynolds numbers beyond a reasonable limit, one should not attempt to prevent transition but rather deal with the ensuing turbulence. Of course early transition to turbulence can be advantageous in some circumstances—for example, to achieve separation delay, enhanced mixing or augmented heat transfer. The task of advancing transition is generally simpler than trying to delay it. Numerous books and articles specifically address the control of laminar-to-turbulence transition [e.g., Gad-el-Hak, 2000, and references therein]. For now, we briefly discuss transition control for various regimes of Reynolds and Mach numbers.

Three Reynolds number regimes can be identified for the purpose of reducing skin friction in wall-bounded flows. First, if the flow is laminar, typically at Reynolds numbers based on a distance from the leading edge  $< 10^6$ , then methods of reducing the laminar shear stress are sought. These are usually velocity-profile modifiers—for example, adverse-pressure gradient, injection, cooling (in water) and heating (in air)—that reduce the fullness of the profile at the increased risk of premature transition and separation. Second, in the range of Reynolds numbers from  $1 \times 10^6$  to  $4 \times 10^7$ , active and passive methods to delay transition as far back as possible are sought. These techniques can result in substantial savings and are broadly classified into two categories: stability modifiers and wave cancellation. The skin-friction coefficient in the laminar flat plate can be as much as an order of magnitude less than that in the turbulent case. Note, however, that all the stability modifiers, such as a favorable pressure gradient, suction or

heating (in liquids), result in an increase in the skin friction over the unmodified Blasius layer. The object is, of course, to keep this penalty below the potential saving; i.e., the net drag will be above that of the flat-plate laminar boundary layer but presumably well below the viscous drag in the flat-plate turbulent flow. Third, for  $Re > 4 \times 10^7$ , transition to turbulence cannot be delayed with any known practical method without incurring a penalty that exceeds the saving. The task is then to reduce the skin-friction coefficient in a turbulent boundary layer. Relaminarization [Narasimha and Sreenivasan, 1979] is an option, although achieving a net saving here is problematic at present.

The Mach number ( $Ma$ ) is the ratio of a characteristic flow velocity to the local speed of sound,  $Ma \equiv v_o/a_o$ . It determines whether the flow is incompressible ( $Ma < 0.3$ ) or compressible ( $Ma > 0.3$ ). The latter regime is further divided into subsonic ( $Ma < 1$ ), transonic ( $0.8 < Ma < 1.2$ ), supersonic ( $Ma > 1$ ) and hypersonic ( $Ma > 5$ ). Each of those flow regimes lends itself to different optimum methods of control to achieve a given goal. Take laminar-to-turbulence transition control as an illustration [Bushnell, 1994]. During transition, the field of initial disturbances is internalized via a process termed *receptivity*, and the disturbances are subsequently amplified by various linear and nonlinear mechanisms. Assuming that bypass mechanisms, such as roughness or high levels of freestream turbulence, are identified and circumvented, delaying transition then is reduced to controlling the variety of possible linear modes: Tollmien–Schlichting modes, Mack modes, cross-flow instabilities and Görtler instabilities. Tollmien–Schlichting instabilities dominate the transition process for two-dimensional boundary layers having  $Ma < 4$  and are damped by increasing the Mach number, by wall cooling (in gases) and by the presence of a favorable pressure gradient. Contrast this to the Mack modes that dominate for two-dimensional hypersonic flows. Mack instabilities are also damped by increasing the Mach number and by the presence of a favorable pressure gradient but are destabilized by wall cooling. Cross-flow and Görtler instabilities are caused by, respectively, the development of inflectional cross-flow velocity profile and the presence of concave streamline curvature. Both of these instabilities are potentially harmful across the speed range but are largely unaffected by Mach number and wall cooling. The cross-flow modes are enhanced by a favorable pressure gradient, while the Görtler instabilities are insensitive. Suction suppresses, to different degrees, all the linear modes discussed here.

### 33.2.5 Convective and Absolute Instabilities

In addition to grouping the different kinds of hydrodynamic instabilities as inviscid or viscous, one could also classify them as convective or absolute based on the linear response of the system to an initial localized impulse [Huerre and Monkewitz, 1990]. A flow is convectively unstable if, at any fixed location, this response eventually decays in time (in other words, if all growing disturbances convect downstream from their source). Convective instabilities occur when there is no mechanism for upstream disturbance propagation, as, for example, in the case of rigid-wall boundary layers. If the disturbance is removed, then the perturbation propagates downstream and the flow relaxes to an undisturbed state. Suppression of convective instabilities is particularly effective when applied near the point where the perturbations originate.

If any of the growing disturbances has zero group velocity, the flow is absolutely unstable. This means that the local system response to an initial impulse grows in time. Absolute instabilities occur when a mechanism exists for upstream disturbance propagation, as, for example, separated flow over a backward-facing step where the flow recirculation provides such a mechanism. In this case, some of the growing disturbances can travel back upstream and continually disrupt the flow even after the initial disturbance is neutralized. Therefore, absolute instabilities are generally more dangerous and more difficult to control; nothing short of complete suppression will work. In some flows (for example, two-dimensional blunt-body wakes), certain regions are absolutely unstable while others are convectively unstable. The upstream addition of acoustic or electric feedback can change a convectively unstable flow to an absolutely unstable one, and self-excited flow oscillations can thus be generated. In any case, identifying the character of flow instability facilitates its effective control (i.e., suppressing or amplifying the perturbation as needed).

### 33.3 The Taming of the Shrew

---

For the rest of this chapter, we focus on reactive flow control specifically targeting the coherent structures in turbulent flows. By comparison with laminar flow control or separation prevention, the control of turbulent flow remains a very challenging problem. Flow instabilities magnify quickly near critical flow regimes; therefore, delaying transition or separation is a relatively easier task. In contrast, classical control strategies are often ineffective for fully turbulent flows. Newer ideas for turbulent flow control to achieve, for example, skin-friction drag reduction focus on the direct onslaught on coherent structures. Spurred by the recent developments in chaos control, microfabrication and soft computing tools, reactive control of turbulent flows, where sensors detect oncoming coherent structures and actuators attempt to favorably modulate those quasi-periodic events, is now in the realm of the possible for future practical devices.

Considering the extreme complexity of the turbulence problem in general and the unattainability of first-principles analytical solutions in particular, it is not surprising that controlling a turbulent flow remains a challenging task, mired in empiricism and unfulfilled promises and aspirations. Brute force suppression, or taming, of turbulence via active, energy-consuming control strategies is always possible, but the penalty for doing so often exceeds any potential benefits. The artifice to achieve a desired effect with minimum energy expenditure. This is, of course, easier said than done. Indeed, suppressing turbulence is as arduous as *The Taming of the Shrew*.

### 33.4 Control of Turbulence

---

Numerous methods of flow control have already been successfully implemented in practical engineering devices. Delaying laminar-to-turbulence transition to reasonable Reynolds numbers and preventing separation can readily be accomplished using a myriad of passive and predetermined active control strategies. Such classical techniques have been reviewed by, among others, Bushnell (1983; 1994), Wilkinson et al. (1988), Bushnell and McGinley (1989), Gad-el-Hak (1989; 2000), Bushnell and Hefner (1990), Fiedler and Fernholz (1990), Gad-el-Hak and Bushnell (1991a; 1991b), Barnwell and Hussaini (1992), Viswanath (1995) and Joslin et al. (1996). Yet, very few of the classical strategies are effective in controlling free-shear or wall-bounded turbulent flows. Serious limitations exist for some familiar control techniques when applied to certain turbulent flow situations. For example, in attempting to reduce the skin-friction drag of a body having a turbulent boundary layer using global suction, the *penalty* associated with the control device often exceeds the *savings* derived from its use. What is needed is a way to reduce this penalty to achieve a more efficient control.

Flow control is most effective when applied near the transition or separation points, in other words, near the critical flow regimes where flow instabilities magnify quickly. Therefore, delaying or advancing laminar-to-turbulence transition and preventing or provoking separation are relatively easier tasks to accomplish. Reducing the skin-friction drag in a nonseparating turbulent boundary layer, where the mean flow is quite stable, is a more challenging problem. Yet, even a modest reduction in the fluid resistance to the motion of, for example, the worldwide commercial airplane fleet is translated into fuel savings estimated to be in the billions of dollars. Newer ideas for turbulent flow control focus on the direct onslaught on coherent structures via reactive control strategies that utilize large arrays of microsensors and microactuators.

The primary objective of this chapter is to advance possible scenarios by which viable control strategies of turbulent flows might be realized. As will be argued in the following sections, future systems for control of turbulent flows, in general, and turbulent boundary layers, in particular, could greatly benefit from the merging of the science of chaos control, the technology of microfabrication and the newest computational tools collectively termed *soft computing*. Control of chaotic, nonlinear dynamical systems has been demonstrated theoretically as well as experimentally, even for multi-degree-of-freedom systems. Microfabrication is an emerging technology that has the potential for producing inexpensive, programmable sensor/actuator chips that have dimensions on the order of a few microns. Soft computing tools include neural networks, fuzzy logic and genetic algorithms and are now more advanced as well as more

widely used as compared to just few years ago. These tools could be very useful in constructing effective adaptive controllers.

Such futuristic systems are envisaged as consisting of a large number of intelligent, interactive, micro-fabricated wall sensors and actuators arranged in a checkerboard pattern and targeted toward specific organized structures that occur quasi-randomly within a turbulent flow. Sensors detect oncoming coherent structures, and adaptive controllers process the sensor information and provide control signals to the actuators, which in turn attempt to favorably modulate the quasi-periodic events. A finite number of wall sensors perceive only partial information about the entire flowfield above. However, a low-dimensional dynamical model of the near-wall region used in a Kalman filter can make the most of the partial information from the sensors. Conceptually, all of this is not too difficult, but in practice the complexity of such a control system is daunting and much research and development work still remain.

The following discussion is organized into ten sections. A particular example of a classical control system—suction—is described in the following section. This will serve as a prelude to introducing the selective suction concept. The different hierarchy of coherent structures that dominate a turbulent boundary layer and that constitute the primary target for direct onslaught are then briefly recalled. The characteristic lengths and sensor requirements of turbulent flows are then discussed in the two subsequent sections. This is followed by a description of reactive flow control and the selective suction concept. The number, size, frequency and energy consumption of the sensor/actuator units required to tame the turbulence on a full-scale air or water vehicle are estimated in that same section. This is followed by an introduction to the topic of magnetohydrodynamics and a reactive flow control scheme using electromagnetic body forces. The emerging areas of chaos control and soft computing, particularly as they relate to reactive control strategies, are then briefly discussed in the two subsequent sections. This is followed by a discussion of the specific use of microelectromechanical systems (MEMS) devices for reactive flow control. Finally, brief concluding remarks are given in the last section.

## 33.5 Suction

---

To set the stage for introducing the concept of targeted or selective control, I shall first discuss in this section global control as applied to wall-bounded flows. A viscous fluid that is initially irrotational will acquire vorticity when an obstacle is passed through the fluid. This vorticity controls the nature and structure of the boundary-layer flow in the vicinity of the obstacle. For an incompressible, wall-bounded flow, the flux of spanwise or streamwise vorticity at the wall (and, hence, whether the surface is a sink or a source of vorticity) is affected by the wall motion (e.g., in the case of a compliant coating), transpiration (suction or injection), streamwise or spanwise pressure gradient, wall curvature, normal viscosity gradient near the wall (caused by, for example, heating or cooling of the wall or introduction of a shear-thinning/shear-thickening additive into the boundary layer) and body forces (such as electromagnetic ones in a conducting fluid). These alterations separately or collectively control the shape of the instantaneous as well as the mean velocity profiles, which in turn determine the skin friction at the wall, the boundary layer ability to resist transition and separation and the intensity of turbulence and its structure.

For illustration purposes, I shall focus on global wall suction as a generic control tool. The arguments presented here and in subsequent sections are equally valid for other global control techniques, such as geometry modification (body shaping), surface heating or cooling, electromagnetic control, etc. Transpiration provides a good example of a single control technique that is used to achieve a variety of goals. Suction leads to a fuller velocity profile (vorticity flux away from the wall) and can, therefore, be employed to delay laminar-to-turbulence transition, postpone separation, achieve an asymptotic turbulent boundary layer (i.e., one having constant momentum thickness) or relaminarize an already turbulent flow. Unfortunately, global suction cannot be used to reduce the skin-friction drag in a turbulent boundary layer. The amount of suction required to inhibit boundary-layer growth is too large to effect a net drag reduction. This is a good illustration of a situation where the penalty associated with a control device might exceed the saving derived from its use.

Small amounts of fluid withdrawn from the near-wall region of a boundary layer change the curvature of the velocity profile at the wall and can dramatically alter the stability characteristics of the flow. Concurrently, suction inhibits the growth of the boundary layer, so that the critical Reynolds number based on thickness may never be reached. Although laminar flow can be maintained to extremely high Reynolds numbers provided that enough fluid is sucked away, the goal is to accomplish transition delay with the minimum suction flow rate. This will reduce not only the power necessary to drive the suction pump, but also the momentum loss due to the additional freestream fluid entrained into the boundary layer as a result of withdrawing fluid from the wall. That momentum loss is, of course, manifested as an increase in the skin-friction drag.

The case of uniform suction from a flat plate at zero incidence is an exact solution of the Navier–Stokes equation. The asymptotic velocity profile in the viscous region is exponential and has a negative curvature at the wall. The displacement thickness has the constant value  $\delta^* = \nu/|v_w|$ , where  $\nu$  is the kinematic viscosity, and  $|v_w|$  is the absolute value of the normal velocity at the wall. In this case, the familiar von Kármán integral equation reads  $C_f = 2C_q$ . Bussmann and Münz (1942) computed the critical Reynolds number for the asymptotic suction profile to be  $Re_{\delta^*} \equiv U_\infty \delta^*/\nu = 70,000$ . From the value of  $\delta^*$  given above, the flow is stable to all small disturbances if  $C_q \equiv |v_w|/U_\infty > 1.4 \times 10^{-5}$ . The amplification rate of unstable disturbances for the asymptotic profile is an order of magnitude less than that for the Blasius boundary layer [Pretsch, 1942]. This treatment ignores the development distance from the leading edge needed to reach the asymptotic state. When this is included into the computation, a higher  $C_q = 1.18 \times 10^{-4}$  is required to ensure stability [Iglisch, 1944; Ulrich, 1944].

In a turbulent wall-bounded flow, the results of Eléna (1975; 1984) and Antonia et al. (1988) indicate that suction causes an appreciable stabilization of the low-speed streaks in the near-wall region. The maximum turbulence level at  $y^+ \approx 13$  drops from 15 to 12% as  $C_q$  varies from 0 to 0.003. More dramatically, the tangential Reynolds stress near the wall drops by a factor of 2 for the same variation of  $C_q$ . The dissipation length scale near the wall increases by 40% and the integral length scale by 25% with the suction.

The suction rate necessary for establishing an asymptotic turbulent boundary layer independent of streamwise coordinate (i.e.,  $d\delta_0/dx = 0$ ) is much lower than the rate required for relaminarization ( $C_q \approx 0.01$ ) but is still not low enough to yield a net drag reduction. For a Reynolds number based on distance from the leading edge,  $Re_x = \mathcal{O}[10^6]$ , Favre et al. (1966), Rotta (1970) and Verollet et al. (1972), among others, report an asymptotic suction coefficient of  $C_q \approx 0.003$ . For a zero-pressure-gradient boundary layer on a flat plate, the corresponding skin-friction coefficient is  $C_f = 2C_q = 0.006$ , indicating higher skin friction than if no suction was applied. To achieve a net skin-friction reduction with suction, the process must be further optimized. One way to accomplish this is to target the suction toward particular organized structures within the boundary layer and not to use it globally as in classical control schemes. This point will be revisited later, but the coherent structures to be targeted and the length scales to be expected are first detailed in the following two sections.

## 33.6 Coherent Structures

The discussion above indicates that achieving a particular control goal is always possible. The challenge is reaching that goal with a penalty that can be tolerated. Suction, for example, would lead to a net drag reduction, if only we could reduce the suction coefficient necessary for establishing an asymptotic turbulent boundary layer to below one half of the unperturbed skin-friction coefficient. A more efficient way of using suction, or any other global control method, is to target particular coherent structures within the turbulent boundary layer. Before discussing this selective control idea, I shall briefly describe in this and the following section the different hierarchy of organized structures in a wall-bounded flow and the expected scales of motion.

The classical view that turbulence is essentially a stochastic phenomenon having a randomly fluctuating velocity field superimposed on a well-defined mean has been changed in the last few decades by the realization that the transport properties of all turbulent shear flows are dominated by quasi-periodic, large-scale vortex motions [Laufer, 1975; Cantwell, 1981; Fiedler, 1988; Robinson, 1991]. Despite the

extensive research work in this area, no generally accepted definition of what is meant by coherent motion has emerged. In physics, coherence stands for well-defined phase relationship. For our purpose, we adopt the rather restrictive definition given by Hussain (1986): “A coherent structure is a connected turbulent fluid mass with instantaneously phase-correlated vorticity over its spatial extent.” In other words, underlying the random, three-dimensional vorticity that characterizes turbulence, there is a component of large-scale vorticity which is instantaneously coherent over the spatial extent of an organized structure. The apparent randomness of the flowfield is, for the most part, due to the random size and strength of the different types of organized structures comprising that field.

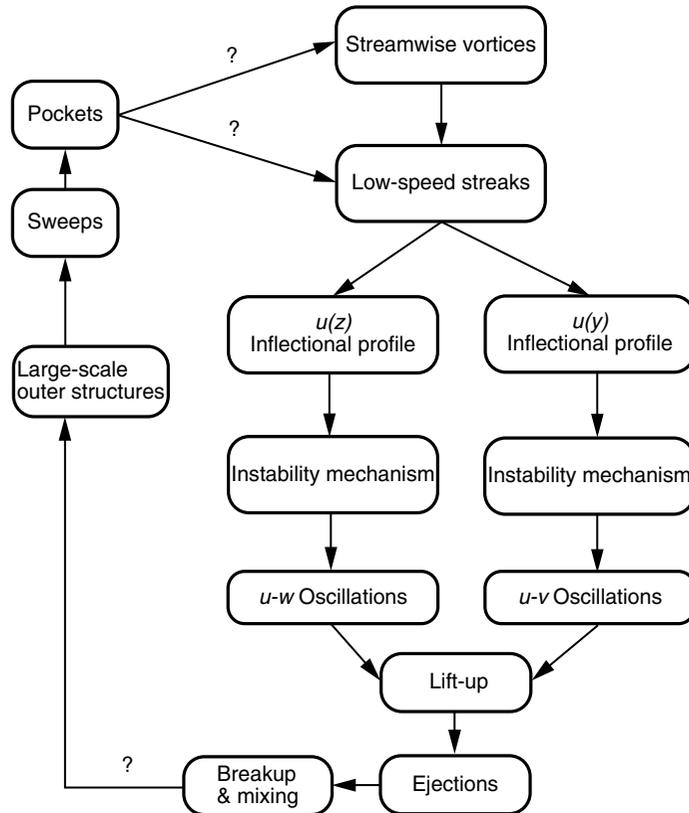

In a wall-bounded flow, a multiplicity of coherent structures have been identified mostly through flow visualization experiments, although some important early discoveries have been made using correlation measurements [Townsend, 1961; 1970; Bakewell and Lumley, 1967]. Although the literature on this topic is vast, no research-community-wide consensus has been reached, particularly on the issues of the origin of and interaction between the different structures, regeneration mechanisms and Reynolds number effects. What follow are somewhat biased remarks addressing those issues, gathered mostly via low-Reynolds-number experiments. The interested reader is referred to the book edited by Panton (1997) and the large number of review articles available [e.g., Kovaszny, 1970; Laufer, 1975; Willmarth, 1975a; 1975b; Saffman, 1978; Cantwell, 1981; Fiedler, 1986; 1988; Blackwelder, 1988; 1998; Robinson, 1991; Delville et al., 1998]. The paper by Robinson (1991) in particular summarizes many of the different, sometimes contradictory, conceptual models offered thus far by different research groups. Those models are aimed ultimately at explaining how the turbulence maintains itself and range from the speculative to the rigorous, but none, unfortunately, is self-contained and complete. Furthermore, the structure research dwells largely on the kinematics of organized motion and little attention is given to the dynamics of the regeneration process.

In a boundary layer, the turbulence production process is dominated by three kinds of quasi-periodic—or, depending on one’s viewpoint, quasi-random—eddies: (1) the large outer structures, (2) the intermediate Falco eddies, and (3) the near-wall events. The large, three-dimensional structures scale with the boundary-layer thickness,  $\delta$ , and extend across the entire layer [Kovaszny et al., 1970; Blackwelder and Kovaszny, 1972]. These eddies control the dynamics of the boundary layer in the outer region, such as entrainment, turbulence production, etc. They appear randomly in space and time, and seem to be, at least for moderate Reynolds numbers, the residue of the transitional Emmons spots [Zilberman et al., 1977; Gad-el-Hak et al., 1981; Riley and Gad-el-Hak, 1985].

The Falco eddies are also highly coherent and three dimensional. Falco (1974; 1977) named them typical eddies because they appear in wakes, jets, Emmons spots, grid-generated turbulence and boundary layers in zero, favorable and adverse pressure gradients. They have an intermediate scale of about  $100 \nu/u_\tau$  (100 wall units;  $u_\tau$  is the friction velocity, and  $\nu/u_\tau$  is the viscous length scale). The Falco eddies appear to be an important link between the large structures and the near-wall events.

The third kind of eddies exist in the near-wall region ( $0 < y < 100 \nu/u_\tau$ ), where the Reynolds stress is produced in a very intermittent fashion. Half of the total production of turbulence kinetic energy ( $-\overline{uv} \partial \overline{U} / \partial y$ ) takes place near the wall in the first 5% of the boundary layer at typical laboratory Reynolds numbers (a smaller fraction at higher Reynolds numbers), and the dominant sequence of eddy motions found there is termed the *bursting phenomenon*. This dynamically significant process, identified during the 1960s by researchers at Stanford University [Kline and Runstadler, 1959; Runstadler et al., 1963; Kline et al., 1967; Kim et al., 1971; Offen and Kline, 1974; 1975], was reviewed by Willmarth (1975a), Blackwelder (1978), Robinson (1991) and, most recently, Panton (1997) and Blackwelder (1998).

To focus the discussion on the bursting process and its possible relationships to other organized motions within the boundary layer, we refer to the schematic in [Figure 33.5](#). Qualitatively, the process, according to at least one school of thought, begins with elongated, counter-rotating, streamwise vortices having diameters of approximately 40 wall units or  $40 \nu/u_\tau$ . The estimate for the diameter of the vortex is obtained from the conditionally averaged spanwise velocity profiles reported by Blackwelder and Eckelmann (1979). There is a distinction, however, between vorticity distribution and a vortex [Saffman and Baker, 1979; Robinson et al., 1989; Robinson, 1991], and the visualization results of Smith and Schwartz (1983) may indicate a much smaller diameter. In any case, referring to [Figure 33.6](#), the counter-rotating

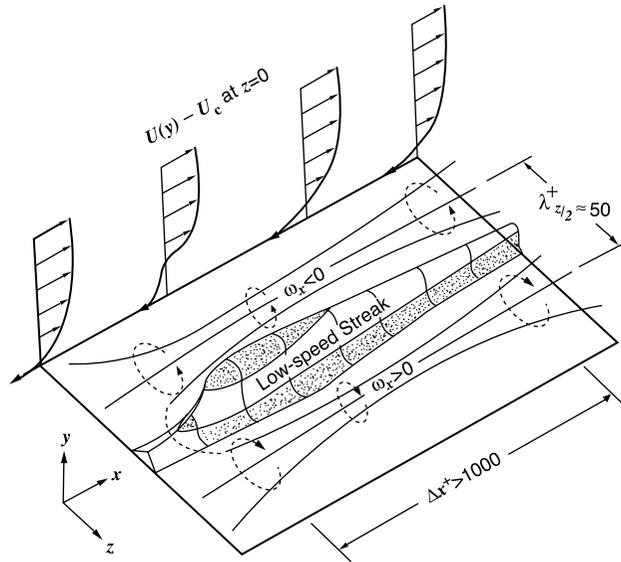

**FIGURE 33.5** Proposed sequence of the bursting process. The arrows indicate the sequential events, and the “?” indicates relationships with less supporting evidence. (Adapted from Blackwelder, 1998; from Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

vortices exist in a strong shear and induce low- and high-speed regions between them. Those low-speed streaks were first visualized by Francis Hama at the University of Maryland [see Corrsin, 1957], although Hama’s contribution is frequently overlooked in favor of the subsequent and more thorough studies conducted at Stanford University and cited above. The vortices and the accompanying eddy structures occur randomly in space and time. However, their appearance is sufficiently regular that an average spanwise wavelength of approximately  $80$  to  $100 \nu/u_\tau$  has been identified by Kline et al. (1967) and others.

It might be instructive at this point to emphasize that the distribution of streak spacing is very broad. The standard of deviation is 30 to 40% of the more commonly quoted mean spacing between low-speed streaks of 100 wall units. Both the mean and standard deviation are roughly independent of Reynolds number in the rather limited range of reported measurements ( $Re_\theta = 300$ – $6500$ ; see Smith and Metzler, 1983; Kim et al., 1987). Butler and Farrell (1993) have shown that the mean streak spacing of  $100 \nu/u_\tau$  is consistent with the notion that this is an optimal configuration for extracting “the most energy over an appropriate eddy turnover time.” In their work, the streak spacing remains 100 wall units at Reynolds numbers based on friction velocity and channel half-width of  $a^+ = 180$ – $360$ .

Kim et al. (1971) observed that the low-speed regions grow downstream, lift up and develop (instantaneous) inflectional  $U(y)$  profiles.<sup>2</sup> At approximately the same time, the interface between the low- and high-speed fluid begins to oscillate, apparently signaling the onset of a secondary instability. The low-speed

<sup>2</sup> According to Swearingen and Blackwelder (1984), inflectional  $U(z)$  profiles are just as likely to be found in the near-wall region and can also be the cause of subsequent bursting events (see Figure 33.5).

**FIGURE 33.6** Model of near-wall structure in turbulent wall-bounded flows. (Adapted from Blackwelder, 1978; from Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

region lifts up away from the wall as the oscillation amplitude increases, and then the flow rapidly breaks up into a completely chaotic motion. The streak oscillations commence at  $y^+ \approx 10$ , and the abrupt breakup takes place in the buffer layer, although the ejected fluid reaches all the way to the logarithmic region. Because the breakup process occurs on a very short time scale, Kline et al. (1967) called it a burst.

Virtually all of the net production of turbulence kinetic energy in the near-wall region occurs during these bursts. Corino and Brodkey (1969) showed that the low-speed regions are quite narrow (i.e.,  $z = 20 \nu/u_\tau$ ) and may also have significant shear in the spanwise direction. They also indicated that the ejection phase of the bursting process is followed by a large-scale motion of upstream fluid that emanates from the outer region and cleanses (sweeps) the wall region of the previously ejected fluid. The sweep phase is, of course, required by the continuity equation and appears to scale with the outer-flow variables. The sweep event seems to stabilize the bursting site, in effect preparing it for a new cycle.

Considerably more has been learned about the bursting process during the last two decades. For example, Falco (1980; 1983; 1991) has shown that when a typical eddy, which may be formed in part by ejected wall-layer fluid, moves over the wall it induces a high  $uv$  sweep (positive  $u$  and negative  $v$ ). The wall region is continuously bombarded by pockets of high-speed fluid originating in the logarithmic and possibly the outer layers of the flow. These pockets appear to scale—at least in the limited Reynolds number range where they have been observed,  $Re_\theta = \mathcal{O}[1000]$ —with wall variables and tend to promote and/or enhance the inflectional velocity profiles by increasing the instantaneous shear leading to a more rapidly growing instability. The relation between the pockets and the sweep events is not clear, but it seems that the former forms the highly irregular interface between the latter and the wall-region fluid. More recently, Klewicki et al. (1994) conducted four-element, hot-wire probe measurements in a low-Reynolds-number canonical boundary layer to clarify the roles of velocity–spanwise vorticity field interactions regarding the near-wall turbulent stress production and transport.

Other significant experiments were conducted by Tiederman and his students [Donohue et al., 1972; Reischman and Tiederman, 1975; Oldaker and Tiederman, 1977; Tiederman et al., 1985], Smith and his colleagues [Smith and Metzler, 1982; 1983; Smith and Schwartz, 1983] and the present author and his collaborators. The first group conducted extensive studies of the near-wall region, particularly the viscous

sublayer, of channels with Newtonian as well as drag-reducing non-Newtonian fluids. Smith's group, using a unique, two-camera, high-speed video system, was the first to indicate a symbiotic relationship between the occurrence of low-speed streaks and the formation of vortex loops in the near-wall region. Gad-el-Hak and Hussain (1986) and Gad-el-Hak and Blackwelder (1987a) have introduced methods by which the bursting events and large-eddy structures are artificially generated in a boundary layer. Their experiments greatly facilitate the study of the uniquely controlled simulated coherent structures via phase-locked measurements.

Blackwelder and Haritonidis (1983) have shown convincingly that the frequency of occurrence of the bursting events scales with the viscous parameters consistent with the usual boundary-layer scaling arguments. An excellent review of the dynamics of turbulent boundary layers has been provided by Sreenivasan (1989). More information about coherent structures in high-Reynolds-number boundary layers is given by Gad-el-Hak and Bandyopadhyay (1994). The book edited by Panton (1997) emphasizes the self-sustaining mechanisms of wall turbulence.

## 33.7 Scales

---

In this and the following section, we develop the equations needed to compute the characteristic lengths and sensor requirements of turbulent flows, in general, and wall-bounded flows, in particular. Turbulence is a high-Reynolds-number phenomenon which is characterized by the existence of numerous length and time scales [Tennekes and Lumley, 1972]. The spatial extension of the length scales is bounded from above by the dimensions of the flowfield and from below by the diffusive and dissipative action of the molecular viscosity.

If we limit our interest to shear flows, which are basically characterized by two large length scales, one in the streamwise direction (the convective or longitudinal length scale) and the other perpendicular to the flow direction (the diffusive or lateral length scale), we obtain a more well-defined problem. Moreover, at sufficiently high Reynolds numbers the boundary-layer approximation applies and it is assumed that there is a wide separation between the lateral and longitudinal length scales. This leads to some attractive simplifications in the equations of motion—for instance, the elliptical Navier–Stokes equations are transferred to the parabolic boundary-layer equations [e.g., Hinze, 1975]. So, in this approximation, the lateral scale is approximately equal to the extension of the flow perpendicular to the flow direction (e.g., the boundary-layer thickness), and the largest eddies typically have this spatial extension. These eddies are most energetic and play a crucial role both in the transport of momentum and contaminants. A constant energy supply is needed to maintain the turbulence, and this energy is extracted from the mean flow into the largest most energetic eddies. The lateral length scale is also the relevant scale for analyzing this energy transfer. However, there is an energy destruction in the flow due to the action of the viscous forces (the dissipation), and for the analysis of this process other, smaller length scales are needed.

As the eddy size decreases, viscosity becomes a more significant parameter, as one property of viscosity is its effectiveness in smoothing out velocity gradients. The viscous and the nonlinear terms in the momentum equation counteract each other in the generation of small-scale fluctuations. While the inertial terms try to produce smaller and smaller eddies, the viscous terms check this process and prevent the generation of infinitely small scales by dissipating the small-scale energy into heat. In the early 1940s, the universal equilibrium theory was developed by Kolmogorov (1941a; 1941b). One cornerstone of this theory is that the small-scale motions are statistically independent of the relatively slower large-scale turbulence. An implication of this is that the turbulence at the small scales depends only on two parameters—namely, the rate at which energy is supplied by the large-scale motion and the kinematic viscosity. In addition, it is assumed in the equilibrium theory that the rate of energy supply to the turbulence should be equal to the rate of dissipation. Hence, in the analysis of turbulence at small scales, the dissipation rate per unit mass  $\epsilon$  is a relevant parameter together with the kinematic viscosity  $\nu$ . Kolmogorov (1941a) used simple dimensional arguments to derive length, time and velocity scales

relevant to the small-scale motion given, respectively, by:

$$\eta = \left( \frac{\nu^3}{\varepsilon} \right)^{\frac{1}{4}} \quad (33.1)$$

$$\tau = \left( \frac{\nu}{\varepsilon} \right)^{\frac{1}{2}} \quad (33.2)$$

$$\nu = (\nu \varepsilon)^{\frac{1}{4}} \quad (33.3)$$

These scales are accordingly called the Kolmogorov microscales, or sometimes the inner scales of the flow. As they are obtained through a physical argument, these scales are the smallest scales that can exist in a turbulent flow and they are relevant for both free-shear and wall-bounded flows.

In boundary layers, the shear-layer thickness provides a measure of the largest eddies in the flow. The smallest scale in wall-bounded flows is the viscous wall unit, which will be shown below to be of the same order as the Kolmogorov length scale. Viscous forces dominate over inertia in the near-wall region, and the characteristic scales there are obtained from the magnitude of the mean vorticity in the region and its viscous diffusion away from the wall. Thus, the viscous time scale,  $t_v$ , is given by the inverse of the mean wall vorticity:

$$t_v = \left[ \left. \frac{\partial \bar{U}}{\partial y} \right|_w \right]^{-1} \quad (33.4)$$

where  $\bar{U}$  is the mean streamwise velocity. The viscous length-scale,  $\ell_v$ , is determined by the characteristic distance by which the (spanwise) vorticity is diffused from the wall, and is thus given by:

$$\ell_v = \sqrt{\nu t_v} = \frac{\sqrt{\nu}}{\sqrt{\left. \frac{\partial \bar{U}}{\partial y} \right|_w}} \quad (33.5)$$

where  $\nu$  is the kinematic viscosity. The wall velocity scale (so-called friction velocity,  $u_\tau$ ) follows directly from the above time and length scales:

$$u_\tau = \frac{\ell_v}{t_v} = \sqrt{\nu \left. \frac{\partial \bar{U}}{\partial y} \right|_w} = \sqrt{\frac{\tau_w}{\rho}} \quad (33.6)$$

where  $\tau_w$  is the mean shear stress at the wall, and  $\rho$  is the fluid density. A wall unit implies scaling with the viscous scales, and the usual  $(\dots)^+$  notation is used; for example,  $y^+ = y/\ell_v = yu_\tau/\nu$ . In the wall region, the characteristic length for the large eddies is  $y$  itself, while the Kolmogorov scale is related to the distance from the wall  $y$  as follows:

$$\eta^+ \equiv \frac{\eta u_\tau}{\nu} \approx (\kappa y^+)^{\frac{1}{4}} \quad (33.7)$$

where  $\kappa$  is the von Kármán constant ( $\approx 0.41$ ). As  $y^+$  changes in the range of 1 to 5 (the extent of the viscous sublayer),  $\eta$  changes from 0.8 to 1.2 wall units.

We now have access to scales for the largest and smallest eddies of a turbulent flow. To continue our analysis of the cascade energy process, it is necessary to find a connection between these diverse scales.

One way of obtaining such a relation is to use the fact that at equilibrium the amount of energy dissipating at high wavenumbers must equal the amount of energy drained from the mean flow into the energetic large-scale eddies at low wavenumbers. In the inertial region of the turbulence kinetic energy spectrum, the flow is almost independent of viscosity, and because the same amount of energy dissipated at the high wavenumbers must pass this ‘inviscid’ region an inviscid relation for the total dissipation may be obtained by the following argument. The amount of kinetic energy per unit mass of an eddy with a wavenumber in the inertial sublayer is proportional to the square of a characteristic velocity for such an eddy,  $u^2$ . The rate of transfer of energy is assumed to be proportional to the reciprocal of one eddy turnover time,  $u/\ell$ , where  $\ell$  is a characteristic length of the inertial sublayer. Hence, the rate of energy that is supplied to the small-scale eddies via this particular wavenumber is of order of  $u^3/\ell$ , and this amount of energy must be equal to the energy dissipated at the highest wavenumber, expressed as:

$$\varepsilon \approx \frac{u^3}{\ell} \quad (33.8)$$

Note that this is an inviscid estimate of the dissipation, as it is based on large-scale dynamics and does not either involve or contain viscosity. More comprehensive discussion of this issue can be found in Taylor (1935) and Tennekes and Lumley (1972). From an experimental perspective, this is a very important expression, as it offers one way of estimating the Kolmogorov microscales from quantities measured in a much lower wavenumber range.

Because the Kolmogorov length and time scales are the smallest scales occurring in turbulent motion, a central question will be how small these scales can be without violating the continuum hypothesis. By looking at the governing equations, it can be concluded that high dissipation rates are usually associated with large velocities, and this situation is more likely to occur in gases than in liquids, so it would be sufficient to show that for gas flows the smallest turbulence scales are normally much larger than the molecular scales of motion. The relevant molecular length scale is the mean free path,  $\mathcal{L}$ , and the ratio between this length and the Kolmogorov length scale,  $\eta$ , is the microstructure Knudsen number and can be expressed as (see Corrsin, 1959):

$$Kn = \frac{\mathcal{L}}{\eta} \approx \frac{Ma^{\frac{1}{4}}}{Re} \quad (33.9)$$

where the turbulence Reynolds number,  $Re$ , and the turbulence Mach number,  $Ma$ , are used as independent variables. It is obvious that a turbulent flow will interfere with the molecular motion only at a high Mach number and low Reynolds number, and this is a very unusual situation occurring only in certain gaseous nebulae<sup>3</sup>. Thus, under normal conditions the turbulence Knudsen number falls in the group of continuum flows. However, measurements using extremely thin hot-wires, small MEMS sensors or flows within narrow MEMS channels can generate values in the slip-flow regime and even beyond; this implies that, for instance, the no-slip condition may be questioned, as thoroughly discussed in Part I of this book.

## 33.8 Sensor Requirements

It is the ultimate goal of all measurements in turbulent flows to resolve both the largest and smallest eddies that occur in the flow. At the lower wavenumbers, the largest and most energetic eddies occur, and normally no problems are associated with resolving these eddies. Basically, this is a question of having access to computers with sufficiently large memory for storing the amount of data that may have to be acquired from a large number of distributed probes, each collecting data for a time period long enough

<sup>3</sup>Note that in microduct flows and the like, the  $Re$  is usually too small for turbulence to even exist. So the issue of a turbulence Knudsen number is moot in those circumstances even if rarefaction effects become strong.

to reduce the statistical error to a prescribed level. However, at the other end of the spectrum, both the spatial and the temporal resolutions are crucial, and this puts severe limitations on the sensors to be used. It is possible to obtain a relation between the small and large scales of the flow by substituting the inviscid estimate of the total dissipation rate, Eq. (33.8), into the expressions for the Kolmogorov microscales, Eqs. (33.1) to (33.3). Thus,

$$\frac{\eta}{\ell} \approx \left(\frac{u\ell}{\nu}\right)^{-\frac{3}{4}} = Re^{-\frac{3}{4}} \quad (33.10)$$

$$\frac{\tau u}{\ell} \approx \left(\frac{u\ell}{\nu}\right)^{-\frac{1}{2}} = Re^{-\frac{1}{2}} \quad (33.11)$$

$$\frac{\nu}{u} \approx \left(\frac{u\ell}{\nu}\right)^{-\frac{1}{4}} = Re^{-\frac{1}{4}} \quad (33.12)$$

where  $Re$  is the Reynolds number based on the speed of the energy containing eddies  $u$  and their characteristic length  $\ell$ . Because turbulence is a high-Reynolds-number phenomenon, these relations show that the small length, time and velocity scales are much less than those of the larger eddies and that the separation in scales widens considerably as the Reynolds number increases. Moreover, this also implies that the assumptions made on the statistical independence and the dynamical equilibrium state of the small structures will be most relevant at high Reynolds numbers. Another interesting conclusion that can be drawn from the above relations is that if two turbulent flowfields have the same spatial extension (i.e., same large-scale) but different Reynolds numbers, there would be an obvious difference in the small-scale structure in the two flows. The low- $Re$  flow would have a relatively coarse small-scale structure, while the high- $Re$  flow would have much finer small eddies.

To spatially resolve the smallest eddies, we need sensors that are of approximately the same size as the Kolmogorov length scale for the particular flow under consideration. This implies that as the Reynolds number increases smaller sensors are required. For instance, in the self-preserving region of a plane-cylinder wake at a modest Reynolds number, based on the cylinder diameter of 1840, the value of  $\eta$  varies in the range of 0.5 to 0.8 mm [Aronson and Löfdahl, 1994]. For this case, conventional hot-wires can be used for turbulence measurements. However, an increase in the Reynolds number by a factor of 10 will yield Kolmogorov scales in the micrometer range and call for either extremely small conventional hot-wires or MEMS-based sensors. Another illustrating example of the Reynolds number effect on the requirement of small sensors is a simple two-dimensional, flat-plate boundary layer. At a momentum thickness Reynolds number of  $Re_\theta = 4000$ , the Kolmogorov length scale is typically of the order of 50  $\mu\text{m}$ ; in order to resolve these scales, it is necessary to have access to sensors that have a characteristic active measuring length of the same spatial extension.

Severe errors will be introduced in the measurements by using sensors that are too large, as such sensors will integrate the fluctuations due to the small eddies over their spatial extension, and the energy content of these eddies will be interpreted by the sensors as an average “cooling.” When measuring fluctuating quantities, this implies that these eddies are counted as part of the mean flow and their energy is “lost.” The result will be a lower value of the turbulence parameter, and this will wrongly be interpreted as a measured attenuation of the turbulence [e.g., Ligrani and Bradshaw, 1987]. However, because turbulence measurements deal with statistical values of fluctuating quantities, it may be possible to loosen the spatial constraint of having a sensor of the same size as  $\eta$ , to allow sensor dimensions which are slightly larger than the Kolmogorov scale, say on the order of  $\eta$ .

For boundary layers, the wall unit has been used to estimate the smallest necessary size of a sensor for accurately resolving the smallest eddies. For instance Keith et al. (1992) state that 10 wall units or less is a relevant sensor dimension for resolving small-scale pressure fluctuations. Measurements of fluctuating

velocity gradients, essential for estimating the total dissipation rate in turbulent flows, are another challenging task. Gad-el-Hak and Bandyopadhyay (1994) argue that turbulence measurements with probe lengths greater than the viscous sublayer thickness (about 5 wall units) are unreliable, particularly near the surface. Many studies have been conducted on the spacing between sensors necessary to optimize the formed velocity gradients [Aronson et al., 1997, and references therein]. A general conclusion from both experiments and direct numerical simulations is that a sensor spacing of 3 to 5 Kolmogorov lengths is recommended. When designing arrays for correlation measurements or for targeted control, the spacing between the coherent structures will be the determining factor. For example, when targeting the low-speed streaks in a turbulent boundary layer, several sensors must be situated along a lateral distance of 100 wall units, the average spanwise spacing between streaks. All this requires quite small sensors, and many attempts have been made to meet these conditions with conventional sensor designs. However, in spite of the fact that conventional sensors such as hot-wires have been fabricated in the micrometer-size range (for their diameter but not their length), they are usually handmade, difficult to handle and too fragile, and here the MEMS technology has really opened a door for new applications.

It is clear from the above that the spatial and temporal resolutions for any probe to be used to resolve high-Reynolds-number turbulent flows are extremely tight. For example, both the Kolmogorov scale and the viscous length scale change from a few microns at the typical field Reynolds number—based on the momentum thickness—of  $10^6$  to a couple of hundred microns at the typical laboratory Reynolds number of  $10^3$ . MEMS sensors for pressure, velocity, temperature and shear stress are at least one order of magnitude smaller than conventional sensors [Ho and Tai, 1996; 1998; Löfdahl et al., 1996; Löfdahl and Gad-el-Hak, 1999]. Their small size improves both the spatial and temporal resolutions of the measurements, typically a few microns and a few microseconds, respectively. For example, a micro-hot-wire (called hot-point) has very small thermal inertia and the diaphragm of a micro-pressure-transducer has correspondingly fast dynamic response. Moreover, the microsensors' extreme miniaturization and low energy consumption make them ideal for monitoring the flow state without appreciably affecting it. Finally, literally hundreds of microsensors can be fabricated on the same silicon chip at a reasonable cost, making them well suited for distributed measurements and control. The UCLA/Caltech team [e.g., Ho and Tai, 1996; 1998, and references therein] has been very effective in developing many MEMS-based sensors and actuators for turbulence diagnosis and control.

## 33.9 Reactive Flow Control

---

### 33.9.1 Introductory Remarks

Targeted control implies sensing and reacting to particular quasi-periodic structures in a turbulent flow. For a boundary layer, the wall seems to be the logical place for such reactive control, because of the relative ease of placing something in there, the sensitivity of the flow in general to surface perturbations and the proximity and therefore accessibility to the dynamically all-important, near-wall coherent events. According to Wilkinson (1990), very few actual experiments have used embedded wall sensors to initiate a surface actuator response [Alshamani et al., 1982; Wilkinson and Balasubramanian, 1985; Nosenchuck and Lynch, 1985; Breuer et al., 1989]. This 10-year-old assessment is quickly changing, however, with the introduction of microfabrication technology that has the potential for producing small, inexpensive, programmable sensor/actuator chips. Witness the more recent reactive control attempts by Kwong and Dowling (1993), Reynolds (1993), Jacobs et al. (1993), Jacobson and Reynolds (1993a; 1993b; 1994; 1995; 1998), Fan et al. (1993), James et al. (1994) and Keefe (1996). Fan et al. and Jacobson and Reynolds even consider the use of self-learning neural networks for increased computational speeds and efficiency. Recent reviews of reactive flow control include those by Gad-el-Hak (1994; 1996), Lumley (1996), McMichael (1996), Mehregany et al. (1996), Ho and Tai (1996) and Bushnell (1998).

Numerous methods of flow control have already been successfully implemented in practical engineering devices. Yet, limitations exist for some familiar control techniques when applied to specific situations. For example, in attempting to reduce the drag or enhance the lift of a body having a turbulent boundary

layer using global suction, global heating/cooling or global application of electromagnetic body forces, the actuator's energy expenditure often exceeds the saving derived from the predetermined active control strategy. What is needed is a way to reduce this penalty to achieve a more efficient control. Reactive control geared specifically toward manipulating the coherent structures in turbulent shear flows, though considerably more complicated than passive control or even predetermined active control, has the potential to do just that. As will be argued in this and the following sections, future systems for control of turbulent flows, in general, and turbulent boundary layers, in particular, could greatly benefit from the merging of the science of chaos control, the technology of microfabrication and the newest computational tools collectively termed soft computing. Such systems are envisaged as consisting of a large number of intelligent, communicative wall sensors and actuators arranged in a checkerboard pattern and targeted toward controlling certain quasi-periodic, dynamically significant coherent structures present in the near-wall region.

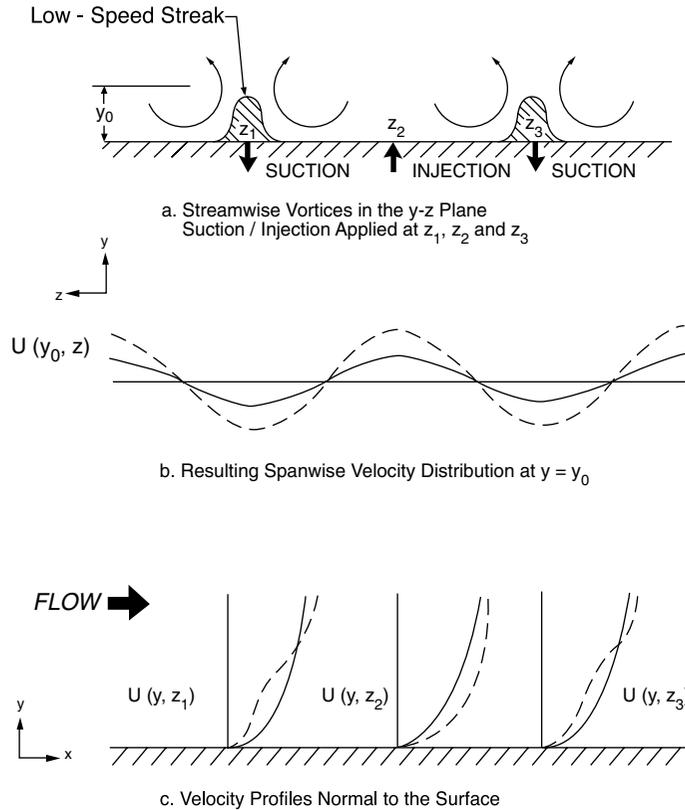

### 33.9.2 Targeted Flow Control

Successful techniques to reduce the skin friction in a turbulent flow, such as polymers, particles or riblets, appear to act indirectly through local interaction with discrete turbulent structures, particularly small-scale eddies, within the flow. Common characteristics of all these passive methods are increased losses in the near-wall region, thickening of the buffer layer and lowered production of Reynolds shear stress [Bandyopadhyay, 1986]. Active control strategies that act directly on the mean flow, such as suction or lowering of near-wall viscosity, also lead to inhibition of Reynolds stress. However, skin friction is increased when any of these velocity-profile modifiers is applied globally.

Could these seemingly inefficient techniques (e.g., global suction) be used more sparingly and optimized to reduce their associated penalty? It appears that the more successful drag-reducing methods (e.g., polymers) act selectively on particular scales of motion and are thought to be associated with stabilization of the secondary instabilities. It is also clear that energy is wasted when suction or heating/cooling is used to suppress the turbulence throughout the boundary layer when the main interest is to affect a near-wall phenomenon. One ponders what would become of wall turbulence if specific coherent structures are targeted by the operator through a reactive control scheme for modification. The myriad organized structures present in all shear flows are instantaneously identifiable, quasi-periodic motions [Cantwell, 1981; Robinson, 1991]. Bursting events in wall-bounded flows, for example, are both intermittent and random in space as well as time. The random aspects of these events reduce the effectiveness of a predetermined active control strategy. If such structures are nonintrusively detected and altered, on the other hand, net performance gain might be achieved. It seems clear, however, that temporal phasing as well as spatial selectivity would be required to achieve proper control targeted toward random events.

A nonreactive version of the above idea is the selective suction technique which combines suction to achieve an asymptotic turbulent boundary layer and longitudinal riblets to fix the location of low-speed streaks. Although far from indicating net drag reduction, the available results are encouraging and further optimization is needed. When implemented via an array of reactive control loops, the selective suction method is potentially capable of a skin-friction reduction that approaches 60%.

The genesis of the selective suction concept can be found in the papers by Gad-el-Hak and Blackwelder (1987b; 1989) and the patent by Blackwelder and Gad-el-Hak (1990). These researchers suggest that one possible means of optimizing the suction rate is identifying where a low-speed streak is located and applying a small amount of suction under it. Assuming that the production of turbulence kinetic energy is due to the instability of an inflectional  $U(y)$  velocity profile, one needs to remove only enough fluid so that the inflectional nature of the profile is alleviated. An alternative technique that could conceivably reduce the Reynolds stress is to inject fluid selectively under the high-speed regions. The immediate effect of normal injection would be to decrease the viscous shear at the wall, resulting in less drag. In addition, the velocity profiles in the spanwise direction,  $U(z)$ , would have a smaller shear,  $\partial U/\partial z$ , because the suction/injection would create a more uniform flow. Swearingen and Blackwelder (1984) and Blackwelder and Swearingen (1990) have found that inflectional  $U(z)$  profiles occur as often as inflection points are

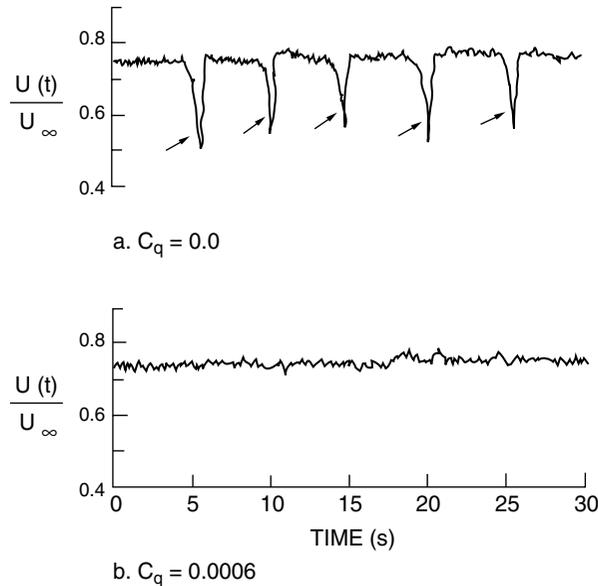

**FIGURE 33.7** Effects of suction/injection on velocity profiles. Broken lines, reference profiles; solid lines, profiles with transpiration applied. (a) Streamwise vortices in the  $y$ - $z$  plane, suction/injection applied at  $z_1, z_2$  and  $z_3$ . (b) Resulting spanwise velocity distribution at  $y = y_0$ . (c) Velocity profiles normal to the surface. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

observed in  $U(y)$  profiles, thus suction under the low-speed streaks and/or injection under the high-speed regions would decrease this shear and hence the resulting instability.

The combination of selective suction and injection is sketched in Figure 33.7. In Figure 33.7a, the vortices are idealized by a periodic distribution in the spanwise direction. The instantaneous velocity profiles without transpiration at constant  $y$  and  $z$  locations are shown by the dashed lines in Figures 33.7b and c, respectively. Clearly, the  $U(y_0, z)$  profile is inflectional, having two inflection points per wavelength. At  $z_1$  and  $z_3$ , an inflectional  $U(y)$  profile is also evident. The same profiles with suction at  $z_1$  and  $z_3$  and injection at  $z_2$  are shown by the solid lines. In all cases, the shear associated with the inflection points would have been reduced. Because the inflectional profiles are all inviscidly unstable with growth rates proportional to the shear, the resulting instabilities would be weakened by the suction/injection process.

The feasibility of the selective suction as a drag-reducing concept has been demonstrated by Gad-el-Hak and Blackwelder (1989) and is shown in Figure 33.8. Low-speed streaks were artificially generated in a laminar boundary layer using three spanwise suction holes as per the method proposed by Gad-el-Hak and Hussain (1986), and a hot-film probe was used to record the near-wall signature of the streaks. An open, feedforward control loop with a phase lag was used to activate a predetermined suction from a longitudinal slot located in between the spanwise holes and the downstream hot-film probe. An equivalent suction coefficient of  $C_q = 0.0006$  was sufficient to eliminate the artificial events and prevent bursting. This rate is five times smaller than the asymptotic suction coefficient for a corresponding turbulent

**FIGURE 33.8** Effects of suction from a streamwise slot on five artificially induced burstlike events in a laminar boundary layer:  $C_q = 0$ , (b)  $C_q = 0.0006$ . (From Gad-el-Hak, M., and Blackwelder, R.F. (1989) *AIAA J.*, 27, 308–314. With permission.)

boundary layer. If this result is sustained in a naturally developing turbulent boundary layer, a skin-friction reduction of close to 60% would be attained.

Gad-el-Hak and Blackwelder (1989) propose to combine suction with nonplanar surface modifications. Minute longitudinal roughness elements, if properly spaced in the spanwise direction, greatly reduce the spatial randomness of the low-speed streaks [Johansen and Smith, 1986]. By withdrawing the streaks forming near the peaks of the roughness elements, less suction should be required to achieve an asymptotic boundary layer. Experiments by Wilkinson and Lazos (1987) and Wilkinson (1988) combine suction/blowing with thin-element riblets. Although no net drag reduction has yet been attained in these experiments, the results indicate some advantage of combining suction with riblets as proposed by Gad-el-Hak and Blackwelder (1987b; 1989).

The recent numerical experiments of Choi et al. (1994) also validate the concept of targeting suction/injection to specific near-wall events in a turbulent channel flow. Based on complete interior flow information and using the rather simple, heuristic control law proposed earlier by Gad-el-Hak and Blackwelder (1987b), Choi et al.'s direct numerical simulations indicate a 20% net drag reduction accompanied by significant suppression of the near-wall structures and the Reynolds stress throughout the entire wall-bounded flow. When only wall information was used, a drag reduction of 6% was observed; a rather disappointing result considering that sensing and actuation took place at every grid point along the computational wall. In a practical implementation of this technique, even fewer wall sensors would perhaps be available, measuring only a small subset of the accessible information and thus requiring even more sophisticated control algorithms to achieve the same degree of success. Low-dimensional models of the near-wall flow and soft computing tools can help in constructing more effective control algorithms. Both of these topics will be discussed later.

Time sequences of the numerical flowfield of Choi et al. (1994) indicate the presence of two distinct drag-reducing mechanisms when selective suction/injection is used: (1) deterring the sweep motion, without modifying the primary streamwise vortices above the wall, and consequently moving the high-shear regions from the surface to the interior of the channel, thus directly reducing the skin friction; and (2) changing the evolution of the wall vorticity layer by stabilizing and preventing lifting of the near-wall

spanwise vorticity, thus suppressing a potential source of new streamwise vortices above the surface and interrupting a very important regeneration mechanism of turbulence.

Three modern developments have relevance to the issue at hand. First, the recently demonstrated ability to revert a chaotic system to a periodic one may provide optimal nonlinear control strategies for further reduction in the amount of suction (or the energy expenditure of any other active wall-modulation technique) needed to attain a given degree of flow stabilization. This is important because, as can be seen from the Kármán integral momentum equation, net drag reduction achieved in a turbulent boundary layer increases as the suction coefficient decreases. Second, selectively removing the randomly occurring low-speed streaks, for example, would ultimately require reactive control. In that case, an event is targeted, sensed and subsequently modulated. Microfabrication technology provides opportunities for practical implementation of the required large array of inexpensive, programmable sensor/actuator chips. Third, newly introduced soft computing tools include neural networks, fuzzy logic and genetic algorithms and are now more advanced as well as more widely used compared to just a few years ago. These tools could be very useful in constructing effective adaptive controllers.

### 33.9.3 Reactive Feedback Control

As was schematically depicted in [Figure 33.3](#), a control device can be passive, requiring no auxiliary power, or active, requiring energy expenditure. Active control is further divided into predetermined or reactive. Predetermined control includes the application of steady or unsteady energy input without regard to the particular state of the flow. The control loop in this case is open, as was shown in [Figure 33.4a](#), and no sensors are required. Because no sensed information is being fed forward, this open control loop is not a feedforward one. Reactive control is a special class of active control where the control input is continuously adjusted based on measurements of some kind. The control loop in this case can either be an open, feedforward one ([Figure 33.4b](#)) or a closed, feedback loop ([Figure 33.4c](#)).

Moin and Bewley (1994) categorize reactive feedback control strategies by examining the extent to which they are based on the governing flow equations. Four categories are discerned: adaptive, physical model-based, dynamical systems-based and optimal control ([Figure 33.3](#)). Note that, except for adaptive control, the other three categories of reactive feedback control can also be used in the feedforward mode or the combined feedforward–feedback mode. Also, in a convective environment such as that for a boundary layer, a controller would perhaps combine feedforward and feedback information and may include elements from each of the four classifications. Each of the four categories is briefly described below.

Adaptive schemes attempt to develop models and controllers via some learning algorithm without regard to the details of the flow physics. System identification is performed independently of the flow dynamics or the Navier–Stokes equations that govern the dynamics. An adaptive controller tries to optimize a specified performance index by providing a control signal to an actuator. In order to update its parameters, the controller thus requires feedback information relating to the effects of its control. The most recent innovation in adaptive flow control schemes involves the use of neural networks, which relate the sensor outputs to the actuator inputs through functions with variable coefficients and nonlinear, sigmoid saturation functions. The coefficients are updated using the so-called back-propagation algorithm, and complex control laws can be represented with a sufficient number of terms. Hand tuning is required, however, to achieve good convergence properties. The nonlinear adaptive technique has been used with different degrees of success by Fan et al. (1993) and Jacobson and Reynolds (1993b; 1995; 1998) to control, respectively, the transition process in laminar boundary layers and the bursting events in turbulent boundary layers.

Heuristic physical arguments can instead be used to establish effective control laws. That approach obviously will work only in situations in which the dominant physics are well understood. An example of this strategy is the active cancellation scheme, used by Gad-el-Hak and Blackwelder (1989) in a physical experiment and by Choi et al. (1994) in a numerical experiment, to reduce the drag by mitigating the effect of near-wall vortices. As mentioned earlier, the idea is to oppose the near-wall motion of the fluid,

caused by the streamwise vortices, with an opposing wall control, thus lifting the high-shear region away from the surface and interrupting the turbulence regeneration mechanism.

Nonlinear dynamical systems theory allows turbulence to be decomposed into a small number of representative modes whose dynamics are examined to determine the best control law. The task is to stabilize the attractors of a low-dimensional approximation of a turbulent chaotic system. The best known strategy is the Ott–Grebogi–Yorke (OGY) method which, when applied to simpler, small number of degrees of freedom systems, achieves stabilization with minute expenditure of energy. This and other chaos control strategies, especially as applied to the more complex turbulent flows, will be discussed later.

Finally, optimal control theory applied directly to the Navier–Stokes equations can, in principle, be used to minimize a cost function in the space of the control. This strategy provides perhaps the most rigorous theoretical framework for flow control. As compared to other reactive control strategies, optimal control applied to the full Navier–Stokes equations is also the most computer-time intensive. In this method, feedback control laws are derived systematically for the most efficient distribution of control effort to achieve a desired goal. Abergel and Temam (1990) developed such an optimal control theory for suppressing turbulence in a numerically simulated, two-dimensional Navier–Stokes flow, but their method requires impractical full flowfield information. Choi et al. (1993) developed a more practical, wall-information-only, suboptimal control strategy which they applied to the one-dimensional stochastic Burgers equation. Later application of the suboptimal control theory to a numerically simulated turbulent channel flow has been reported by Moin and Bewley (1994) and Bewley et al. (1997; 1998). The recent book edited by Sriitharan (1998) provides eight articles that focus on the mathematical aspects of optimal control of viscous flows.

### 33.9.4 Required Characteristics

The randomness of the bursting events necessitates temporal phasing as well as spatial selectivity to effect selective control. Practical applications of methods targeted at controlling a particular turbulent structure to achieve a prescribed goal would therefore require implementing a large number of surface sensors/actuators together with appropriate control algorithms. That strategy for controlling wall-bounded turbulent flows has been advocated by, among others and in chronological order, Gad-el-Hak and Blackwelder (1987b; 1989), Lumley (1991; 1996), Choi et al. (1992), Reynolds (1993), Jacobson and Reynolds (1993a; 1993b; 1994; 1995; 1998), Gad-el-Hak (1993; 1994; 1996; 1998; 2000), Moin and Bewley (1994), McMichael (1996), Mehregany et al. (1996), Blackwelder (1998), Delville et al. (1998) and Perrier (1998).

It is instructive to estimate some representative characteristics of the required array of sensors/actuators. Consider a typical commercial aircraft cruising at a speed of  $U_\infty = 300$  m/s and at an altitude of 10 km. The density and kinematic viscosity of air and the unit Reynolds number in this case are, respectively,  $\rho = 0.4$  kg/m<sup>3</sup>,  $\nu = 3 \times 10^{-5}$  m<sup>2</sup>/s, and  $Re = 10^7$ /m. Assume further that the portion of fuselage to be controlled has turbulent boundary-layer characteristics identical to those for a zero-pressure-gradient flat plate at a distance of 1 m from the leading edge. In this case, the skin-friction coefficient<sup>4</sup> and the friction velocity are, respectively,  $C_f = 0.003$  and  $u_\tau = 11.62$  m/s. At this location, one viscous wall unit is only  $\nu/u_\tau = 2.6$   $\mu$ m. In order for the surface array of sensors/actuators to be hydraulically smooth, it should not protrude beyond the viscous sublayer, or  $5 \nu/u_\tau = 13$   $\mu$ m.

Wall-speed streaks are the most visible, reliable and detectable indicators of the preburst turbulence production process. The detection criterion is simply low velocity near the wall, and the actuator response should be to accelerate (or to remove) the low-speed region before it breaks down. Local wall motion, tangential injection, suction, heating or electromagnetic body force, all triggered on sensed wall-pressure or wall-shear stress, could be used to cause local acceleration of near-wall fluid.

---

<sup>4</sup>Note that the skin friction decreases as the distance from the leading edge increases. It is also strongly affected by such things as the externally imposed pressure gradient. Therefore, the estimates provided in here are for illustration purposes only.

The recent numerical experiments of Berkooz et al. (1993) indicate that effective control of a bursting pair of rolls may be achieved by using the equivalent of two wall-mounted shear sensors. If the goal is to stabilize or to eliminate *all* low-speed streaks in the boundary layer, a reasonable estimate for the spanwise and streamwise distances between individual elements of a checkerboard array is, respectively, 100 and 1000 wall units,<sup>5</sup> or 260  $\mu\text{m}$  and 2600  $\mu\text{m}$ , for our particular example. A reasonable size for each element is probably one tenth of the spanwise separation, or 26  $\mu\text{m}$ . A 1-m  $\times$  1-m portion of the surface would have to be covered with about  $n = 1.5$  million elements. This is a colossal number, but the density of sensors/actuators could be considerably reduced if we moderate our goal of targeting every single bursting event (and also if less conservative assumptions are made).

It is well known that not every low-speed streak leads to a burst. On the average, a particular sensor would detect an incipient bursting event every wall-unit interval of  $P^+ = Pu_\tau^2/\nu = 250$ , or  $P = 56 \mu\text{s}$ . The corresponding dimensionless and dimensional frequencies are  $f^+ = 0.004$  and  $f = 18 \text{ kHz}$ , respectively. At different distances from the leading edge and in the presence of a nonzero pressure gradient, the sensors/actuators array would have different characteristics, but the corresponding numbers would still be in the same ballpark as estimated in here.

As a second example, consider an underwater vehicle moving at a speed of  $U_\infty = 10 \text{ m/s}$ . Despite the relatively low speed, the unit Reynolds number is still the same as estimated above for the air case,  $Re = 10^7/\text{m}$ , due to the much lower kinematic viscosity of water. At 1 m from the leading edge of an imaginary flat plate towed in water at the same speed, the friction velocity is only  $u_\tau = 0.39 \text{ m/s}$ , but the wall unit is still the same as in the aircraft example,  $\nu/u_\tau = 2.6 \mu\text{m}$ . The density of the required sensors/actuators array is the same as computed for the aircraft example,  $n = 1.5 \times 10^6 \text{ elements/m}^2$ . The anticipated average frequency of sensing a bursting event is, however, much lower at  $f = 600 \text{ Hz}$ .

Similar calculations have been recently made by Gad-el-Hak (1993; 1994; 1998; 2000), Reynolds (1993) and Wadsworth et al. (1993). Their results agree closely with the estimates made here for typical field requirements. In either the airplane or the submarine case, the actuator's response need not be too large. As will be shown later, wall displacement on the order of 10 wall units (26  $\mu\text{m}$  in both examples), suction coefficient of about 0.0006 or surface cooling and heating on the order of 40°C and 2°C (in the first and second example, respectively) should be sufficient to stabilize the turbulent flow.

As computed in the two examples above, both the required size for a sensor/actuator element and the average frequency at which an element would be activated are within the presently known capabilities of microfabrication technology. The number of elements needed per unit area is, however, alarmingly large. The unit cost of manufacturing a programmable sensor/actuator element would have to come down dramatically, perhaps matching the unit cost of a conventional transistor,<sup>6</sup> before the idea advocated in here would become practical.

An additional consideration besides the size, amplitude and frequency response is the energy consumed by each sensor/actuator element. Total energy consumption by the entire control system obviously has to be low enough to achieve net savings. Consider the following calculations for the aircraft example. One meter from the leading edge, the skin-friction drag to be reduced is approximately 54  $\text{N/m}^2$ . Engine power needed to overcome this retarding force per unit area is 16  $\text{kW/m}^2$ , or 10<sup>4</sup>  $\mu\text{W/sensor}$ . If a 60% drag-reduction is achieved,<sup>7</sup> this energy consumption is reduced to 4320  $\mu\text{W/sensor}$ . This number will increase by the amount of energy consumption of a sensor/actuator unit, but (it is hoped) not back to

<sup>5</sup> These are equal to, respectively, the average spanwise wavelength between two adjacent streaks and the average streamwise extent for a typical low-speed region. One can argue that those estimates are too conservative: Once a region is relaminarized, it would perhaps stay as such for quite a while as the flow convects downstream. The next row of sensors/actuators may therefore be relegated to a downstream location well beyond 1000 wall units. Relatively simple physical or numerical experiments could settle this issue.

<sup>6</sup> The transistor was invented in 1947. In the mid-1960s, a single transistor sold for around \$70. In 1997, Intel's Pentium II processor (microchip) contained  $7.5 \times 10^6$  transistors and cost around \$500, which is less than \$0.00007 per transistor!

<sup>7</sup> A not-too-far-fetched goal according to the selective suction results presented earlier.

the uncontrolled levels. The voltage across a sensor is typically in the range of  $V = 0.1\text{--}1$  V, and its resistance is in the range of  $R = 0.1\text{--}1$  M $\Omega$ . This means a power consumption by a typical sensor in the range of  $P = V^2/R = 0.1\text{--}10$   $\mu\text{W}$ , well below the anticipated power savings due to reduced drag.

For a single actuator in the form of a spring-loaded diaphragm with a spring constant of  $k = 100$  N/m and oscillating up and down at the bursting frequency of  $f = 18$  kHz with an amplitude of  $y = 26$   $\mu\text{m}$ , the power consumption is  $P = (1/2)ky^2f = 600$   $\mu\text{W}/\text{actuator}$ . If suction is used instead,  $C_q = 0.0006$  and, assuming a pressure difference of  $\Delta p = 10^4$  N/m<sup>2</sup> across the suction holes/slots, the corresponding power consumption for a single actuator is  $P = C_q U_\infty \Delta p / n = 1200$   $\mu\text{W}/\text{actuator}$ . It is clear then that when the power penalty for the sensor/actuator is added to the lower level drag, a net saving is still achievable. The corresponding actuator power penalties for the submarine example are even smaller ( $P = 20$   $\mu\text{W}/\text{actuator}$  for the wall motion actuator and  $P = 40$   $\mu\text{W}/\text{actuator}$  for the suction actuator), and larger savings are therefore possible.

## 33.10 Magneto hydrodynamic Control

---

### 33.10.1 Introductory Remarks

Magneto hydrodynamics (MHD) is the science underlying the interaction of an electrically conducting fluid with a magnetic field. Several decades ago a number of researchers from around the world were vigorously attempting to exploit the electric current and thus electric power that result when a fluid conductor moves in the presence of a magnetic field. Thus, the fluid internal energy (or enthalpy) is directly converted into electrical energy, eliminating the traditional intermediate mechanical step. The usual turbine and generator in conventional power plants are therefore combined in a single unit, in essence an electromagnetic turbine with no moving parts. The inverse device is an electromagnetic pump where, in the presence of a magnetic field, a conducting fluid is caused to move when electric current passes through it. An excellent primer for the topic of MHD can be found in the book by Shercliff (1965).

Examples of conducting fluids (in descending order of electrical conductivities) include liquid metals, plasmas, molten glass and sea water. The electrical conductivity of mercury is  $\sigma \approx 10^6$  mhos/m, and that for seawater is  $\sigma \approx 4$  mhos/m. Possible useful applications include MHD power generation, propulsion and liquid metals used as coolants for magnetically confined fusion reactors. Though fictitious, the Soviet submarine in Tom Clancy's bestseller *The Hunt for Red October* was endowed with an extremely quiet MHD propulsion system. With the collapse of communism, the interest in this field has shifted somewhat to more peaceful uses, such as, for example, flow control or, in other words, the ability to manipulate a flowfield in order to achieve a beneficial goal such as drag reduction, lift enhancement and mixing augmentation. Here the so-called Lorentz body forces that result when a conducting fluid moves in the presence of a magnetic field are exploited to effect desired changes in the flowfield—for example, to suppress turbulence.

Of particular interest to this chapter is the development of efficient reactive control strategies that employ the Lorentz forces to enhance the performance of sea vessels. Methods to delay transition, prevent separation and reduce skin-friction drag in turbulent boundary layers are sought. Control strategies targeted toward certain coherent structures in a turbulent flow are particularly sought. We start here by developing the von Kármán momentum integral equation and the instantaneous equations of motion at the wall, both in the presence of Lorentz force. This should prove useful to make quick estimates of system behavior under different operating conditions. Results are usually not as accurate as solving the differential conservation equations themselves but are more accurate than dimensional analysis. This is followed by an outline of a suggested reactive control strategy that exploits electromagnetic body forces.

### 33.10.2 The von Kármán Equation

The Lorentz force (body force per unit volume) is given by the cross-product of the current density vector  $\vec{j}$  and the magnetic flux density vector  $\vec{B}$ :

$$\vec{F} = \vec{j} \times \vec{B} \quad (33.13)$$

where the current is the sum of the applied and induced contributions:

$$\vec{j} = \sigma (\vec{E} + \vec{u} \times \vec{B}) \quad (33.14)$$

where  $\sigma$  is the electrical conductivity of the fluid,  $\vec{E}$  is the applied electric field vector, and  $\vec{u}$  is the fluid velocity vector. Thus, the Lorentz force is, in general, given by:

$$\vec{F} = \sigma (\vec{E} \times \vec{B}) + \sigma (\vec{u} \times \vec{B}) \times \vec{B} \quad (33.15)$$

Due to the rather low electrical conductivity of seawater, the induced Lorentz force is typically very small in such an application, and the only way to effect a significant body force is to cross the magnetic field with an applied electric field. For such application, therefore, the term electromagnetic forcing (EMHD) is commonly used in place of MHD.

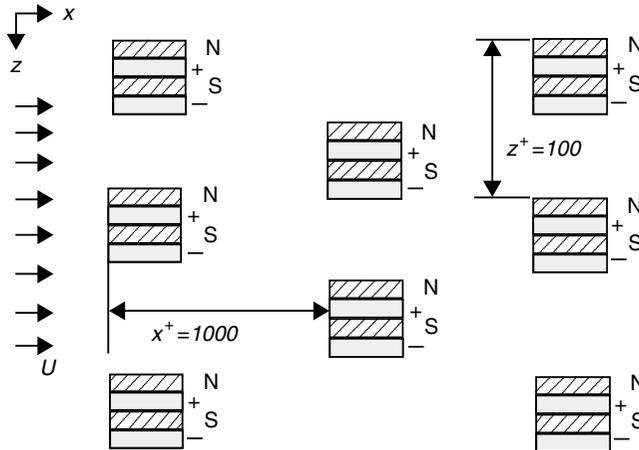

Assume a two-dimensional boundary-layer flow of a conducting fluid. Further assume that the magnetic and electric fields are generated using alternating electrodes and magnets parallel to the streamwise direction (see Figure 33.9). Basically, both fields are in the plane ( $y, z$ ). The resulting Lorentz force has components in the streamwise ( $x$ ), normal ( $y$ ) and spanwise ( $z$ ) directions given by, respectively:

$$F_x = \sigma(E_y B_z - E_z B_y) - \sigma u (B_z^2 + B_y^2) \quad (33.16)$$

$$F_y = 0 - \sigma v B_z^2 \quad (33.17)$$

$$F_z = 0 - \sigma v B_z B_y \quad (33.18)$$

where  $u$  and  $v$  are, respectively, the streamwise and normal velocity components. Each of the first terms on the right-hand sides of Eqs. (33.16) to (33.18) is due to the applied electric field. The second term is

**FIGURE 33.9** EMHD tiles for reactive control of turbulent boundary layers. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

the induced Lorentz force and is negligible for low-conductivity fluids such as seawater. Therefore, for such an application and particular arrangement of electrodes/magnets, the electromagnetic body force is predominately in the streamwise direction,  $F_x \approx \sigma(E_y B_z - E_z B_y)$ .

We now write the continuity and streamwise momentum equations. For an incompressible, two-dimensional flow and neglecting the gravitational body force:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (33.19)$$

$$\rho \frac{\partial u}{\partial t} + \rho u \frac{\partial u}{\partial x} + \rho v \frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial \tau}{\partial y} + \sigma(E_y B_z - E_z B_y) - \sigma u(B_z^2 + B_y^2) \quad (33.20)$$

where  $\tau$  is the viscous shear stress. The pressure term can be written in terms of the velocity outside the boundary layer  $U_o$  which in general is a function of  $x$  and  $t$ . Note that the total drag should be the sum of the usual viscous and form drags plus (or minus) the Lorentz force. In Eq. (33.20), the induced Lorentz force is always negative (for positive  $u$ ). The applied force can be positive or negative depending on the direction of the applied electric field,  $\vec{E}$ , relative to the magnetic field,  $\vec{B}$ . In any case, when the Lorentz force is positive, it constitutes a thrust (negative drag).

At a given  $x$  location, the streamwise momentum equation can readily be integrated in  $y$  from the wall to the edge of the boundary layer. Invoking the continuity equation and using the usual definitions for the skin friction coefficient ( $C_f$ ), and the displacement and momentum thicknesses ( $\delta^*$  and  $\delta_\theta$ ), the resulting integral equation reads:

$$C_f \equiv \frac{2\tau_w}{\rho U_o^2} = \frac{2}{U_o^2} \frac{\partial(U_o \delta^*)}{\partial t} + 2 \frac{\partial \delta^*}{\partial x} - 2 \frac{v_w}{U_o} + 2 \delta_\theta \left( 2 + \frac{\delta^*}{\delta_\theta} \right) \frac{1}{U_o} \frac{\partial U_o}{\partial x} + \frac{2\sigma}{\rho U_o^2} \int_0^\infty [E_y B_z - E_z B_y] dy - \frac{2\sigma}{\rho U_o^2} \int_0^\infty u [B_z^2 + B_y^2] dy \quad (33.21)$$

where  $v_w$  is the injection (or suction) velocity normal to the wall. Note that upward and downward wall motions are equivalent to wall injection and suction. If  $\sigma$  is not constant, it has to be included in the two integrals on the right-hand side of Eq. (33.21).

It is clear that the following effects contribute to an *increase* in skin friction: temporal acceleration of freestream, growth of momentum thickness, wall suction (or downward wall motion), favorable pressure gradient and positive streamwise Lorentz force. When such force points opposite of the flow direction, the skin friction decreases and the velocity profile tends to become more inflectional. But, once again remember to add (or subtract) the drag (or thrust) due to the applied as well as induced Lorentz forces.

Note that Eq. (33.21) is valid for steady or unsteady flows, for Newtonian or non-Newtonian fluids and for laminar or turbulent flows (mean quantities are used in the latter case). The two integrals in Eq. (33.21) can be computed once the electric and magnetic fields are known and an approximate velocity profile is assumed. For seawater, the last integral in Eq. (33.21) is neglected.

### 33.10.3 Vorticity Flux at the Wall

Another very useful equation is the differential momentum equation written at the wall ( $y = 0$ ). Here, we assume a Newtonian fluid but allow viscosity to vary spatially and the flow to be three dimensional. For a non-moving wall,<sup>8</sup> the instantaneous streamwise, normal and spanwise momentum equations read,

<sup>8</sup>The wall is not moving in the streamwise and spanwise directions. Normal wall motions are equivalent to suction/injection and hence are allowed in this formulation.

respectively:

$$\rho v_w \frac{\partial u}{\partial y} \Big|_{y=0} + \frac{\partial p}{\partial x} \Big|_{y=0} - \frac{\partial \mu}{\partial y} \Big|_{y=0} \frac{\partial u}{\partial y} \Big|_{y=0} - \sigma [E_y B_z - E_z B_y]_{y=0} = \mu \frac{\partial^2 u}{\partial y^2} \Big|_{y=0} \quad (33.22)$$

$$0 + \frac{\partial p}{\partial y} \Big|_{y=0} - 0 - F_y \Big|_{y=0} = \mu \frac{\partial^2 v}{\partial y^2} \Big|_{y=0} \quad (33.23)$$

$$\rho v_w \frac{\partial w}{\partial y} \Big|_{y=0} + \frac{\partial p}{\partial z} \Big|_{y=0} - \frac{\partial \mu}{\partial y} \Big|_{y=0} \frac{\partial w}{\partial y} \Big|_{y=0} - F_z \Big|_{y=0} = \mu \frac{\partial^2 w}{\partial y^2} \Big|_{y=0} \quad (33.24)$$

where  $F_y|_{y=0}$  and  $F_z|_{y=0}$  are, respectively, the wall values of the Lorentz force in the normal and spanwise directions. In Eq. (33.22), the streamwise Lorentz force at the wall,  $F_x|_{y=0}$ , is due only to the applied electric field (the induced force is zero at the wall as  $u$  vanishes there for nonmoving walls). The expression for  $F_x$  in Eq. (33.22) is for an array of alternating electrodes and magnets parallel to the streamwise direction,<sup>9</sup> but the streamwise Lorentz force can readily be computed for any other configuration of magnets and electrodes. If the electric conductivity varies spatially, the value of  $\sigma$  at the wall should be used in Eq. (33.22).

The right-hand side of Eq. (33.22) is the (negative of) wall flux of spanwise vorticity, while that of Eq. (33.24) is the (negative of) wall flux of streamwise vorticity. Much like transpiration, pressure-gradient or viscosity variations, the wall value of the Lorentz force determines the sign and intensity of wall vorticity flux. Streamwise force contributes to spanwise vorticity flux, and spanwise force contributes to streamwise vorticity flux. Take, for example, a positive streamwise Lorentz force. This is a negative term on the left-hand side of Eq. (33.22), which makes the curvature of the streamwise velocity profile at the wall more negative (i.e., instantaneously fuller velocity profile). The wall is then a source of spanwise vorticity, and the flow is more resistant to transition and separation. In a turbulent flow, a positive streamwise Lorentz force leads to suppression of normal and tangential Reynolds stresses.

### 33.10.4 EMHD Tiles for Reactive Control

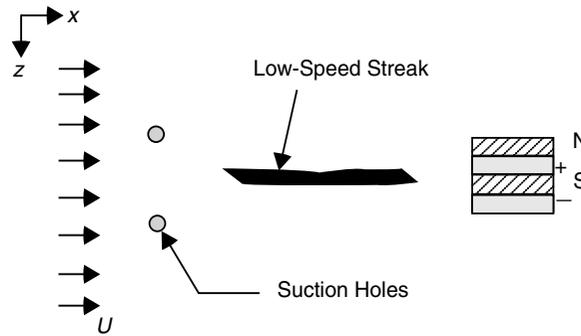

In this section, I shall outline a reactive control strategy that exploits the Lorentz forces to modulate the flow of an electrically conducting fluid such as seawater. The idea here is to target the low-speed streaks in the near-wall region of a turbulent boundary layer. The electric field is applied only when and where it is needed; hence, the power consumed by the reactive control system is kept far below that consumed by a predetermined active control system. According to recent numerical and experimental results, brute force application of steady or time-dependent Lorentz force—to reduce drag, for example—do not achieve the breakeven point, the reason being the high energy expenditure by predetermined control systems (see, for example, the two meeting proceedings edited by Gerbeth, 1997, and Meng, 1998).

The top view in Figure 33.9 depicts the proposed distribution of EMHD tiles to achieve targeted control in a turbulent wall-bounded flow. Each tile consists of two streamwise strips constituting the north and south poles of a permanent magnet and another two strips constituting positive and negative electrodes.<sup>10</sup> The tiles are staggered in a checkerboard configuration and are separated by 100 wall units in the spanwise direction ( $z$ ) and 1000 wall units in the streamwise direction ( $x$ ). The length and width of each tile are about 50 wall units.<sup>11</sup>

<sup>9</sup>Note that, for such an array, the applied part of both  $F_y|_{y=0}$  and  $F_z|_{y=0}$  is identically zero, but the induced part is nonzero if  $v_w \neq 0$ . In seawater applications, the induced Lorentz force is negligible regardless of any suction/injection or normal wall motion.

<sup>10</sup>The cathode and anode are interchangeable depending on the desired direction of the Lorentz force.

<sup>11</sup>The length and width of each magnet pole (or electrode) are thus 50 and 12.5 wall units, respectively.

**FIGURE 33.10** Control of a single artificial low-speed streak. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

A shear-stress sensor having a spatial resolution of 2 to 5 wall units is placed just upstream and along the centerline of each tile. Each sensor and corresponding actuator is connected via a closed feedback control loop. The tile is activated to give a positive or negative streamwise Lorentz force when a low- or high-speed region is detected. The control law used can be based on simple physical arguments or a more complex self-learning neural network. Other possible albeit more sophisticated control laws can be based on nonlinear dynamical systems theory or optimal/suboptimal control theory.

For a simpler physical or numerical experiment that does not require sensors and complex closed-loop control, a single low-speed streak is artificially generated in a laminar boundary layer using two suction holes as depicted in the  $(x-z)$  view in Figure 33.10. The two holes are separated in the spanwise direction by 100 wall units, and each is about 0.5-wall unit in diameter. Such a method was successfully used by Gad-el-Hak and Hussain (1986) to generate artificial low-speed streaks as well as simulated bursting events in a laminar environment. In the proposed experiment, high-speed regions and counter-rotating streamwise vortices are also generated, and, if desired, one can readily target any of these simulated events for elimination. The necessary actuation would, of course, depend on the kind of coherent structure to be targeted.

A single EMHD tile is placed about 50 wall units directly downstream of the suction holes and is activated with a suitable time delay after a suction pulse is applied, in essence using a simple, predetermined, open-loop control. A single electric pulse<sup>12</sup> triggers a positive Lorentz force to eliminate the artificially generated low-speed streak. The experiment would of course be repeated several times, and the actuator location, phase lag, strength and duration could be optimized to achieve the desired goal.

The streamwise Lorentz force necessary to eliminate the resulting artificial low-speed streak could be computed from the measurements, thus the energy expenditure necessary to eliminate all the low-speed streaks in a real turbulent boundary layer could readily be estimated.

### 33.11 Chaos Control

In the theory of dynamical systems, the so-called butterfly effect denotes sensitive dependence of nonlinear differential equations on initial conditions, with phase-space solutions initially very close together separating exponentially. The solution of nonlinear dynamical systems of three or more degrees of freedom may be in the form of a strange attractor whose intrinsic structure contains a well-defined mechanism to produce a chaotic behavior without requiring random forcing. Chaotic behavior is complex and aperiodic and, though deterministic, appears to be random.

<sup>12</sup> Note that in this simulated environment the electric pulse would have the same polarity if only low-speed streaks are to be obliterated.

A question arises naturally: Just as small disturbances can radically grow within a deterministic system to yield rich, unpredictable behavior, can minute adjustments to a system parameter be used to reverse the process and control (i.e., regularize) the behavior of a chaotic system? Recently, that question was answered in the affirmative theoretically as well as experimentally, at least for system orbits that reside on low-dimensional strange attractors (see the review by Lindner and Ditto, 1995). Before describing such strategies for controlling chaotic systems, we first summarize the recent attempts to construct a low-dimensional dynamical systems representation of turbulent boundary layers. Such construction is a necessary first step to be able to use chaos control strategies for turbulent flows. Additionally, as argued by Lumley (1996), a low-dimensional dynamical model of the near-wall region used in a Kalman filter [Banks, 1986; Petersen and Savkin, 1999] can make the most of the partial information assembled from a finite number of wall sensors. Such a filter minimizes in a least-square sense the errors caused by incomplete information and thus globally optimizes the performance of the control system.

### 33.11.1 Nonlinear Dynamical Systems Theory

Boundary-layer turbulence is described by a set of nonlinear partial differential equations and is characterized by an infinite number of degrees of freedom. This makes it rather difficult to model the turbulence using a dynamical systems approximation. The notion that a complex, infinite-dimensional flow can be decomposed into several low-dimensional subunits is, however, a natural consequence of the realization that quasi-periodic coherent structures dominate the dynamics of seemingly random turbulent shear flows. This implies that low-dimensional, localized dynamics can exist in formally infinite-dimensional extended systems—such as open turbulent flows. Reducing the flow physics to finite-dimensional dynamical systems enables a study of its behavior through an examination of the fixed points and the topology of their stable and unstable manifolds. From the dynamical systems theory viewpoint, the meandering of low-speed streaks is interpreted as hovering of the flow state near an unstable fixed point in the low-dimensional state space. An intermittent event that produces high wall stress—a burst—is interpreted as a jump along a heteroclinic cycle to different unstable fixed point that occurs when the state has wandered too far from the first unstable fixed point. Delaying this jump by holding the system near the first fixed point should lead to lower momentum transport in the wall region and, therefore, to lower skin-friction drag. Reactive control means sensing the current local state and through appropriate manipulation keeping the state close to a given unstable fixed point, thereby preventing further production of turbulence. Reducing the bursting frequency by, say, 50%, may lead to a comparable reduction in skin-friction drag. For a jet, relaminarization may lead to a quiet flow and very significant noise reduction.

In one significant attempt, the proper orthogonal, or Karhunen-Loève, decomposition method has been used to extract a low-dimensional dynamical system from experimental data of the wall region [Aubry et al. 1988; Aubry, 1990]. Aubry et al. (1988) expanded the instantaneous velocity field of a turbulent boundary layer using experimentally determined eigenfunctions in the form of streamwise rolls. They expanded the Navier-Stokes equations using these optimally chosen, divergence-free, orthogonal functions, applied a Galerkin projection, and then truncated the infinite-dimensional representation to obtain a ten-dimensional set of ordinary differential equations. These equations represent the dynamical behavior of the rolls and are shown to exhibit a chaotic regime as well as an intermittency due to a burst-like phenomenon. However, Aubry et al.'s ten-mode dynamical system displays a regular intermittency, in contrast both to that in actual turbulence as well as to the chaotic intermittency encountered by Pomeau and Manneville (1980) in which event durations are distributed stochastically. Nevertheless, the major conclusion of Aubry et al.'s study is that the bursts appear to be produced autonomously by the wall region even without turbulence but are triggered by turbulent pressure signals from the outer layer. More recently, Berkooz et al. (1991) generalized the class of wall-layer models developed by Aubry et al. (1988) to permit uncoupled evolution of streamwise and cross-stream disturbances. Berkooz et al.'s results suggest that the intermittent events observed in Aubry et al.'s representation do not arise solely because of the effective closure assumption incorporated, but rather are rooted deeper in the dynamical

phenomena of the wall region. The book by Holmes et al. (1996) details the Cornell University research group attempts at describing turbulence as a low-dimensional dynamical system.

In addition to the reductionist viewpoint exemplified by the work of Aubry et al. (1988) and Berkooz et al. (1991), attempts have been made to determine directly the dimension of the attractors underlying specific turbulent flows. Again, the central issue here is whether or not turbulent solutions to the infinite-dimensional Navier–Stokes equations can be asymptotically described by a finite number of degrees of freedom. Grappin and Léorat (1991) computed the Lyapunov exponents and the attractor dimensions of two- and three-dimensional periodic turbulent flows without shear. They found that the number of degrees of freedom contained in the large scales establishes an upper bound for the dimension of the attractor. Deane and Sirovich (1991) and Sirovich and Deane (1991) numerically determined the number of dimensions needed to specify chaotic Rayleigh–Bénard convection over a moderate range of Rayleigh numbers,  $Ra$ . They suggested that the intrinsic attractor dimension is  $\mathcal{O}[Ra^{2/3}]$ .

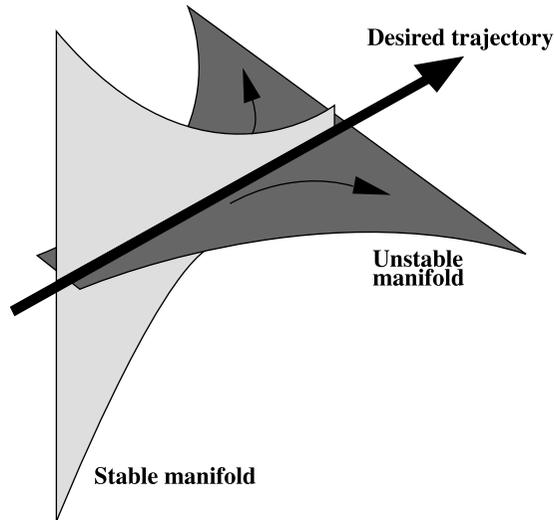

The corresponding dimension in wall-bounded flows appears to be dauntingly high. Keefe et al. (1992) determined the dimension of the attractor underlying turbulent Poiseuille flows with spatially periodic boundary conditions. Using a coarse-grained numerical simulation, they computed a lower bound on the Lyapunov dimension of the attractor to be approximately 352 at a pressure-gradient Reynolds number of 3200. Keefe et al. (1992) argue that the attractor dimension in fully resolved turbulence is unlikely to be much larger than 780. This suggests that periodic turbulent shear flows are deterministic chaos and that a strange attractor does underlie solutions to the Navier–Stokes equations. Temporal unpredictability in the turbulent Poiseuille flow is thus due to the exponential spreading property of such attractors. Although finite, the computed dimension invalidates the notion that the global turbulence can be attributed to the interaction of a *few* degrees of freedom. Moreover, in a physical channel or boundary layer, the flow is not periodic and is open. The attractor dimension in such case is not known but is believed to be even higher than the estimate provided by Keefe et al. for the periodic (quasi-closed) flow.

In contrast to closed, absolutely unstable flows, such as Taylor–Couette systems, where the number of degrees of freedom can be small, local measurements in open, convectively unstable flows, such as boundary layers, do not express the global dynamics, and the attractor dimension in that case may inevitably be too large to be determined experimentally. According to the estimate provided by Keefe et al. (1992), the colossal data required (about  $10^D$ , where  $D$  is the attractor dimension) for measuring the dimension simply exceed current computer capabilities. Turbulence near transition or near a wall is an exception to that bleak picture. In those special cases, a relatively small number of modes are excited and the resulting simple turbulence can therefore be described by a dynamical system of a reasonable number of degrees of freedom.

### 33.11.2 Chaos Control

There is another question of greater relevance here. Given a dynamical system in the chaotic regime, is it possible to stabilize its behavior through some kind of active control? While other alternatives have been devised [e.g., Fowler, 1989; Hübler and Lüscher, 1989; Huberman, 1990; Huberman and Lumer, 1990], the recent method proposed by workers at the University of Maryland [Ott et al., 1990a; 1990b; Shinbrot et al., 1990; 1992a; 1992b; 1992c; 1998; Romeiras et al., 1992] promises to be a significant breakthrough. Comprehensive reviews and bibliographies of the emerging field of chaos control can be found in the articles by Shinbrot et al. (1993), Shinbrot (1993; 1995; 1998) and Lindner and Ditto (1995).

Ott et al. (1990a) demonstrated, through numerical experiments with the Henon map, that it is possible to stabilize a chaotic motion about any pre-chosen, unstable orbit through the use of relatively small perturbations. The procedure consists of applying minute time-dependent perturbations to one of the system parameters to control the chaotic system around one of its many unstable periodic orbits. In this context, targeting refers to the process whereby an arbitrary initial condition on a chaotic attractor is steered toward a prescribed point (target) on this attractor. The goal is to reach the target as quickly as possible using a sequence of small perturbations (Kostelich et al., 1993a).

**FIGURE 33.11** The OGY method for controlling chaos. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

The success of the Ott–Grebogi–Yorke’s (OGY) strategy for controlling chaos hinges on the fact that beneath the apparent unpredictability of a chaotic system lies an intricate but highly ordered structure. Left to its own recourse, such a system continually shifts from one periodic pattern to another, creating the appearance of randomness. An appropriately controlled system, on the other hand, is locked into one particular type of repeating motion. With such reactive control the dynamical system becomes one with a stable behavior.

The OGY-method can be simply illustrated by the schematic in [Figure 33.11](#). The state of the system is represented as the intersection of a stable manifold and an unstable one. The control is applied intermittently whenever the system departs from the stable manifold by a prescribed tolerance; otherwise, the control is shut off. The control attempts to put the system back onto the stable manifold so that the state converges toward the desired trajectory. Unmodeled dynamics cause noise in the system and a tendency for the state to wander off in the unstable direction. The intermittent control prevents that and the desired trajectory is achieved. This efficient control is not unlike trying to balance a ball in the center of a horse saddle [Moin and Bewley, 1994]. There is one stable direction (front/back) and one unstable direction (left/right). The restless horse is the unmodeled dynamics, intermittently causing the ball to move in the wrong direction. The OGY control needs to be applied, in the most direct manner possible, only when the ball wanders off in the left/right direction.

The OGY method has been successfully applied in a relatively simple experiment in which reverse chaos was obtained in a parametrically driven, gravitationally buckled, amorphous magnetoelastic ribbon [Ditto et al., 1990; Ditto and Pecora, 1993]. Garfinkel et al. (1992) applied the same control strategy to stabilize drug-induced cardiac arrhythmias in sections of a rabbit ventricle. Other extensions, improvements and applications of the OGY strategy include higher dimensional targeting [Auerbach et al., 1992; Kostelich et al., 1993b]; controlling chaotic scattering in Hamiltonian (i.e., nondissipative, area conservative) systems [Lai et al., 1993a; 1993b]; synchronization of identical chaotic systems that govern communication, neural or biological processes [Lai and Grebogi, 1993]; use of chaos to transmit information [Hayes et al., 1994a; 1994b]; control of transient chaos [Lai et al., 1994] and taming spatio-temporal chaos using a sparse array of controllers [Chen et al., 1993; Qin et al., 1994; Auerbach, 1994].

In a more complex system, such as a turbulent boundary layer, there exist numerous interdependent modes and many stable as well as unstable manifolds (directions). The flow can then be modeled as coherent structures plus a parameterized turbulent background. The proper orthogonal decomposition

(POD) is used to model the coherent part because POD guarantees the minimum number of degrees of freedom for a given model accuracy. Factors that make turbulence control a challenging task are the potentially quite large perturbations caused by the unmodeled dynamics of the flow, the nonstationary nature of the desired dynamics and the complexity of the saddle shape describing the dynamics of the different modes. Nevertheless, the OGY control strategy has several advantages that are of special interest in the control of turbulence: (1) the mathematical model for the dynamical system need not be known, (2) only *small* changes in the control parameter are required, and (3) noise can be tolerated (with appropriate penalty).

Recently, Keefe (1993a; 1993b) made a useful comparison between two nonlinear control strategies as applied to fluid problems: the OGY feedback method described above and the model-based control strategy originated by Hübler [e.g., Hübler and Lüscher, 1989; Lüscher and Hübler, 1989], the H method. Both novel control methods are essentially generalizations of the classical perturbation cancellation technique: Apply a prescribed forcing to subtract the undesired dynamics, and impose the desired one. The OGY strategy exploits the sensitivity of chaotic systems to stabilize existing periodic orbits and steady states. Some feedback is needed to steer the trajectories toward the chosen fixed point, but the required control signal is minuscule. In contrast, Hübler's scheme does not explicitly make use of the system sensitivity. It produces general control response (periodic or aperiodic) and requires little or no feedback, but its control inputs are generally large. The OGY strategy exploits the nonlinearity of a dynamical system; indeed, the presence of a strange attractor and the extreme sensitivity of the dynamical system to initial conditions are essential to the success of this method. In contrast, the H method works equally for both linear and nonlinear systems.

Keefe (1993a) first examined numerically the two schemes as applied to fully developed and transitional solutions of the Ginzburg–Landau equation, an evolution equation that governs the initially weakly nonlinear stages of transition in several flows and that possesses both transitional and fully chaotic solutions. The Ginzburg–Landau equation has solutions that display either absolute or convective instabilities and is thus a reasonable model for both closed and open flows. Keefe's main conclusion is that control of nonlinear systems is best obtained by making maximum possible use of the underlying natural dynamics. If the goal dynamics is an unstable nonlinear solution of the equation and the flow is nearby at the instant control is applied, both methods perform reliably and at low-energy cost in reaching and maintaining this goal. Predictably, the performance of both control strategies degrades due to noise and the spatially discrete nature of realistic forcing.

Subsequently, Keefe (1993b) extended the numerical experiment in an attempt to reduce the drag in a channel flow with spatially periodic boundary conditions. The OGY method reduces skin friction to 60–80% of the uncontrolled value at a mass-flux Reynolds number of 4408. The H method fails to achieve any drag reduction when starting from a fully turbulent initial condition but shows potential for suppressing or retarding laminar-to-turbulence transition. Keefe (1993a) suggests that the H strategy might be more appropriate for boundary-layer control, while the OGY method might best be used for channel flows.

It is also relevant to note here the work of Bau and his colleagues at the University of Pennsylvania [Singer et al., 1991; Wang et al., 1992] who devised a feedback control to stabilize (relaminarize) the naturally occurring chaotic oscillations of a toroidal thermal convection loop heated from below and cooled from above. Based on a simple mathematical model for the thermosyphon, Bau and his colleagues constructed a reactive control system that was used to alter significantly the flow characteristics inside the convection loop. Their linear control strategy, perhaps a special version of the OGY chaos control method, consists simply of sensing the deviation of fluid temperatures from desired values at a number of locations inside the thermosyphon loop and then altering the wall heating either to suppress or to enhance such deviations. Wang et al. (1992) also suggested extending their theoretical and experimental method to more complex situations such as those involving Bénard convection [Tang and Bau, 1993a; 1993b]. Hu and Bau (1994) used a similar feedback control strategy to demonstrate that the critical Reynolds number for the loss of stability of planar Poiseuille flow can be significantly increased or decreased.

Other attempts to use low-dimensional dynamical systems representation for flow control include the work of Berkooz et al. (1993), Corke et al. (1994), and Coller et al. (1994a; 1994b). Berkooz et al. (1993)

applied techniques of modern control theory to estimate the phase-space location of dynamical models of the wall-layer coherent structures and used these estimates to control the model dynamics. Because discrete wall sensors provide incomplete knowledge of phase-space location, Berkooz et al. maintain that a nonlinear observer, which incorporates past information and the equations of motion into the estimation procedure, is required. Using an extended Kalman filter, they achieved effective control of a bursting pair of rolls with the equivalent of two wall-mounted shear sensors. Corke et al. (1994) used a low-dimensional dynamical system based on the proper orthogonal decomposition to guide control experiments for an axisymmetric jet. By sensing the downstream velocity and actuating an array of miniature speakers located at the lip of the jet, their feedback control succeeded in converting the near-field instabilities from spatial-convective to temporal-global. Coller et al. (1994a; 1994b) developed a feedback control strategy for strongly nonlinear dynamical systems, such as turbulent flows, subject to small random perturbations that kick the system intermittently from one saddle point to another along heteroclinic cycles. In essence, their approach is to use local, weakly nonlinear feedback control to keep a solution near a saddle point as long as possible, but then to let the natural, global nonlinear dynamics run its course when bursting (in a low-dimensional model) does occur. Though conceptually related to the OGY strategy, Coller et al.'s method does not actually stabilize the state but merely holds the system near the desired point longer than it would otherwise stay.

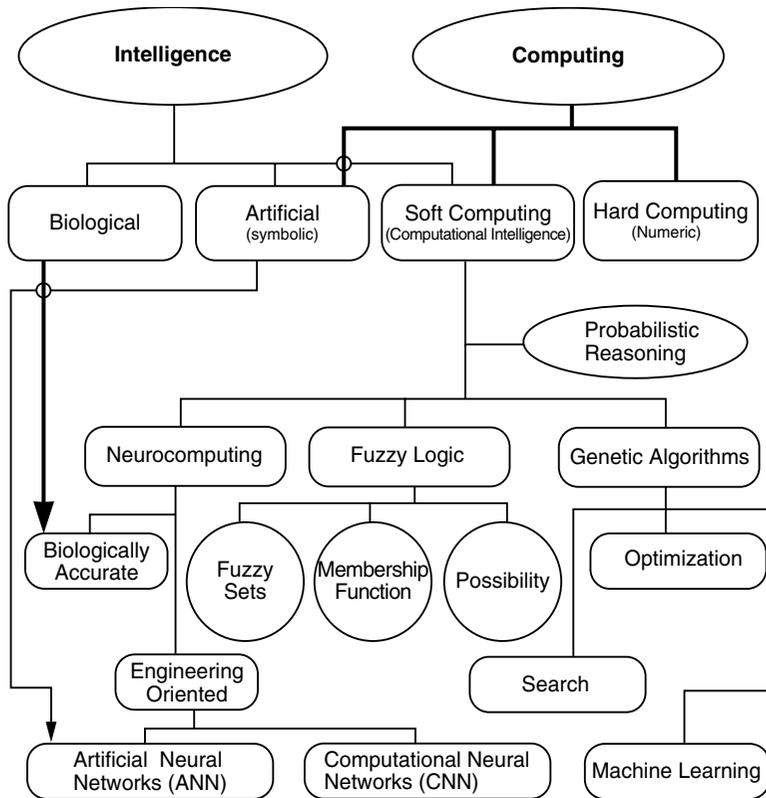

Shinbrot and Ottino (1993a; 1993b) offer yet another strategy presumably most suited for controlling coherent structures in area-preserving turbulent flows. Their geometric method exploits the premise that the dynamical mechanisms that produce the organized structures can be remarkably simple. By repeated stretching and folding of “horseshoes” present in chaotic systems, Shinbrot and Ottino have demonstrated numerically as well as experimentally the ability to create, destroy and manipulate coherent structures in chaotic fluid systems. The key idea to create such structures is to intentionally place folds of horseshoes near low-order periodic points. In a dissipative dynamical system, volumes contract in state space and the co-location of a fold with a periodic point leads to an isolated region that contracts asymptotically to a point. Provided that the folding is done properly, it counteracts stretching. Shinbrot and Ottino (1993a) applied the technique to three prototypical problems: a one-dimensional chaotic map, a two-dimensional one and a chaotically advected fluid. Shinbrot (1995; 1998) and Shinbrot et al. (1998) provide recent reviews of the stretching/folding as well as other chaos control strategies.

## 33.12 Soft Computing

---

The term *soft computing* was coined by Lotfi Zadeh of the University of California, Berkeley, to describe several ingenious modes of computations that exploit tolerance for imprecision and uncertainty in complex systems to achieve tractability, robustness and low cost [Yager and Zadeh, 1992; Bouchon-Meunier et al., 1995a; 1995b; Jang et al., 1997]. The principle of complexity provides the impetus for soft computing: as the complexity of a system increases, the ability to predict its response diminishes until a threshold is reached beyond which precision and relevance become almost mutually exclusive [Noor and Jorgensen, 1996]. In other words, precision and certainty carry a cost. By employing modes of reasoning—probabilistic reasoning—that are approximate rather than exact, soft computing can help in searching for globally optimal design or achieving effectual control while taking into account system uncertainties and risks.

Soft computing refers to a domain of computational intelligence that loosely lies in between purely numerical (hard) computing and purely symbolic computations. Alternatively, one can think about symbolic computations as a form of artificial intelligence lying in between biological intelligence and computational intelligence (soft computing). The schematic in [Figure 33.12](#) illustrates the general idea. Artificial intelligence relies on symbolic information-processing techniques and uses logic as representation and inference mechanisms. It attempts to approach the high level of human cognition. In contrast, soft computing is based on modeling low-level cognitive processes and strongly emphasizes modeling of uncertainty as well as learning. Computational intelligence mimics the ability of the human brain to employ modes of reasoning that are approximate. Soft computing provides a machinery for the numeric

**FIGURE 33.12** Tools for soft computing. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

representation of the types of constructs developed in the symbolic artificial intelligence. The boundaries between these paradigms are, of course, *fuzzy*.

The principal constituents of soft computing are neurocomputing, fuzzy logic and genetic algorithms, as depicted in [Figure 33.12](#). These elements, together with probabilistic reasoning, can be combined in hybrid arrangements resulting in better systems in terms of parallelism, fault tolerance, adaptivity and uncertainty management. To my knowledge, only neurocomputing has been employed for fluid flow control, but the other tools of soft computing may be just as useful to construct powerful controllers and have in fact been used as such in other fields such as large-scale subway controllers and video cameras. A brief description of these three constituents follows.

Neurocomputing is inspired by the neurons of the human brain and how they work. Neural networks are information-processing devices that can learn by adapting synaptic weights to changes in the surrounding environment; can handle imprecise, fuzzy, noisy and probabilistic information; and can generalize from known tasks (examples) to unknown ones. Actual engineering oriented hardware are termed artificial neural networks (ANN) while algorithms are called computational neural networks (CNN). The nonlinear, highly parallel networks can perform any of the following tasks: classification, pattern matching, optimization, control and noise removal. As modeling and optimization tools, neural networks are particularly useful when good analytic models are either unknown or extremely complex.

An artificial neural network consists of a large number of highly interconnected processing elements—essentially equations known as “transfer functions”—that are analogous to human neurons and are tied together with weighted connections that are analogous to human synapses. A processing unit takes weighted signals from other units, possibly combines them, and gives a numeric result. The behavior of neural networks—how they map input data—is influenced primarily by the transfer functions of the

processing elements, how the transfer functions are interconnected, and the weights of those interconnections. Learning typically occurs by example, through exposure to a set of input–output data, where the training algorithm adjusts the connection weights (synapses). These connection weights store the knowledge necessary to solve specific problems. As an example, it is now possible to use neural networks to sense (smell) odors in many different applications [Ouellette, 1999]. The electronic noses (e-noses) are on the verge of finding commercial applications in medical diagnostics, environmental monitoring and the processing and quality control of foods. Neural networks as used in fluid flow control will be covered in the following subsection.

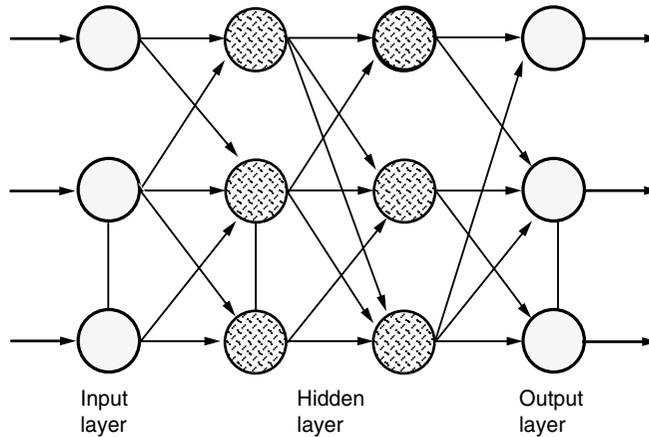

Fuzzy logic was introduced by Lotfi Zadeh in 1965 as a mathematical tool to deal with uncertainty and imprecision. The book edited by Yager and Zadeh (1992) is an excellent primer to the field. For computing and reasoning, general concepts (such as size) are implemented into a computer algorithm by using mostly words (such as small, medium or large). Fuzzy logic, therefore, provides a unique methodology for computing with words. Its rationalism is based on three mathematical concepts: fuzzy sets, membership function and possibility. As dictated by a membership function, fuzzy sets allow a gradual transition from belonging to not belonging to a set. The concept of possibility provides a mechanism for interpreting factual statements involving fuzzy sets. Three processes are involved in solving a practical problem using fuzzy logic: fuzzification, analysis and defuzzification. Given a complex, unsolvable problem in real space, those three steps involve enlarging the space and searching for a solution in the new superset, then specializing this solution to the original real constraints.

Genetic algorithms are search algorithms based loosely on the mechanics of natural selection and natural genetics. They combine survival of the fittest among string structures with structured yet randomized information exchange and are used for search, optimization and machine learning. For control, genetic algorithms aim at achieving minimum cost function and maximum performance measure while satisfying the problem constraints. The books by Goldberg (1989), Davis (1991) and Holland (1992) provide gentle introductions to the field.

In the Darwinian principle of natural selection, the fittest members of a species are favored to produce offspring. Even biologists cannot help but being awed by the complexity of life observed to evolve in the relatively short time suggested by the fossil records. A living being is an amalgam of characteristics determined by the (typically tens of thousands) genes in its chromosomes. Each gene may have several forms or alternatives called *alleles* which produce differences in the set of characteristics associated with that gene. The chromosomes are therefore the organic devices through which the structure of a creature is encoded, and this living being is created partly through the process of decoding those chromosomes. Genes transmit hereditary characters and form specific parts of a self-perpetuated deoxyribonucleic acid (DNA) in a cell nucleus. Natural selection is the link between the chromosomes and the performance of their decoded structures. Simply put, the process of natural selection causes those chromosomes that encode successful structures to reproduce more often than those that do not.

In an attempt to solve difficult problems, John H. Holland of the University of Michigan introduced in the early 1970s the manmade version of the procedure of natural evolution. The candidate solutions to a problem are ranked by the genetic algorithm according to how well they satisfy a certain criterion, and the fittest members are the most favored to combine amongst themselves to form the next generation of the members of the species. Fitter members presumably produce even fitter offspring and therefore better solutions to the problem at hand. Solutions are represented by binary strings, and each trial solution is coded as a vector called a *chromosome*. The elements of a chromosome are described as *genes*, and its varying values at specific positions are called *alleles*. Good solutions are selected for reproduction based on a fitness function using genetic recombination operators such as crossover and mutation. The main advantage of genetic algorithms is their global parallelism, in which the search efforts in many regions of the search area are simultaneously allocated.

Genetic algorithms have been used for the control of different dynamical systems, such as, for example, optimization of robot trajectories, but to my knowledge and at the time of writing this chapter reactive control of turbulent flows has yet to benefit from this powerful soft computing tool. In particular, when a finite number of sensors is used to gather information about the state of the flow, a genetic algorithm

**FIGURE 33.13** Elements of a neural network. (From Gad-el-Hak, M. (2000) *Flow Control: Passive, Active, and Reactive Flow Management*. Reprinted with permission of Cambridge University Press, New York.)

perhaps combined with a neural network can adapt and learn to use current information to eliminate the uncertainty created by insufficient *a priori* information.

### 33.12.1 Neural Networks for Flow Control

Biologically inspired neural networks are finding increased applications in many fields of science and technology. Modeling of complex dynamical systems, adaptive noise canceling in telephones and modems, bomb sniffers, mortgage-risk evaluators, sonar classifiers, and word recognizers are but a few of the existing uses of neural nets. The book by Nelson and Illingworth (1991) provides a lucid introduction to the field, and the review article by Antsaklis (1993) focuses on the use of neural nets for the control of complex dynamical systems. For flow control applications, neural networks offer the possibility of adaptive controllers that are simpler and potentially less sensitive to parameter variations as compared to conventional controllers. Moreover, if a colossal number of sensors and actuators is to be used, the massively parallel computational power of neural nets will surely be needed for real-time control.

The basic elements of a neural network are schematically shown in Figure 33.13. Several inputs are connected to the nodes (neurons or processing elements) that form the input layer. There are one or more hidden layers, followed by an output layer. Note that the number of connections is higher than the total number of nodes. Both numbers are chosen based on the particular application and can be arbitrarily large for complex tasks. Simply put, the multitask—albeit simple—job of each processing element is to evaluate each of the input signals to that particular element, calculate the weighted sum of the combined inputs, compare that total to some threshold level and finally determine what the output should be. The various weights are the adaptive coefficients which vary dynamically as the network learns to perform its assigned task; some inputs are more important than others. The threshold, or transfer, function is generally nonlinear, the most common one being the continuous sigmoid, or S-shaped, curve, which approaches a minimum and maximum value at the asymptotes. If the sum of the weighted inputs is larger than the threshold value, the neuron generates a signal; otherwise, no signal is fired. Neural networks can operate in feedforward or feedback mode.<sup>13</sup> Complex systems, for which dynamical equations may not be known or may be too difficult to solve, can be modeled using neural nets.

<sup>13</sup>Note that this terminology refers to the direction of information through the network. When a neural net is used as a controller, the overall control loop is, however, a feedback, closed loop: The self-learning network dynamically updates its various parameters by comparing its output to a desired output, thus requiring feedback information relating to the effect of its control.

For flow control, neural networks provide convenient, fast, nonlinear, adaptive algorithms to relate sensor outputs to actuator inputs via variable-coefficient functions and nonlinear, sigmoid saturation functions. With no prior knowledge of the pertinent dynamics, a self-learning neural network develops a model for the dynamics through observations of the applied control and sensed measurements. The network is by nature nonlinear and can therefore better handle nonlinear dynamical systems, a difficult task when classical (linear or weakly nonlinear) control strategies are attempted. The feedforward type of neural network acts as a nonlinear filter forming an output from a set of input data. The output can then be compared to some desired output, and the difference (error) is typically used in a back-propagation algorithm that updates the network parameters.

The number of researchers using neural networks to control fluid flows is growing rapidly. Here, we provide only a small sample. Using a pre-trained neural network, Fan et al. (1993) conducted a conceptual reactive flow control experiment to delay laminar-to-turbulence transition. Numerical simulations of their flow control system demonstrate almost complete cancellation of single and multiple artificial wave disturbances. Their controller also successfully attenuated a natural disturbance signal with developing wave packets from an actual wind-tunnel experiment.

Jacobson and Reynolds (1993b; 1995; 1998) used neural networks to minimize the boundary velocity gradient of three model flows: the one-dimensional stochastic Burgers equation, a two-dimensional computational model of the near-wall region of a turbulent boundary layer and a real-time turbulent flow with a spanwise array of wall actuators together with upstream and downstream wall sensors. For all three problems, the neural network successfully learned about the flow and developed into proficient controllers. For the laboratory experiments, however, Jacobson and Reynolds (1995) report that the neural network training time was much longer and the performance was no better than a simpler *ad hoc* controller that they developed. Jacobson and Reynolds emphasize that alternative neural net configurations and convergence algorithms may, however, greatly improve the network performance.

Using the angle of attack and angular velocity as inputs, Faller et al. (1994) trained a neural network to model the measured unsteady surface pressure over a pitching airfoil (see also Schreck et al., 1995). Following training and using the instantaneous angle of attack and pitch rate as the only inputs, their network was able to accurately predict the surface pressure topology as well as the time-dependent aerodynamic forces and moments. The model was then used to develop a neural network controller for wing-motion actuator signals which in turn provided direct control of the lift-to-drag ratio across a wide range of time-dependent motion histories.

As a final example, Kawthar-Ali and Acharya (1996) developed a neural network controller for use in suppressing the dynamic stall vortex that periodically develops in the leading edge of a pitching airfoil. Based on the current state of the unsteady pressure field, their control system specified the optimum amount of leading-edge suction to achieve complete vortex suppression.

### 33.13 Use of MEMS for Reactive Control

---

Current usage for microelectromechanical systems (MEMS) includes accelerometers for airbags and guidance systems, pressure sensors for engine air intake and blood analysis, rate gyroscopes for antilock brakes, microrelays and microswitches for semiconductor automatic test equipment and microgrippers for surgical procedures [Angell et al., 1983; Gabriel et al., 1988; 1992; O'Connor, 1992; Gravesen et al., 1993; Bryzek et al., 1994; Gabriel, 1995; Ashley, 1996; Ho and Tai, 1996; 1998; Hogan, 1996; Ouellette, 1996; Paula, 1996; Robinson et al., 1996a; 1996b; Madou, 1997; Tien, 1997; Amato, 1998; Busch-Vishniac, 1998; Kovacs, 1998; Knight, 1999; Epstein, 2000; O'Connor and Hutchinson, 2000]. Considerable work is under way to include other applications, one example being the micro steam engine described by Lipkin (1993), Garcia and Sniegowski (1993; 1995) and Sniegowski and Garcia (1996). A second example is the 3-cm  $\times$  1.5-cm digital light processor, which contains 0.5 to 2 million individually addressable micromirrors, each typically measuring 16  $\mu\text{m}$  on a side. Texas Instruments, Inc., is currently producing such a device with a resolution of 2000  $\times$  1000 pixels for high-definition televisions and other

display equipments. The company maintains that when mass produced such a device would cost on the order of \$100 (i.e., less than \$0.0001 per actuator).

MEMS would be ideal for the reactive flow control concept advocated in this chapter. Methods of flow control targeted toward specific coherent structures involve nonintrusive detection and subsequent modulation of events that occur randomly in space and time. To achieve proper targeted control of these quasi-periodic vortical events, temporal phasing as well as spatial selectivity are required. Practical implementation of such an idea necessitates the use of a large number of intelligent, communicative wall sensors and actuators arranged in a checkerboard pattern. In this chapter, we have provided estimates for the number, characteristics and energy consumption of such elements required to modulate the turbulent boundary layer which develops along a typical commercial aircraft or nuclear submarine. An upper-bound number to achieve total turbulence suppression is about 1 million sensors/actuators per square meter of the surface, although as argued earlier the actual number needed to achieve effective control could perhaps be one to two orders of magnitude below that.

The sensors would be expected to measure the amplitude, location and phase or frequency of the signals impressed upon the wall by incipient bursting events. Instantaneous wall-pressure or wall-shear stress can be sensed, for example. The normal or in-plane motion of a minute membrane is proportional to the respective point force of primary interest. For measuring wall pressure, microphone-like devices respond to the motion of a vibrating surface membrane or an internal elastomer. Several types are available, including variable-capacitance (condenser or electret), ultrasonic, optical (e.g., optical-fiber and diode-laser) and piezoelectric devices [e.g., Löfdahl et al., 1993; 1994; Löfdahl and Gad-el-Hak, 1999]. A potentially useful technique for our purposes has been tried at MIT [Warkentin et al., 1987; Young et al., 1988; Haritonidis et al., 1990a; 1990b]. An array of extremely small (0.2 mm in diameter), laser-powered microphones (termed *picophones*) was machined in silicon using integrated circuit fabrication techniques and was used for field measurement of the instantaneous surface pressure in a turbulent boundary layer. The wall-shear stress, though smaller and therefore more difficult to measure than pressure, provides a more reliable signature of the near-wall events.

Actuators are expected to produce a desired change in the targeted coherent structures. The local acceleration action needed to stabilize an incipient bursting event can be in the form of adaptive wall, transpiration, wall heat transfer or electromagnetic body force. Traveling surface waves can be used to modify a locally convecting pressure gradient such that the wall motion follows that of the coherent event causing the pressure change. Surface motion in the form of a Gaussian hill with height  $y^+ = \mathcal{O}[10]$  should be sufficient to suppress typical incipient bursts [Lumley, 1991; Carlson and Lumley, 1996]. Such time-dependent alteration in wall geometry can be generated by driving a flexible skin using an array of piezoelectric devices (dilate or contract, depending on the polarity of current passing through them), electromagnetic actuators, magnetoelastic ribbons (made of nonlinear materials that change their stiffness in the presence of varying magnetic fields) or Terfenol-d rods (a novel metal composite developed at Grumman Corporation that changes its length when subjected to a magnetic field). Note should also be made of other exotic materials that can be used for actuation. For example, electrorheological fluids [Halsey and Martin, 1993] instantly solidify when exposed to an electric field and may thus be useful for the present application. Recently constructed microactuators specifically designed for flow control include those by Wiltse and Glezer (1993), James et al. (1994), Jacobson and Reynolds (1995), Vargo and Muntz (1996) and Keefe (1996).

Suction/injection at many discrete points can be achieved by simply connecting a large number of minute streamwise slots, arranged in a checkerboard pattern, to a low-pressure/high-pressure reservoir located underneath the working surface. The transpiration through each individual slot is turned on and off using a corresponding number of independently controlled microvalves. Alternatively, positive-displacement or rotary micropumps [e.g., Sen et al., 1996; Sharatchandra et al., 1997] can be used for blowing or sucking fluid through small holes/slits. Based on the results of Gad-el-Hak and Blackwelder (1989), equivalent suction coefficients of about 0.0006 should be sufficient to stabilize the near-wall region. Assuming that the skin-friction coefficient in the uncontrolled boundary layer is  $C_f = 0.003$  and assuming further that the suction used is sufficient to establish an asymptotic boundary layer ( $d\delta_0/dx = 0$ , where  $\delta_0$  is the

momentum thickness), the skin friction in the reactively controlled case is then  $C_f = 0 + 2C_q = 0.0012$ , or 40% of the original value. The net benefit will, of course, be reduced by the energy expenditure of the suction pump (or micropumps) as well as the array of microsensors and microvalves.

Finally, if the bursting events are to be eliminated by lowering the near-wall viscosity, direct electric-resistance heating can be used in liquid flows, and thermoelectric devices based on the Peltier effect can be used for cooling in the case of gaseous boundary layers. The absolute viscosity of water at 20°C decreases by approximately 2% for each 1°C rise in temperature, while for room-temperature air  $\mu$  decreases by approximately 0.2% for each 1°C drop in temperature. The streamwise momentum equation written at the wall can be used to show that a suction coefficient of 0.0006 has approximately the same effect on the wall curvature of the instantaneous velocity profile as a surface heating of 2°C in water or a surface cooling of 40°C in air [Liepmann and Nosenchuck, 1982; Liepmann et al., 1982].

Sensors and actuators of the types discussed in this section can be combined on individual electronic chips using microfabrication technology. The chips can be interconnected in a communication network controlled by a massively parallel computer or a self-learning neural network, perhaps each sensor/actuator unit communicating only with its immediate neighbors. In other words, it may not be necessary for one sensor/actuator to exchange signals with another far-away unit. Factors to be considered in an eventual field application of chips produced using microfabrication processes include sensitivity of sensors, sufficiency and frequency response of actuators' action, fabrication of large arrays at affordable prices, survivability in the hostile field environment and energy required to power the sensors/actuators. As argued by Gad-el-Hak (1994; 1996; 2000), sensor/actuator chips currently produced are small enough for typical field application and can be programmed to provide a sufficiently large/fast action in response to a certain sensor output (see also Jacobson and Reynolds, 1995). Current prototypes are, however, still quite expensive as well as delicate, but so was the transistor when first introduced! It is hoped that the unit price of future sensor/actuator elements would follow the same dramatic trends witnessed in the cases of the simple transistor and the even much more complex integrated circuit. The price anticipated by Texas Instruments for an array of 1 million mirrors hints that the technology is well on its way to mass-producing phenomenally inexpensive microsensors and microactuators. Additionally, current automotive applications are a rigorous proving ground for MEMS: under-the-hood sensors can already withstand harsh conditions such as intense heat, shock, continual vibration, corrosive gases and electro-magnetic fields.

### 33.14 Parting Remarks

---

In this chapter, I have emphasized the frontiers of the field of flow control, reviewing the important advances that took place during the past few years and providing a blueprint for future progress. The future of flow control is in the taming of turbulence by targeting its coherent structures: *reactive control*. Recent developments in chaos control, microfabrication and soft computing tools are making it more feasible to perform reactive control of turbulent flows to achieve drag reduction, lift enhancement, mixing augmentation and noise suppression. Field applications, however, have to await further progress in those three modern areas.

The outlook for reactive control is quite optimistic. Soft computing tools and nonlinear dynamical systems theory are developing at a fast pace. MEMS technology is improving even faster. The ability of Texas Instruments to produce an array of one million individually addressable mirrors for around 0.01 ¢ per actuator foretells spectacular advances in the near future. Existing automotive applications of MEMS have already proven the ability of such devices to withstand the harsh environment under the hood. For the first time, targeted control of turbulent flows is now in the realm of the possible for future practical devices. What is needed now is a focused, well-funded research and development program to make it all come together for field application of reactive flow control systems.

In parting, it may be worth recalling that a mere 10% reduction in the total drag of an aircraft translates into a saving of \$1 billion in annual fuel cost (at 1999 prices) for the commercial fleet of aircraft in the

U.S. alone. Contrast this benefit to the annual worldwide expenditure of perhaps a few million dollars for all basic research in the broad field of flow control. Taming turbulence, though arduous, will pay for itself in gold. Reactive control, as difficult as it seems, is neither impossible nor pie in the sky. Beside, lofty goals require strenuous efforts. Easy solutions to difficult problems are likely to be wrong, as implied by the witty words of the famed journalist Henry Louis Mencken (1880–1956): “*There is always an easy solution to every human problem—neat, plausible and wrong.*”

### 34.1 Introduction

---

Recently, interest in how to control thermal and fluid phenomena has increased significantly due to an immense need of control technologies aimed at drag reduction, noise reduction and mixing enhancement. In the case of large-scale vehicles, such as an airplane or oil tanker, the skin-friction drag is about 70 to 90% of the total drag. Therefore, reducing turbulent fluctuations to reduce skin-friction is one of the most important problems in fluid mechanics. On the other hand, a great benefit can be obtained by increasing turbulence. For example, turbulence should be increased in order to mix air and fuel efficiently or to decrease form drag of bluff bodies such as a golf ball.

In spite of its importance, research on flow control has been limited because most flows occurring in industrial machinery and transportation vehicles are turbulent. Before the 1960s, turbulent flow was considered to be a completely irregular motion, but now we know that coherent structures exist in turbulent flow, which play an important role in momentum transport [Cantwell, 1981; Robinson, 1991]. One of the most important coherent structures in wall-bounded flows may be the near-wall streamwise vortex, which is responsible for the turbulence production and skin-friction increase near the wall [Kline et al., 1967; Kim et al., 1971; Kravchenko et al., 1993; Choi et al., 1994]. Therefore, attempts to control turbulent flows for engineering applications have been focused on the manipulation of these coherent structures.

In the past (before the 1990s), most turbulence-control strategies for wall-bounded flows were based on passive approaches such as riblets or LEBUs (large-eddy breakup devices). Such devices play a passive role in that there is no feedback (or feedforward) loop to sense or manipulate flow structures; also, no energy input is required. So far, it is known that the riblet is one of the most successful passive devices for skin-friction reduction, which produces maximum 8% drag reduction [Walsh, 1982]. However, there is a limit to reducing skin-friction drag by passive devices alone.

Since 1990, there have been a few studies on the active feedback or feedforward (i.e., reactive) control of dynamically significant coherent structures to achieve skin-friction reduction using direct numerical simulation. The basic strategy of the most successful controls is to manipulate the coherent structures,

especially the near-wall streamwise vortices. For example, in Choi et al. (1994), the blowing or suction velocity at the wall was given as exactly opposite to the wall-normal component of the velocity at  $y^+ = yu_\tau/\nu = 10$ , which is associated with the wall-normal velocity induced by the near-wall streamwise vortices, resulting in more than 25% drag reduction. Here,  $y$  is the wall-normal distance from the wall,  $u_\tau$  is the wall-shear velocity, and  $\nu$  is the kinematic viscosity. However, sensing at  $y^+ = 10$  is not an easy task, so controls based on sensing at the wall have been suggested in the literature [Lee et al., 1997; 1998; Koumoutsakos, 1999]. On the other hand, blowing or suction from a hole or slot is difficult to do in real life; for example, at high altitude, icing blocks the hole such that the actuation mechanism completely fails. Thus, wall movement instead of blowing and suction has also been suggested in the literature [Carlson and Lumley, 1996; Endo et al., 2000; Kang and Choi, 2000]. In spite of all these successful results, real implementation of the reactive-control algorithm is still a very difficult task, mainly because the size of near-wall streamwise vortices is so small (submillimeter) and their occurrence is irregular in space and time. Therefore, detecting the vortices is very difficult, as is controlling them. Fortunately, the recent development of micromachining technology makes it possible to fabricate mechanical parts of micron size [Ho and Tai, 1996; 1998]. Such technology provides us with microsensors and microactuators that can be applied to reactive flow control.

Quite a few review papers on flow control exist in the literature. Therefore, we do not intend to cover all the different aspects of flow control here but rather will limit our discussion to reactive flow controls based on sensing of coherent structures for skin-friction reduction. For those who are interested in the general aspects of flow control, refer to Bushnell and McGinley (1989), Moin and Bewley (1994), Gad-el-Hak (1994, 1996) and Ho and Tai (1996, 1998).

In this chapter, we will first talk about the near-wall streamwise vortices in a boundary layer and then review some successful reactive control strategies for skin-friction reduction using blowing and suction or active wall motion based on sensing of coherent structures. Finally, some issues on practical implementation will be given in the last section.

## 34.2 Near-Wall Streamwise Vortices

---

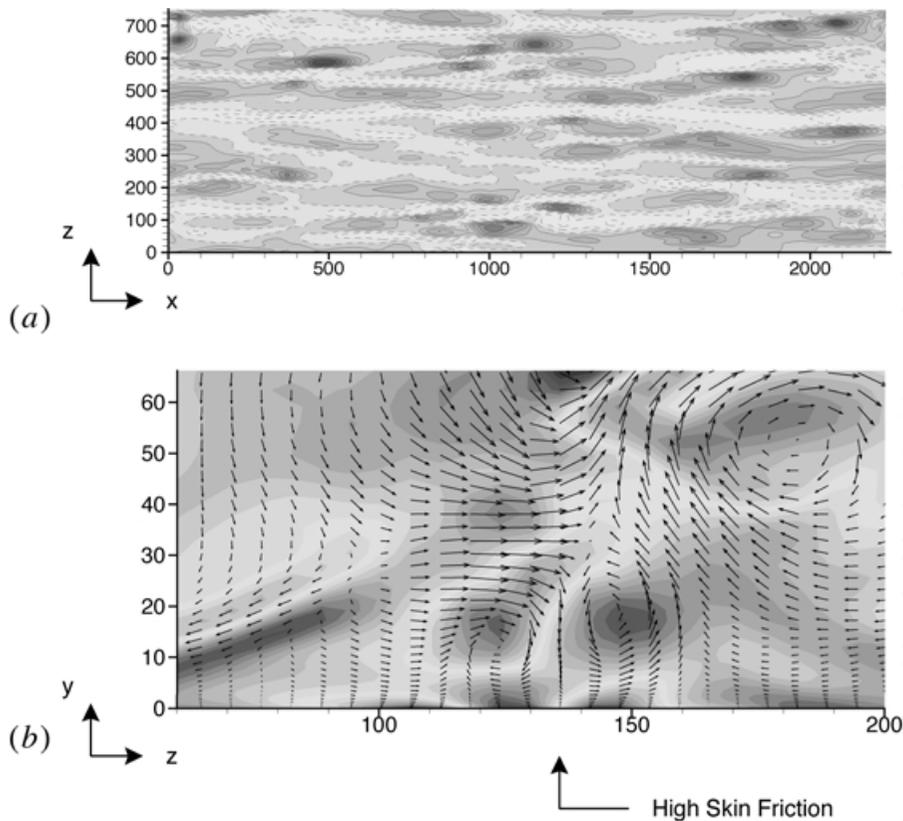

The most well-known structure in the turbulent boundary layer is the streaky structure as shown in Figure 34.1a. Here, the streaky structure denotes the alternating low- and high-speed fluid pattern in the spanwise direction. Kline et al. (1967) showed through flow visualization that turbulent production in the boundary layer is closely associated with lift up, oscillation and breakup of the streaky structures. Corino and Brodkey (1969) reported that turbulent production occurs locally when high-speed fluids approach the wall (called *sweep*). This streaky structure is closely related to the near-wall streamwise vortices that produce sweep and ejection and thus generate turbulence production. Recently, Choi et al. (1994) and Kravchenko et al. (1993) showed that high skin friction on the wall has high correlation with the near-wall streamwise vortices, and the sweep event by them significantly increases the skin friction nearby (Figure 34.1b).

As a successful passive device, the riblets produce maximum 8% drag reduction, in which viscous drag is reduced by restricting the location of streamwise vortices above the wetted surface such that only a limited area of the riblets is exposed to downwash of the high-speed fluid induced by them (Choi et al., 1993a). Therefore, it is a natural consequence to search for a reactive control method that is efficient and more effective in controlling the near-wall streamwise vortices to achieve greater skin-friction reduction than the riblets are.

## 34.3 Opposition Control—Control Based on Physical Intuition

---

Gad-el-Hak and Blackwelder (1989) experimentally investigated the feasibility of removing some or all of the turbulence-producing eddy structures in a turbulent boundary layer using selective suction with knowledge of the spatial location of the eddy structure. They showed that the selective suction eliminates the low-speed streak and prevents bursting at much lower suction strength than that required from the conventional suction method, implying that selective suction may be a good control strategy for skin-friction reduction.

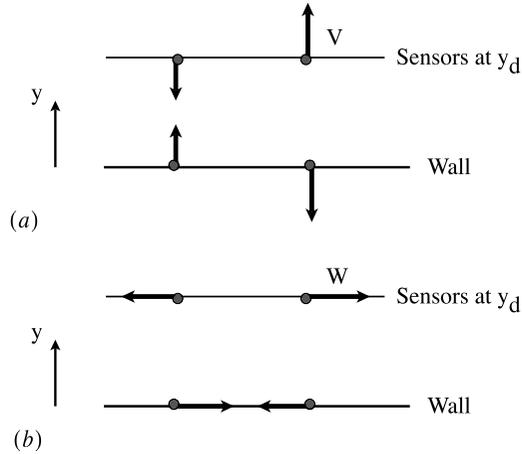

**FIGURE 34.1** (a) Contours of the skin-friction fluctuations at the wall. Negative contours are dashed. (b) Contours of the streamwise vorticity and cross-flow vector  $(v, w)$  in a  $(y, z)$  plane. Contours in gray denote high magnitudes of the streamwise vorticity.

Choi et al. (1994) proposed two active control strategies for the purpose of drag reduction using direct numerical simulation of turbulent channel flow: control with the wall-normal velocity (blowing and suction) at the wall ( $v$  control; Figure 34.2a) and control with the spanwise velocity at the wall ( $w$  control; Figure 34.2b). The control algorithm was that the control-input velocity at the wall is negatively proportional to the instantaneous velocity at a location near the wall. For instance, in the case of  $v$  control, the blowing and suction velocity at the wall was exactly opposite to the wall-normal component of the velocity at a prescribed  $y$  location,  $y_d^+$ ; i.e.,  $v_w = -v|_{y=y_d^+}$  (Figure 34.2a).

Figure 34.3a shows the time histories of the pressure gradients that were required to drive a fixed-mass flow rate for the unmanipulated, fully developed channel flow and for manipulated ( $v$  control) channel flows. Substantial skin-friction reduction was obtained ( $\approx 25\%$  on each wall) with  $y_d^+ \approx 10$ . For other  $y_d^+$  locations, either the drag was substantially increased ( $y_d^+ \approx 26$ ) or the reduction was small ( $y_d^+ \approx 5$ ). Noting that the streamwise vortices lead to strong spanwise velocity as well as wall-normal velocity, the out-of-phase boundary condition was applied to the spanwise velocity at the surface; i.e.,  $w_w = -w|_{y=y_d^+}$  (Figure 34.2b). Several sensor locations ranging from  $y_d^+ \approx 5$  to 26 were tested, and the best result was obtained with  $y_d^+ \approx 10$ , yielding about 30% drag reduction (Figure 34.3b), which is slightly better than the optimum  $v$  control. With  $y_d^+ > 20$ , the drag was increased.

The velocity, pressure and vorticity fluctuations as well as the Reynolds shear stress were significantly reduced throughout the channel (see Figure 34.4 for the change in strength of the streamwise vorticity). Instantaneous flowfields showed that streaky structures below  $y^+ \approx 5$  were clearly diminished by the active control, and the physical spacing of the streaky structure above  $y^+ \approx 5$  was increased in the

**FIGURE 34.2** Schematic diagram of controls used by Choi et al. (1994): (a)  $v$  control; (b)  $w$  control. (Reprinted from Choi, H. et al. (1994) *J. Fluid Mech.* **262**, p. 75. With permission of Cambridge University Press.)

manipulated channels. The active blowing and suction or spanwise velocity at the wall significantly affected turbulence statistics above the wall.

A schematic diagram of the drag-reduction mechanism is shown in Figure 34.5. The high shear-rate regions on the wall are moved to the interior of the channel ( $y^+ \approx 5$ ) by the control schemes. The sweep motion due to strong streamwise vortices is directly deterred by active controls. Note that, in the case of  $w$  control, a wall-normal velocity is induced very near the wall by the imposed spanwise velocity distribution at the wall; from the continuity equation at the wall,  $\partial v/\partial y = -\partial w/\partial z \neq 0$ , leading to higher values of  $v$  near the wall.

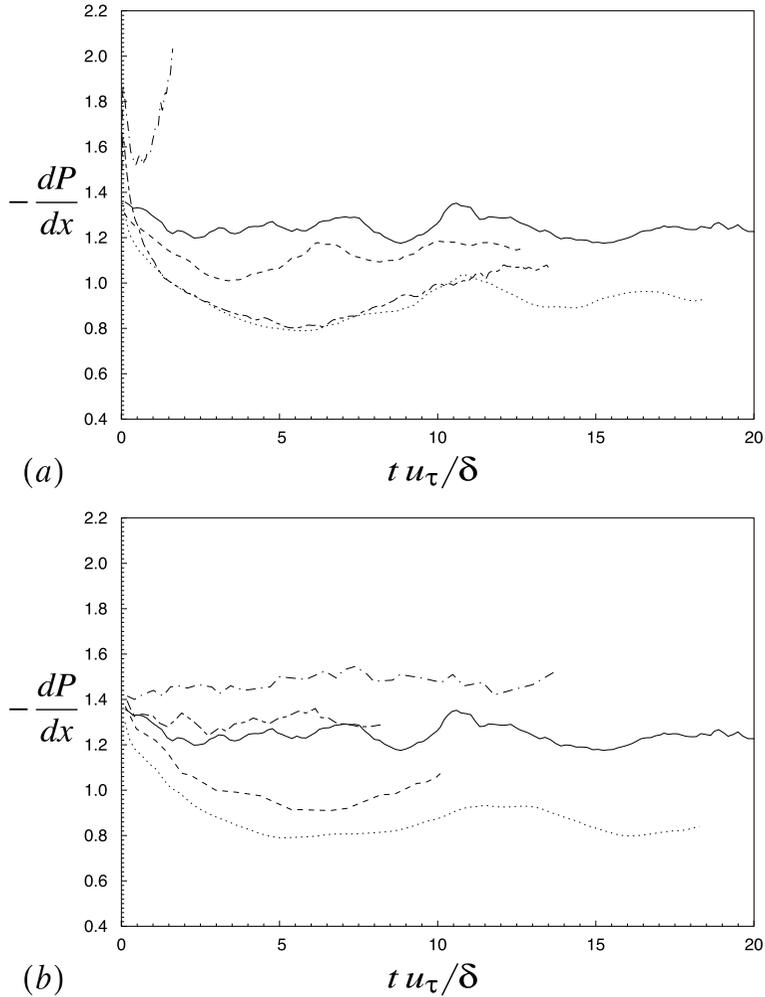

## 34.4 Reactive Controls Based on Sensing at the Wall

Even though Choi et al. (1994) showed that turbulent skin friction could be reduced by suppressing the dynamically significant coherent structures present in the wall region (i.e., near-wall streamwise vortices), practical implementation of their control scheme is nearly impossible at this time because one has to measure spatial distribution of the wall-normal velocity at  $y^+ = 10$ . They also considered control of turbulent boundary layer by placing sensors only at the wall for practical implementation; using the Taylor series expansion, the wall-normal velocity at  $y^+ = 10$  was approximated as  $v|_{y^+=10} \sim -\frac{\partial}{\partial z} \frac{\partial w}{\partial y}|_w$ . However, a control based on this variable yielded only about 6% drag reduction, which is smaller than the maximum drag reduction by the riblets.

Motivated by the drag reduction techniques discussed in Choi et al. (1994), two successful active control methods based on wall measurement for skin-friction reduction have been presented. One uses the neural network [Lee et al., 1997] and the other uses the suboptimal control theory [Lee et al., 1998]. Both approaches applied blowing and suction to turbulent channel flow. Very recently, Koumoutsakos (1999) presented a feedback-control result in a turbulent channel flow, where the sensing variable is the vorticity flux at the wall and the actuation is blowing and suction at the wall. In this section, we summarize these three studies.

### 34.4.1 Neural Network

The objective of the work reported in Lee et al. (1997) was to seek wall actuations to obtain skin-friction reduction, in the form of blowing and suction at the wall, based on sensing of the wall shear stress. This requires knowledge of how the wall shear stress responds to wall actuation. Because of the complexity of turbulent flow, however, it is not possible to find such a correlation in a closed form or to approximate

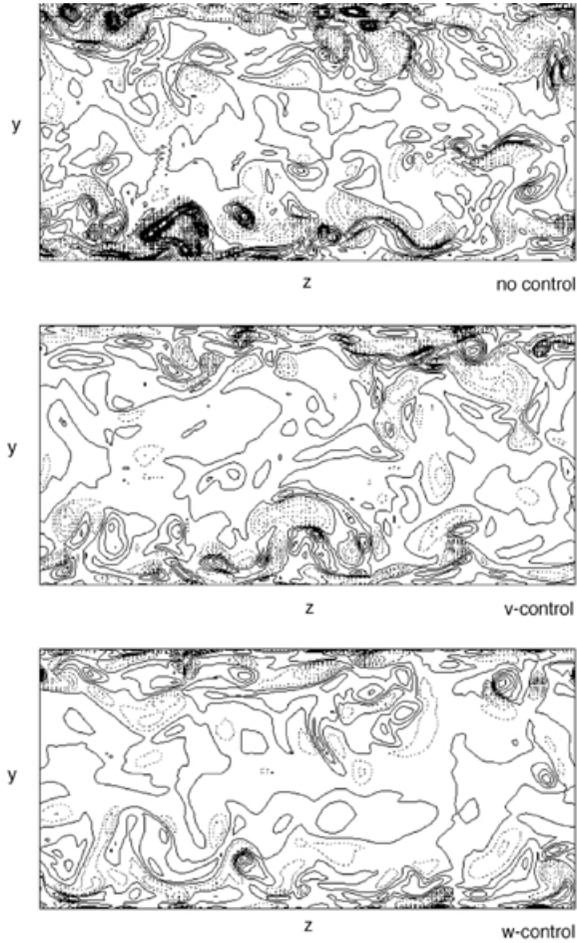

**FIGURE 34.3** Time history of the pressure gradient required to drive a fixed-mass flow rate in the cases of (a)  $\nu$  control and (b)  $w$  control. *Note:* —, unmanipulated channel; ---, manipulated channel with sensors at  $y_d^+ \approx 5$ ; .....  $y_d^+ \approx 10$ ; - - - - ,  $y_d^+ \approx 20$ ; and - · - · - ,  $y_d^+ \approx 26$ . (Reprinted from Choi, H. et al. (1994) *J. Fluid Mech.*, **262**, 75. With permission of Cambridge University Press.)

it in a simple form. Thus, they used a neural network to approximate the correlation that predicts the optimal wall actuation to achieve minimum skin-friction drag.

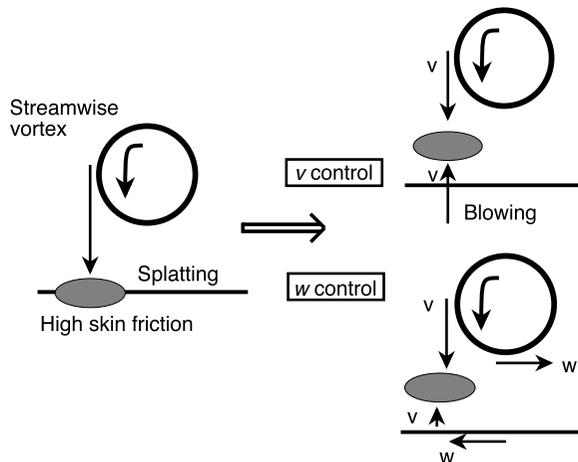

A standard two-layer feedforward network with hyperbolic tangent hidden units and a linear output unit were used. The functional form of the final neural network was

$$v_w(x, z, t) = W_a \tanh \left( \sum_{j=-(N-1)/2}^{(N-1)/2} W_j \frac{\partial w}{\partial y} \Big|_w (w, z + j\Delta z, t) - W_b \right) - W_c \quad (34.1)$$

where  $W$  denotes the weights,  $N$  is the total number of input weights, and  $\Delta z$  is the grid spacing in the spanwise direction. Seven neighboring points ( $N = 7$ ), including the point of interest, in the spanwise direction (corresponding to approximately 90 wall units) were found to provide enough information to adequately train and control the near-wall structures responsible for high skin friction. The network was trained to minimize the sum of a weighted-squared error that is proportional to the square of the

**FIGURE 34.4** Contours of the streamwise vorticity in a cross-flow plane. The contour levels are the same for the cases with and without control, and negative contours are dotted. FIGURE 34.6 Weight distribution: —, from neural network; ----, suboptimal control.

difference between the desired control input and the network control input. In their off-line training and control, the wall-normal velocity at  $y^+ = 10$  was considered as a desired control input. After training was completed, the weight distribution in the spanwise direction was obtained, which is shown in Figure 34.6. Applying this control scheme to a turbulent channel flow at low Reynolds number resulted in about 20% drag reduction. The computed flow fields were examined to determine the mechanism by which the drag reduction was achieved. The most salient feature of the controlled case was that the strength of the near-wall streamwise vortices was substantially reduced. This result further substantiates the notion that a successful suppression of the near-wall streamwise vortices leads to a significant reduction in drag.

Lee et al. (1997) further considered a neural network with continuous on-line training, from which a very simple control scheme was obtained:

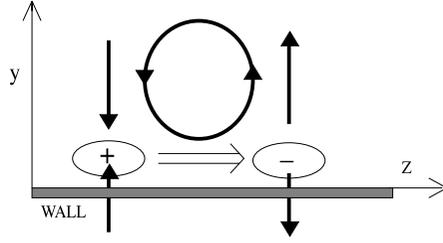

$$\hat{v}_w = C \frac{ik_z}{|k_z|} \frac{\partial \hat{w}}{\partial y} \Big|_w \quad (34.2)$$

Here, the hat ( $\hat{\cdot}$ ) denotes the Fourier component,  $k_z$  is the spanwise wavenumber, and  $C$  is a positive scale factor that determines the root-mean-square (rms) value of the actuation. This control worked equally well as Eq. (34.1).

### 34.4.2 Suboptimal Control

A systematic approach based on an optimal control theory was proposed by Abergel and Temam (1990). Choi et al. (1993b) proposed a “suboptimal” control procedure, in which the iterations required for global optimal control were avoided by seeking an optimal condition over a short time period. Lee et al. (1998) derived a simple control scheme by minimizing cost functions that are related to the near-wall streamwise vortices. They demonstrated that a wise choice of the cost function coupled with a variation of the formulation can lead to a more practical control law. They showed how to choose a cost function and how to minimize it to yield simple feedback control laws that require quantities measurable only at the wall. One of the laws requires spatial information on the wall pressure over the entire wall and the other requires information on one component of the wall shear stress. They then derive more practical control schemes that require only local wall pressure or local wall shear-stress information and show that the schemes work equally well. Here, we will explain the suboptimal control approach based on sensing of the wall shear stress.

In Lee et al. (1998), a cost function was chosen based on observation of the successful controls by Choi et al. (1994). The blowing and suction by Choi et al. (1994), equal and opposite to the wall-normal

**FIGURE 34.7** Effect of active blowing and suction on the pressure and spanwise velocity gradient near the wall. (Reprinted from Lee, C. et al. (1998) *J. Fluid Mech.*, **358**, 245. With permission of Cambridge University Press.)

velocity component at  $y^+ = 10$ , effectively suppress a streamwise vortex by counteracting up-and-down motion induced by the vortex. This blowing and suction action creates locally high pressure in the near-wall region marked + and low pressure in the region marked - in Figure 34.7. A crucial aspect of their analysis is the observation that this blowing and suction action *increases* the pressure gradient in the spanwise direction under the streamwise vortex near the wall and subsequently increases the spanwise velocity gradient  $\partial w/\partial y$  near the wall. The above argument suggests that we should seek the blowing and suction velocity that increases  $\partial w/\partial y$  near the wall for a short time period (i.e., in the suboptimal sense), in order to achieve a drag reduction similar to that achieved by Choi et al. (1994). The cost function  $J(v_w)$  to be minimized is then:

$$J(v_w) = \frac{l}{2A\Delta t} \int_S \int_t^{t+\Delta t} v_w^2 dt dS - \frac{1}{2A\Delta t} \int_S \int_t^{t+\Delta t} \left( \frac{\partial w}{\partial y} \right)_w^2 dt dS \quad (34.3)$$

where the integrations are over the wall,  $S$ , in space and over a short duration in time,  $\Delta t$ , which typically corresponds to the time step used in the numerical computation;  $l$  is the relative price of the control, as the first term on the right-hand side represents the cost of the actuation  $v_w$ . Note that there is a minus sign in front of the second term, as we want to maximize  $\partial w/\partial y$  at the wall. It should be noted that the spanwise velocity gradient at the wall will *eventually* be reduced when the strength of the near-wall streamwise vortices is reduced through successful control. Here, blowing and suction that increase the spanwise-velocity gradient for the next step are sought as a suboptimal control. After some mathematical procedure, the blowing and suction velocity of minimizing the cost function is obtained as:

$$\hat{v}_w = C \frac{ik_z \partial \hat{w}}{k \partial y} \Big|_w, \quad (34.4)$$

where the hat denotes the Fourier coefficient;  $k^2 = k_x^2 + k_z^2$ ,  $k_x$  and  $k_z$  are the streamwise and spanwise wavenumbers, respectively; and  $C$  is a positive scale factor that determines the cost of the actuation. The above equation indicates that the optimum wall actuation should be proportional to the spanwise derivative of the spanwise shear at the wall, ( $\hat{v}_w \sim \frac{\partial \partial w}{\partial z \partial y} \Big|_w$ ), with the high wavenumber components reduced by  $1/k$ . Note that the scale factor,  $C$ , in Eq. (34.4) is arbitrary: In the simulations, the rms value of  $v_w$  was taken to be equal to that of the wall-normal velocity at  $y^+ = 10$ , which gives the same rms value of wall actuations as that of Choi *et al.* (1994). Applying Eq. (34.4) to turbulent channel flow produced about 22% drag reduction. Turbulence modification was also very similar to those shown in Choi et al. (1994) and Lee et al. (1997).

Note that the control law from the neural network (Lee et al. 1997) shown in Eq. (34.2) produced almost the same distribution of blowing and suction as Eq. (34.4), because the near-wall structures have a relatively slow variation in the streamwise direction (the  $k_x = 0$  component is dominant). This blowing and suction distribution is also very similar to the one based on  $y^+ = 10$  data.

The control scheme presented above, however, is still impractical to implement, because it is expressed in terms of the Fourier components (i.e., in wavenumber space), which require information over the

entire spatial domain. Therefore, the inverse transform of  $ik_z/k$  was sought numerically so that the convolution integral could be used to express the control law in physical space. For example, the discrete representation of the control law, Eq. (34.4), then became:

$$v_w(x, z, t) = C \sum_j W_j \left. \frac{\partial w}{\partial y} \right|_w (x, z + j\Delta z, t) \quad (34.5)$$

The weights,  $W_j$ , decayed rapidly with distance from the point of interest, suggesting that the optimum actuation can be obtained by a local weighted average of  $\partial w/\partial y|_w$ . The result obtained using an 11-point average yielded about the same drag reduction as that obtained from full integration using Eq. (34.4). It is remarkable that localized information can produce such a significant drag reduction. The weight distribution,  $W_j$ , was very similar to the one found by applying the neural network to the same turbulent flow (see Figure 34.6).

### 34.4.3 Vorticity Flux Control

For an incompressible viscous flow over a stationary wall, the vorticity fluxes at the wall are directly proportional to the pressure gradients:

$$v \left. \frac{\partial \omega_x}{\partial y} \right|_w = \frac{1}{\rho} \left. \frac{\partial p}{\partial z} \right|_w, \quad -v \left. \frac{\partial \omega_z}{\partial y} \right|_w = \frac{1}{\rho} \left. \frac{\partial p}{\partial x} \right|_w \quad (34.6)$$

where  $p$  is the pressure, and  $\omega_x$  and  $\omega_z$  are the streamwise and spanwise vorticity components. The flux of the wall-normal vorticity,  $\omega_y$ , can be determined from the kinematic condition ( $\nabla \cdot \omega = 0$ ).

A feedback-control vorticity-flux algorithm was presented and applied to a turbulent channel flow in Koumoutsakos (1999), where the wall pressure was sensed and its gradient (the wall vorticity flux) was calculated. Unsteady blowing and suction at the wall were the control inputs and the strength was calculated explicitly by formulating Lighthill's mechanism of vorticity generation at a no-slip wall. He considered a series of vorticity flux (or, equivalently, pressure gradient) sensors on the wall at locations  $(x_i, z_i)$ ,  $i = 1, 2, 3, \dots, M$ , and determined the blowing and suction strengths necessary to achieve a desired vorticity flux profile at the wall at a time instant,  $k$ , by solving the linear set of:

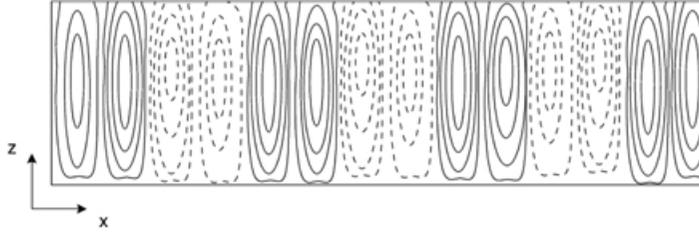

$$Bu_k + X_{k-1} = D_k, \quad (34.7)$$

where  $D_k$  is an  $M \times 1$  vector of the *desired* vorticity flux at the sensor locations,  $X_{k-1}$  is an  $M \times 1$  vector of the *measured* vorticity flux at the sensor locations, and  $u_k$  is an  $N \times 1$  vector of blowing and suction strengths at the actuator locations.  $B$  is an  $M \times N$  matrix whose elements  $B_{ji}$  are a function of the relative locations of the sensors ( $j$  index) and actuators ( $i$  index) (see Koumoutsakos, 1999, for more details). The unknown blowing and suction strengths were determined by solving Eq. (34.7).

An additional equation that determines how the desired and measured vorticity flux components are related was given as:

$$\begin{pmatrix} v \frac{\partial \omega_x}{\partial y} \\ v \frac{\partial \omega_z}{\partial y} \end{pmatrix}_{\text{control}} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} v \frac{\partial \omega_x}{\partial y} \\ v \frac{\partial \omega_z}{\partial y} \end{pmatrix}_{\text{measured}} \quad (34.8)$$

where the coefficients,  $a, b, c, d$ , can be chosen *a priori* and may be constant or spatially varying. The simulations presented in Koumoutsakos (1999) have been conducted with the set of parameters  $a = b = c = 0$  and  $d = \pm 1$ , equivalent to considering the *in-* and *out-of-phase* control, respectively, of the *spanwise* vorticity flux. Here, the in-phase control implies enhancement of the wall vorticity flux, whereas the out-of-phase control implies cancellation of the induced vorticity flux. He presented the results for the case of out-of-phase control.

**FIGURE 34.8** Highly spanwise correlated pattern of the blowing and suction as seen in Koumoutsakos (1999): —, blowing; ----, suction. (Reprinted from Koumoutsakos, p. (1999) *Phys. Fluids* **11**, p. 248. With permission of American Institute of Physics.)

For the out-of-phase control, the streaks were eliminated and highly spanwise correlated patterns were established for the spanwise vorticity flux, shear stresses and actuation strengths (see, for example, Figure 34.8). These spanwise-correlated structures and further flow visualizations suggested the formation of unsteady spanwise vortical rollers in the inner layer of the wall. These spanwise vortical rollers resulted in the formation of positive and negative shear stresses at the wall. The elimination of streaks and disruption of the near-wall processes by establishment of the particular vortical rollers resulted in skin-friction reduction on the order of 40%. The regularity in the resulting actuation strength as shown in Figure 34.8 suggests that it may be possible to devise an open-loop control law, but further study in that direction was not conducted.

## 34.5 Active Wall Motion—Numerical Studies

Although the control schemes presented in the previous section (i.e., sensing at the wall) are a significant improvement over that of Choi et al. (1994), which requires velocity information above the wall, other issues must be resolved before these control schemes can be implemented in real situations (e.g., time delay between sensing and actuation). Other approaches, such as active wall motion using deformable actuators, may be more practical. So far, three studies involving active wall motion have been carried out using numerical simulation. A brief overview of these studies is given in this section.

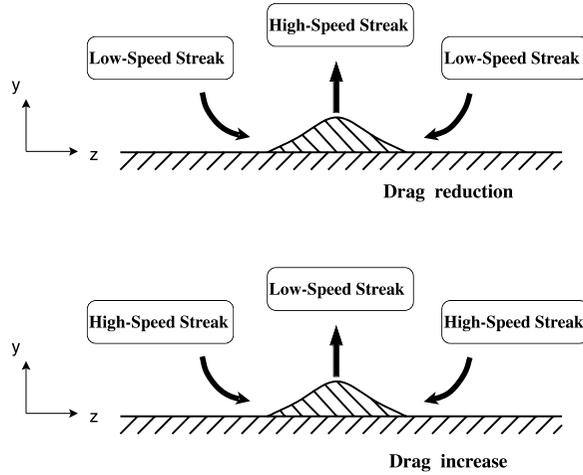

### 34.5.1 Streak Control

Carlson and Lumley (1996) simulated turbulent flow in a minimal channel with time-dependent wall geometries in order to investigate the effect of wall movement on skin friction. The control device consisted of *one* actuator (Gaussian shape and about 12 wall units in height) on one of the channel walls:

$$h(x, z, t) = \varepsilon(t) \exp \left\{ -\sigma^{-2} \left[ (x - x_o)^2 + \left( \frac{z - z_o}{\mu} \right)^2 \right] \right\} \quad (34.9)$$

where  $h$  is the time-varying (due to  $\varepsilon(t)$ ) height of the actuator;  $(x_o, z_o)$  is the center location of the actuator;  $\sigma = 0.18\delta$ ;  $\mu = 1\delta$  or  $2\delta$ ; and  $\delta$  is the channel half-width. The control device located underneath either a high-speed streak or a low-speed streak (note that the minimal channel investigated in Carlson and Lumley has only one vortical structure on one side of the channel, thus only one pair of high- and low-speed streaks exists on the controlled wall).

Raising the actuator underneath a low-speed streak increased drag, but raising it underneath a high-speed streak reduced drag. They claimed that fast-moving fluid in the high-speed region is lifted by the actuator away from the wall, allowing the adjacent low-speed region to expand, thereby lowering the average wall shear stress. Conversely, raising an actuator underneath a low-speed streak allows the adjacent high-speed region to expand, which increases the skin friction (Figure 34.9). However, they could not present the amount of time-averaged drag reduction due to wall motion because only a short time control was conducted in their study.

**FIGURE 34.9** Schematic diagram of the mechanism for drag reduction or increase due to wall motion as seen in Carlson and Lumley (1996). (Reprinted from Carlson, A., and Lumley, J.L. (1996) *J. Fluid Mech.* **329**, p. 341. With permission of Cambridge University Press.)

Later, Endo et al. (2000) designed a realistic array of deformable actuators elongated in the streamwise direction. Each actuator moved up and down and induced the wall-normal velocity at the wall. The wall velocity of the actuator was determined by:

$$v_w(x, z, t) = v_m(t)f(x) \exp\left[-\frac{(z-z_0)^2}{\sigma_z^2}\right] \sin\left[\frac{2\pi(z-z_0)}{m_z}\right] \quad (34.10)$$

$$v_m(t) = \begin{cases} \alpha \tanh\left(\frac{\partial}{\partial z} \frac{\partial u}{\partial y} \frac{1}{\beta}\right) - \gamma y_m & \text{if } \frac{\partial}{\partial z} \frac{\partial w}{\partial y} < 0, \\ -\gamma y_m & \text{otherwise} \end{cases} \quad (34.11)$$

where  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\sigma_z$ ,  $m_z$  and  $y_m$  are the control parameters;  $f(x)$  is a hyperbolic-tangent function (see Endo et al., 2000); and  $v_m$  is the wall velocity at the center of the actuator ( $x_0, z_0$ ). Each sensor measured the spanwise distribution of the streamwise wall shear rate,  $\left.\frac{\partial}{\partial z} \frac{\partial u}{\partial y}\right|_w$  (see Eq. (34.11)), located in front of the actuator.

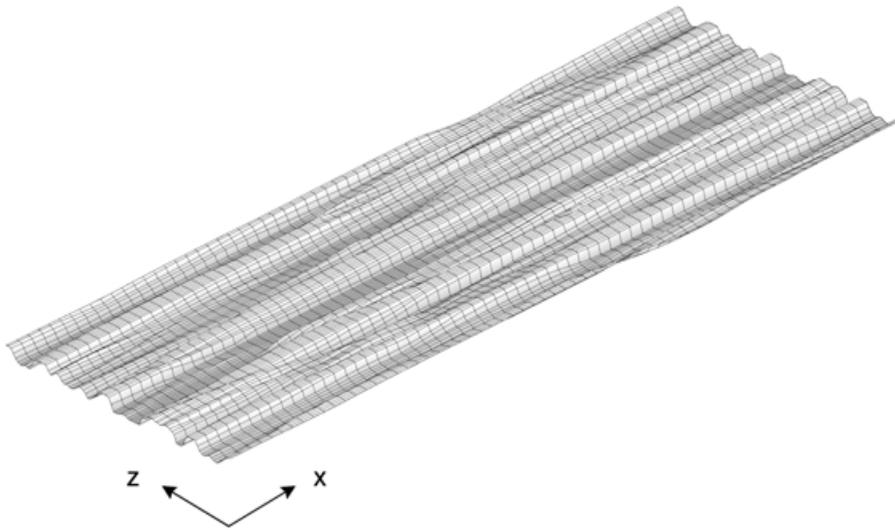

With the control scheme above, Endo et al. (2000)<sup>w</sup> obtained about 10% drag reduction. Because measurement of the streamwise shear rate was a concern in their approach, the main mechanism of the drag reduction is believed to attenuate and stabilize streak meandering and thus to hamper the regeneration cycle of the near-wall turbulence [Hamilton et al., 1995].

### 34.5.2 Near-Wall Streamwise-Vortex Control

Kang and Choi (2000) conducted numerical simulations to investigate a possibility of reducing skin-friction drag in a turbulent channel flow with active wall motions. The wall was locally (and continuously) deformed according to the successful control strategy developed from the suboptimal control [Lee et al., 1998] and thus the induced velocity at the wall by wall motion was represented as:

$$\hat{v}_w = C \frac{ik_z}{k} \frac{\partial \hat{w}}{\partial y} \Big|_w \quad (34.12)$$

which is the same as Eq. (34.4). Because the Fourier transformation is not realistic (one needs information on an entire wall), a more realistic wall-motion control strategy was devised by applying the 11-point weighted average of  $\partial w / \partial y|_w$  in physical space (see Eq. (34.5)).

**FIGURE 34.10** Instantaneous wall shape. (Reprinted from Kang, S., and Choi, H. (2000) *Phys. Fluids*, **12**, 3301. With permission of American Institute of Physics.)

As a result, about 13 to 15% drag reduction was obtained due to active wall motions. Active wall motions significantly weakened the strength of the streamwise vortices near the wall. An instantaneous wall shape during control is shown in [Figure 34.10](#). The rms amplitude of wall deformation was about 3 wall units. The wall shapes were elongated in the streamwise direction and resembled riblets in appearance (a similar wall shape was also observed by Endo et al., 2000). The average peak-to-peak distance of the grooved wall shape was around 100 wall units, with which riblets hardly reduce the skin-friction drag; therefore, the mechanism of the drag reduction is essentially different from that of riblets. That is, the active wall motion directly suppresses the near-wall streamwise vortices by the induced blowing and suction, whereas passive riblets restrict the location of the streamwise vortices above the wetted surface such that only a limited area of the riblets is exposed to the downwash motion that the vortices induce.

## 34.6 Concluding Remarks

There have been many experimental studies on passive or open-loop active control in a turbulent boundary layer. Most work has focused on understanding the flow response to external disturbances, such as uniform or periodic blowing and suction, or surface roughness. This work did not seriously consider drag reduction performance because measuring the skin friction in a perturbed turbulent boundary layer is not easy. To the best of the author's knowledge, no study has shown an experimental evidence of drag reduction using an active open-loop control strategy with a constraint of zero-net mass flow rate. Only a very few preliminary experimental studies so far have considered reactive (feedback or feedforward) control for skin-friction reduction in a turbulent or laminar boundary layer. Jacobson and Reynolds (1998) implemented a spring-board-type actuator in a laminar boundary layer, which produced a quasi-steady pair of counter-rotating streamwise vortices. They showed that transition was delayed by 40 displacement thicknesses, and the mean and spanwise variation of wall shear stress was substantially reduced downstream of a single transverse array of actuators. Rathnasingham and Breuer (1997) constructed a linear feedforward control algorithm and applied it to a turbulent boundary layer for skin-friction reduction. It was shown that using three wall-based sensors and a single actuator, the control produced a maximum of 31% reduction in the rms streamwise velocity fluctuations. However, they did not show the detailed skin-friction variation due to the measurement difficulty.

In this chapter, we have shown that the skin friction can be reduced by manipulating the near-wall streamwise vortices or streaks using either blowing and suction or wall motion. For the past 10 years,

quite a few different successful control strategies have been presented using numerical simulations, and they have provided information about what to manipulate for skin-friction reduction. The maximum reduction of skin-friction drag obtained so far is relaminarization at low Reynolds number (see Choi et al., 1994, for  $v$  and  $w$  control; Bewley et al., 2000, for optimal control). The control methods based on wall sensing using neural network or suboptimal control produced a maximum of 20% drag reduction. However, in a practical implementation, sensing and controlling the vortices are difficult tasks. One of the main reasons is that the near-wall structures appear randomly in space and in time. Thus, one has to place the sensors and actuators over the entire surface in order to obtain a substantial decrease of drag. Another reason is that the typical diameter of the near-wall streamwise vortices is about 30 wall units [Kim et al., 1987], which is about 100  $\mu\text{m}$  in laboratory experiments. In order to detect and control these vortices, the size of sensors and actuators should be comparable to that of the vortices.

Practical implementation of reactive control algorithms developed from numerical studies has been hampered by difficulties in manufacturing microsensors and actuators using traditional machining tools. However, recent development of micromachining technology now makes it possible to fabricate micron-size mechanical parts, thus microsensors and microactuators can be mass produced. So far, microelectromechanical system (MEMS) technology has been successfully applied to active open-loop control of flow over bluff bodies [e.g., Ho and Tai, 1998, and the references therein]. Also, microsensors and microactuators for boundary-layer flow have been developed using MEMS technology (Ho and Tai, 1998). Spatial distribution of the skin friction has been measured using microsensors, and changes in boundary-layer flow due to microactuators have been thoroughly investigated. Researchers are now implementing the reactive control algorithms in laboratory experiments using MEMS technology and are expecting a significant amount of skin-friction reduction comparable to that obtained from numerical studies.

In most numerical studies mentioned in the previous sections, sensors and actuators are collocated and distributed all over the computational domain. In reality, sensors and actuators cannot be collocated and actuators should be located downstream of the sensors. Therefore, how to efficiently distribute the sensors and actuators is an important issue. The second issue is how to develop a new control method that is well suited for an experimental approach (note that most control methods investigated so far started from numerical studies). The third issue is the Reynolds number effect. Relaminarization of turbulent flow due to control, as has been observed in numerical studies, might happen because of a low Reynolds numbers. At low Reynolds numbers, the dynamics of boundary-layer flow is mostly governed by near-wall phenomena, whereas it is not only affected by the near-wall behavior but also by the fluid motion in the buffer or outer layer. Therefore, various control algorithms may have to be developed depending on the Reynolds number.

### 35.1 Introduction

---

Interest in application of microelectromechanical systems (MEMS) technology to flow control and diagnostics started around the early 1990s. During this relatively short time period, a handful attempts have been aimed at using the new technology to develop and implement reactive control of various flow phenomena. The ultimate goal of these attempts has been to capitalize on the unique ability of MEMS to integrate sensors, actuators, driving circuitry and control hardware in order to attain *autonomous* active flow management. To date, however, there has been no demonstration of a fully functioning MEMS flow control system, whereby the multitude of information gathered from a distributed MEMS sensor array is successfully processed in real time using on-chip electronics to produce an effective response by a distributed MEMS actuator array.

Notwithstanding the inability of research efforts in the 1990s to realize autonomous MEMS control systems, the lessons learned are invaluable in understanding the strengths and limitations of MEMS in flow applications. In this chapter, the research work aimed at MEMS-based autonomous control of free-shear flows over the past decade is reviewed. The main intent is to use the outcome of these efforts as a telescope to peek through and project a vision of future MEMS systems for free-shear flow control. The presentation of the material is organized as follows: First, important classifications of free-shear flows are introduced in order to facilitate subsequent discussions, and, second, a fundamental analysis concerning the usability of MEMS in different categories of free-shear flows is provided. This is followed by an outline of autonomous flow control system components, with a focus on MEMS in free-shear flow

applications, and related issues. Finally, the bulk of the chapter is used to review prominent research efforts in the 1990s, leading to a vision of future systems.

## 35.2 Free-Shear Flows: A MEMS Control Perspective

---

Free-shear flows refer to the class of flows that develop without the influence imposed by direct contact with solid boundaries. However, in the absence of thermal gradients, nonuniform body-force fields or similar effects, the vorticity in free-shear flows is actually acquired through contact with a solid boundary at one point in the history of development of the flow. The “free-shear state” of the flow is attained when it separates from the solid wall, carrying with it whatever vorticity is contained in the boundary layer at the point of separation. The mean velocity profile of the shear layer at the point of separation is inflectional and hence is inviscidly unstable; that is, it is extremely sensitive to small perturbations if excited at the appropriate frequencies. This point is of fundamental importance to MEMS-based control.

Because MEMS devices are micron in scale, they are only capable of delivering proportionally small energies when used as actuators. Therefore, if it were not for the high sensitivity of free-shear flows to disturbances at the point of separation, there would be no point in attempting to use MEMS actuators for shear-layer control. Moreover, it should be emphasized that active control of free-shear flows using MEMS as a disturbance source must be applied at, or extremely close to, the point of separation. The same statement can be extended to the more powerful conventional actuators, such as glow-discharge, large-scale piezoelectric devices, large-scale flaps, etc., if high-gain or efficient control is desired.

From a control point of view, it is useful to classify free-shear flows according to whether the separation line is stationary or moving. Stationary separation line (SSL) flows include jets, single- or two-stream shear layers and backward-facing step flows. In these flows, separation takes place at the sharply defined trailing edge of a solid boundary at the “origin” of the free-shear flow. On the other hand, moving separation line (MSL) flows include dynamic separation over pitching airfoils and wings, periodic flows through compressors and forward-facing step flows. The separation point in the latter, although steady on average, jitters around due to the lack of a sharp definition of the geometry at separation (such as the nozzle lip for the shear layer surrounding a jet).

Whether the free-shear flow to be controlled is of the SSL or MSL type is extremely important, not only from the point of view of control feasibility and ease but also concerning the need for MEMS vs. conventional technology. In particular, in SSL flows, actuators (MEMS or conventional) can be located directly at the known point of separation where they would be effective. As the operating conditions change (for example, through a change in the speed of a jet) the same set of actuators can be used to affect the desired control. In contrast, in an MSL flow, the instantaneous location of the separation line has to be known and only actuators located along this line should be used for control.

To fix the ideas further, consider controlling dynamic separation over a pitching two-dimensional airfoil. As the airfoil is pitched from, say, zero to a sufficiently large angle of attack, a separated shear layer is formed. The separation line of this shear layer moves with increasing angle of attack. In order to control this separating flow using MEMS or other conventional actuators, it is necessary to track the location of the separation point in real time in order to activate only those actuators located along the separation line. This would require distributed, or array, measurements on the surface of the airfoil. Furthermore, because the separation-line-locating algorithm is likely to employ spatial derivatives of the surface measurements, the surface sensors must have high spatial resolution and be packed densely. Therefore, in MSL problems, it seems inevitable to use MEMS sensor arrays if autonomous control is to be successful. Note that this statement is believed to be true regardless of whether MEMS or conventional technology is used for actuation.

When considering MEMS control systems, another useful classification is that associated with the characteristic size of the flow. With the advent of MEMS, it is now common to observe flows confined to domains that are no larger than a few hundred microns in characteristic size. Such flows may be found in different microdevices including pumps, channels, nozzles, turbines, etc. Therefore, it is important to distinguish between microscale (MIS) flows and their macro counterpart (MAS). In particular, there

should be no ambiguity about whether or not only MEMS, or perhaps even NEMS (nanoelectromechanical systems), are the only feasible method of control within a microdevice.

A good example of where free-shear flows may be encountered in microdevices is the MIT microengine project [Epstein et al., 1997]. In the intricate, complex devices engineered in this project, shear layers exist in the microflows over the stator and rotor of the compressor and turbine and in the sudden expansion leading to the combustion chamber. Whether or not those shear layers and their susceptibility to excitation within the confines of the microdevice mimic those of macroscale shear layers is yet to be established. However, as indicated above, if control is to be exercised, the limitation imposed by the scale of the device dictates that any actuators and or sensors have to be as small, if not smaller, than the device itself.

It should be noted here that active control of MIS flows is an area that is yet to be explored. This, in part, is because of the fairly short time since interest in such flows started. Therefore, further discussion of the subject would be appropriately left to a future date when sufficient literature is available.

## 35.3 Shear-Layer MEMS Control System Components and Issues

To facilitate subsequent discussion of the research work pertaining to MEMS-based control of free-shear flows, the different components of the control system will be discussed and analyzed here. Of particular importance are the issues specific to utilization of MEMS technology to realize the control system components. Figure 35.1 displays a general functional block diagram for feedback control systems in SSL and MSL flows. As seen from Figure 35.1, for both types of flows the information obtained from surface-mounted sensor arrays is fed to a flowfield estimator in order to predict the state of the flowfield being controlled. If the desired flowfield, and deviations from it, can be defined in terms of a signature measurable at the surface, the flow estimator may be bypassed all together. Any difference between the measured and desired flow states is used to drive surface-mounted actuators in a manner that would force the flow towards the desired state. In the case of the MSL flow, the current location of the separation line must also be identified and fed to the controller in order to operate the actuator set located nearest or at the position of separation (see Figure 35.1, bottom).

### 35.3.1 Sensors

When attempting to use MEMS sensors for implementing autonomous control of free-shear flows, several issues should be considered.

#### 35.3.1.1 Sensor Types

From a practical point of view, it is very difficult, if not impossible, to use sensors that are embedded inside the flow to achieve the information feedback necessary for implementing closed-loop control. This is primarily due to the inability to use a sufficiently large number of sensors to provide the needed information without blocking and/or significantly altering the flow. Therefore, the deployment of the MEMS sensor arrays should be restricted to the surface. Flows where no heat transfer occurs limit the measurements to primarily those of the surface stresses: wall shear ( $\tau_w$ ), or tangential component, and wall pressure ( $p_w$ ), or normal component. The former has one component in the streamwise ( $x$ ) and the other in the spanwise ( $z$ ) direction. For a comprehensive review of MEMS surface shear and pressure sensors, the reader is referred to Chapters 25 and 26 in this handbook.

In addition to surface stresses, near-wall measurements of flow velocity may be achieved nonintrusively via optical means. An example of such a system is currently being developed by Gharib et al. (1999), who are utilizing miniature diode lasers integrated with optics in a small package to develop a mini-LDA (laser Doppler anemometer) for measurements of the wall shear and near-wall velocity. With the continued miniaturization of components, it is not difficult to envision an array of MEMS-based LDA sensors deployed over surfaces of aero- and hydrodynamic devices. Of course, with LDA sensors, flow seeding is necessary; hence, such optical techniques may only be practical for flows where natural contamination is present or when practical means for seeding the flow locally in the vicinity of the measurement volume can be devised.

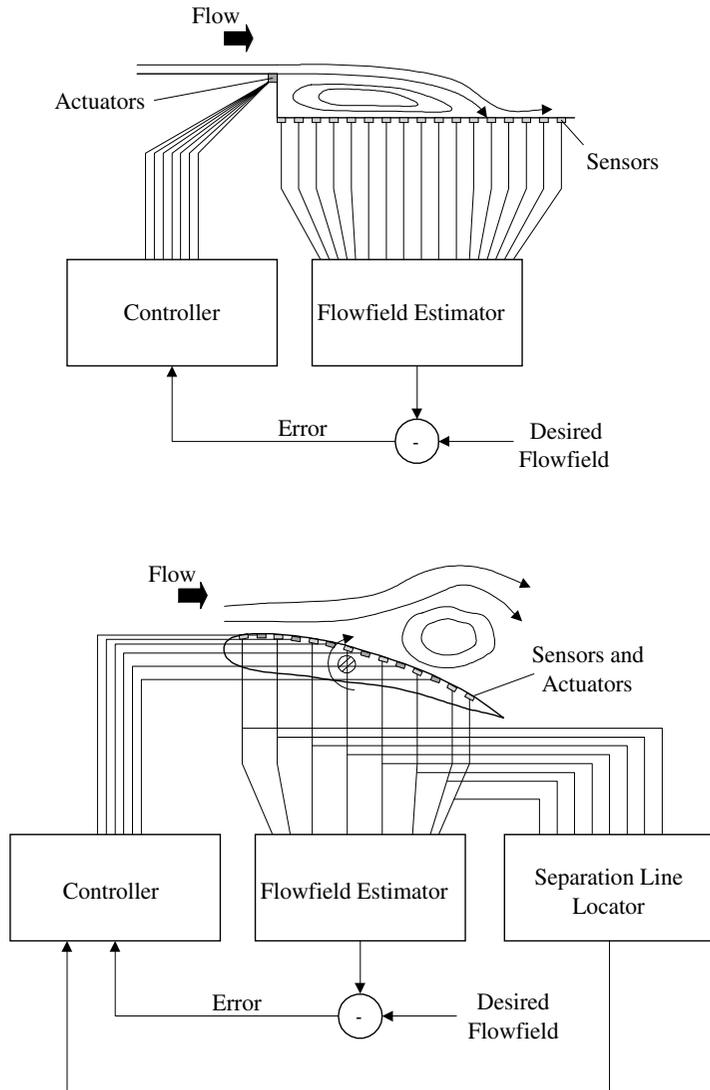

FIGURE 35.1 Conceptual block diagram of autonomous control systems for SSL (top) and MSL (bottom) flows.

It should be added here that, whereas for MSL flows surface sensors should cover the surface surrounding the flow to be controlled, in SSL flows, sensors would typically be placed at the trailing edge. However, in certain instances, placement of the sensors downstream of the trailing edge may be feasible. Examples include sudden expansion and backward-facing step flows (Figure 35.1, top) and jet flows, where a sting may be extended at the center of the jet for sensor mounting.

### 35.3.1.2 Sensor Characteristics

Properly designed and fabricated MEMS sensors should possess very high spatial and temporal resolution because of their extremely small size. Therefore, when considering the *response* of MEMS sensors for surface measurements, only the sensitivity and signal-to-noise ratio (SNR) are of concern. The need for high sensitivity and SNR is particularly important in detecting separation, as the wall shear values are near zero in the vicinity of the separation line ( $\tau_w = 0$  at separation for steady flows). Also, hydrodynamic surface pressure fluctuations are typically small for low-speed flows and require microphone-like sensitivities for measurements.

The concern regarding MEMS sensor sensitivity does not include indirect measurements of surface shear, such as that conducted using thermal anemometry, which can be achieved with higher sensitivity using MEMS sensors as compared to conventional ones [e.g., Liu et al., 1994; Cain et al., 2000]. On the other hand, both direct measurements of the surface shear (using a floating element) and pressure measurements (through a deflecting diaphragm) rely on the force produced by those stresses acting on the area of the sensor. Because typical MEMS sensor dimensions are less than 500  $\mu\text{m}$  on the side, the resulting force is extremely small. Because of this, currently no MEMS pressure sensor is known to have a sensitivity comparable to that of 1/8-in. capacitive microphones [Naguib et al., 1999a]. Also, notwithstanding the creativity involved in developing a number of floating-element designs and detection schemes [Padmanabhan et al., 1996; Reshotko et al., 1996], the signal-to-noise ratio of such sensors remains significantly below that achievable with thermal sensors. It should be pointed out here, however, that because of the direction-reversing nature of separated flows, thermal shear sensors are generally not too useful in MSL flows. Direct or other direction-sensitive sensors are required for conducting appropriate measurements in such flows.

### 35.3.1.3 Nature of the Measurements

Fundamentally, the information inferred from measurements of the wall-shear stress and near-wall velocity differs from that obtained from the surface pressure. The latter is known to be a “global” quantity that is influenced by both near-surface and remote flow structures. On the other hand, measurements of the shear stress and flow velocity provide information concerning flow structures that are in “direct contact” with the sensors.

Because of the global nature of pressure measurements, pressure sensors are probably the most suitable type of sensors for conducting measurements at the trailing edge in SSL flows. More specifically, in most, if not all, instances involving SSL flows, the control objective is aimed at controlling the flow downstream of the trailing edge, and local measurements of the wall shear and velocity would not be of great use in predicting the flow structure downstream of the trailing edge. A possible exception is when hydrodynamic feedback mechanisms are present, such as the case in a backward-facing step, where some structural influences downstream are naturally fed back to the trailing edge. In such flows, however, the instability of the shear layer may be *absolute* rather than *convective* [Huerre and Monkewitz, 1990]. Fiedler and Fernholz (1990) suggested that absolutely unstable flows are less susceptible to local periodic excitation such as that discussed here. Control provisions aimed at blocking the hydrodynamic feedback loop seem to be more effective in such cases.

Another important issue concerning the nature of surface pressure measurements is that they inevitably contain contributions from hydrodynamic as well as acoustic sources. The latter could be either a consequence of the flow itself (such as jet noise) or environmental, emanating from other surrounding sources that are not related to the flowfield. Typically, when the sound is produced by the flow, knowledge of the general characteristics of the acoustic field (direction of propagation, special symmetries, etc.) enables separation of the hydrodynamic and acoustic contributions to pressure measurements. In general, attention must be paid to ensure that the appropriate component of the pressure measurements is extracted.

### 35.3.1.4 Robustness and Packaging

Perhaps the primary challenge for the use of MEMS in practical systems is whether the minute, fairly fragile devices can withstand the operating environment. One solution is to package the devices in isolation from their environment. This solution has been adopted, for example, in the commercially available MEMS accelerometers from Analog Devices, Inc. Such a solution, although possibly feasible for the mini-LDA systems discussed above, is in general not useful for flow applications. Most wall-shear and -pressure sensors and all actuators must interact directly with the flow. Therefore, the ability of the minute devices to withstand harsh, high-temperature, chemically reacting environments is of concern. Also, the possibility for mechanical failure during routine operation and maintenance must be accounted for.

### 35.3.1.5 Ability to Integrate with Actuators and Electronics

Although many types of MEMS sensors have been fabricated and characterized for use in flow applications (see Chapters 24 through 26 for more details), most of these sensors have been designed for isolated operation individually or in arrays. If autonomous control is to be achieved using the unique capability of MEMS for integration of components, the sensor fabrication technology must be compatible with that of the actuators and the circuitry. More specifically, if a particular fabrication sequence is successful in constructing a pressure sensor with certain desired characteristics, the same sequence may be unusable when the sensors are to be integrated with actuators on the same chip. Examples of the few integrated MEMS systems that were developed for autonomous control include the fully integrated system used by Tsao et al. (1997) for controlling the drag force in turbulent boundary layers and the actuator-sensor systems from Huang et al. (1996) aimed at controlling supersonic jet screech (discussed in detail later in this chapter).

Tsao et al. (1997) utilized a CMOS-compatible technology to fabricate three magnetic flap-type actuators integrated with 18 wall-shear stress sensors and control electronics. In contrast, Huang et al. (1996; 1998) developed hot-wire and pressure sensor arrays integrated with resonant electrostatic actuators. Typically two actuators were integrated with three to four sensors in the immediate vicinity of the actuators.

## 35.3.2 Actuators

### 35.3.2.1 Actuator Types and Receptivity

When thinking of ways to excite a shear layer, there seems to be a multitude of possibilities that differ in their nature of excitation (mechanical, fluidic, acoustic, thermal, etc.; see Chapters 26 and 27), relative orientation to the flow (e.g., tangential vs. lateral actuation), domain of influence (local vs. global) and specific positioning with respect to the shear layer. Given the wide range of actuator types, it is rather confusing to choose the most appropriate type of actuation for a particular flow-control application. Because of the micron-level disturbances introduced by MEMS actuators, it is, however, obvious that the actuation scheme providing “the most bang for the money” should be utilized—that is, the type of actuation that is most efficient or to which the flow has the largest *receptivity*. The ambiguity in picking and choosing from the list of actuators is for the most part due to our lack of understanding of the receptivity of flows to the different types of actuation.

When selecting a MEMS (or conventional, for that matter) actuator for flow control, one is faced with a few fundamental questions: What type of actuator will achieve the control objective with minimum input energy? That is, what type of actuator produces the largest receptivity? Is it a mechanical, fluidic, acoustic or other type of actuator? If mechanical, should it oscillate in the normal, streamwise or spanwise direction? What actuator amplitude is needed in order to generate a certain flow-velocity disturbance magnitude? In the vicinity of the point of separation, is there an optimal location for the chosen type of actuator? All of these questions are very fundamental to not only the design of the actuation system, but also the assessment of the feasibility of using MEMS actuators to accomplish the control goal.

### 35.3.2.2 Forcing Parameters

Perhaps one of the most limiting factors on the applicability of MEMS actuators in flow control is their micron-size forcing amplitude. Typical mechanical MEMS actuators are capable of delivering oscillation amplitudes ranging from a few microns to tens of microns. In shear flows evolving from the separation of a thin laminar boundary layer, such small amplitudes can be comparable to the momentum thickness of the separating boundary layer, resulting in significant flow disturbance. This is particularly true in SSL flows, where the actuator location can be maintained in the immediate vicinity of the separation point.

To appreciate the susceptibility of shear layers to very low-level actuation, it is instructive to consider an order of magnitude analysis. For example, consider a situation where it is desired to attenuate, or eliminate, naturally existing two-dimensional disturbances in a laminar incompressible single-stream shear layer. One approach to attaining this goal is through “cancellation” of the disturbance during its

initial linear growth phase, where the streamwise development of the instability velocity amplitude, or *rms*, is given by:

$$u'(x) = u'_o e^{-\alpha_i(x-x_o)} \quad (35.1)$$

where,  $u'$  is an integral measure of the instability amplitude at streamwise location  $x$  from the point of separation of the shear layer (trailing edge in this example),  $u'_o$  is the *initial* instability amplitude,  $x_o$  is the “virtual origin” of the shear layer, and  $\alpha_i$  is the imaginary wavenumber component, or spatial growth rate, of the instability wave.

To cancel the flow instability, a periodic disturbance at the same frequency but 180° out of phase may be introduced at some location  $x = x^*$  near the point of separation of the shear layer. The amplitude of the disturbance introduced by the control should be of the same order of magnitude as that of the natural flow instability at the location of the actuator. This may be estimated from Eq. (35.1) as follows:

$$u'(x^*) = u'_o e^{-\alpha_i(x^*-x_o)} \quad (35.2)$$

The location of the actuator should be less than one to two wavelengths ( $\lambda$ ) of the flow instability downstream of the trailing edge to be within the linear region. This allows superposition of the control and natural instabilities, leading to cancellation of the latter. At the end of the linear range (approximately  $2\lambda$ ), the natural instability amplitude may be calculated from Eq. (35.1) as:

$$u'(2\lambda) = u'_o e^{-\alpha_i(2\lambda-x_o)} \quad (35.3)$$

Dividing Eq. (35.2) by Eq. (35.3), one may obtain an estimate for the required actuator-induced disturbance amplitude in terms of the flow instability amplitude at the end of the linear growth zone:

$$u'(x^*) = u'(2\lambda) e^{-\alpha_i(x^*-2\lambda)} \quad (35.4)$$

The instability amplitude at the end of the linear region may be estimated from typical amplitude saturation levels (about 10% of the freestream velocity,  $U$ ). Also, if the natural instability corresponds to the most unstable mode, its frequency would be given by [e.g., Ho and Huerre, 1984]:

$$St = f\theta/U = 0.016 \quad (35.5)$$

where  $St$  is the Strouhal number, and  $\theta$  is the local shear layer thickness. For the most unstable mode, the instability convection speed is equal to  $U/2$  and  $-\alpha_i\theta = 0.1$  [e.g., Ho and Huerre, 1984]. Using this information and writing the frequency in terms of the wavelength and convection velocity, Eq. (35.5) reduces to:

$$-\alpha_i\lambda \approx (2 \times 0.16)^{-1} \quad (35.6)$$

for the most unstable mode.

Now, for the sake of the argument, assuming the actuator to be located at the shear-layer separation point ( $x^* = 0$ ), estimating  $u'(2\lambda)$  as  $0.1U$ , and substituting from Eq. (35.6) into Eq. (35.4), one obtains:

$$u'(x^*) = 0.1U e^{-\frac{2}{2 \times 0.16}} \approx 10^{-4}U \quad (35.7)$$

That is, the required actuator-generated disturbance velocity amplitude should be about 0.01% of the free-stream velocity. Also, the actual forcing amplitude is not that given by Eq. (35.7) but rather one that is related to it through an amplitude receptivity coefficient. That is,

$$u'_{\text{act.}} = u'(x^*) \times R \quad (35.8)$$

where  $R$  is the receptivity coefficient, and  $u'_{\text{act.}}$  is the actuation amplitude. Thus, if  $R$  is a number of order one, the required actuator velocity amplitude for exciting flow structures of comparable strength to the natural coherent structures in a high-speed shear layer (say,  $U = 100$  m/s) is equal to 1 cm/s (i.e., of the order of a few cm/s). If the actuator can oscillate at a frequency of 10 kHz (easily achievable with MEMS), the corresponding actuation amplitude is only about a few microns!

In MSL flows, the ability of the sensor array and associated search algorithm to locate the instantaneous separation location of the shear layer, and the actuator-to-actuator spacing, may not permit flow excitation as close to the separation point as desired. Thus, in this case, even for extremely thin laminar shear layers, stronger actuators may be needed to compensate for the possible suboptimal actuation location. MEMS actuators that are capable of delivering hundreds of microns up to order of 1 mm excitation amplitude have been devised. These include the work of Miller et al. (1996) and Yang et al. (1997).

The more powerful, large-amplitude actuators, although providing much needed “muscle” to the miniature devices, nullify one of the main advantages of MEMS technology: the ability to fabricate actuators that can oscillate mechanically at frequencies of hundreds of kHz. Traditionally, high-frequency (few to tens of kHz) excitation of flows was only possible via acoustic means. With the ability of MEMS to fabricate devices with “micro inertia,” it is now possible to excite high-speed flows using mechanical devices [e.g., see Naguib et al., 1997].

To estimate the order of magnitude of the required excitation frequency, the frequency of the linearly most unstable mode in two-dimensional shear layers may be used. This frequency may be estimated from Eq. (35.5). Using such an estimate, it is straightforward to show that the most unstable mode frequency for typical high-speed MAS (macroscale) shear layers, such as those found in transonic and supersonic jets, is of the order of tens to hundreds of kHz. On the other hand, if one considers a microscale (MIS) shear layer, with a momentum thickness in the range of 1 to 10  $\mu\text{m}$  and a modest speed of 1 m/s, the corresponding most unstable frequency is in the range of 1.6 to 16 kHz. Of course, this estimate assumes that the MIS shear layer instability characteristics are similar to those of the MAS shear layer, an assumption that awaits verification.

A characteristic inherent to high-frequency MEMS actuators with oscillation amplitudes of tens of microns is that they tend to be of the resonant type. Moreover, the Q factor of such “large-amplitude” microresonators tends to be large. Therefore, these high-frequency actuators are typically useful only at or very close to the resonant frequency of the actuator. This is a limiting factor not only from the perspective of shear layer control under different flow conditions, but also when multimode forcing is desired. For instance, Corke and Kusek (1993) have shown that resonant subharmonic forcing of the shear layer surrounding an axisymmetric jet leads to a substantial enhancement in the growth of the shear layer. To implement this forcing technique it was necessary to force the flow at two different frequencies simultaneously using an array of miniature speakers. Although the modal shapes of the forcing employed by Corke and Kusek (1993) can be easily implemented using a MEMS actuator array distributed around the jet exit, only one frequency of forcing can be targeted with a single actuator design as discussed above. However, a possible remedy is one where the MEMS capability of fabricating densely packed structures is used to develop an interleaved array of two different actuators with two different resonant frequencies.

### 35.3.2.3 Robustness, Packaging and Ability to Integrate with Sensors and Electronics

Similar to sensors, robustness of the MEMS actuators is essential for them to be useful in practice. In fact, actuators tend to be more vulnerable to adverse effects of the flow environment than sensors are, as they typically protrude further into the flow, exposing themselves to higher flow velocities, temperatures, forces, etc. Additionally, as discussed earlier, the fabrication processes of the actuators must be compatible

with those of the sensors and circuitry if they are to be packaged together into an autonomous control system.

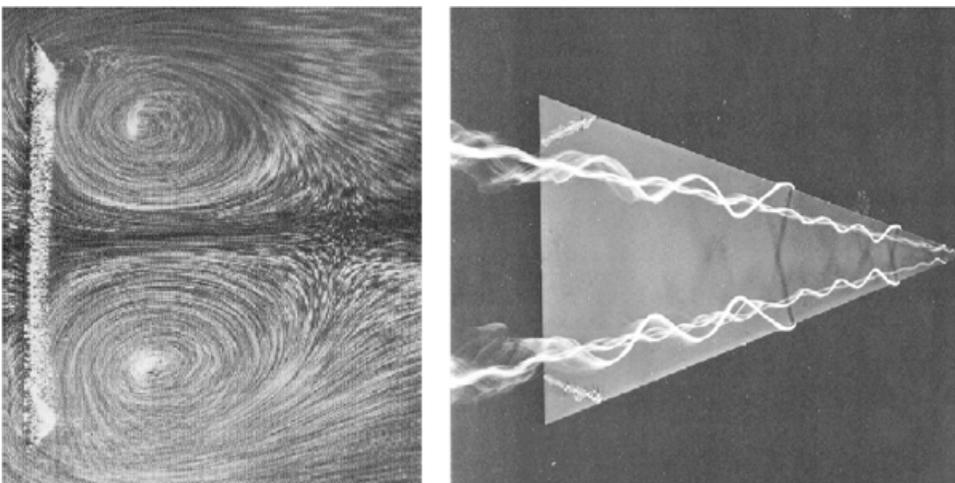

### 35.3.3 Closing the Loop: The Control Law

Perhaps one of the most challenging aspects of realizing MEMS autonomous systems in practice is one that is not related to the microfabrication technology itself. Given an integrated array of MEMS sensors and actuators that meets the characteristics described above, a fundamental question arises: How should the information from the sensors be processed to decide on where, when and how much actuation should be exercised to maintain a desired flow state? That is, what is the appropriate control law?

Of course, to arrive at such a control law, one needs to know the response of the flow to the range of possible actuation. This, however, is far from a straightforward task given the nonlinearity of the system being controlled by that governed by the Navier–Stokes equations. Moin and Bewley (1994) provide a good summary of various approaches that have been attempted to develop control laws for flow applications. Additional discussion on this topic can be found in this handbook in Chapter 34. Detailed discussion of the topic is not part of this chapter and it is only mentioned in passing here to underline its significance for implementation of autonomous MEMS control systems.

## 35.4 Control of the Roll Moment on a Delta Wing

In this section, a MEMS system aimed at realizing autonomous control of the roll moment acting on a delta wing is discussed. The material is based on the work of fluid dynamics researchers from the University of California Los Angeles (UCLA) in collaboration with microfabrication investigators from Caltech. The premise of the control pursued by the UCLA/Caltech group is based on the dominating influence of the suction-side vortices of a delta wing on the lift force. In particular, when a delta wing is placed at a high angle of attack, the shear layer separating around the side edge of the wing rolls up into a persistent vortical structure. A pair of these vortices (one from each side of the wing) is known to be responsible for generating about 40% of the lift force. Plan- and end-view flow visualization images of such vortices, captured by the UCLA group, are given in [Figure 35.2](#). Because the vortical structures evolve from a separating shear layer, their characteristics (e.g., location above the wing and strength) may be manipulated indirectly through alteration of the shear layer at or near the point of separation. Such a manipulation may be used to change the characteristics of only one of the vortices, thus breaking the symmetry of the flow structure and leading to a net rolling moment.

**FIGURE 35.2** End (left) and plan (right) visualization of the flow around a delta wing at high angle of attack.

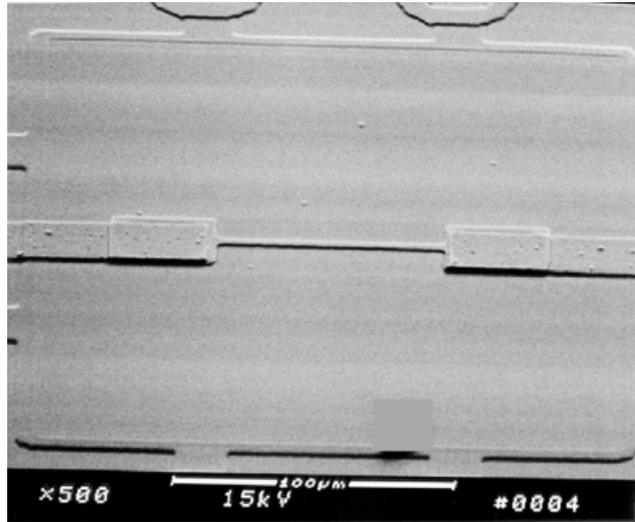

FIGURE 35.3 SEM image of the UCLA/Caltech shear stress sensor.

The shear layer separating from the edge of the delta wing is thin (order of 1 mm for the UCLA/Caltech work) and very sensitive to minute changes in the geometry. Therefore, as discussed earlier in this chapter, the use of microactuators to alter the shear-layer, and ultimately the vortical-structure, characteristics has good potential for success. Furthermore, when the edge of the wing is rounded, rather than sharp, the specific separation point location will vary with the distance from the wing apex, the flow velocity and the position of the wing relative to the flow. Therefore, a distributed sensor/actuator array is needed to cover the area around the edge of the delta wing for detection of the separation line and actuation in the immediate vicinity of it.

### 35.4.1 Sensing

To detect the location of the separation line around the edge of the delta wing, the UCLA/Caltech group utilized an array of MEMS hot-wire shear sensors. The sensors, which are described in detail by Liu et al. (1994), consisted of 2- $\mu\text{m}$  wide  $\times$  80- $\mu\text{m}$  long polysilicon resistors that were micromachined on top of an evacuated cavity (an SEM view of one of the sensors is provided in Figure 35.3). The vacuum cavity provided thermal isolation against heat conduction to the substrate in order to maximize sensor cooling by the flow. The resulting sensitivity was about 15 mV/Pa, and the frequency response of the sensors was 10 kHz. For more comprehensive coverage of this and other MEMS hot-wire sensors, the reader is referred to Chapter 26.

Because of directional ambiguity of hot-wire measurements and the three-dimensionality of the separation line, it was not possible to identify the location of separation from the instantaneous shear-stress values measured by the MEMS sensors. Instead, Lee et al. (1996) defined the location of the separation line as that separating the pressure- and suction-side flows in the vicinity of the edge of the wing. The distinction between the pressure and suction sides was based on the *rms* level of the wall-shear signal. This was possible, as the unsteady separating flow on the suction side produced a highly fluctuating wall-shear signature in comparison to the more steady attached flow on the pressure side.

A typical variation in the *rms* value of the wall-shear sensor is shown as a function of the position around the leading edge of the wing in Figure 35.4. Note that the position around the edge is expressed in terms of the angle from the bottom side of the edge, as demonstrated by the insert in Figure 35.4. It should also be pointed out that, because the *rms* is a time-integrated quantity, the detection criterion was primarily useful in identifying the average location of separation. In a more dynamic situation, where,

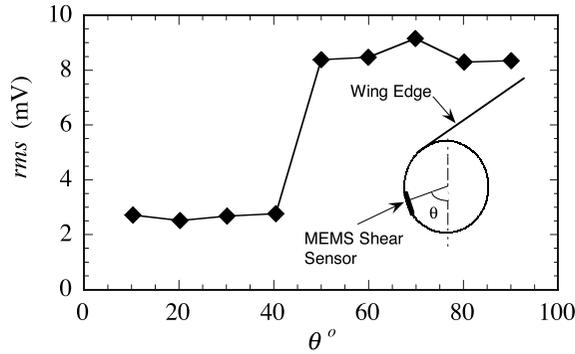

FIGURE 35.4 Distribution of surface-shear stress *rms* values around the edge of the delta wing.

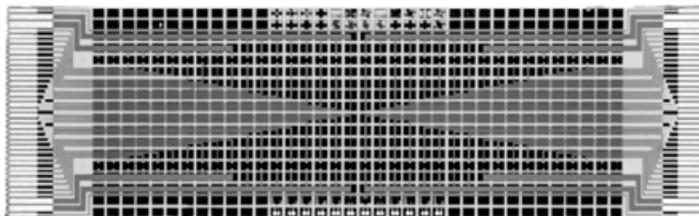

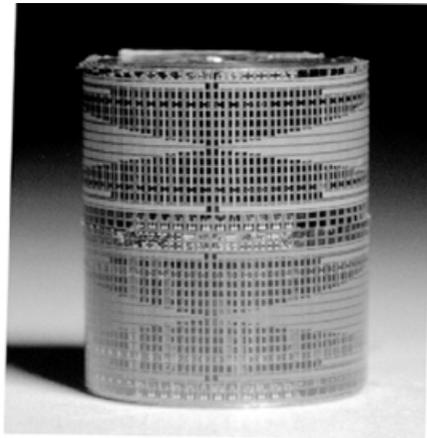

FIGURE 35.5 UCLA/Caltech flexible shear-stress sensor array skin.

for example, the wing is undergoing a pitching motion, different criteria or sensor types should be used to track the instantaneous location of separation.

To map the separation position along the edge of the wing, Ho et al. (1998) utilized 64 hot-wire sensors which were integrated during the fabrication process on a flexible shear stress skin. This 80- $\mu\text{m}$ -thick skin, shown in Figure 35.5, covered a  $1 \times 3\text{-cm}^2$  area and was wrapped around the curved leading edge of the delta wing. Using the *rms* criterion discussed in the previous paragraph, the separation line was identified for different flow speeds. A plot demonstrating the results is given in Figure 35.6, where the angle at which separation occurs (see insert in Figure 35.4 for definition of the angle) is plotted as a function of the distance from the wing apex. As seen from the figure, the separation line is curved, demonstrating the three-dimensional nature of the separation. Additionally, the separation point seems to move closer to the pressure side of the wing with increasing flow velocity.

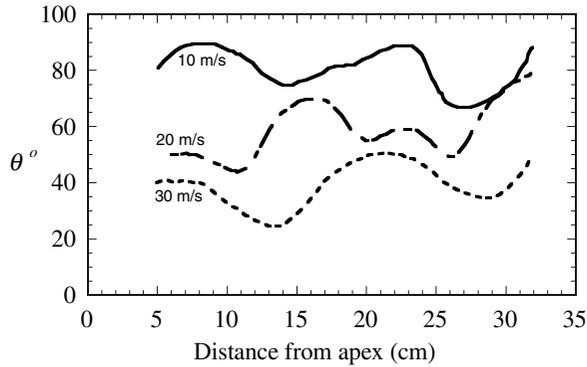

FIGURE 35.6 Separation line along the edge of the delta wing for different flow velocities.

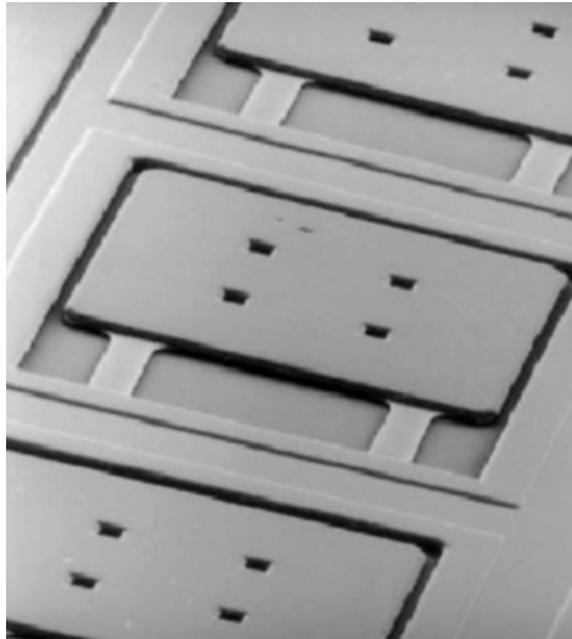

FIGURE 35.7 SEM view of passive-type flap actuators.

### 35.4.2 Actuation

Two different types of actuators were fabricated for use in the MEMS rolling-moment control system: (1) magnetic flap actuators, and (2) bubble actuators. The electromagnetic driving mechanism of the former was selected because of its ability to provide larger forces and displacements than the more common electrostatic type. Passive as well as active versions of the magnetic actuator were conceived. In the passive design, a  $1 \times 1\text{-mm}^2$  polysilicon flap (Figure 35.7) was supported by two flexible straight beams on a substrate. A  $5\text{-}\mu\text{m}$ -thick permalloy (80% Ni and 20% Fe) was electroplated on the surface of the  $1.8\text{-}\mu\text{m}$ -thick flap. The permalloy layer caused the flap to align itself with the magnetic field lines of a permanent magnet. Hence, it was possible to move the flap up or down by rotating a magnet embedded inside the edge of the wing, as seen in Figure 35.8. The actuator is described in more detail in Liu et al. (1995).

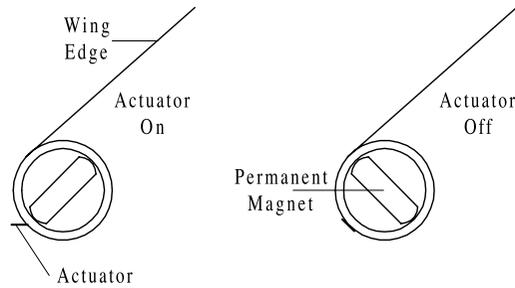

FIGURE 35.8 Permanent magnet actuation mechanism inside delta wing.

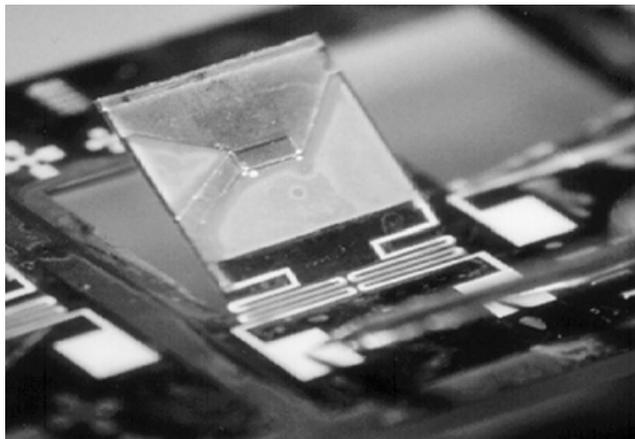

FIGURE 35.9 SEM view of active-type flap actuator.

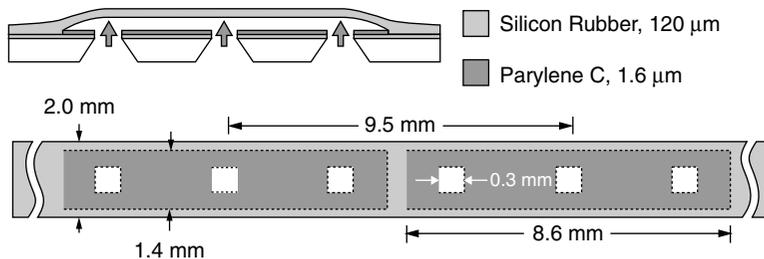

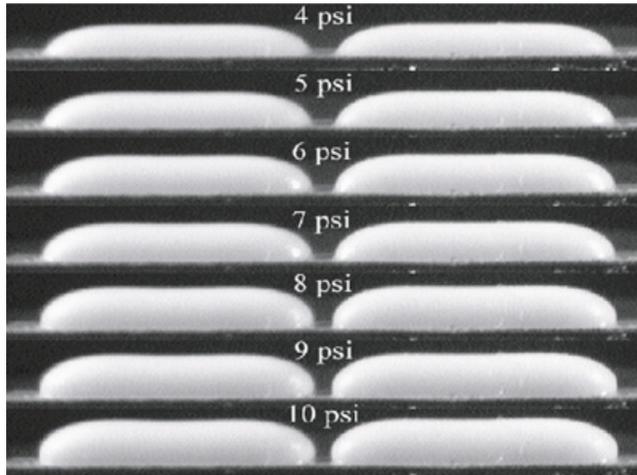

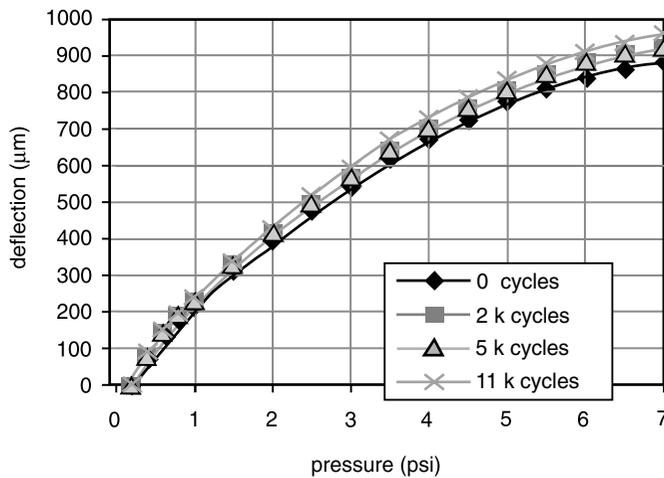

FIGURE 35.10 A schematic of bubble actuator details.

A photograph of the active flap actuator is shown in Figure 35.9. The construction of this device is generally the same as the passive one, except for a copper coil that is deposited on the silicon nitride flap. A time-varying current can be passed through the coil to modulate the flap motion around an average position (determined by the permalloy layer electroplated on the flap and the magnetic field imposed by an external permanent magnet). The actuator response was characterized by Tsao et al. (1994). The results demonstrated the ability of the actuator to produce tip displacements of more than 100 μm at frequencies of more than 1 kHz.

To develop more robust actuators that are usable not only in wind tunnels but also in practice, Grosjean et al. (1998) fabricated “balloon” or bubble actuators. The basic principle of the actuators is based on inflating flush-mounted, flexible silicon membranes using pressurized gas. As seen in Figure 35.10, the

(a)

(b)

FIGURE 35.11 Bubble actuators (a) and their characteristics (b).

gas can be supplied through ports that are integrated under the membrane during the microfabrication process. When inflated, the bubbles can extend to heights close to 1 mm. Figure 35.11 demonstrates bubble inflation with increasing pressure.

### 35.4.3 Flow Control

To test the ability of the actuators to produce a significant change in the roll moment on a delta wing, a  $56.5^\circ$  swept-angle model was used. The model, which was 30 cm long and 1.47 cm thick, was placed inside a  $91\text{-cm}^2$  test section of an open return wind tunnel. For different angles of attack and flow speeds, the moment and forces on the wing were measured using a six-component force/moment transducer.

Figures 35.12a–d display measurements of the change in the rolling moment as a function of the location of the actuator around the leading edge of the wing. Each of the four plots in Figure 35.12

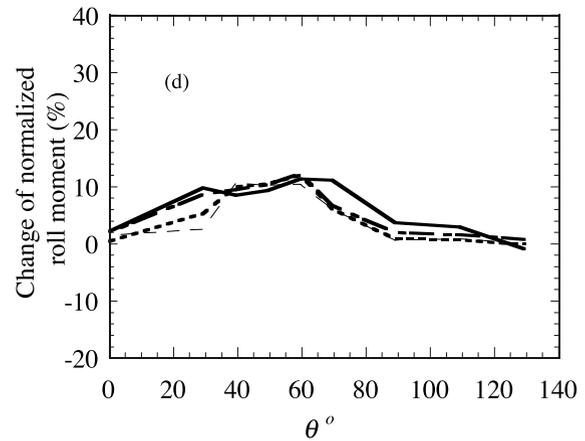

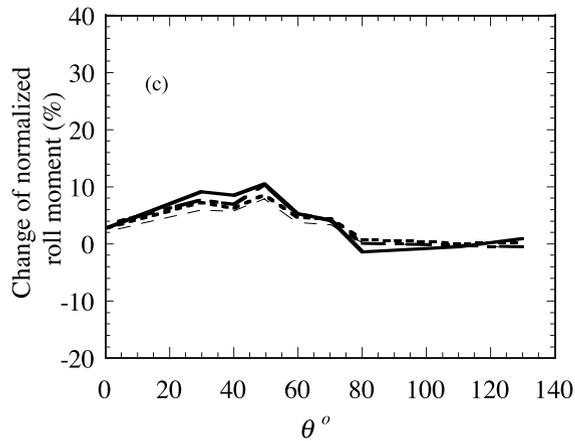

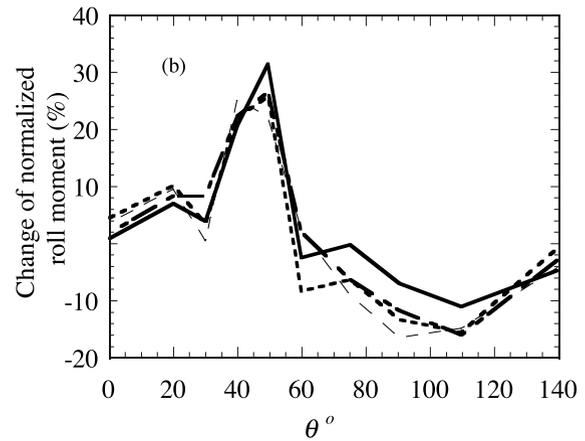

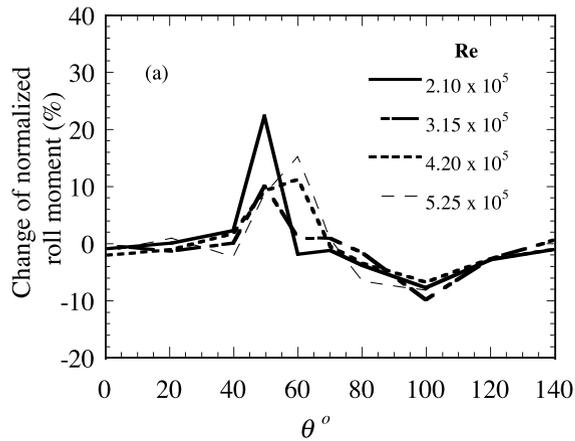

FIGURE 35.12 Actuation effect on delta wing rolling moment for different angles of attack: (a) 20°; (b) 25°; (c) 30°; (d) 35°.

represents data acquired at a different angle of attack:  $\alpha = 20^\circ, 25^\circ, 30^\circ$  and  $35^\circ$ , for plots a through d, respectively. Also, different lines represent different Reynolds numbers.

The results shown in Figure 35.12 were obtained for the magnetic flap actuators; however, similar results were also produced using bubble actuators [Ho et al., 1998]. In all cases, the actuators were deflected by 2 mm only on one side of the wing. The results demonstrate a significant change in the rolling moment (up to 40% for  $\alpha = 25^\circ$ ) for all angles of attack. The largest positive roll-moment (rolling towards the actuation side) change is observed around an actuator location approximately  $50^\circ$  from the pressure side of the wing. The location of maximum influence was found to be slightly upstream of the separation line (identified earlier using the MEMS sensor array; see Figure 35.6) as anticipated. Another important feature in Figure 35.12 is the apparent collapse of the different lines, which suggests that the actuation impact is affected very little, if any, by changing Reynolds number.

In addition to producing a net positive roll moment, the miniature actuators are also capable of producing net negative moment at the lower angles of attack as implied by the negative peak depicted in Figures 35.12a and b. Although the largest negative roll value (found for an actuator location approximately  $100^\circ$  from the pressure side) is not as strong as the largest positive moment, it can be used to augment the total roll moment control authority in a particular direction by using a two-sided actuation scheme. That is, if actuators at the appropriate locations on both edges of the delta wing were operated simultaneously to produce an upward motion on one side and a downward one on the other, the two effects would superimpose to produce a larger net rolling moment. This type of moment augmentation was verified by Lee et al. (1996), as seen from the plot in Figure 35.13. An interesting aspect of the results shown in Figure 35.13 is that the net rolling moment produced by the two-sided actuation is equal to the sum of the moments produced by actuation on either side individually. This seems to suggest that the manipulation of the vortices is independent of each one.

From a physical point of view, the production of a net rolling moment by the upward motion of the actuator is caused by a resulting shift in the location of the nearby vortex core. This was demonstrated clearly in the flow visualization images from Ho et al. (1998). Two of these images may be seen in Figure 35.14. In each image, a light-sheet cut was used to make the cores of the two edge vortices visible. The top image corresponds to the flow without actuation, whereas the bottom one was captured when the right-side actuators (of the bubble type in this case) were activated. A clear outward shift of approximately one vortex diameter is observed for the right-side vortex core. A corresponding shift in the surface-pressure signature of the vortex presumably produces the observed net rolling moment.

The amount of vortex core shift, and resulting net moment, appears to be proportional to the actuation stroke. This can be seen from the results in Figure 35.15, where the change in rolling moment due to actuation on one side is displayed for two different actuator displacements: 1 and 2 mm. As observed from the data, the peak moment produced by the 2-mm actuator is about five times larger than that due

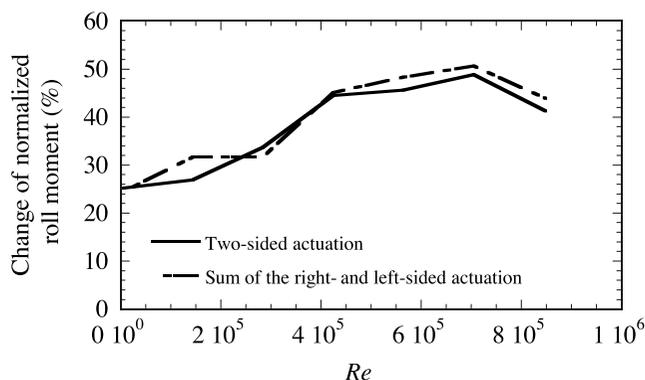

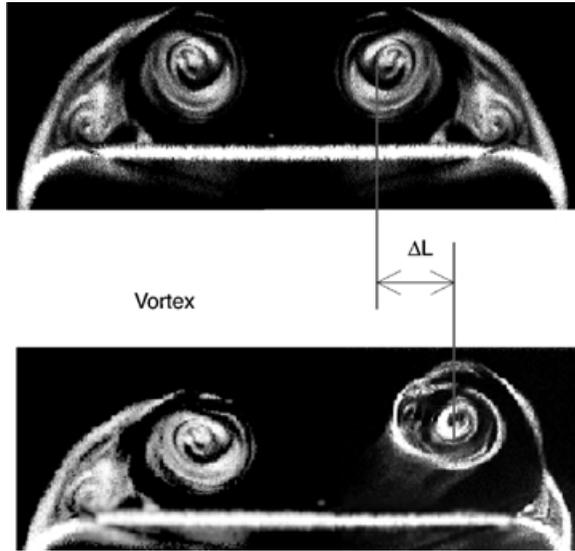

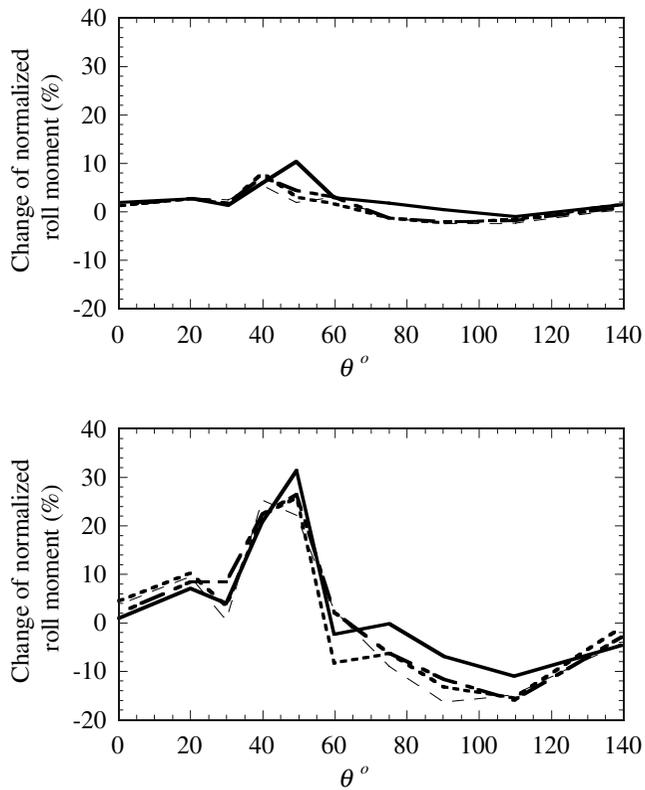

FIGURE 35.13 Roll-moment augmentation using two-sided actuation.

**FIGURE 35.14** Flow visualization of the vortex structure on the suction side of the delta wing without (top) and with (bottom) actuation.

**FIGURE 35.15** Effect of actuation amplitude on roll moment: 1 mm (top) and 2 mm (bottom).

to the 1-mm actuator. It is unclear, however, if the increase in the moment is a linear or nonlinear function of the actuator size, or stroke. In either case, the ability to adjust the amount of moment produced through the actuation scheme is essential if proportional control of the rolling moment is desired.

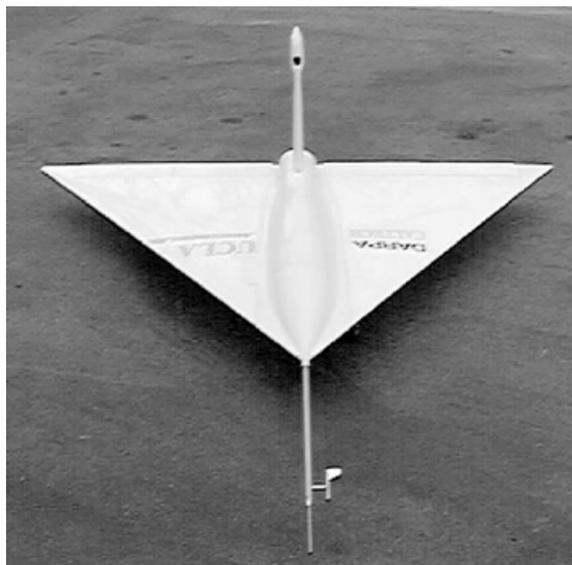

Finally, Lee et al. (1996) also demonstrated that the utility of the delta wing control system is not limited to the roll component of the moment vector. The ability to control the pitch and yaw moments was demonstrated as well.

#### 35.4.4 System Integration

Although sensing and actuation components of the MEMS roll-moment control system were fabricated and demonstrated successfully by the UCLA/Caltech group, demonstration of a fully integrated system in operation has yet to take place—that is, demonstration of a real-time control action whereby the separation location is detected by the hot-wire sensor array and the output is fed to the appropriate algorithms to engage the actuators along the separation line, all being done autonomously and for dynamic separation-line conditions. Such a demonstration is perhaps more challenging from a fluid mechanics perspective than from the technology, or MEMS, point of view.

So far, the work conducted by the UCLA/Caltech group has shown the ability to use MEMS to fabricate the sensors and actuators necessary to significantly modify the rolling moment on a delta wing (at least at the scale of the test model and under controlled wind-tunnel conditions). This includes the compatibility of the fabrication processes of the sensor and actuators so that they can be integrated in arrays on the same substrate. However, from a fluid mechanics point of view, the use of hot-wires to detect the location of dynamic three-dimensional separation is almost impossible. This is particularly true if real-time control is to be implemented where the separation position is to be located instantaneously rather than on average.

Finally, it should be added here that the UCLA/Caltech group has recently collaborated with AeroVironment to develop an instrumented research UAV (unmanned aerial vehicle) for testing of advanced MEMS control concepts for maneuvering of aircraft. The vehicle, called “GRYPHON,” is shown in the [Figure 35.16](#) photograph.

**FIGURE 35.16** GRYPHON: UCLA/Caltech MEMS flight research unmanned aerial vehicle.

## 35.5 Control of Supersonic Jet Screech

Reminiscent of several of the early efforts aimed at developing MEMS sensor/actuator systems for flow control, this study involved the collaboration of fluid dynamics researchers from the Illinois Institute of Technology (IIT) and microfabrication experts from the Center for Integrated Sensors and Circuits, Solid-State Electronics Laboratory at University of Michigan (UM). The selection of supersonic screech noise to test the scope of a MEMS control system was motivated by the desire to push, and therefore, identify the limits of MEMS technology, rather than the eventual implementation of such a system in practice. That is, the jet screech environment provided a harsh high-speed flow surroundings within which the devices not only had to operate but also produce a significant disturbance of the flow.

To explain further, it is useful to describe the general characteristics of jet screech. When a supersonic jet is operating at an off-design Mach number (i.e., the jet is under- or over-expanded), a set of shock cells forms. These cells interact with the axisymmetric or helical flow structures that originate from the instability of the shear layer surrounding the jet at its exit to produce acoustic noise. The noise is primarily radiated in the upstream direction, where it excites the jet shear layer regenerating the flow structure. Thus, a self-sustained feedback cycle (first recognized by Powel, 1953) is established during screech.

The basic principle of the proposed IIT/UM screech-control strategy is that of mode cancellation. Because the existence of axisymmetric or helical shear layer modes is a necessary link in the screech-generation chain of events, their elimination, or weakening, is anticipated to result in a corresponding cancellation, or attenuation, of screech noise. Such an elimination is to be achieved by the independent excitation of a flow structure of the same mode shape as (but out of phase with) that existing in the shear layer using MEMS actuators distributed around the nozzle lip. Because the MEMS forcing is achieved at the jet lip where the shear layer stability growth is likely to be linear, the natural and forced disturbances will superpose destructively to weaken the shear layer structure. Also, the placement of the actuators in the *immediate* vicinity of the jet lip, or point of separation of the shear layer, renders the flow susceptible to the minute disturbances produced by the MEMS actuators.

The spatially fixed location of the shear-layer separation point in the jet flow alleviates the need for using sensor arrays to detect and locate the point of separation. Nevertheless, sensors are needed to provide reference information concerning the mode shape and phase of the existing shear-layer structure. In this manner, the appropriate forcing phase of the actuators can be selected and adjusted with varying flow conditions.

### 35.5.1 Sensing

Two types of sensors were developed by the IIT/UM group to provide the necessary measurements: hot-wires and microphones. The former sensors were intended for direct measurements of the disturbance velocity in the shear layer near the nozzle lip, while the latter ones were aimed at measuring the feedback acoustic waves that generate the disturbances during screech, as explained above. A close-up view of one of the MEMS hot-wires overhanging a glass substrate is shown in [Figure 35.17](#). Briefly, the hot-wire is made from  $p^{++}$  polysilicon with typical dimensions of 12- $\mu\text{m}$  thickness, 4- $\mu\text{m}$  width and 100- $\mu\text{m}$  length. The corresponding resistance is in the range of 200 to 800  $\Omega$ . The glass substrate under the wire provides a good thermal-insulating base. Fabrication details are provided in Huang et al. (1996).

A sample calibration of one of the hot-wires, shown in [Figure 35.18](#), was performed when the wire was operated at an overheat ratio of 1.05. Three different calibrations separated by time intervals of 1 hour and 10 days are included in the figure. The calibration results display a change of about 2 V of the hot-wire output for a velocity range of up to 35 m/s. A conventional hot-wire at even larger overheats of more than 1.5 would exhibit a voltage output range of less than 1 V. Hence, [Figure 35.18](#) demonstrates the high sensitivity of MEMS (polysilicon) hot-wires. Furthermore, considering the calibration results from the three different trials, very little change in the sensor characteristics is observed. Given the long time interval between some of the calibrations, it is seen that the MEMS sensors are generally very stable. Further characterization of the sensors may be found in Naguib et al. (1999b).

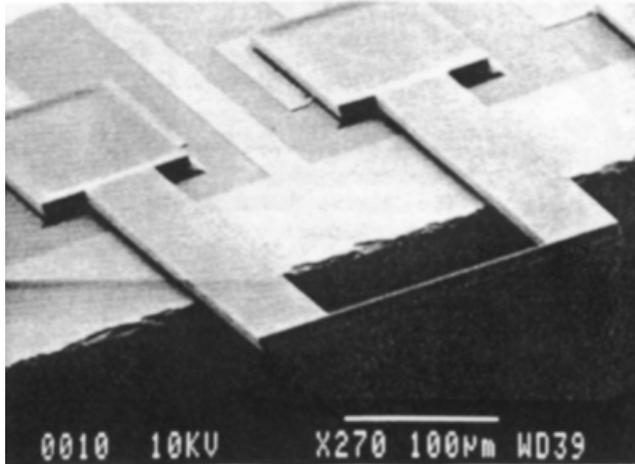

FIGURE 35.17 SEM view of the IIT/UM hot-wire sensor.

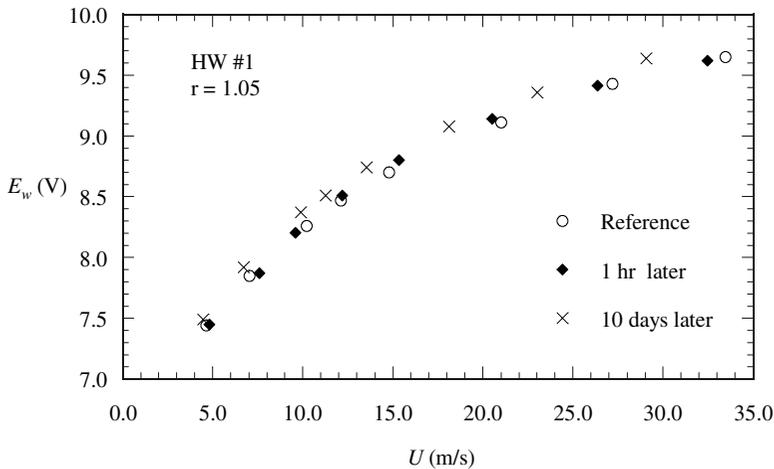

FIGURE 35.18 Static calibration of one of the IIT/UM hot-wire sensors.

On the other hand, the MEMS acoustic sensor, shown using a SEM view in Figure 35.19, consists of a stress-compensated plasma-enhanced chemical vapor deposition (PECVD) silicon nitride/oxide, 0.4- $\mu\text{m}$ -thick diaphragm together with four monocrystalline ion-implanted p<sup>++</sup> silicon piezoresistors. The coefficient,  $\pi_{44}$ , for this type of piezoresistor is about four times larger than that based on p-type polysilicon, thus leading to a higher transducer sensitivity. The piezoresistors are arranged in a full Wheatstone-bridge configuration for detection of the diaphragm deflection. For fabrication details, the reader is referred to Huang et al. (1998).

Figure 35.20 provides the frequency characteristics of a 710-  $\times$  710- $\mu\text{m}^2$  MEMS sensor obtained by Naguib et al. (1999a). For reference, the sensitivities of commercial silicon Kulite sensor and 1/8-in. B&K microphone are also provided in the figure. The open and closed circles represent calibration results for the same sensor obtained 2 months apart. The results demonstrate that very good agreement is found between the open and closed circles. This agreement indicates that the MEMS transducers are stable and reliable. For frequencies below 1 kHz, the sensitivity of the MEMS sensors seems to be almost an order of magnitude larger than the sensitivity of the commercial Kulite sensor. At higher frequencies, however, the MEMS sensitivity is attenuated.

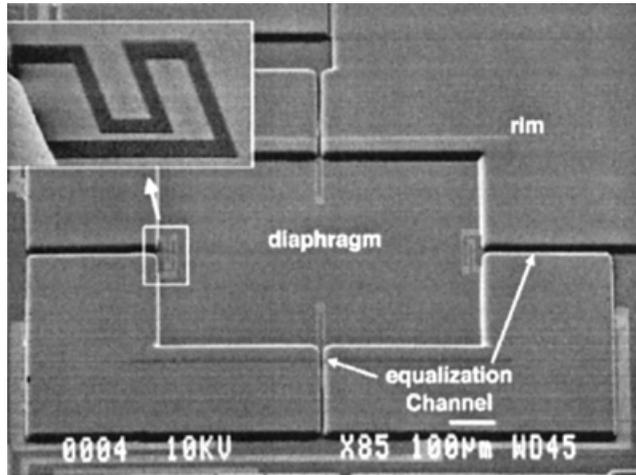

FIGURE 35.19 SEM view of IIT/UM acoustic sensor.

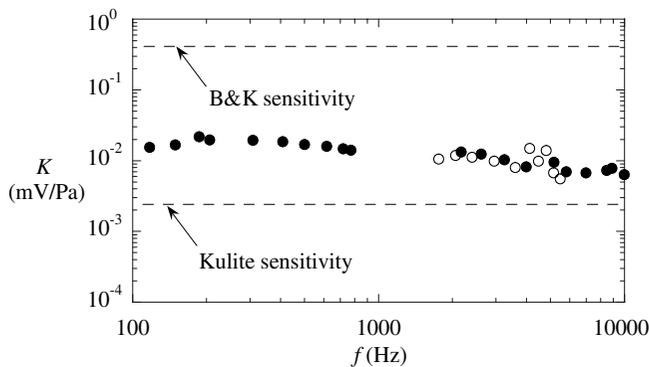

FIGURE 35.20 Frequency response of one of the IIT/UM acoustic sensors.

### 35.5.2 Actuation

The most common form of excitation of high-speed jets and shear layers has been via internal and external acoustic sources [e.g., Moore, 1977]. The popularity of acoustic forcing has been primarily due to ease of implementation and the ability to generate the high-frequency disturbances required for effective forcing of high-speed shear flows. However, the receptivity of the jet to acoustic excitation requires matching of the wavenumbers of the acoustic and instability waves [Tam, 1986]. Although such a condition is achievable in supersonic jets, at low Mach numbers the instability wavelength is much smaller than the acoustic wavelength. In this case, conversion of acoustic energy into instability waves is dependent on the “efficiency” of the unsteady Kutta condition at the nozzle lip.

Historically, studies utilizing mechanical actuators have been limited to low flow speeds due to the inability of the mechanical actuators, with their large inertia, to operate at frequencies higher than tens to hundreds of hertz. Therefore, the emergence of MEMS carried with it the potential to break this barrier through the fabrication of mechanical actuators with “microinertia” that can oscillate at high frequency. Ultimately, this may lead to the realization of more efficient actuators that can act directly on the flow without the need for a Kutta-like condition. For these reasons, micromechanical actuators were selected for the screech control problem.

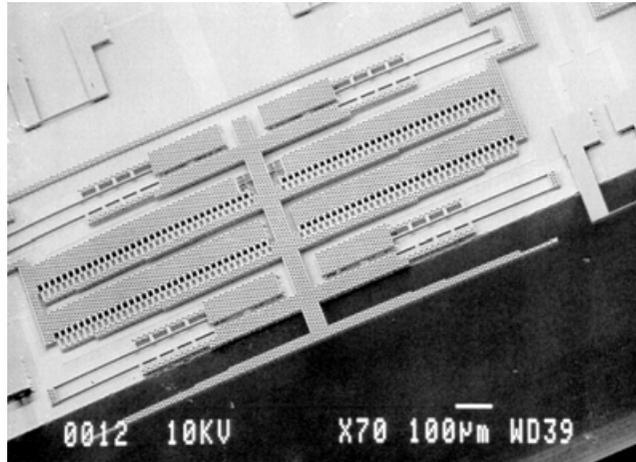

FIGURE 35.21 SEM view of IIT/UM electrostatic actuator.

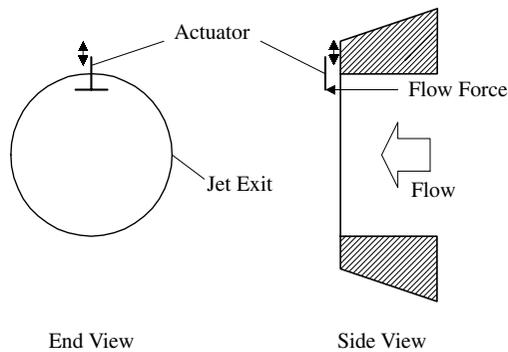

FIGURE 35.22 A schematic demonstrating the direction of flow forces acting on the MEMS actuator.

Figure 35.21 shows a SEM photograph of one of the electrostatic actuators used in the jet study. The device consists of a free-floating section that is mounted to a glass substrate underneath using elastic, folded beams. At the lower end of the floating section is a roughly  $6\text{-}\mu\text{m} \times 30\text{-}\mu\text{m} \times 1300\text{-}\mu\text{m}$  T-shaped actuator head. The actuator head is made to oscillate at an amplitude up to  $70\text{ }\mu\text{m}$  and a resonant frequency that can be tailored by adjusting the mass and stiffness of the actuator structure. Also, notice the porous actuator body, which results in a reduced dynamic load on the actuator head. For more details on the construction and manufacturing of the actuators, see Huang et al. (1996).

Two actuator designs were developed with resonant frequencies of 5 and 14 kHz. These values were selected to match the frequency of different screech modes in the High-Speed Jet Facility (HSJF) at IIT. The actuators were driven using a combination of 20-V dc and 40-V peak-to-peak sinusoidal voltage at the actuator resonant frequency.

The relative placement of one of the T-actuators with respect to the jet is illustrated in Figure 35.22. As depicted in the figure, the rigidity of the actuator with respect to out-of-plane deflection caused by flow forces is primarily dependent on the thickness of the device. For the device shown in Figure 35.21, the thickness was limited to a value of less than  $12\text{ }\mu\text{m}$  because of the wet-etching methodology employed in the fabrication sequence. An alternate fabrication approach, which utilized deep RIE (reactive ion etching) etching, was later utilized to fabricate thicker, more rigid actuators. Using this approach, actuators with a thickness of  $50\text{ }\mu\text{m}$  were obtained. A SEM view of one of the thick actuators is provided in Figure 35.23.

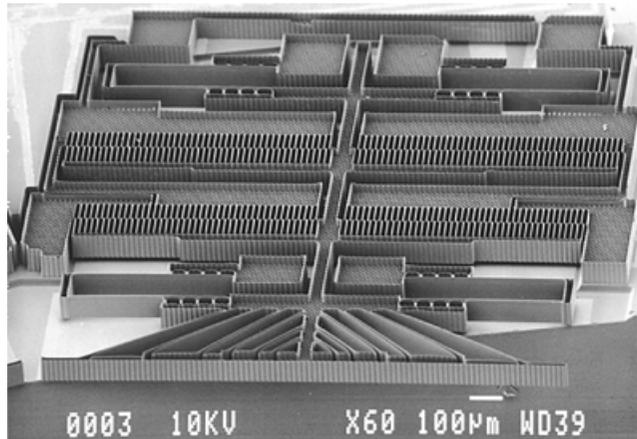

FIGURE 35.23 SEM view of a thick (50- $\mu\text{m}$ ) actuator.

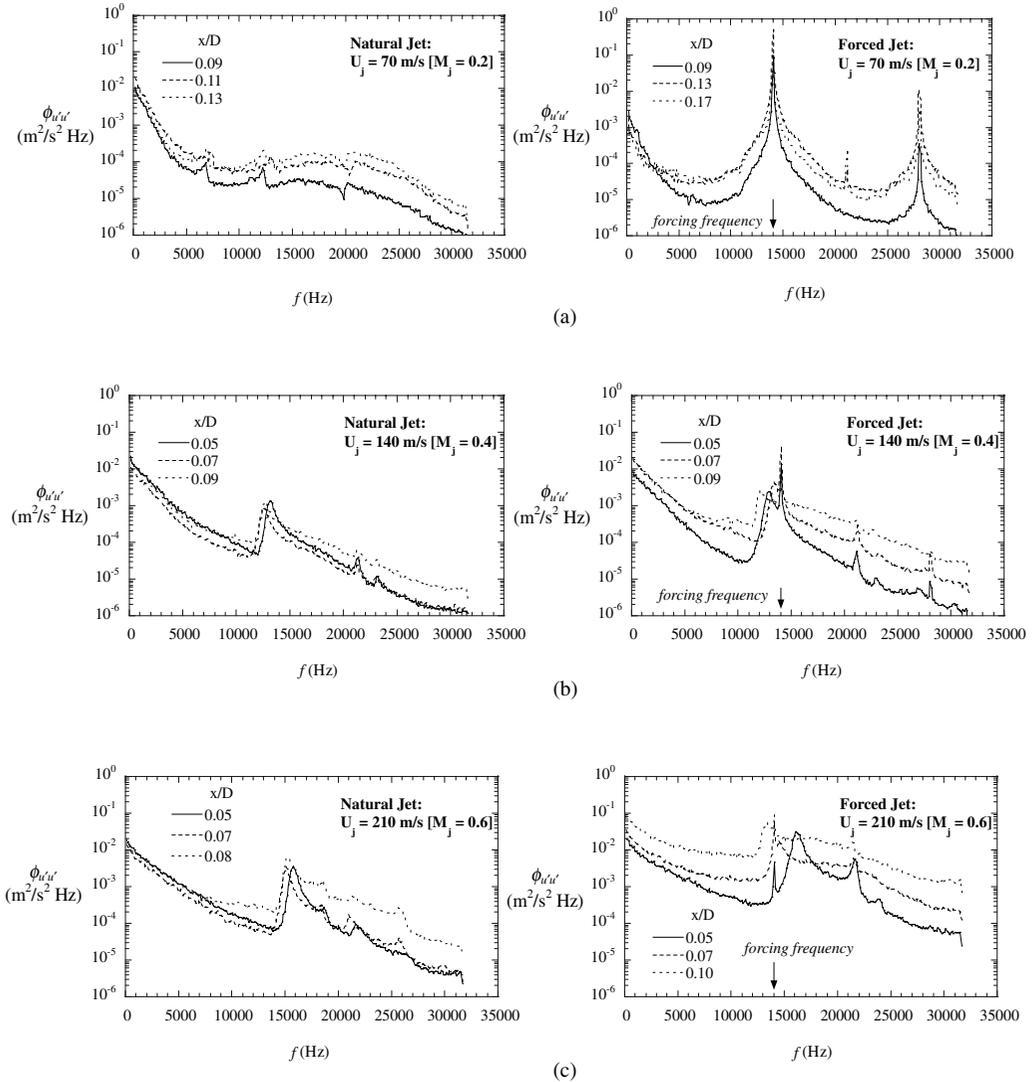

### 35.5.3 Flow Control

The ability of the microactuators to disturb the shear layer surrounding the jet was tested for flow speeds of 70, 140 and 210 m/s. The corresponding Mach ( $M_j$ ) and Reynolds numbers ( $Re$ ; based on jet diameter,  $D$ ) were 0.2, 0.4 and 0.6 and 118533, 237067 and 355600, respectively. The corresponding, linearly most unstable frequency of the jet shear layer was estimated to be 16, 44 and 91 kHz, in order of increasing Mach number. Because the largest effect on the flow is achieved when forcing as close as possible to the most unstable frequency, it is seen that the actuator frequency of 14 kHz was substantially lower than desired for the two largest jet speeds.

Using hot-wire measurements on the shear layer center line, velocity spectra of the natural and forced jet flows at the different Mach numbers were obtained. Those results are shown in Figure 35.24. The different lines in each of the plots represent spectra obtained at different streamwise ( $x$ ) locations. For a Mach number of 0.2, the spectra obtained in the natural jet seem to be wideband, except for two fairly small peaks at approximately 7 and 13 kHz. When MEMS forcing is applied, a very strong peak is observed at the forcing frequency (Figure 35.24, top right). The magnitude of the peak seems to rise initially with downstream distance and then fall. In addition to the peak at the forcing frequency, a second strong peak at 28 kHz is observed at all streamwise locations. A third peak is also depicted at a frequency of 21 kHz at the second and third  $x$  locations. The existence of multiple peaks in the spectrum at frequencies which are multiples of the forcing frequency and its subharmonic suggests that the MEMS-introduced disturbance has a large enough amplitude to experience nonlinear effects of the flow.

The disturbance spectra for the natural jet at Mach number of 0.4 are shown on the left side of the middle part of Figure 35.24. The corresponding spectra for the forced jet are shown on the opposite side. As seen from Figure 35.24, the natural jet spectra possess a fairly large and broad peak at a frequency of about 13 kHz. Because the most unstable frequency of the jet shear layer at this Mach number is expected to be around 44 kHz, the 13-kHz peak does not seem to correspond to the natural mode of the shear layer or its subharmonic. When operating the MEMS actuator, a clear peak is depicted in the spectrum at the forcing frequency. The peak magnitude initially magnifies to reach a magnitude of more than an order of magnitude larger than the fairly strong peak depicted in the natural spectrum at 13 kHz. The MEMS-induced peak is also significantly sharper than the natural peak, presumably because of the more organized nature of forced modes.

Finally, the spectra obtained at a Mach number of 0.6 are displayed in the bottom of Figure 35.24. Similar to the results for 0.4 Mach number, a broad, fairly strong peak is depicted in the natural jet spectra. The frequency of this peak appears to be about 16 kHz at  $x/D = 0.1$ , which is considerably lower than the estimated most unstable frequency of 91 kHz. The peak frequency value decreases with increasing  $x$ .

**FIGURE 35.24** Natural (left) and forced (right) spectra in the IIT high-speed jet for a Mach number of: (a) 0.2; (b) 0.4; (c) 0.6.

This decrease in the peak frequency with  $x$  may be symptomatic of probe feedback effects [Hussein and Zaman, 1978]. In spite of this strong peak, when forced using the MEMS actuator a clearly observable peak at the forcing frequency is depicted in the spectrum of the forced shear layer. Unlike the results for the forced jet at Mach numbers of 0.2 and 0.4, the forced jet spectrum for Mach number of 0.6 does not contain spectral peaks at higher harmonics of the forcing frequency.

To evaluate the level of the disturbance introduced into the shear layer by the MEMS actuator, the energy content of the spectral peak at the forcing frequency was calculated from the phase-averaged spectra (to avoid inclusion of background turbulence energy). The forced disturbance energy ( $\langle u_{rms,f} \rangle$ ) dependence on the streamwise location is shown for all three Mach numbers in Figure 35.25. The disturbance energy is normalized by the jet velocity ( $U_j$ ), and the streamwise coordinate is normalized by the jet diameter. Inspection of Figure 35.25 shows that for both Mach numbers of 0.2 and 0.4 no region of linear growth is detectable. For these two Mach numbers,  $\langle u_{rms,f} \rangle$  only increases slightly before

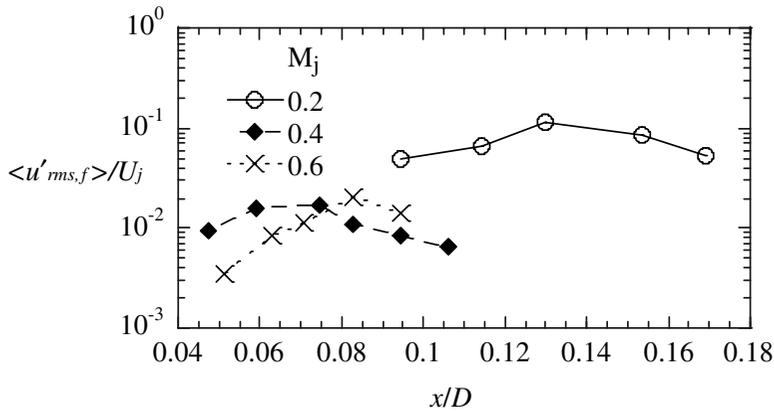

FIGURE 35.25 Streamwise development of the MEMS-induced disturbance *rms*.

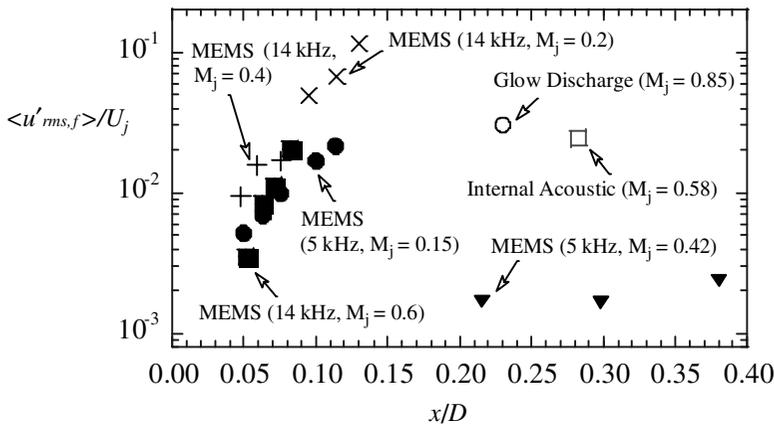

FIGURE 35.26 MEMS-induced disturbance *rms* compared to “macroscale” forcing schemes.

reaching a peak followed by a gradual decrease in value, a process reminiscent of nonlinear amplitude saturation.

On the other hand, the disturbance energy corresponding to a Mach number of 0.6 appears to experience linear growth over the first four streamwise positions before saturating. It may be noticed also that for only 0.6 Mach number the disturbance *rms* level is appreciably lower than 1% of the jet velocity at the first streamwise location. In the work of Drubka et al. (1989), the fundamental and subharmonic modes in an acoustically excited, incompressible, axisymmetric jet were seen to saturate when their *rms* value exceeded 1 to 2% of the jet velocity. Therefore, it seems that the IIT/UM MEMS actuator is capable of providing an excitation to the shear layer that is sufficient not only to disturb the flow but also to produce nonlinear forcing levels.

The magnitude of the MEMS forcing may also be appreciated further by comparison to other types of “macroscale” forcing. Thus, the disturbance *rms* value produced by internal acoustic (Lepicovsky et al., 1985) and glow discharge (Corke and Cavalieri, 1996) forcing is compared to the corresponding *rms* values produced by MEMS forcing in Figure 35.26. The results for MEMS forcing contained in the figure are those from Naguib et al. (1997) using the high-frequency MEMS actuators as well as those from the earlier study by Alnajjar et al. (1997), using the same type of MEMS actuators but at a forcing frequency of 5 kHz.

As seen from Figure 35.26, for most cases of MEMS forcing, the MEMS-generated disturbance grows to a level that is similar to that produced by glow discharge and acoustic forcing. For Mach number of 0.2, the forcing frequency of 14 kHz is almost equal to the most unstable frequency of the shear layer and the resulting flow disturbance is at a level which is significantly higher than even that produced by the “macroscale” forcing methods. On the other hand, at the 0.42 Mach number, the 5-kHz MEMS actuator excites the flow at a frequency which is almost an order of magnitude lower than the most amplified frequency of the shear layer. The small amplification rate associated with a disturbance at a frequency which is significantly smaller than the natural frequency of the flow is believed to be responsible for the resulting small disturbance level at the Mach number of 0.42 when forcing with the 5-kHz actuator.

The ability of the MEMS devices to excite the flow in par with other macro forcing devices is believed to be due to the ability to position the MEMS extremely close to the point of high receptivity at the nozzle lip where the flow is sensitive to minute disturbances. To investigate this matter further, the radial position of the MEMS actuator with respect to the nozzle lip ( $y_{\text{off}}$ ) was varied systematically. For all actuator positions, the flow was maintained at 70 m/s, while the actuator was traversed in the range from about 50  $\mu\text{m}$  (outside the flow) to  $-150 \mu\text{m}$  (inside the flow) relative to the nozzle lip. The boundary layer at the exit of the jet at 70 m/s was laminar and had a momentum thickness of about 72  $\mu\text{m}$ . Therefore, at its innermost location, the actuator penetrated into the flow a distance which was less than 20% of the boundary layer thickness, and hence, based on a Blasius profile, it was exposed to a velocity less than one fifth of the jet speed.

The energy content of the spectral peak at the forcing frequency was calculated from the disturbance spectra obtained at  $x/D = 0.1$  for different radial actuator locations. The results are displayed in Figure 35.27. For reference, a dimension indicating the momentum thickness of the boundary layer emerging at the exit of the jet ( $\theta_0$ ) is included in the figure. As observed from the figure, the largest disturbance energy is produced when the actuator is closest to the nozzle lip ( $y_{\text{off}} = 0$ ) and into the flow. If the actuator is placed a distance as small as 75  $\mu\text{m}$  (less than the size of a human hair) off the position corresponding to maximum response, an order of magnitude reduction in disturbance *rms* value is observed.

The reduction in actuator effectiveness as it is traversed radially outward is presumably because of the increased separation between the actuator and the shear layer. However, the reasons for observing the same trend when locating the actuator further into the flow are not equally clear. In fact, recently, Alnajjar et al. (2000), using piezoelectric actuators, found the response of the same jet flow used for MEMS testing to be fairly insensitive to the radial location of the actuator inside the shear layer, with the largest response found near the center of the shear layer. This suggests that the reduced actuation impact seen in Figure 35.27

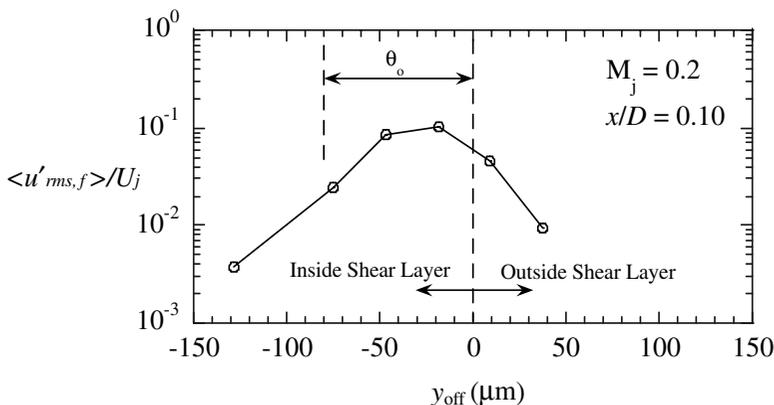

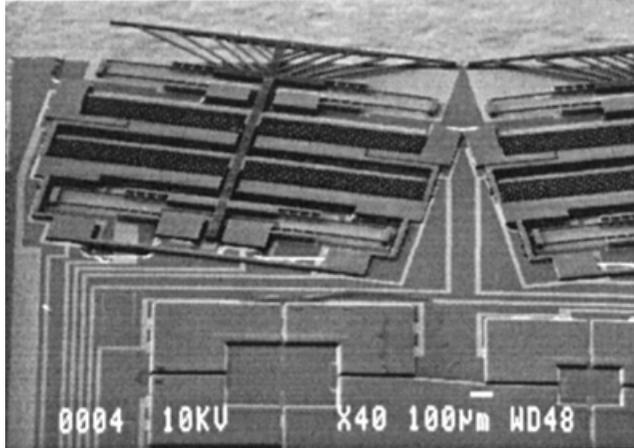

FIGURE 35.27 Effect of MEMS actuator radial position on the generated shear layer disturbance level.

**FIGURE 35.28** Two acoustic sensors integrated with two actuators.

as the actuator is positioned further into the flow is most likely due to a change in the behavior of the actuator itself. In particular, it is not unreasonable to expect that, as the actuator head is exposed to larger flow speeds for positions further into the flow, it may experience larger out-of-plan deflections. These deflections would cause the overlap area between the stationary and moving parts of the comb drives to become smaller, leading to a smaller actuation force and amplitude.

#### 35.5.4 System Integration

The fabrication sequence of the sensors for the screech-control system was developed carefully to ensure its compatibility with that of the actuators. As discussed at the beginning of the chapter, the compatibility of the fabrication sequence of the individual components is necessary if one is to capitalize on the MEMS technology advantage of integrating component arrays to form full autonomous systems. For instance, to machine the MEMS acoustic sensors shown in [Figure 35.19](#) integrated with the actuators on the same chip, a total of nine masks were required [Huang et al., 1998]. In contrast, fabrication of a similar sensor in isolation would probably require no more than three to four masks. SEM views of the electrostatic actuators integrated with hot wires and acoustic sensors are given in [Figures 35.21](#) and [35.28](#), respectively.

To make external input–output connections to the sensors and actuators the glass substrate supporting the MEMS devices was fixed to a sector-shaped printed-circuit board using epoxy. Close-up and full views of the board may be seen in [Figure 35.29](#). The full sensor/actuator array was then assembled by mounting the 16 sector boards on a special jet faceplate. Each of the individual boards was supported on a radial miniature traversing system to enable precise placement of the actuators at the location of maximum response (as dictated by the results in [Figure 35.27](#)). [Figure 35.30](#) shows a schematic diagram of the jet faceplate, sector PC-boards and miniature traverses. An image of the full MEMS array as mounted on the jet can be seen in [Figure 35.31](#).

The distributed 16-actuator array provided the capability of exciting flow structures with azimuthal modes up to a mode number ( $m$ ) of eight. This was verified using single hot-wire measurements at different locations around the perimeter of the jet. At each measurement location the wire was located approximately at the center of the shear layer. The amplitude and phase information of the measured disturbance was obtained from the cross-spectrum between the hot wire data and the driving signal of one of the actuators. The results are demonstrated in [Figure 35.32](#). As seen from the amplitude data, a fair amount of scatter is observed around an average value over the full circumference. The observed

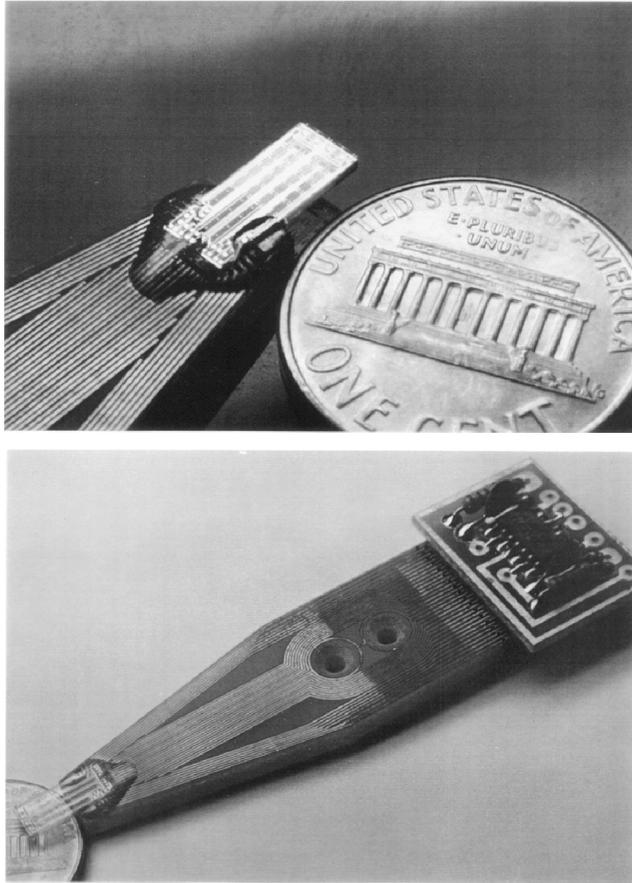

FIGURE 35.29 Packaging of the IIT/UM sensor-actuator system.

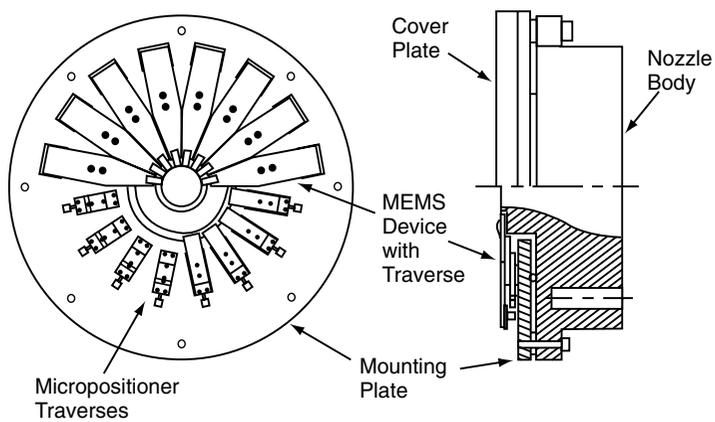

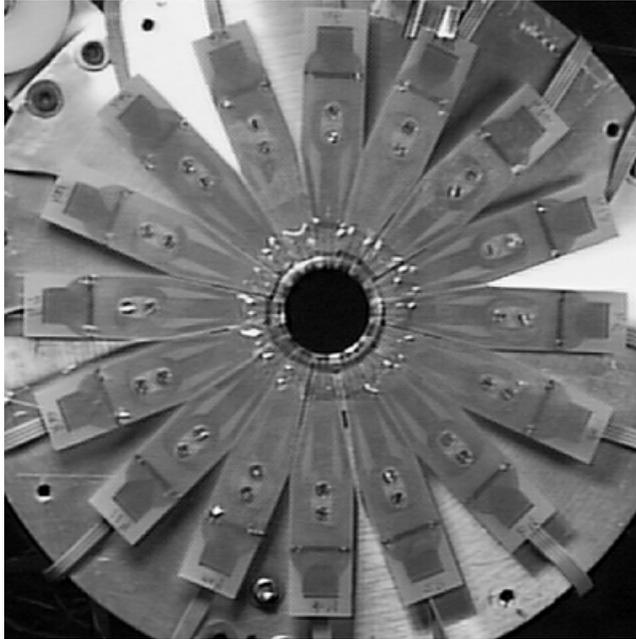

FIGURE 35.30 MEMS PC boards mounting provisions on the jet faceplate.

**FIGURE 35.31** Photograph of the MEMS sensor/actuator array mounted on the jet.

scatter is believed to be due to imprecise positioning of the hot wire at the center of the shear layer and variation in the amplitude of the different actuators. On the other hand, the phase results (bottom plot in [Figure 35.32](#)) indicate that the disturbance phase measured in the shear layer agrees with the excited flow modes.

The nonuniformity of the MEMS actuator amplitudes can be easily remedied by adjustment of the individual actuator driving voltages to provide uniform forcing. A more significant problem encountered in forcing with the full array was the slight deviations in resonant frequency of the individual devices. For the most part, this deviation did not exceed  $\pm 2\%$  of the average resonant frequency for a particular batch. This may not seem to be a substantial deviation; however, MEMS resonant devices tend to have very small damping ratios (high Q factor) which lead to very narrow resonant peaks. As a result, the devices cannot be operated at frequencies that deviate more than 0.5 to 1% from the resonance frequency while maintaining more than 20% of their resonance amplitude.

With the different actuators operating at slightly different frequencies it was not possible to sustain a specific phase relationship amongst the different actuators for extended periods of time. Therefore, the data shown in [Figure 35.32](#) were acquired using a transient forcing scheme whereby the actuators were used to force a particular azimuthal mode only for as long as the largest phase deviation did not exceed an acceptable tolerance. The best remedy to the problem, with the current MEMS technology, appears to be the fabrication of a large batch of devices, so only those with matching resonant frequencies are used.

In summary, the IIT/UM work has resulted in the realization of integrated actuators and a sensors system capable of autonomous control of shear layers in high-speed jets. The system was not actually used to control screech, as the actuators operated successfully up to a Mach number of 0.8 but not in the highly unsteady-pressure environment encountered during screech. Nevertheless, the ability of the less-than-hair-width actuators to operate up to such a high speed while producing significant disturbance into the flow (even at frequencies less than 1/10 of the most unstable frequency) was quite an impressive demonstration of the potential of the technology.

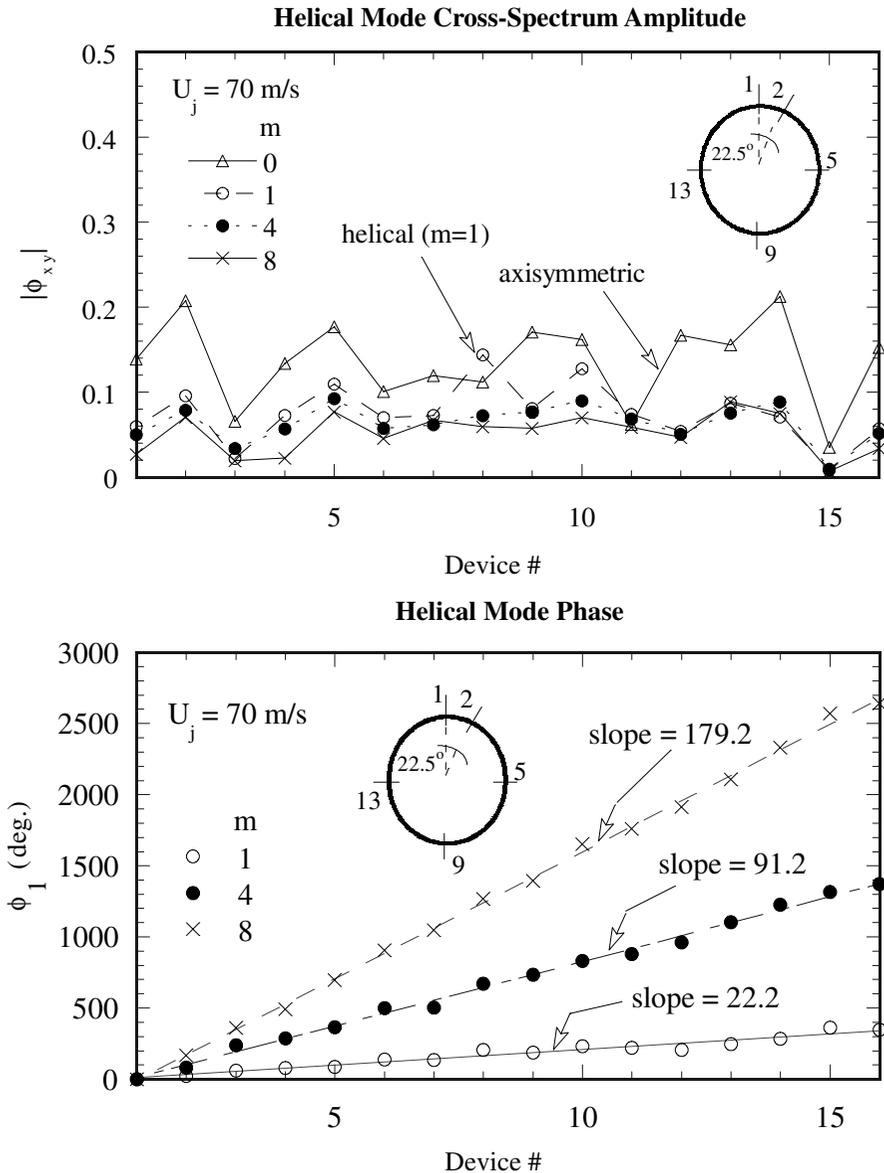

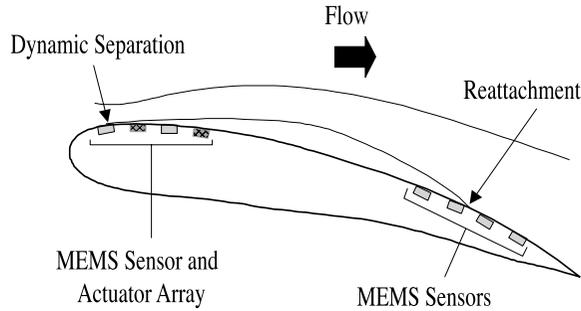

FIGURE 35.32 Azimuthal amplitude (top) and phase (bottom) distribution of the MEMS-induced disturbance.

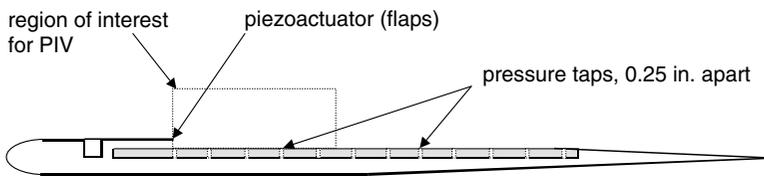

## 35.6 Control of Separation over Low-Reynolds-Number Wings

Recently, researchers from the University of Florida have proposed a MEMS system for controlling separation at low Reynolds numbers. The primary motivation of the proposed system was to enhance the lift-to-drag ratio in micro-air-vehicle (MAV) flight. Because of their small size (a few centimeters' characteristic size) and low speed, MAVs experience low-Reynolds-number flow phenomena during flight. One of these is an unsteady laminar separation that occurs near the leading edge of the wing and affects the aerodynamic efficiency of the wing adversely.

Figure 35.33 displays a schematic of the proposed control-system components and test-model geometry. The main idea is based on the deployment of integrated MEMS sensors and actuators near the

**FIGURE 35.33** Control system components for University of Florida low-Reynolds-number wing-control project.

**FIGURE 35.34** Test model for separation control experiments of University of Florida.

leading edge of an airfoil, or wing section. Additional sensor arrays are to be used near the trailing edge of the wing. The leading-edge sensors are intended for detection of the separation location in order to activate those actuators closest to that location for efficient control, as discussed in previous sections. On the other hand, the trailing edge sensors are to be utilized to sense the location of flow reattachment. In this manner, it would be possible to adapt the magnitude and location of actuation in response to changes in the flow in order to, for instance, maintain the flow attached at a particular location on the wing. The ultimate benefit of such a control system is the manipulation of the aerodynamic forces on the wing for increased efficiency as well as maneuverability without the use of cumbersome mechanical systems.

In actual implementation, the University of Florida group adopted a *hybrid* approach, whereby conventional-scale piezoelectric devices were used for actuation and MEMS sensors were used for measurements. Additionally, it appears that because of the difficulty in detecting the instantaneous separation location, as discussed in the delta wing control problem, a small step in the surface of the wing was introduced near the leading edge at the actuation location. Thus, the location of separation was fixed and there was no need for using leading-edge sensors for initial testing of the controllability of the flow. The flow control test model is shown in [Figure 35.34](#).

### 35.6.1 Sensing

To measure the unsteady wall shear stress, platinum surface hot-wire sensors were microfabricated. The devices consisted of a  $0.15\text{-}\mu\text{m}$ -thick  $\times$   $4\text{-}\mu\text{m}$ -wide  $\times$   $200\text{-}\mu\text{m}$ -long platinum wire deposited on top of a  $0.15$  silicon nitride membrane. Beneath the membrane is a  $10\text{-}\mu\text{m}$ -deep vacuum cavity with a diameter of  $200\text{ }\mu\text{m}$ . Similar to the UCLA/Caltech sensor, the evacuated cavity was incorporated in the sensor design to maximize the thermal insulation to cooling effects other than that due to the flow. As a result, the sensor exhibited a static sensitivity as high as  $11\text{ mV/Pa}$  when operating at an overheat ratio (operating resistance/cold resistance) of up to  $2.0$ . The sensor details can be seen in the SEM image in [Figure 35.35](#). For a detailed characterization of the static and dynamic response of the sensor, the reader is referred to Chandrasekaran (2000) and Cain (2000).

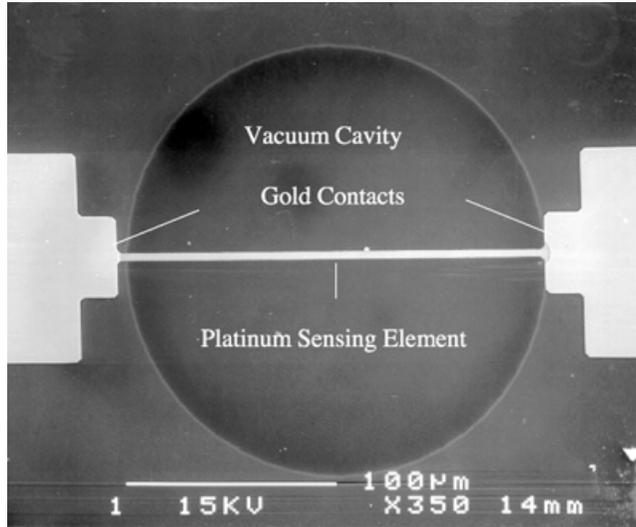

FIGURE 35.35 (Color figure follows p. 12.26.) SEM view of University of Florida MEMS wall-shear sensor.

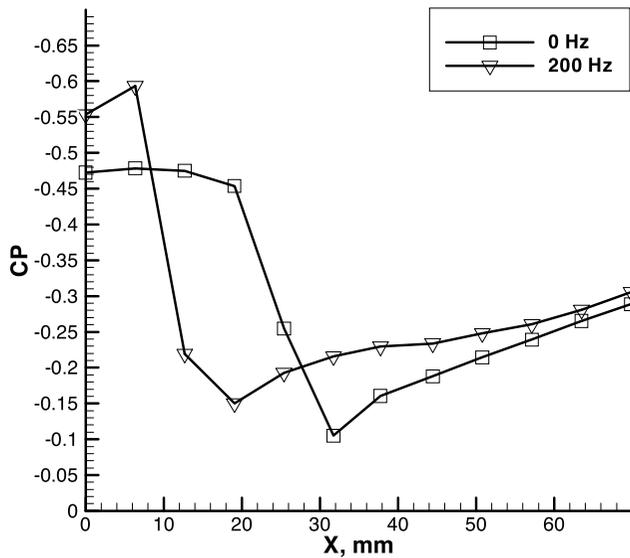

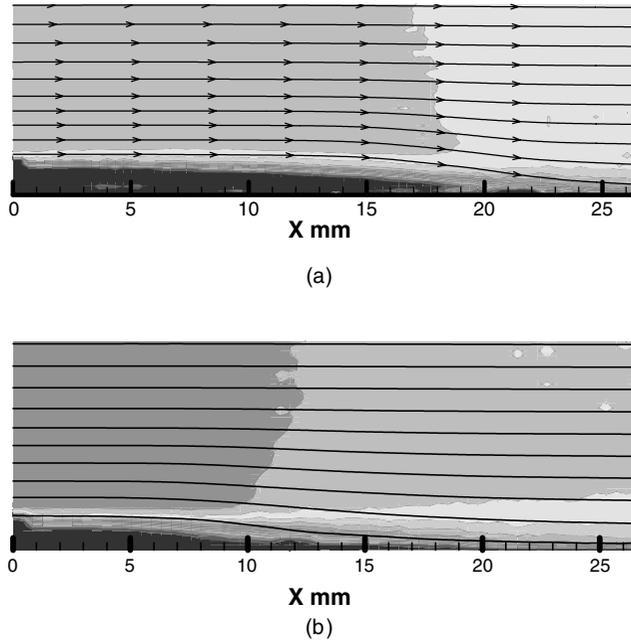

FIGURE 35.36 Static pressure distribution with and without control.

### 35.6.2 Flow Control

Static surface pressure measurements and particle image velocimetry (PIV) images were used by Fuentes et al. (2000) to characterize the response of the reattaching flow to forcing with the piezoelectric actuators. The 51-mm-wide  $\times$  16-m-long flap-type actuators (see Figure 35.34) were operated at their resonance frequency of 200 Hz. The resulting static pressure (plotted as a coefficient of pressure,  $CP$ ) distribution downstream of the 1.4-mm-high step is given in Figure 35.36. Similar results without forcing are also provided in the figure for comparison. As seen from the figure, the minimum negative peak of  $CP$ , corresponding to the location of reattachment, shifts upstream with excitation. The extent of the shift is fairly significant, amounting to about 30% or so of the uncontrolled reattachment length.

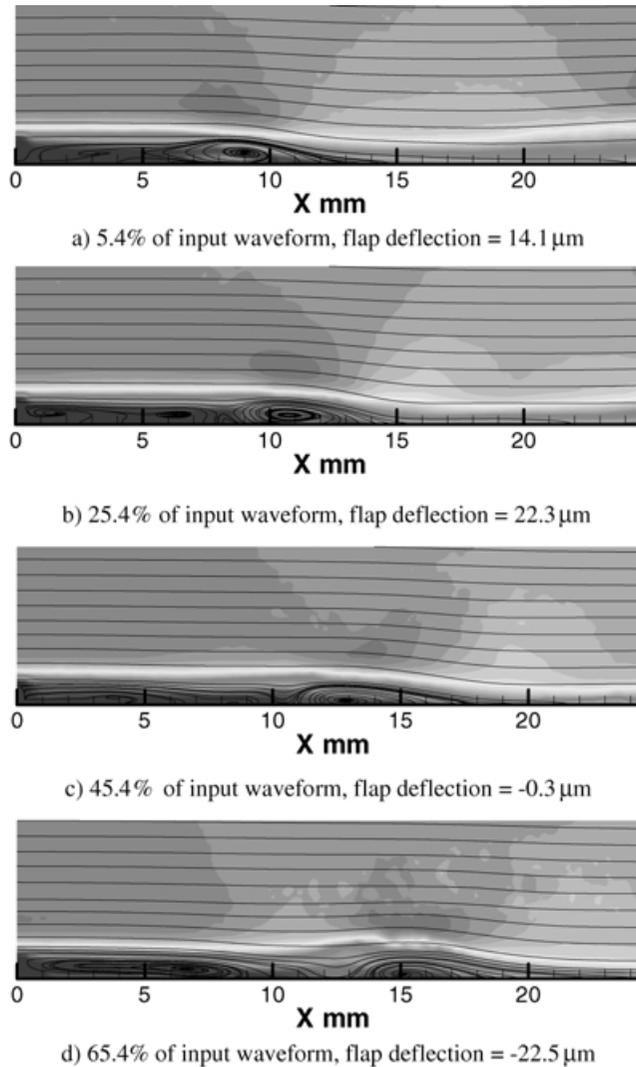

**FIGURE 35.37** (Color figure follows p. 12.26.) Streamlines of the flow over the step without (a) and with (b) actuation.

The reduction in the reattachment length with forcing can also be seen in the streamline plots obtained from PIV measurements (see [Figure 35.37](#)). However, the real benefit of the PIV data was revealing the nature of the flow structure associated with actuation by capturing images that were phase-locked to different points of the forcing cycle. Those results are provided in [Figure 35.38](#) for an approximately full cycle of the forcing. A convecting vortex structure is clearly seen in the sequence of streamline plots (a) through (d). The observed vortex structures were periodic when an actuation amplitude of about 22  $\mu\text{m}$  was used. For substantially smaller forcing amplitude, the generated vortices were found to be aperiodic.

Similar to the UCLA/Caltech and IIT/UM efforts, the University of Florida work has demonstrated the ability to alter the flow significantly through low-level forcing. Additionally, high-sensitivity MEMS sensors were developed and tested. However, for all three efforts there remains to be seen a demonstration of a fully autonomous system in operation.

## 35.7 Reflections on the Future

When it comes to the potential for using MEMS for flow control, it is not difficult to find contradictory views within the fluid dynamics community. This is not too surprising given the number of challenges facing the implementation and use of this fairly young technology. Challenges aside, however, one needs to recognize that there are certain capabilities that can only be achieved with MEMS technology. Examples include tens-of-kHz distributed mechanical actuators, sensor arrays that are capable of resolving the spatiotemporal character of the flow structure in high-Reynolds-number flows, integration of actuators, sensors and electronics, etc.—that is, the kind of capabilities that seem to be needed if we are to have any hope of controlling such a difficult system as that governed by the Navier–Stokes equations. Therefore, it is significantly much more constructive for us to identify the challenges facing the use of MEMS and strive to find solutions to these challenges, rather than simply dismiss the technology (along with its potential benefits). In this section, some of the leading challenges facing the attainment of

**FIGURE 35.38** (Color figure follows p. 12.26.) Phase-averaged streamline plots at different phases of the forcing cycle.

autonomous MEMS control systems for shear layer control are highlighted. These are accompanied by the author's perspective on the hope of overcoming these challenges.

One of the main concerns regarding the implementation of MEMS devices is regarding their *robustness*, particularly if they have to be operated in harsh, high-temperature environments. For the most part, this concern stems from the micron size of the MEMS devices which renders them vulnerable to large external forces. However, it is important to remember that as one shrinks the size of a structure, the flow forces acting on it decrease along with its ability to sustain such forces. That is, to a certain extent, the microscale devices may be as strong as, if not stronger than, their larger scale equivalent (at least if they are designed well). That is probably why the actuators from Naguib et al. (1997) operated properly while immersed in a Mach-0.8 shear layer, and the actuators and sensors of Huang et al. (2000) successfully completed a test flight while attached on the outside of an F-15 fighter jet. Furthermore, as new microfabrication techniques are devised for more resilient, chemically inert, harder materials other than silicon, it will be possible to construct microdevices for harsh, high-temperature, chemically reacting environments. Some of the current notable efforts in this area are those concerned with micromachining of silicon carbide and diamond.

The robustness question is probably more critical from a practical point of view; that is, whereas a MEMS array of surface stress sensors deployed over an airplane wing may survive during flight, the array may easily be crushed by a person during routine maintenance. However, it appears that such issues should, and could, be addressed at the design stage where, for instance, the sensor array may be designed to be normally hidden away but to deploy during flight only. Additionally, the inherent array-fabricating ability of MEMS could be used to increase system robustness through redundancy. If a few sensors break, other on-chip sensors may be used instead. If the number of malfunctioning sensors becomes unacceptable, the entire chip could be replaced with a new one. The economics of replacing MEMS system modules will likely be justified, as it seems natural that MEMS will eventually follow in the path of the integrated circuit chip with its low-cost, bulk-fabrication technologies.

Beyond robustness, there is a need to develop innovative approaches to enhance the *signal-to-noise ratio* of MEMS sensors. As discussed before, when the size of sensors is shrunk, often, but not always, their sensitivity decreases proportionally. Because, for the most part, traditional transduction approaches have been used with the smaller sensors, the overall signal-to-noise ratio cannot be maintained at desired levels. Hence, there is a need to identify *ultra-sensitive* transduction methods. An example of such methods is the intra-grain, poly-diamond piezoresistive technology developed recently by Salhi and Aslam (1998). This technology promises the ability to integrate inexpensive poly-diamond piezoresistive gauges with a gauge factor of up to 4000 (20 times more sensitive than the best silicon sensors) into microsensors.

Finally, when it comes to actuation, one of the most challenging issues that need to be addressed is the sufficiency of MEMS actuation amplitudes. Notwithstanding the successful demonstrations of the IIT/UM and UCLA/Caltech groups discussed earlier in this chapter, in practice boundary layers tend to be significantly thicker and more turbulent at separation than those encountered in the cited experiments. Therefore, it is most likely that the use of MEMS actuators will be confined to controlled experiments in the laboratory (where they may be used, for example, for proof-of-concept experiments) and flows in microdevices. For large-scale flows, successful autonomous control systems will most probably be hybrid, consolidating macroactuators with MEMS sensors arrays, as was done, for instance, in the University of Florida work discussed earlier. This will require developing clever techniques for integrating the fabrication processes of MEMS with those of large-scale devices in order to capitalize on the full advantage of MEMS.

### 36.1 Introduction

---

As discussed in previous chapters of this volume, microelectromechanical systems (MEMS) are typically constructed on the micrometer scale, with some thin layers being perhaps in the nanometer range. As has already been demonstrated by microelectronic circuits, the lateral dimensions of MEMS are being pushed into the nanometer range as well. This advance has been dubbed “nanoelectromechanical systems,” or NEMS. The ultimate utility of nanomachining (that is to say, the application of capable robots on the molecular scale to solving a range of problems) is limitless. Such a regime will likely be attainable only by the “bottom-up” approach in which atoms are individually manipulated to construct macromolecules or molecular machines. Properties of pure molecules, such as heat conduction, electrical conduction (low power dissipation), speed of performance and strength, without the limits of boundaries to other molecules and resulting materials defects, vastly exceed those of bulk materials.

Drexler wrote about molecular machinery that could be modeled after the ultimate existing nanoelectromechanical system, the biological cell [Drexler, 1981]. He discussed analogs within the cell for such mechanical devices as cables, solenoids, drive shafts, bearings, etc. Proteins exhibit a remarkable range of functionality, and compared with current MEMS technology, are extremely small. Reasoning that proteins are ideal models upon which to design nanomachines, Drexler envisioned the development of machinery that would allow us to artificially produce such nanoscale mechanical components as those listed above. Imagining complex machinery operating at the molecular scale gives rise to images of

nanorobots repairing our organs [Langreth, 1993], smart materials that intelligently conform to our bodies by adjusting a vast number of rigid nanoplates and incorporating robots that scour our clothing for debris and keep them clean [Forrest, 1995] and ones that build yet more complex nanomachinery. The list of possibilities is endless.

However, at this time, such intriguing visions still reside in the realm of science fiction. If the creation of complex nanosystems of any kind is to be accomplished, it will likely happen soonest by manipulation of biological systems to perform feats of engineering that exploit their existing programming, or by chemical synthesis of ever more complex molecules in a beaker. Although the field of molecular electronics is progressing rapidly, molecules are currently combined with relatively large and cumbersome connections in order to study their properties [Reed, 1999], and to our knowledge, no molecular mechanical system has yet been synthesized from its basic atomic constituents. The future is long, though, and progress is unpredictable and often rapid. The advent of scanning probe microscopes, including scanning tunneling and atomic force microscopes, was a turning point in the advancement of nanoscience and technology, allowing us to manipulate single atoms [Binnig and Rohrer, 1987]. Even this great advancement is trivial compared with the requirements of assembling thousands of atoms in complex shapes, powering them, observing them, and controlling them. The problems posed in reaching this capability are staggering.

For the purposes of this chapter, we will define NEMS as the extension of current MEMS technology. However, this chapter includes a discussion of atomic-scale lithography and concludes with a discussion of the synthesis of nanoscale systems by purely biological and molecular synthetic means. Although these latter techniques are in their infancy, it is likely that in the nearer term, using more conventional fabrication techniques, we will be able to exploit new functionality possible only on the nanoscale. These might include frictional, thermal or viscosity properties of materials; interaction with electromagnetic radiation at very small wavelengths; or ultrahigh-frequency resonances. These regimes will be approachable by the more conventional “top-down” approach of defining small areas by high-resolution lithography and pattern transfer. In this chapter, we will discuss mainly top-down approaches, except for that of atomic holography, and scanning probes based on scanning tunneling or atomic force microscopes, which can be used in either approach. In top-down patterning, several techniques for achieving nanometer resolution of arbitrary shapes have been developed. These include mainly electron beam lithography (EBL), ion beam lithography (IBL) and X-ray lithography (XRL). Here we will discuss electron beam lithography and X-ray lithography, as due to expense, complexity and somewhat lower resolution than EBL, IBL is not as commonly used. We will also discuss two related techniques for achieving a parallel process for high throughput and small features, namely microcontact printing and nanoimprint lithography.

Using these processing techniques, it is certainly possible to machine silicon and related materials in the nanometer regime. Namatsu et al. (1995) used EBL and reactive ion etching (RIE), coupled with etching in KOH/propanol solutions, to create 100-nm vertical walls with a thickness of 6 to 9 nm. Using nanomachined tips (fabricated in a manner similar to contamination resist lithography, discussed in this chapter), Irmer et al. (1998) used a scanning probe “ploughing” technique to modify thin Al layers, resulting in  $100 \times 100 \text{ nm}^2$  Josephson junctions. Others have sought to exploit very high frequency resonances in ultrasmall beams. Erbe et al. (1998) used electromechanical resonators with dimensions of about 150 nm to control physically adjustable tunneling contacts at frequencies up to 73 MHz at room temperature. In a comprehensive review of nanoelectromechanical systems, Roukes (2000) discusses the limits of mechanical resonators made of various semiconducting materials. He reports that at the 10- to 100-nm scale, SiC resonators should oscillate in the 10-GHz range, and at molecular scales nanodevices should exhibit resonant frequencies in the THz range.

Finally, we recognize that biological systems are the ultimate nanomachines, with internal operation of a single cell being more complicated than any human-made factory. In each cell, tens of thousands of different kinds of proteins and enzymes go about their complex tasks in a highly elaborate interplay of activity. We conclude our chapter with a discussion of how some cellular activities are being harnessed as future nanomachines.

## 36.2 NEMS-Compatible Processing Techniques

---

### 36.2.1 Electron Beam Lithography

Electron beam lithography is a technique in which the energy imparted by a directed stream of electrons modifies a film on the surface of a substrate. In general, EBL is utilized for direct writing of patterns on semiconductor substrates, as well as defining mask patterns for optical and X-ray lithographies. In direct-write mode, a key issue in manufacturing is throughput, a characteristic for which EBL has had difficulty competing with other technologies such as optical projection lithography. Variations of EBL include exposures by Gaussian distributed beams, shaped beams in which the pattern of energy deposition is shaped by apertures, and a promising technique for manufacturing called “scattering with angular limitation in projection electron beam lithography,” or SCALPEL [Berger et al., 1991]. SCALPEL works by the imaging on a substrate of a pattern of mask features through which electrons are either transmitted without scattering or are scattered at obstructions on the mask. An aperture in the optical column passes preferentially those electrons that are not scattered so the pattern of unscattered electrons is printed on the wafer. Although shaped beams offer improved throughput compared with Gaussian beams, SCALPEL is superior in this regard and, among the electron beam technologies, offers the most promise for manufacturing. For an excellent discussion of electron beam systems, see McCord and Rook (1997). In this chapter we are concerned primarily with resolution, as opposed to other aspects of more interest to mass production of patterns. Although these issues cannot be ignored for a technology to be ultimately viable, we discuss those issues that limit our ability to create nanomachines at the limits of physical possibility.

It is fortuitous that the reliance of nano-EBL on very narrow electron beams is the same as that required of high-resolution scanning electron microscopy (SEM), which now is a mature field. It is common for researchers to modify SEMs [Bazán and Bernstein, 1993],<sup>1</sup> to control the position of the beam, and, in conjunction with a beam blanker that modulates the beam current, obtain very high resolution patterning. Most commercial EBL systems are optimized for such issues as throughput and placement accuracy and make it less of a priority to achieve resolution in the nanometer range.

#### 36.2.1.1 Resolution Limits

It is useful to understand the dependence of the ultimate size of patterning by EBL on all of the various steps involved. These include creation of the narrowest and brightest beam, choice of electron beam resist, forward- and backscattering of electrons in the resist and substrate, beam–resist interactions, resist development and, finally, pattern transfer to the substrate. Each of these issues will be addressed in turn.

##### 36.2.1.1.1 Beam Size

The formation of a narrow, bright beam is critical to the formation of the smallest possible patterns. In all scanning electron optical systems, the column demagnifies an image of the electron source and projects this demagnified image onto the substrate. Electron lenses use magnetic fields created by current in coils to produce an effect of focusing much like that of optical lenses. The central function of the column is to demagnify the first crossover point at the source to a small, intense spot in the plane of the wafer. Because the diameter of the beam at the target is some fraction of the diameter of the source, starting with a small, bright source is of central importance. The five types of electron emitters commonly used in electron beam systems can be broadly classified as either thermionic emitters or field emitters. In order of decreasing source size, these are (a) tungsten hairpin filament, or thermionic; (b) lanthanum hexaboride, LaB<sub>6</sub>, and the related CeB<sub>6</sub>; (c) Schottky emitter; (d) thermal field emitter; and (e) cold cathode field emitter.

---

<sup>1</sup>EBL systems for SEMs are available commercially from Raith USA, Inc., 6 Beech Road, Islip, NY 11751-4907; and J.C. Nabity Lithography Systems, P.O. Box 5354, Bozeman, MT 59717.

**TABLE 36.1** Properties of Various Cathodes Used for Electron Beam Lithography

Type	Vacuum (Pa)	Work Function (eV)	Cathode Temp. (K)	$\Delta E$ (eV)	Source Diameter or Tip Radius ( $\mu\text{m}$ )	Emission Current Density ( $\text{A}/\text{cm}^2$ )	Brightness ( $\text{A}/\text{cm}^2/\text{Sr}$ )	Probe Diameter (nm)	Lifetime (hours)
W	$10^{-3}$	4.6	2700	2	50	2	$10^5$	4	50
LaB <sub>6</sub>	$10^{-5}$	2.7	1800	1	10	40	$10^6$	3	2000
ZrO/W Schottky	$10^{-7}$	2.8	1800	0.8	1	500	$10^{10}$	2	Several thousand
CCFE	$10^{-8}$	4.6	300	0.3	0.1	$10^5$	$10^8$	1	Several thousand

Table 36.1 lists the important properties of each emitter, except for the thermal field emitter. Note that these are representative values only and are highly dependent on manufacturers' specifications, beam energy, column design, etc. Tungsten hairpin filaments are historically the most common and easiest sources to use. These emitters operate by passing current through the filament to raise its temperature to the vicinity of 2700 K, so that electrons can overcome the work function and enter the electron optical column. They require the least stringent vacuum conditions (approximately  $10^{-3}$  Pa), so the overall systems tend to be less expensive. Most importantly, the effective diameter of the emission spot at the crossover below the filament is about 50  $\mu\text{m}$ , resulting in a typical spot size of about 3 to 5 nm. Also important is the brightness of the source, expressed in units of Amperes/cm<sup>2</sup>/steradian. As spot size is reduced through changes in column conditions, a large fraction of electrons is lost by scattering outside of the optical path. In a typical tungsten filament system, 100  $\mu\text{A}$  of current from the source translates to perhaps 10 pA at the sample in obtaining the smallest spot size. This makes imaging at the highest resolution more difficult, so in addition to increased throughput at a given spot size a practical benefit of increased brightness is the ability to form a crisp image during focusing, thereby forming the narrowest possible spot. This translates to better spot size control and ultimately higher resolution patterning.

Besides suffering from a large size at the source for tungsten filaments, the thermal energy spread of the beam is about 4.5 eV, which can contribute to an increase in the beam diameter. Although this is a small fraction of the accelerating voltage (typically 30 to 100 kV), it is enough to create noticeable chromatic aberrations, so that focusing of the electrons at a single spot is hampered by the differing focal lengths for electrons with different energies. Because the minimum spot size for each energy is achieved at different focal lengths, the overall minimum spot at any one distance (i.e., at the surface of the substrate) is enlarged.

Closely related to the tungsten hairpin filament is the LaB<sub>6</sub>, lanthanum hexaboride emitter, and related CeB<sub>6</sub>, cerium hexaboride. These materials are often referred to as lab-6 and cebix, respectively. This emitter is a sharpened piece of single crystal that is heated either by passing current directly through it or heating it by a separate heater, to about 1800 K. The tip is machined for some optimum shape and produces an effective source diameter of typically 10  $\mu\text{m}$ . Due to its lower work function of 2.7 eV and attending lower energy spread of about 1 eV, it is brighter and produces less chromatic aberration. CeB<sub>6</sub> offers a slightly lower work function and greater robustness but is not as commonly used. In order to protect the tip from "poisoning," a better vacuum, typically  $10^{-5}$  Pa, is required of a LaB<sub>6</sub> system. In most cases, given the quality of vacuum system, tungsten hairpin and LaB<sub>6</sub> sources can be used interchangeably. One important advantage is an operating lifetime for LaB<sub>6</sub> of up to 2000 hours vs. less than 100 hours for thermionic tungsten.

A significant improvement in resolution and brightness over the previous sources is provided by the Schottky emitter. This source consists of a ZrO-coated W tip sharpened to about 0.5  $\mu\text{m}$ . The reduced work function (from 4.6 eV in W to 2.8 eV) and enhanced electric field, which lowers the barrier (Schottky effect), allow the electrons to be extracted at a temperature of about 1800 K. The advantages of this source are high stability and brightness combined with much higher resolution (smaller spot size) than

the thermionic sources. Spot sizes of about 3 nm or better are achievable in these systems. Schottky emitters are becoming the most common in advanced EBL systems for their combination of beam stability, long lifetime (a few thousand hours), high brightness and small spot size.

The highest resolution beams for scanning electron microscopy are produced using field emission sources. These consist of a very sharp, single-crystal tungsten tip ( $r = 0.01$  to  $0.1 \mu\text{m}$ ) operated under a high electric field. One variation, called thermal field emission (TFE), is to heat the tip; another, called cold cathode field emission (CCFE), is to run the tip at room temperature. The TFE emitter has not commonly been used since the advent of the Schottky emitter. In the CCFE case, a high extraction field renders the potential barrier so thin (about 10 nm) that electrons can tunnel through even at relatively low temperatures. Because of this, thermal energy is reduced to about 0.2 eV, and chromatic aberrations are significantly reduced. Because of the reduced area of emission and reduced chromatic aberrations, probe sizes as small as about 0.5 to 1 nm can be produced. CCFE sources are not commonly used in EBL applications because the beam is inherently unstable due to adsorption of gas layers that affect the emission properties. Heating the tip, as in the case of TFE cathodes, solves this problem. In CCFE SEMs, this instability is dealt with by feeding back a current signal instantaneously to the video monitor to produce a clean image with little or no evidence of current fluctuations. However, for purposes of beam writing, this can lead to fluctuations in instantaneous dose at the wafer and therefore to poor linewidth control. In spite of this, Dial et al. (1998) have reported excellent lithographic results using a CCFE SEM by building feedback into their exposure rates. Their system has demonstrated a regular array of dots with diameters of 10 nm on a pitch of 25 nm in polymethylmethacrylate (PMMA) at 30 keV.

### 36.2.1.1.2 Electron Scattering

Formation of a high-quality beam is only the first step in pattern formation. For very narrow beams, a larger contribution to pattern size is scattering of electrons in the resist and in the substrate. When an electron beam impinges on a resist layer, the electrons scatter through both elastic and inelastic processes. Elastic scattering results in backscattering of the electrons at energies close to the primary beam and in negligible energy transfer to the resist and substrate. Inelastic scattering leads to spreading of the primary beam and generation of low-energy secondary electrons that, in turn, expose the resist. In PMMA, a positive resist, the mechanism of exposure is the scission of bonds in the high-molecular-weight polymer to create regions of lower molecular weight. The lower molecular weight is more soluble in suitable developer solutions, so the resist is removed where exposed. In negative resist, energy deposition results in cross-linking of the polymer, and the resist is rendered less soluble and so remains behind after development and removal of unexposed resist.

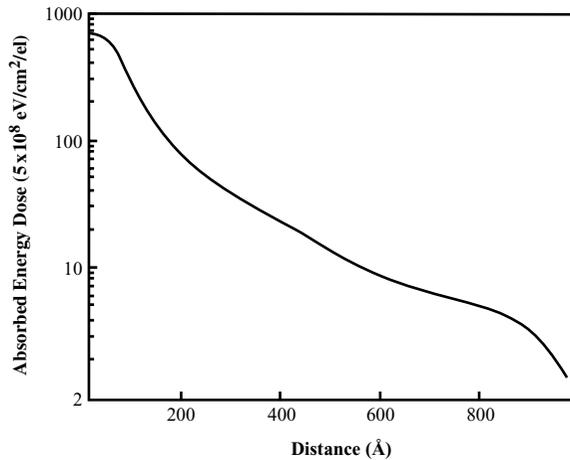

The spread of the primary beam in the resist layer can be described by:

$$b = 625 \frac{Z}{E_0} t^{3/2} \left( \frac{\rho}{A} \right)^{1/2} \text{ cm} \quad (36.1)$$

where  $b$  is the spread of the beam at a distance  $t$  into the resist;  $Z$ ,  $A$  and  $\rho$  are the atomic number, atomic weight ( $\text{g/mol}$ ) and density ( $\text{g/cm}^3$ ), respectively; and  $E_0$  is the beam energy (keV). For PMMA ( $(\text{C}_5\text{O}_2\text{H}_8)_n$ ),  $Z = 3.6$ ,  $A = 6.7$ , and  $\rho$  is 1.2. For a delta function beam (i.e., an ideal beam with zero width) of energy 40 keV, the beam spreads out by 7.5 nm after 100 nm. This leads to a slight undercut profile that helps in lifting off metal patterns, so it is not necessarily undesirable. However, it does suggest that thin resists are preferable for achieving the highest resolution and pattern density. In thicker resists, it is often the case that the width of a lifted-off metal line is wider than the opening at the top surface, as metal can be deposited over the entire width of the line at the wafer surface; therefore, it can sometimes be deceiving to assume that the width of achievable resolution is that observed at the resist surface.

The Bethe retardation law,

$$\frac{dE}{dx} = -7.85 \times 10^4 \left( \frac{Z\rho}{AE_m} \right) \ln \left( \frac{1.66E}{J} \right) \frac{\text{keV}}{\text{cm}} \quad (36.2)$$

**FIGURE 36.1** Absorbed energy due to exposure by a 2-nm beam of 100-keV electrons in 100 nm of PMMA. Energy deposition is primarily due to secondary electrons, and minimum feature size is limited to approximately 10 nm. (Adapted from Joy, 1983.)

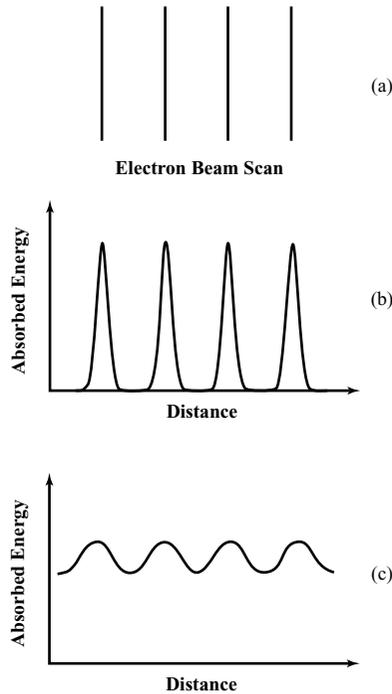

(where  $dE/dX$  is the energy loss of the beam per unit distance in the solid;  $E_m$  is the mean electron energy along the path;  $Z$ ,  $A$  and  $\rho$  are as defined above; and  $J$  is the mean ionization potential (keV)), tells us that low-energy electrons are more efficient than high-energy electrons at transferring energy to the resist and are in fact responsible for breaking bonds in PMMA. Also, although secondary electrons are generated at energies up to a significant fraction of the beam energy, those at lower energies are again much more effective at exposing resist.

Using the Monte Carlo approach, Joy (1983) has investigated the minimum possible features achievable in PMMA. Because low-energy secondary electrons lose energy more readily than high-energy electrons, they are the dominant agents for transferring energy to the resist. Figure 36.1 shows the absorbed energy due to exposure by a 2-nm beam of 100 keV electrons in 100 nm of PMMA. For finite contrast of the developer/resist system, the plateau of energy absorption is developed uniformly, and a spatial resolution of approximately 10 nm results. Smaller lines can result with high-contrast developers and very careful processing to take advantage of slight differences in absorbed energy within the plateau region. Chen and Ahmed (1993a) demonstrated linewidths approaching 5 nm with ultrasonic developers and reactive ion etching for pattern transfer. These narrow linewidths are not necessarily developed all the way through the resist, which is necessary to allow pattern transfer to the substrate by liftoff. Chen and Ahmed demonstrated lifted-off lines that were slightly less than 10 nm [Chen and Ahmed, 1993b], in good agreement with Joy's results.

The interaction volume of primary electrons in a substrate can be described by the Kanaya–Okayama (K–O) range [Goldstein, 1981], given by:

$$R_{KO} = 0.0276 \frac{AE_0^{1.67}}{Z^{0.889} \rho} \mu m \quad (36.3)$$

where  $A$ ,  $E_0$ ,  $Z$  and  $\rho$  are as defined above. Electrons that are backscattered from the substrate are usually modeled as being Gaussian distributed with a characteristic width of about half of the K–O range. The effect of backscattered electrons is to expose the resist at some (usually) undesirable background level that depends on the surrounding patterns. This phenomenon is referred to as the “proximity effect” and much effort has gone into techniques for modifying pattern files to compensate exposure doses. The effect of backscattered electrons on the final resolution of an isolated pattern is less pronounced but can adversely affect the minimum resolution obtainable in dense patterns. Figure 36.2 shows the effect on

**FIGURE 36.2** Absorbed energy in resist due to proximity effect. (a) Line scans, (b) energy deposition without proximity effect, and (c) total energy deposition including proximity effect. As the space between the line scans absorbs more energy, it is more difficult for the developer to resolve the patterns, and linewidths increase. (Adapted from Huang et al., 1993.)

absorbed energy of exposing lines closer together. Note that the spaces between the lines absorb more energy, and the difference in effective exposure dose between the intended patterns and spaces is reduced. This makes the job of developing only the lines a more difficult one for the developer to accomplish, as explained in more detail below.

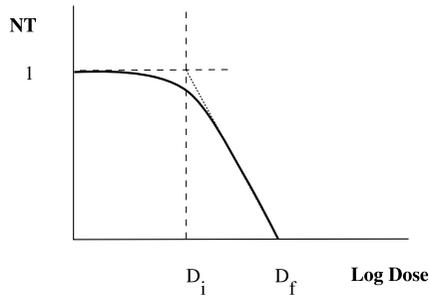

A common technique for reducing the effects of backscattered electrons is to expose patterns on thin membranes (typically silicon nitride) formed by patterning the backside of a silicon wafer and etching through to expose the membrane over a usable area. Although not very practical for making electronic devices, this technique has been used to demonstrate very high resolution lithography and to allow direct imaging of the results in a transmission electron microscope.

### 36.2.1.1.3 Conventional Resists and Developers

The quality of a developer for a particular resist is defined in terms of the sensitivity and contrast. A typical dose/exposure plot showing normalized thickness of the resist after development for positive resist is shown in Figure 36.3. (A curve for negative resist is zero at low doses and maximum at high doses.) The threshold dose for positive resist can be defined as that which results in clearing of the resist in the exposed areas. It is generally desirable for the threshold dose to be as small as possible for purposes of throughput, but if it is too small, then statistical effects due to the number of electrons required to expose a single pixel can become important. In general, resists that exhibit highest resolution are also the slowest (least sensitive).

The contrast of a resist (using a particular developer under a particular set of conditions) is defined as:

$$\gamma = \log\left(\frac{D_i}{D_f}\right)^{-1} \quad (36.4)$$

**FIGURE 36.3** Dose/exposure plot of normalized positive resist thickness after development.

where (for positive resist)  $D_i$  is the dose at the steepest part of the contrast curve extrapolated to full thickness, and  $D_f$  is that dose extrapolated to zero thickness. The role of contrast is central to obtaining the finest pattern dimensions. As discussed above, each exposure results in some spatially varying energy deposition. Contrast (for positive resist) is the ability of the developer to selectively remove resist that has absorbed more than a critical value and ignore that resist that has absorbed less. For an infinite contrast, the contrast curve would be vertical; resist above a sharp value of absorbed energy would be perfectly developed and below that value would be totally unaffected. In this case, we could arbitrarily approach the peak in [Figure 36.1](#) and obtain patterns equal to the beam width. In addition, we could make the lines arbitrarily close together, as the lines could be perfectly selectively removed. In reality, the slope of a real dose/exposure curve is finite, so a range of absorbed energy contours is removed, and it is difficult to achieve much less than the 10 nm discussed by Joy.

Typical unexposed, high-resolution PMMA has a molecular weight of about  $10^6$  Da, which is reduced to a few thousand Da after exposure [Harris, 1973]. The role of the developer is to selectively remove the lower molecular mass polymer components that result from chain scission of larger ones. The two most common developers of PMMA are methyl isobutyl ketone (MIBK) mixed with IPA in a ratio of 1:3, and 2-ethoxyethanol (Cellosolve) mixed with MeOH in a ratio of 3:7. The  $\gamma$  values provided by these mixtures are about  $-6$  to  $-9$  [Bernstein et al., 1992]. Bernstein et al. reported that the addition of about 1% methyl ethyl ketone (MEK) increases the contrast of these developers to greater than  $-12$ . This is ascribed to enhanced removal of higher molecular weight components that are not sufficiently broken at lower doses, without significantly affecting the solubility of the low-molecular-weight components.

As mentioned above, Chen and Ahmed (1993a) found that developing with ultrasonic agitation offers benefits to resolution and using this technique demonstrated 5- to 7-nm lines. They assert that, for exposures smaller than 10 nm, the resulting exposed PMMA fragments are trapped in a potential well created by the adjoining unexposed molecules. By exposing lines wider than 10 nm, the developer is able to dissolve the exposed resist but cannot remove them in the narrower lines. In the case of narrower lines, ultrasonic agitation can provide additional energy by which the exposed fragments can escape this potential well in the presence of the developer. (They used the Cellosolve solution mentioned above.) Although lift-off was not demonstrated, the patterns were transferred to a Si substrate by reactive ion etching. Even smaller features have been demonstrated by allowing regions of exposure by secondary electrons to overlap. Using this technique, Cumming et al. (1996) have created metal lines by lift-off as small as 3 nm. These are perhaps the smallest features ever created by exposure of PMMA.

Finally, upon exposure to very high doses (i.e., greater than about  $10^{-3}$  C/cm<sup>2</sup>), PMMA will cross-link to act as a negative resist. Tada and Kanayama (1995) report that with careful control, highly dosed PMMA developed in acetone can yield features as small as 10 nm. As the dose is increased, resistance to dry etching increases as well, to about twice that of unexposed PMMA. Using an electron cyclotron resonance (ECR) etcher, they created Si pillars with a width of 10 nm and a height of 95 nm.

The process of nanomachining can benefit from the use of high-resolution negative resists as well. One of the highest resolution (conventional) negative resists is Shipley's SAL 601-ER7, a member of the

Shipley ANR series of resists. It has been demonstrated to provide features as small as 50 nm [Bernstein et al., 1988]. This resist is one example of a chemically amplified resist, consisting of three components: an acid generator, cross-linker and resin matrix. Exposure by the electron beam generates an acid that, upon heating, catalyzes the cross-linking of the linker and the resin matrix, leading to very high sensitivity. Typical threshold exposure doses are about an order of magnitude less than for PMMA. Other negative resists that exhibit nearly similar resolution include IBM APEX-E and Shipley UVIIHS.

Because many deep ultraviolet optical resists are also sensitive to electron beams, a plethora of choices exists for resists that maximize sensitivity, resolution, dry-etch resistance or other properties. These include PBS (Mead), RE-4200N (Hitachi), APEX-E and KRS (IBM), UVIIHS and UV-5 (Shipley), AZ-PF514 and AZ-PN114 (Hoechst Celanese) and ZEP-520 (Nippon Zeon). Several of these are capable of achieving sub-100-nm resolution.

#### **36.2.1.1.4 Unconventional Resists**

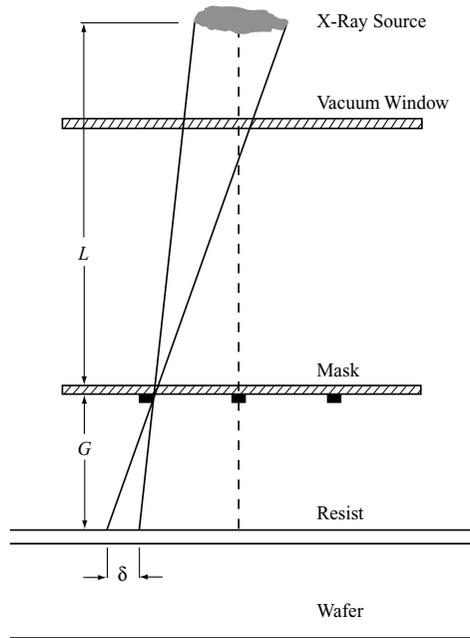

Many other alternative resist schemes for defining patterns with an electron beam have been investigated. One common technique is the condensation of carbon compounds from the vapors present in electron beam vacuum systems. This is referred to as “contamination resist” lithography because it utilizes the same mechanism that often causes contamination and degradation of imaging quality in electron microscopes. As early as 1964, Broers (1964), using a 10-nm electron beam, obtained a resolution of 50 nm after ion milling a contamination resist mask. It is generally accepted that the mechanism of deposition is the cracking by secondary electrons of adsorbed hydrocarbons at the sample surface. As with PMMA, the resolution of this technique benefits by the use of membranes for supporting the patterns. Contamination resist cannot be used in a lift-off mode, but it does perform reasonably well as an etch mask. Broers (1995) later demonstrated 5-nm Au–Pd lines created by deposition on a membrane followed by ion milling.

In an effort to merge with molecular electronics, self-assembled monolayers (SAMs) have more recently been investigated as electron beam resists. Because these layers are only a few nanometers thick, it is thought that the resolution achieved in this system will ultimately be higher than with PMMA. Also, very low energies can be used to expose thin layers, which can be beneficial to backscattering issues and also allow the use of exposure by low-energy scanning probe tips. SAMs consist of an ordered layer of single molecules adsorbed to a surface. Examples include *n*-octadecyltrichlorosilane (OTS), *n*-octadecanethiolate (ODT), [Lercel et al., 1993], octadecylsiloxanes (ODS) [Lercel et al., 1996], and dodecanethiol (DDT). Their value lies in the presence of alkyl groups at the outer surface which give them hydrophobic properties and resistance to wet etching. Exposure by an electron beam (or ultraviolet radiation) removes the alkyl group, rendering them hydrophilic so exposed areas can be etched. They are, therefore, positive tone in nature. Using ODS SAMs, Lercel et al. exposed individual dots with diameters of approximately 6 nm. These are roughly the size of individual molecules that could be anchored for NEMS systems.

Another technique employing an electron beam for lithography is that of direct sublimation of material. This is often referred to as simply “drilling” through a layer of inorganic material. This is quite literally a nanomachining process. Materials that are amenable to drilling include Al<sub>2</sub>O<sub>3</sub>, LiF, NaCl, CaF<sub>2</sub>, MgO and AlF<sub>3</sub>. Mochel et al. (1983) has demonstrated 1-nm holes drilled in Al<sub>2</sub>O<sub>3</sub>, which is perhaps the highest resolution ever demonstrated with a high-energy beam of electrons. In a related technique, Hiroshima et al. (1995) created lines on a 15-nm pitch by exposure of SiO<sub>2</sub>. Development was performed in a buffered HF solution. Such a technique might have applications in nanomachining.

## **36.2.2 X-Ray Lithography**

X-ray lithography (XRL) is basically an extension of optical proximity printing using much higher energy X-ray photons, with wavelengths in the range of about 0.1 to 10 nm. It was first described by Spears and Smith (1972). For MEMS technology, it has been extended to the LIGA process for creating microscale machined pieces such as gears and other mechanical parts. (This is described in detail in Chapter 17 of this text.) Because the use of X-rays is so common for micromachining applications, it is worthwhile to

**FIGURE 36.4** Schematic diagram of basic X-ray lithography exposure configuration.  $\delta$  is the amount of penumbral blurring due to a finite-sized source.

investigate the limits of resolution for nanomachined systems. An excellent review of XRL is provided by Cerrina and Rai-Choudhury (1997).

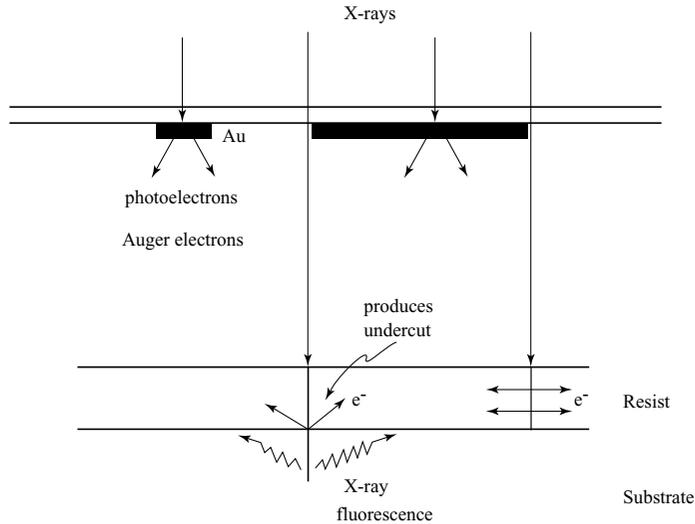

Figure 36.4 shows schematically a basic X-ray exposure configuration. The main issue in achieving workable X-ray systems in manufacturing is the development of suitable X-ray sources, masks and alignment techniques. The problems involved in developing bright, collimated X-ray sources are, in general, shared with the LIGA community but are even more pronounced for nanolithography. For example, the geometrical considerations of a finite-sized source, such as penumbral blurring and runout produced by an X-ray tube or plasma source, would be more severe (as a fraction of their total size) for nanometer-scale features. Because synchrotron sources produce nearly parallel beams, these would be most advantageous for printing ultrasmall patterns. In the late 1980s, IBM installed a minisynchrotron source [Andrews and Wilson, 1989] capable of servicing more than a dozen steppers. The cost of such an X-ray source today would be on the order of about \$20M [Cerrina, 2000] and might compete economically with advanced optical steppers.

For proximity printing in general, resolution is limited by diffraction effects as the minimum linewidth is approximately:

$$W = k\sqrt{G\lambda} \tag{36.5}$$

where  $k$  is a process-dependent parameter in the range of 0.6 to 1 [Cerrina, 1996],  $G$  is the gap, and  $\lambda$  is the wavelength. The  $k$  parameter depends on the processing conditions, including type of mask, resist and other conditions. With the use of phase-shift mask technology, 40-nm features at 20- $\mu\text{m}$  gaps have been achieved [Chen et al., 1997].

With conventional masks, for a  $\lambda$  of 1  $\text{\AA}$  and a relatively narrow gap of 5  $\mu\text{m}$ , we can expect to achieve feature sizes of a few tens of nanometers. This is well within the useful range of nanomachining. For even smaller gaps, better results can be achieved. However, there are other potential limitations to the maximum resolution. Feldman and Sun (1992) and Chlebek et al. (1987) have discussed several potential contributions to degradation of resolution, shown in Figure 36.5. First, photoelectrons and Auger

**FIGURE 36.5** Contributions by scattered energy deposition in resist for X-ray lithography, including photoelectrons and Auger electrons from the mask and photoelectrons from the resist and substrate.

electrons that are energetic enough to expose the resist are released from the mask. Second, photons that pass along the edge of the absorber create photoelectrons in the resist that expose regions at the edge and under the absorber shadow. Third, strong photoabsorption at the substrate creates additional photoelectrons that can lead to undercutting of the resist. According to Feldman and Sun, the high-energy photoelectrons do not contribute significantly to the limits to resolution, and according to Chlebek et al. neither do fluorescence photons.

It appears, then, that the limits to X-ray lithography resolution in PMMA are nearly identical to those determined by Joy (1983) as discussed above, with the source of energy, either X-ray photons or electrons, not being a significant factor. In fact, Flanders (1980) performed experiments demonstrating very high resolution XRL of PMMA. The masks used in this experiment were nanomachined (partially employing angled shadow evaporation) to have alternating, vertical, 100-nm-thick bands of 17.5-nm-wide tungsten and carbon layers. As seen vertically by the X-ray source, this resulted in a mask of alternating regions of differing transmission values. In fact, successful contact printing of this pattern demonstrated that resolution of XRL in PMMA is comparable to that of high-resolution EBL. Using a similar technique, Early et al. (1990) demonstrated 30-nm lines independent of wavelengths ranging from 0.83 to 4.5 nm. The limit to useful printing scales in practical XRL systems will depend on other factors, such as patterning accuracy and mask distortions. Even including all of these effects, XRL will likely be an important technology for future NEMS applications.

### 36.2.3 Other Parallel Nanoprinting Techniques

Two other printing methods deserve mention due to their simplicity, potential high-resolution capability and potentially high throughput, which will be necessary for a commercially feasible technology. These are “microcontact printing,” developed by Whitesides, and “nanoimprint lithography,” developed by Chou. Both of these techniques function by physical contact between a patterned stamp and a substrate.

In the first case, the stamp is a pliable, elastomeric material, namely polydimethylsiloxane (PDMS), that is coated with a SAM (typically one of those mentioned above) and then pressed onto a substrate, resulting in printing of a monolayer of SAM molecules. The stamps are formed by first preparing a master pattern etched into a hard substrate made typically of glass, resists, polymers or silicon. The master is made using standard photolithography and etching techniques. The elastomer is poured onto the master, cured, peeled off and then treated with an appropriate SAM “ink.” Finally, the stamp is pressed directly onto

the target material by hand or with some other simple pressing system. Using this technique, remarkably high-quality patterns and processing applications are possible. St. John and Craighead (1995) have demonstrated the use of OTS as ink, followed by plasma etching to demonstrate 5- $\mu\text{m}$  patterns in silicon. Kumar and Whitesides (1993) used a variety of thiol-based SAMs to pattern Au layers that were used for further processing of substrates. They demonstrated features as small as 200 nm using hexadecanethiolate as the ink, and wet etching of underlying gold layers using KCN solutions. Additional techniques demonstrated were selective area plating of nickel and selective area condensation of water vapor in hydrophilic regions for use as optical diffraction gratings.

The second stamping technique utilizes a rigid stamp in contact with a viscoelastic polymer, typically PMMA. The stamp is pressed into a resist layer that is heated above the glass transition temperature,  $T_g$ . Polymers such as PMMA are mixtures of amorphous and crystalline morphologies.  $T_g$  is an important parameter because it is the temperature at which the polymer chains begin to slip in their amorphous arrangement, and the material can flow easily when subjected to pressure. (Note that relaxation of the crystalline portion of the arrangement is referred to as “melting,” which is not important to this discussion.)  $T_g$  for bulk, heterotactic PMMA is approximately 105°C. According to Kleideiter et al. (1999),  $T_g$  in general can vary depending on the thickness of the film and the substrate upon which it is cast. It is important for a successful resist used in nanoimprinting to have a low glass-transition temperature, low viscosity, low sticking forces to the stamp, high stability and high dry-etch resistance. Typical imprint temperatures are about 90°C greater than  $T_g$ .

Chou et al. (1997) have demonstrated 10-nm holes on a 40-nm pitch in PMMA. In order to ensure a clean surface after imprinting, the residual PMMA at the bottom of the patterns is etched away using an oxygen plasma. These patterns are then suitable for lift-off of metal patterns. By additional etching of the stamp features, 6-nm metal dots were lifted off. Schulz et al. (2000) have investigated alternative resists including thermoplastic polymers based on aromatic polymethacrylates and thermoset polymers based on multifunctional allylesters. These exhibit overall lower  $T_g$  (as low as 39°C in the case of the allylesters before imprinting), improved dry-etch resistance and imprint performance comparable to PMMA.

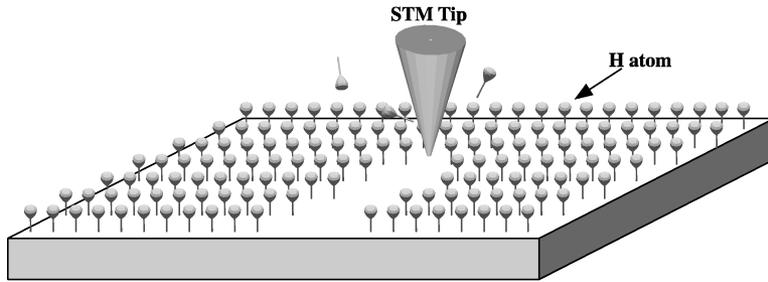

## 36.2.4 Achieving Atomic Resolution

The above lithographic techniques are not capable of achieving atomic resolution, but proximal, or scanning, probes offer a path for scaling fabrication down to atomic dimensions. The two basic types of scanned probes used for lithography include atomic force microscopes (AFMs) and scanning tunneling microscopes (STMs). With its proven atomic resolution, STM has been used to pattern substrates with the highest resolution reported to date, approximately 0.5 nm. AFM patterning has yet to attain this level of resolution, but the introduction of carbon nanotube tips promises to increase the resolution toward 5 nm.

### 36.2.4.1 STM Patterning

The most successful technique demonstrated for STM patterning has been the passivation and selective depassivation of silicon. In this method, pioneered by Lyding et al. (1997), a silicon surface is prepared and hydrogen passivated in an ultrahigh-vacuum (UHV) environment. Surface preparation is, of course, crucial to this process. The sample must be carefully cleaned before inserting it into the UHV chamber, which must achieve pressures on the order of  $10^{-8}$  Pa to preserve the cleanliness of the surface. The sample is flash-heated to a temperature of 1200 to 1300°C for 1 minute, while maintaining  $4 \times 10^{-8}$ -Pa pressure, to drive off any surface contamination and oxides. At a temperature of 650°C, hydrogen is introduced into the chamber to bring the pressure to  $\sim 10^{-4}$  Pa. The hydrogen molecules are cracked using a tungsten filament, and hydrogen atoms attach to the dangling bonds on the silicon surface. The result for a (100) Si surface is a  $2 \times 1$  reconstructed surface passivated by hydrogen.

To perform lithography, an STM tip is brought close to the surface (still in UHV), and a tip voltage of approximately  $-5$  V relative to the sample is applied. Electrons streaming from the tip to the substrate transfer energy to the hydrogen atoms and break bonds between the hydrogen and silicon. Approximately  $10^6$  electrons are needed to remove each hydrogen atom. As the tip is scanned across the surface, lines

**FIGURE 36.6** Depassivation of a silicon surface using an STM tip. Hydrogen atoms are knocked off the surface by electrons tunneling from tip to substrate.

of hydrogen atoms are removed, leaving depassivated Si atoms, as shown in [Figure 36.6](#). Lyding et al. (1997) have demonstrated that, with proper control of the depassivation process, individual hydrogen atoms can be removed, yielding true atomic resolution.

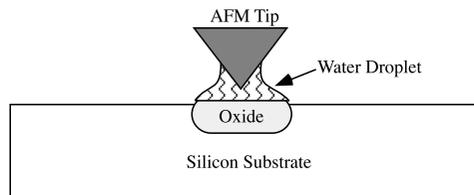

The depassivated silicon atoms are far more chemically active than when bonded to hydrogen, and this difference can be used to transfer the pattern into the substrate by selective chemistry. Perhaps the simplest method is to dose the surface with  $O_2$  molecules at  $10^{-4}$  Pa. These molecules will react with the depassivated silicon to form a thin  $SiO_2$  layer but leave the passivated silicon unchanged. While the oxide layers obtained by dosing with  $O_2$  at low pressures are sub-monolayer, thicker (~4-nm) layers have been formed with oxygen at higher pressures, although with higher defect levels [Shen et al., 1995]. Thin nitride layers can be formed by similar treatments with  $NH_3$ . While these layers are very thin, layers of similar thickness have been used to transfer patterns into silicon [Snow et al., 1996].

The formation of nanoscale metal lines by STM is also being pursued. All future applications of nanofabrication, both electronic and nanomechanical, will require very small lines of metal to connect circuits and subsystems or to connect the nanosystem to the outside world. Work in this area using STM has been attempted but with limited success. Some of the techniques attempted include the field evaporation of gold from a gold tip, which yielded acceptable metal dots but gave only discontinuous lines [Mamin et al., 1990]. STM-assisted deposition of metals from organometallic precursors has been attempted, but the resulting lines are contaminated with impurities [Rubel et al., 1994]. Selective metal deposition has also been investigated. The most successful method uses thermal chemical vapor deposition (CVD) of metal on selectively depassivated substrates. Deposition can be performed at a temperature of ~400°C, which is low enough to preserve the hydrogen passivation. Proper choice of a precursor produces deposition on the depassivated areas, while the passivated areas are unaffected. Using trimethylphosphine-Au, a selective deposition was achieved on depassivated areas of Si.

While STM has demonstrated atomic-level patterning on silicon substrates, many challenges remain before it can be incorporated into the fabrication of NEMS and nanomachines. First, the patterns produced are very fragile. It will be a significant challenge to a pattern-transfer process to retain this resolution while producing the three-dimensional structures often needed for NEMS. There is also the issue of throughput, which applies to all scanned probe fabrication. Because the probe must form each feature sequentially, complex patterns will take a very long time to write. Work by Quate [Wilder et al., 1999] on multi-tip systems offers the possibility of high-throughput lithography systems. Scanned probe lithography can also be used to form the masks for other high-resolution, but more parallel, fabrication techniques such as the nanoimprint lithography discussed above.

#### 36.2.4.2 AFM Patterning

Atomic force microscopes can also be used for ultra-high-resolution lithography. Approaches investigated range from the use of the AFM tip as scribe to locally activated oxidation of silicon or metals. AFM lithography in general has a much lower resolution than that of STM lithography. While STMs achieve

**FIGURE 36.7** Anodic oxidation of a silicon surface using an AFM tip. A water droplet forms between the tip and substrate. The substrate is oxidized when a voltage is applied between tip and substrate.

atomic resolution by tunneling electrons out of only a tiny area of an already very sharp tip, AFM resolution is limited by the shape and size of the full tip. Indeed, a trade-off must be made between resolution and tip durability in many applications, especially those that require a mechanical modification of the surface by the tip. In scribing lithography, the tip is used to scratch the substrate surface. The substrate is typically covered with a soft material, such as PMMA, which can be displaced by the tip without excessive wear of the tip. A limitation of this technique is that the soft film is stressed and distorted as material is moved, and the displaced material has to go somewhere. Because this displaced material can intrude on nearby features, the packing density is limited. The resolution is strongly influenced by the size and shape of the tip. Work has been done using electron-beam-grown “super-tips,” which are formed from contamination, as discussed previously, but these ultra-sharp tips are more prone to breakage and wear-induced degradation.

Anodic oxidation induced by an AFM tip is a technique that, while having a resolution lower than that of STM, produces patterns that are more durable. To perform the anodic oxidation of a silicon substrate, the substrate is first cleaned using standard silicon cleaning techniques and finishing with an HF dip and water rinse, leaving the surface hydrogen passivated. The sample is then placed in a controlled humidity atmosphere (humidity = 20–80%) at ambient pressure, and an AFM tip is brought to the surface. A meniscus of water forms between the tip and sample, as shown in Figure 36.7, and the surface oxidizes when a voltage of  $-2$  to  $-10$  V is applied to the tip. If no voltage is applied, the surface does not oxidize, so the surface can be imaged independently of the oxidation. The resulting oxide is approximately 1.5 nm thick [Snow et al., 2000]. While this is a very thin oxide, it is sufficiently thick for transfer into the underlying substrate. Both wet- and dry-etching techniques have been used. Wet etching is attractive because its lack of a physical sputtering component allows a very high selectivity with the proper choice of etchant. Snow et al. (1996) used a 1-nm oxide mask to etch through the 0.3- $\mu\text{m}$ -thick top silicon layer of an SOI wafer using 70% hydrazine. Wet etching has limitations due to the isotropic or crystallographic nature of the etch which can degrade the resolution of the pattern transfer. Dry etching can give very anisotropic etch profiles, but the physical component of the etch reduces the selectivity of the etch relative to the mask, a serious concern when the mask is only 1 to 1.5 nm thick. For this reason, dry etching is best carried out in high-density plasma systems, such as electron cyclotron resonance (ECR) or inductively coupled plasma (ICP), where the physical component is separately controlled and can be kept low. ECR etching has been investigated as a pattern-transfer mechanism [Snow et al., 1995]. Silicon structures 10 nm wide and 30 nm deep were etched using a  $\text{Cl}_2/\text{O}_2$  plasma. Oxidation of metallic films has also been demonstrated and may be useful for the fabrication of fine metallic lines and the electronic devices associated with a nanomechanical device. Ti, Al and Nb have been selectively oxidized in this fashion [Snow and Campbell, 1995; Schmidt et al., 1998; Matsumoto, 1999], and the technique has been used to fabricate a room-temperature, single-electron transistor [Matsumoto, 2000].

The resolution of anodic oxidation is largely limited by the size of the AFM tip. Using conventional tips, features as small as 10 nm have been demonstrated. The development of carbon nanotube tips opens the way for dramatic improvement in the resolution, and features as small as 5 nm may be possible. As with all scanning probe techniques, AFM patterning is a serial technique and is therefore slow, but as with STM lithography multi-tip systems may improve the throughput. AFM lithography has some advantages

over STM. Because it is an ambient pressure technique, the experiment setup is much simpler and less expensive.

### 36.2.4.3 Atomic Holography

It is also possible to directly control the placement of individual atoms as they deposit on a surface using a variation of holography. Holography is familiar as a technique using optical waves to create three-dimensional images by utilizing both the amplitude and phase information carried by the light. However, holography can be applied to any wave, including matter waves [Sone et al., 1999]. In matter waves, the “image” produced is made up of atoms and, if a substrate is placed in the image plane, the atoms will deposit on the surface. In this way, it is possible to create very small patterns. While optical holography uses a photographic plate to manipulate the optical wavefront, in atomic holography a nanofabricated membrane is used to manipulate the atomic wavefront. The design of this hologram is critical to the formation of the desired image and requires intensive calculations. Using the pattern that is to be created on the substrate, one must calculate back to find what wavefront must leave the membrane. The hologram then becomes a series of holes etched into the surface of the membrane which allows portions of the matter front to pass through in the required areas. The interference of the atomic wave from each hole as it propagates toward the surface produces the desired image. The membrane is typically 100-nm-thick silicon nitride, and the holes etched through the membrane have a typical dimension of 200 nm.

The key to atomic holography is to produce a mono-energetic beam of atoms (one wavelength), analogous to the coherent light used in optical holography. This is done by producing a beam of ionized atoms in a dc discharge, extracting the atoms and then choosing a particular species with a mass selector. The atoms are then passed through a Zeeman Slower, then caught in an atom trap, a magneto-optical trap with four laser beams, as shown in Figure 36.8. The cooled atoms are removed from the trap by the transfer laser and fall vertically shown under the gravitational force. The atoms are passed through the etched membrane hologram, where the beam is diffracted to form a reconstructed image at the substrate. In initial demonstrations, this substrate is a microchannel-plate (MCP) electron multiplier that detects the impact of atoms and produces a corresponding image on a fluorescent screen. This allows an image to be directly viewed and recorded by computer. The spatial resolution of the image is therefore limited by the resolution of the MCP, which is typically a few tens of microns. The actual resolution of the pattern is limited by the wavelength of the atomic beam, which is typically on the nanometer scale, in contrast to optical beams, for which the wavelength is typically more than 200 nm.

A challenge to be faced by atomic holography is to deposit useful materials by this technique. Initial demonstrations have used atoms of limited utility, such as neon and sodium [Behringer et al., 1996;

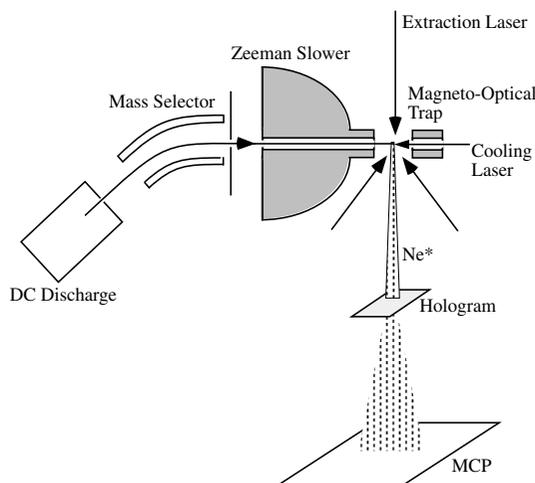

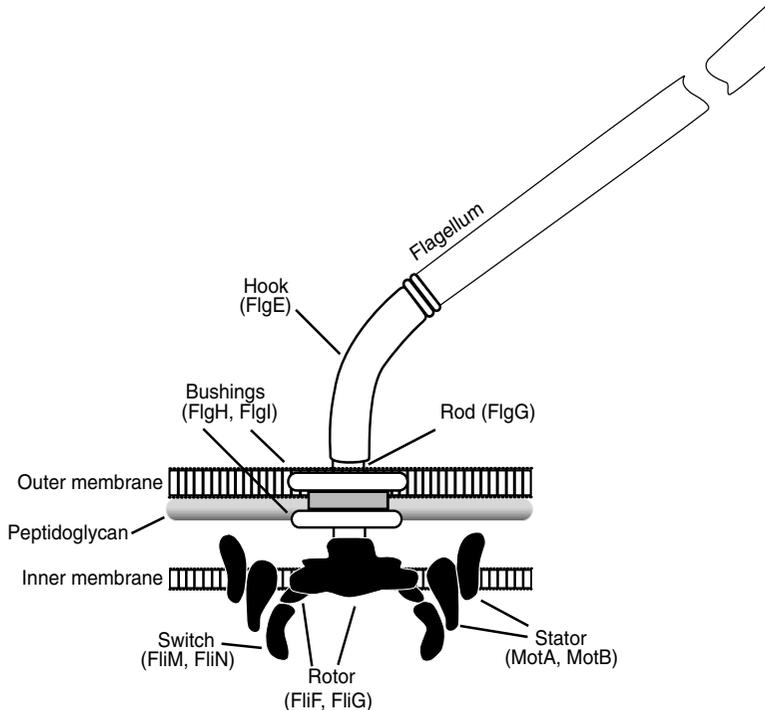

FIGURE 36.8 Schematic of an atomic holography system. (Adapted from Sone et al., 1999.)

Matsui and Fujita, 1998]. These atoms were chosen due to properties that make them attractive for atomic beam manipulations rather than for their usefulness as materials. In order for this technique to become widely applied, depositions of materials such as aluminum or copper must be demonstrated.

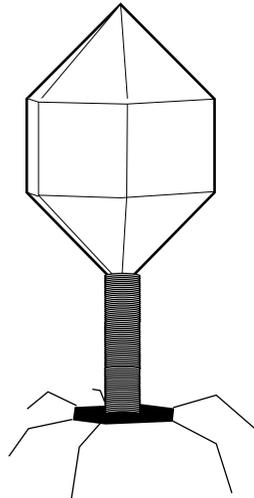

### 36.3 Fabrication of Nanomachines: The Interface with Biology

The preceding pages have described the current state and predicted future of MEMS manufacturing based on real and projected advances in electronics, materials science and chemistry. As discussed, it is expected that many of the most important advances will come as a result of cross-fertilizations between these fields. However, there is a growing consensus that the greatest advances, indeed the future of nanotechnology itself, lie in integration of biological tools and systems into nanotechnological design, function and manufacturing.

The basis for this statement is the obvious fact that nature has performed feats of nanotechnological engineering that we are only beginning to describe or understand. Modern approaches to biological research have revealed molecular machines that are remarkable in their beauty, surprising in their efficiency and sometimes astounding in their self-assembled, three-dimensional complexity. On the one hand are “simple” machines such as the bacterial flagellar motor, which powers the movement of organisms such as *Escherichia coli* through viscous media (Figure 36.9; see DeRosier, 1998, for an electron micrograph). The striking beauty of this rotating assembly (complete with drive shaft, bushing and universal joint) is all the more remarkable when one realizes that it is only 50 nm in diameter, is capable of rotating at 300 revolutions per second and produces a torque of 550 pN-nm [DeRosier, 1998]. Another example is bacteriophage T4, a virus (thankfully specific for bacteria) that bears a

**FIGURE 36.9** Representation of the bacterial flagellar motor. Gene names for proteins comprising individual components are given in parentheses. Protons pass through MotA to drive rotation of the propeller (the “flagellum”). Figure is drawn approximately to scale (width of motor = 50 nm). (Adapted from Berg, 1995 and Mathews, 2000.)

**FIGURE 36.10** Representation of bacteriophage T4 (a bacterial virus). The phage attaches to the bacterium with specific receptors on its “legs” and injects the DNA stored in its “head” through the tailpiece and into the bacterium to initiate the process of infection. The head is approximately 85 to 115 nm.

remarkable resemblance to a lunar lander (Figure 36.10). For electron micrographs, see, for example, Nelson and Cox (2000) or <http://www.asmus.org/division/m/foto/T4Mic.html>. This nanosyringe (only 85 nm in diameter) lands on and attaches specifically to the surface of a susceptible bacterium and then uses its tail projection to inject its DNA into the bacterium. Once the DNA is inside the cell, it essentially reprograms the bacterium, converting it into a factory for making more viruses. Though these examples exist on the nanoscale, the existence of our brains and bodies demonstrates that biological nanotechnology can be integrated and coordinated into three-dimensional structures more than 7 orders of magnitude larger.

### 36.3.1 Inspiration from Biology

Producing an engineered version of a system as complex as the human brain is obviously still in the realm of science fiction, but nanotechnological engineers in the present are finding inspiration in a number of biological sources. The most obvious sources are existing biological molecules. Biological molecules are finding application both as functional components and as structural components. Some molecules have natural functions that engineers hope to harness directly. These include the molecular motors such as the flagellar motor described above [DeRosier, 1998; Mehta et al., 1999; Vale and Milligan, 2000] (see also below) as well as electric switches or ion pumps like the voltage-gated ion channels found in nerve cells. More complicated systems, such as the photosynthetic apparatus, are also key targets [Gust and Moore, 1994]. One example of proteins that are naturally useful in a structural way is bacterial “S proteins.” These pore-forming proteins found on the extracellular surface of bacteria can be extracted and then experimentally reassembled (on a variety of surfaces) into matrices with specific characteristics as variable as the number of different species of bacteria [Sleytr et al., 1997; Sleytr and Beveridge, 1999]. One could imagine that naturally assembling filamentous proteins such as cytoskeletal proteins could be utilized in similar ways.

Some of the most exciting developments may come from application of the natural characteristics of biological molecules in completely novel ways. For example, DNA has been used as a “rope” of defined length that can be positioned in specific places by virtue of its sequence-specific “sticky” cohesive ends and then used as a scaffold on which silver wires are deposited [Braun et al., 1998]. The self-organizing capacity of these sequence-specific “sticky” ends has also been utilized to assemble simple mixtures of cross-linked DNA units into well-organized two-dimensional “DNA crystals” with repeating surface features of various widths [Winfree et al., 1998]. Other DNA molecules have been used to construct more

complicated three-dimensional structures, including cubes and truncated octahedrons [Seeman, 1999]. The fact that specific positions in these DNA molecules can be derivatized in a large variety of ways suggests that DNA may become an important structural tool for the design and manufacture of molecular electronic and other nanotechnological devices [Winfree et al., 1998].

Though biological molecules are useful, it is the harnessing of biological ideas, such as self-assembly and evolution by “natural selection,” which may in the end have the greatest impact. Two obvious problems for nanotechnology are (1) how does one design a molecule with the activity desired, and (2) how does one assemble it? As noted above, nature has solved both of these problems to create “machines” of daunting complexity and remarkable ability. It has been argued that there is no reaction for which Nature has not developed an enzyme. This array of well-honed activities has been achieved by random mutation followed by reproductive “selection” of the more efficient variants. In design-based engineering, we are limited by our imagination and our ability to model. With mutation/selection-based engineering, one is limited only by the number of variants that can be tested and the efficiency with which improved variants can be selected. The difficult part of applying this idea is figuring out how to identify and isolate or reproduce the molecules with desired characteristics. Combinatorial chemists are actively using this approach to identify new drugs [Floyd et al., 1999], while biologists have used it to develop entirely new enzymatic activities, either *in vivo* (bioremediation) [Chen et al., 1999] or *in vitro* [Wilson and Szostak, 1999]. The breadth of practical future applications for “directed evolution” is difficult to predict, but it is clear that the idea is powerful.

The problem of three-dimensional self-assembly is closely related to that of structure and design. Indeed, natural machines have been selected by evolution to self-assemble (or to assemble in the assisting presence of other natural machines called “chaperones”; see Nelson, 2000, for an introduction to this process). For example, an enzyme is a linear chain of amino acids which folds into a complex and reproducible three-dimensional structure. This precise array of amino acid side chains endows it with specific affinities for other molecules and a specific chemical activity. To properly place these side chains artificially in three-dimensional space would be difficult, if not impossible, with existing technology. On the other hand, many proteins will spontaneously fold into the correct three-dimensional structure in seconds. These proteins can then assemble into larger machines of remarkable complexity and function. One beautiful example is the ribosome, a biological machine that functions (according to the analogy of Peter Moore) rather like a programmable loom [Ban et al., 2000; Nissen et al., 2000]. The ribosome “reads” the sequence of a given messenger RNA molecule and strings together amino acids according to this mRNA program, thus synthesizing the prescribed protein. The ribosome is indeed a programmable, positional, assembly-fabrication device existing on the nanometer scale, thus demonstrating that such nanofabrication devices are possible [Merkle, 1999].

The problem of how to predict three-dimensional structure from the linear sequence of amino acids is one of the remaining “Holy Grails” of molecular biology. If one could figure out how to predict three-dimensional structure from a sequence, it seems likely that one could figure out how to design a sequence necessary to produce a particular structure (see DeGrado et al. (1999) and Koehl and Levitt (1999a; 1999b) for discussions of current attempts to achieve this aim). However, there is the very real problem of whether this thermodynamically designed protein fold could be achieved in a kinetically realistic amount of time. One possibility is to model new proteins on old (evolutionarily selected) folds [Koehl and Levitt, 1999a; 1999b]. It also seems likely that engineers could use *in vitro* evolution to optimize the self-assembly (folding ability) of these designed protein machines. If single proteins could be designed *de novo*, why not entire complexes? If (when) this aim of *de novo* protein design is achieved, the machines of nanotechnology could very well start assembling themselves.

### 36.3.2 Practical Fabrication of Biological Nanotechnology

In order to begin to understand how devices based on biological molecules might be fabricated now, it is necessary to review some general techniques for the production of biological molecules. Many of the DNA-based applications described above require small DNA molecules (<100 basepairs), and small DNA molecules are relatively easy to make in large amounts either chemically (available commercially; 0.1  $\mu\text{mol}$

of a 20 mer oligonucleotide can be made for less than \$1/base, 10  $\mu\text{mol}$  for less than \$20/base by Sigma Genosys, for example) or by biological replication. One advantage of the synthetic approach is that the nucleotides at specific sites can be chemically derivatized in a wide variety of ways, limited only by the compatibility of the derivatization with the chemical process of DNA synthesis. Another advantage of chemical synthesis is that the engineer defines the sequence. For pieces of DNA larger than 100 bases (and up to chromosome size), biological manufacture is often preferable. Biological manufacture of DNA is performed by replicating an existing molecule, and it is done either *in vitro* or *in vivo*. *In vitro* replication is performed by putting the starting DNA and the necessary purified components and enzymes into a test tube, and letting the enzymes do their job. The polymerase chain reaction (PCR) is one particularly useful enzymatic approach for producing large numbers of replicas of a DNA fragment in the range of 0.1 to 10 kilobasepairs. In order to replicate a desired piece of DNA *in vivo*, it is ligated into a plasmid (a different piece of DNA that can replicate in bacteria independently of the chromosome), the plasmid is grown in bacteria, and then the plasmid (containing the DNA of interest) is purified out of the bacteria. The desired DNA can then be cut out of the plasmid using sequence-specific restriction enzymes and purified away from the rest of the plasmid DNA. In this process, the amount of DNA produced is limited only by the quantity of bacteria grown (indeed possible on an industrial scale).

Proteins also can be made either chemically or biologically, but most useful proteins are too large to be easily made in reasonable amounts chemically. Therefore, they are made biologically by inserting a piece of DNA encoding the desired protein into a cell type suitable for making the protein. Bacteria are usually the most productive hosts for protein production, but many human proteins cannot be grown in bacteria either because they are not folded properly into their three-dimensional shape or because they are not modified properly (proteins can require phosphorylations, sugar additions, etc.). Yeast cells, insect cells and human cells are (in that order) more likely to make active protein but are also less productive and (considerably) more expensive.

After the problem of how to express active protein is solved, the protein must be purified away from other cellular proteins. This problem can be made considerably easier by engineering into the DNA (and therefore the protein) an "affinity tag." This tag is a specific amino acid sequence that enables the engineered protein to stick specifically to a particular affinity matrix (several types exist), allowing the tagged protein to be retained on the matrix and the vast majority of undesired proteins to wash away. In addition, a variety of tags or modifications can be chemically added to the protein after it is purified. A tag of one form or another is often necessary to allow positioning of the protein in the desired place and in the desired orientation; it also may be necessary to harness the protein to other mechanical devices (for example, in the case of a molecular motor). For more details on the processes of working with DNA or protein, see Ausubel et al. (2000) and Coligan et al. (2000).

To understand these issues in more practical terms, it is useful to describe the approaches used by two engineers in trying to harness the work of the molecular motor enzyme, F1 ATPase. The F1 ATPase is a rotary motor present in essentially every living cell. Its natural purpose is to synthesize the energy carrier molecule adenosine triphosphate (ATP) by harnessing the flow of protons down an electrochemical gradient. During ATP synthesis, the central subunit rotates in a clockwise direction. However, if given a supply of ATP, the motor will utilize the ATP to drive rotation in a counter-clockwise direction. Montemagno and Bachand (1999) have produced and purified a tailored form of this molecule that they have attached specifically and in a specific orientation to a substrate. They attached the central subunit specifically to a latex bead and used it to drive the rotation of the latex bead.

In order to do this, Montemagno and Bachand first isolated the pieces of DNA encoding the subunits of the ATP synthase using standard molecular biology procedures. They spliced these pieces of DNA into a bacterial plasmid (see above) engineered so that production of the ATPase proteins could be turned on or off in response to an externally applied chemical signal (the sugar analog IPTG). They then tailored the DNA encoding the ATPase subunits to provide solutions to the other problems. For example, they modified the DNA of one of the subunits at the base of the ATPase by fusing it to a His tag, which is simply a string of 6 to 10 histidines that allows any protein (or complex of proteins) to bind specifically to the element nickel. This His tag allowed the ATPase complex to be purified on a column of nickel resin.

It also allowed the ATPase complex to bind to a nickel substrate with a defined orientation. As a final bit of genetic engineering, Montemagno and Bachand changed to cysteine one of the amino acids at the tip of the central rotating subunit (the “driveshaft”). Cysteine can be chemically cross-linked to a variety of different molecules, and this engineered cysteine allowed them to cross-link the driveshaft to biotin. Because biotin binds streptavidin specifically and tightly, the biotin-linked driveshaft bound specifically to a streptavidin-coated bead. This bead was therefore coupled to the rotating driveshaft, enabling the motor to be harnessed to move the bead.

Though as yet these experiments are just a demonstration of principle, it is easy to imagine replacing the latex bead with some form of molecular drivetrain. Thus far, it is true that the integration of biology into nanotechnology has yet to live up to expectations. However, with the breathtaking advances in biotechnology and the enormous breadth of biochemical biodiversity, the expectations are great indeed.

## 36.4 Summary

---

This chapter has attempted to provide an overview of technologies from established to nascent that might be used to create nanostructures suitable for future nanoelectromechanical systems. There exist many visions of what is possible in the near and further future for ultrasmall mechanical devices, so it is difficult to tell at this time which of the various fabrication technologies available today might become the most useful in the future. It is likely that some combination of many technologies will find applications. In order to address this, we discussed the most common nanofabrication technologies, such as electron beam and X-ray lithographies, and what limits their resolution in achieving the smallest possible pattern dimensions. We also discussed an alternative method, microcontact printing, for achieving high throughput at very small dimensions. We showed that these techniques were capable of achieving 10-nm resolution in a straightforward manner. Using exotic techniques, much smaller features are attainable.

In order to attain true atomic resolution, scanning probe techniques have proven to be viable technologies. We discussed the use of scanning tunneling microscopy and atomic force microscopy in defining Angstrom-scale patterns and pointed out a method of achieving high throughput with this technique, as well. One distinctive technique discussed is that of atomic holography which might someday be used to build up NEMS devices by direct deposition of the constituent atoms.

We concluded this chapter with a discussion of how biological systems qualify as NEMS and how future technologists might exploit existing cellular structures to create artificial nanomachines. We discussed specific cellular functions that are similar in function to potential nanomachines, including flagellar motors, voltage switches, ion pumps, cytoskeletal proteins for structural support and even DNA for use as a patterning template. We discussed how biologists succeed in customizing and fabricating batch quantities of these potential NEMS structural elements.
